objective lens 27 and the first information medium 23, so that the diffracted light L6 transmits through the first information medium 23 having the thickness T1 and is converged on the medium 23 to form the diffraction-limited converging spot S5 without any aberration. A method for designing the hologram lens 42 having an aberration correcting function is described.

After the diffracted light L6 is converged on the first information medium 23, spherical waves diverge from the converging spot S5 and transmit through the first substrate 22 and the objective lens 27. Thereafter, the spherical waves transmit through the transparent substrate 28 and optically interfere with the incident light L3. Therefore, an interference pattern is formed by the interference between the spherical waves and the incident light L3. The interference pattern can be calculated by adding the phase of the spherical waves to an inverted phase obtained by inverting the phase of the incident light L3. Accordingly, the grating pattern P3 of the hologram lens 42 which agrees with the interference pattern calculated can be easily formed according to a computer generated hologram technique.

Accordingly, because the hologram lens 42 functions as a convex lens for the first-order diffracted light L6, a curvature of the objective lens 27 can be lowered. Also, a glass material having a high refractive index is not required to produce the objective lens 27.

Also, because the first-order diffracted light L6 formed in the hologram lens 42 converges before the diffracted light L6 is incident on the objective lens 27, the distance in an optical axis direction between the converging spots S5, S6 can be lengthened to about 1 mm. Therefore, even though the transmitted light L4 (or the first-order diffracted light L6) is converged on the converging spot S6 (or S5) in focus to record or read a piece of information, the light L6 (or L4) is not converged on the converging spot S6 (or S5) in focus to reduce the intensity of the light L6 (or L4) at the converging spot S6 (or S5). Accordingly, no adverse influence is exerted on the recording or reproduction of the information

Also, because the hologram lens 42 functions as a convex lens for the first-order diffracted light L6, the occurrence of a chromatic aberration can be prevented in the imaging optical system 41. In detail, the focal length of the hologram lens 42 is shortened as the wavelength of the incident light L3 becomes longer. In contrast, the focal length of the objective lens 27 is lengthened as the wavelength of the incident light L3 becomes longer. That is, the dependence of the focal length on the wavelength in the objective lens 27 is opposite to that of the focal length on the wavelength in the hologram lens 42. Therefore, the compound objective lens 43 having an achromatic function can be formed by the combination of the lenses 27, 42, and the occurrence of the chromatic aberration can be prevented.

Also, because the hologram lens 42 is a plane type of element, a lightweight type of compound objective lens can be made in large scale manufacture.

Also, because the diffraction efficiency of the hologram lens 42 is gradually decreased toward an inner direction of the pattern region 42A, the numerical aperture of the objective lens 27 for the first-order diffracted light L6 becomes substantially enlarged. Therefore, the intensity of the first-order diffracted light L6 can be enlarged to record or reproduce a piece of information on or from the first information medium 23.

Also, in cases where the incident light L3 is radiated from a semiconductor laser, a far field pattern of the incident light L3 is distributed in a Gaussian distribution as shown in FIG. 13A. Therefore, because the diffraction efficiency of the hologram lens 42 is gradually decreased toward the inner direction of the grating pattern P2, a far field pattern of the first-order diffracted light L6 is distributed in a gently-sloping shape. Accordingly, secondary maxima of the first-order diffracted light L6 converged on the converging spot S5 can be moreover suppressed in the third embodiment as compared with in the first embodiment. That is, the recording and reproducing of the information can be performed without any deterioration of the information by utilizing the imaging optical system 41.

In addition, in cases where the transmitted light L4 is converged on the second information medium 25 to form the diffraction-limited converging spot S6, a numerical aperture of the objective lens 27 for the transmitted light L4 is low because the diffraction efficiency of the hologram lens 42 is increased toward an outer direction of the grating pattern 42A. As a result, the intensity of the transmitted light L4 becomes lowered. In cases where a transmission efficiency of the hologram lens 42 is heightened to increase the intensity of the transmitted light L4, the intensity of the first-order diffracted light L6 at its inner beam portion is largely decreased, and secondary maxima (or side lobes) of the first-order diffracted light L6 at the converging spot S6 is undesirably increased. Therefore, the incident light L3 of which the far field pattern is distributed in the Gaussian distribution is radiated to the hologram lens 42 to increase the intensity of the transmitted light L4 without any increase of the second maxima. In detail, as shown in FIG. 18A, the incident light L3 distributed in not only a central portion of the Gaussian distribution but also a peripheral portion of the Gaussian distribution transmits through the hologram lens 42 and is refracted by the objective lens 27 because the diameter of the grating pattern P3 is equal to or larger than the aperture of the objective lens 27. Therefore, a numerical aperture NA of the objective lens 27 at a light source side for the incident light L3 becomes higher than that in the first embodiment, and a transmission efficiency of the hologram lens 42 is heightened. As a result, the intensity of the transmitted light L4 converged on the second information medium 25 can be increased, as shown in FIG. 18B. Also, because the intensity of the incident light L3 at the peripheral portion of the Gaussian distribution is low and because the diffraction efficiency of the hologram lens 42 is decreased toward the inner direction of the grating pattern 42A, the first-order diffracted light L6 is distributed in a gently-sloping shape as shown in FIG. 18C. Accordingly, secondary maxima of the first-order diffracted light L6 at the converging spot S5 can be suppressed.

Examples of the utilization of the imaging optical system 41 for various types of optical disks are described.

In cases where the image optical system 41 is utilized for an optical disk device in which pieces of information recorded in a thin type of high density optical disk and a thick type of compact disk are exclusively reproduced, the diffraction efficiency of the hologram lens 42 for the incident light L3 is set in a range from about 20% to 70%. In this case, the intensity of the transmitted light L4 converged on the compact disk is almost the same as that of the first-order diffracted light L6

converged on the high density optical disk. Therefore, the output power of the incident light L3 can be minimized.

Also, in cases where the image optical system **41** is utilized for an optical disk device in which pieces of information recorded in a thin type of high density optical disk are recorded or reproduced and pieces of information recorded in a thick type of optical disk are exclusively reproduced, the diffraction efficiency of the hologram lens **42** for the incident light L3 is set to a value equal to or higher than 55%. In this case, even though a high intensity of the first-order diffracted light L6 is required to record a piece of information on the high density optical disk, the recording of the information can be reliably performed without increasing the intensity of the incident light L3 because the diffraction efficiency of the hologram lens **42** for changing the incident light L3 to the first-order diffracted light L6 is high. In other words, a utilization efficiency of the incident light L3 can be enhanced when a piece of information is recorded on the high density optical disk, so that the output power of the incident light L3 can be minimized. Also, because the diffraction efficiency of the hologram lens **42** is gradually decreased toward an inner direction of the pattern region **42A**, the numerical aperture of the objective lens **27** for the first-order diffracted light L6 becomes substantially enlarged. Therefore, the intensity of the first-order diffracted light L6 can be enlarged to record or reproduce a piece of information on or from the high density optical disk.

In the third embodiment, the grating pattern P3 positioned in the pattern region **42A** of the transparent substrate **28** is gradually changed toward the outer direction of the pattern region **42A** from the step-wise shape shown in FIG. **12B** to the step-wise shape shown in FIG. **12A** through the step-wise shape shown in FIG. **12C** while increasing the height H of the grating pattern P3. However, because the occurrence of unnecessary diffracted light such as minus first-order diffracted light can be effectively prevented in the middle portion of the transparent substrate **28** in which the grating pattern P3 is formed in the step-wise shape shown in FIG. **12C**, it is preferred that the middle portion occupy a large part of the pattern region **42A** of the hologram lens **42**. In this case, the intensity sum of the transmitted light L4 and the first-order diffracted light L6 can be maximized, so that a utilization efficiency of the incident light L3 can be enhanced.

Also, because the first etching width W1 of the grating pattern P3 is gradually decreased toward the inner direction of the pattern region **42A**, it is applicable that the grating pattern P3 formed in the step-wise shape shown in FIG. **12B** be changed to a step-wise shape shown in FIG. **12D** when the first width W1 is decreased to a value lower than about 1 μm. In this case, the grating pattern P3 formed in the step-wise shape shown in FIG. **12D** can be easily made. In addition, in cases where a height H4 of the grating pattern P3 formed in the step-wise shape shown in FIG. **12D** is moreover decreased toward the inner direction of the pattern region **42A**, it is preferred that the grating pattern P3 be formed in a step-wise shape shown in FIG. **12E**. In this case, a third etching width W3 is gradually decreased toward the inner direction of the pattern region **42A** while decreasing a height H5 of the grating pattern P3. Therefore, the diffraction efficiency of the hologram lens **42** can be gradually decreased toward the inner direction of the pattern region **42A** without any manufacturing difficulty of the grating pattern P3.

In the first to third embodiments of the image optical systems **21**, **31** and **41**, the grating patterns P1, P2 and P3 of the hologram lenses **26**, **32** and **42** are respectively formed on a front side of the transparent substrate **28** not facing the objective lens **27**. Therefore, a beam of light reflected at the front side of the transparent substrate **28** does not adversely influence as stray light on the recording or reproduction of the information. In detail, because the reflected light is diffracted by the hologram lens, the reflected light is scattered. Also, even though the first-order diffracted light L5 or L6 is reflected at a reverse side of the transparent substrate **28**, the diffracted light reflected is again diffracted by the hologram lens and is scattered. Therefore, the light reflected at the front or reverse side of the hologram lens does not adversely influence on the recording or reproduction of the information.

However, in cases where an anti-reflection film is coated on a front side of the hologram lens **28** at which the grating pattern is not formed, it is applicable that the grating patterns P1, P2 and P3 of the hologram lenses **26**, **32** and **42** be respectively formed on a reverse side of the transparent substrate **28** facing the objective lens **27**. In this case, because the first-order diffraction light L5, L6 is not refracted at the front side of the hologram lens **28**, the design of the image optical systems **21**, **31** and **41** can be simplified.

Also, in the first to third embodiments, the grating patterns P1, P2 and P3 of the hologram lenses **26**, **32** and **42** are respectively formed in relief to produce a phase modulation type of hologram lens. However, as is described in Provisional Publication No. 189504/86 (S61-189504) and Provisional Publication No. 241735/88 (S63-241735), the phase modulation type of hologram lens can be produced by utilizing a liquid crystal cell. Also, the phase modulation type of hologram lens can be produced by utilizing a birefringece material such as lithium niobate. For example, the phase modulation type of hologram lens can be produced by proton-exchanging a surface part of a lithium niobate substrate.

(Fourth Embodiment)

Also, in the first to third embodiments, the compound objective lens **29**, **34** or **43** having two focal points is composed of the objective lens **27** and the hologram lens **26**, **32** or **42**. However, as a compound objective lens according to a fourth embodiment is shown in FIG. **19A**, it is preferred that each of the hologram lenses **26**, **32** and **42** and the objective lens **27** be unified with a packaging means **44** to form a compound objective lens **45** in which a relative position between each of the hologram lenses **26**, **32** and **42** and the objective lens **27** is fixed. In this case, the transmitted light L4 and the first-order diffracted light LS, L6 can be easily converged on the first or second information medium **23**, **25** by adjusting the position of the packing means **44** with an actuator. Also, as another compound objective lens according to a modified fourth embodiment is shown in FIG. **19B**, it is preferred that each of the grating patterns P1, P2 and P3 be directly drawn on a curved side of the objective lens **27** facing a light source side to form a compound objective lens **46** in which each of the hologram lenses **26**, **32** and **42** is integrally formed with the objective lens **27**.

Accordingly, the central axis of the objective lens **27** can always agree with that of each of the hologram

lenses 26, 32 and 42, so that abaxial aberrations of each of the hologram lenses 26, 32 and 42 such as a coma aberration and an astigmatic aberration occurring in the first-order diffracted light can be prevented in the fourth embodiment.

(Fifth Embodiment)

Also, as a compound objective lens according to a fifth embodiment is shown in FIG. 20, it is preferred that each of the grating patterns P1, P2 and P3 be directly drawn on a side of the objective lens 27 facing the information medium 23 or 25 to form a compound objective lens 47 in which each of the hologram lenses 26, 32 and 42 is integrally formed with the objective lens 27. In this case, a curvature at the side of the objective lens 27 can be small or in a plane shape. Therefore, each of the grating patterns P1, P2 and P3 can be made at a low cost. Also, in cases where an aberration is caused by tilting the hologram lens from the optical axis, the aberration can be prevented by fixing the hologram lens and a light source of the incident light L3 on the same base.

(Sixth Embodiment)

An optical head apparatus with one of the compound objective lenses 29, 29M, 34, 43, 45, 46 and 47 shown in the first to fifth embodiments is described with reference to FIGS. 21 to 26 according to a sixth embodiment of the present invention. X, Y and Z co-ordinates shown in FIGS. 21 to 26 are utilized in common.

FIG. 21 is a constitutional view of an optical head apparatus according to a sixth embodiment.

As shown in FIG. 21, an optical head apparatus 51 for recording or reproducing pieces of information on or from the information medium 23 or 25, comprises a light source 52 such as a semiconductor laser for radiating the incident light L3, a collimator lens 53 for collimating the incident light L3, a beam splitter 54 for transmitting the incident light L3 on an outgoing optical path and reflecting a beam of transmitted light L4R formed by reflecting the transmitted light L4 on the information medium 23 or 25 or a beam of diffracted light L5R (or L6R) formed by reflecting the diffracted light L5 (or L6) on the information medium 23 or 25 on an incoming optical path, the compound objective lens 29 (or 29M, 34, 43, 45, 46 or 47) composed of the hologram lens 26 (or 26M, 32, 33 or 42) and the objective lens 27, a converging lens 55 for converging the transmitted light L4R or the diffracted light L5R reflected by the beam splitter 54, a wavefront changing device 56 such as a hologram for changing a wavefront of the transmitted light L4R or the diffracted light L5R to form a plurality of converging spots of the transmitted light L4R or the diffracted light L5R, a photo detector 57 for detecting intensities of the converging spots of the transmitted light L4R or the diffracted light L5R of which the wavefront is changed by the wavefront changing device 56 to obtain an information signal recorded on the information medium 23 or 25 and servo signals such as a focus error signal and a tracking error signal, and an actuating unit 58 for moving the compound objective lens composed of the hologram lens 26 and the objective lens 27 according to the servo signals.

In the above configuration, a beam of incident light L3 radiated from the light source 52 is collimated in the collimator lens 53 and transmits through the beam splitter 54. Thereafter, a part of the incident light L3 transmits through the compound objective lens 29 without any diffraction, and a remaining part of the incident light L3 is diffracted.

Thereafter, in cases where a piece of information is recorded or reproduced on or from the first information medium 23, the transmitted light L4 is converged on the first information medium 23 to form the first converging spot S1. That is, the transmitted light L4 is incident on a rear surface of the first information medium 23, and the first converging spot S1 is formed on a front surface of the first information medium 23. Thereafter, a beam of transmitted light L4R reflected at the front surface of the first information medium 23 passes through the same optical path in the reverse direction. That is, a part of the transmitted light L4R again transmits through the compound objective lens 29 without any diffraction and is reflected by the beam splitter 54. In this case, the transmitted light L4R is collimated. Thereafter, the transmitted light L4R is converged by the converging lens 55, and the wavefront of a large part of the transmitted light L4R is changed to form a plurality of converging spots on the photo detector 57. Thereafter, the intensities of the converging spots of the transmitted light L4R are detected in the photo detector 57. Therefore, an information signal and servo signals such as a focus error signal and a tracking error signal are obtained. The actuating unit 58 are operated according to the servo signals to move the compound objective lens 29 at high speed, so that the transmitted light L4 is converged on the first information medium 23 in focus.

Also, in cases where a piece of information is recorded or reproduced on or from the second information medium 25, the diffracted light L5 is converged on the second information medium 25 to form the second converging spot S2. That is, the diffracted light L5 is incident on a rear surface of the second information medium 25, and the second converging spot S2 is formed on a front surface of the second information medium 25. Thereafter, a beam of diffracted light L5R reflected at the front surface of the second information medium 25 passes through the same optical path in the reverse direction. That is, a part of the diffracted light L5R is again diffracted by the hologram lens 26 and is reflected by the beam splitter 54. In this case, the diffracted light L5R is collimated. Thereafter, the diffracted light L5R is converged by the converging lens 55, and the wavefront of a large part of the diffracted light L5R is changed to form a plurality of converging spots on the photo detector 57. In this case, the diffracted light L5R incident on the converging lens 55 is collimated in the same manner as the transmitted light L4R incident on the converging lens 55, the converging spots of the diffracted light L5R are formed at the same positions as those of the transmitted light L4R. Thereafter, the intensities of the converging spots of the diffracted light L5R are detected in the photo detector 57. Therefore, an information signal and servo signals such as a focus error signal and a tracking error signal are obtained. The actuating unit 58 are operated according to the servo signals to move the compound objective lens 29 at high speed, so that the diffracted light L5 is converged on the second information medium 25 in focus.

In this case, because the transmitted light L4R again transmits through the compound objective lens without any diffraction and the diffracted light L5R is again diffracted by the hologram lens 26, the outgoing optical path agrees with the incoming optical path in a range between the information medium 23 or 25 and the beam

splitter **54** even though the converging spot **S1** differs from the converging spot **S2**. Therefore, a converging spot **S7** on the photo detector **57** at which the light **L4R** or **L5R** not diffracted by the wavefront changing device **56** is converged relates to a radiation point of the light source **52** in a mirror image, so that the light **L4R** and **L5R** not diffracted by the wavefront changing device **56** are converged at the same converging point **S7**. In the same manner, the light **L4R** and **L5R** diffracted by the wavefront changing device **56** are converged at the same other converging points.

Accordingly, even though the compound objective lens has two focal points, the wavefront changing unit **56** and the photo detector **57** required to detect the intensity of the transmitted light **L4R** can be utilized to detect the intensity of the diffracted light **L5R**. Therefore, the number of parts required to manufacture the optical head apparatus **51** can be reduced, and a small sized optical head apparatus can be manufactured at a low cost and in light weight even though pieces of information are recorded or reproduced on or from an information medium by utilizing the optical head apparatus **51** regardless of whether the information medium is thick or thin.

In cases where the hologram lens **26** (or **32, 33, 42**) is integrally formed with the objective lens **27** as shown in FIG. **19A**, **19B** or **20**, each of the compound objective lenses **45, 46** and **47** can be manufactured in light weight because the hologram lens **26** (or **32, 33, 42**) is a plane type of optical device. For example, the hologram lens **26** (or **32, 33, 42**) is less than several tens mg in weight. Therefore, the hologram lens **26** integrally formed with the objective lens **27** can be easily moved by the actuating unit **58**.

Next, a detecting method of the servo signals is described. FIG. **22** is a plan view of the wavefront changing unit **56**. FIG. **23** is an enlarged view of first-order diffracted light and transmitted light detected in the photo detector **57**. As shown in FIG. **22**, the wavefront changing unit **56** is partitioned into a diffracted light generating region **56*a*** in which a grating pattern **P4** is drawn and a pair of diffracted light generating regions **56*b*, 56*c*** in which a pair of grating patterns **P5, P6** are drawn. The light **L4R** or **L5R** incident on the diffracted light generating region **56*a*** is diffracted to obtain a focus error signal. The light **L4R** or **L5R** incident on each of the diffracted light generating regions **56*b*, 56*c*** is diffracted to obtain a tracking error signal.

Initially, a spot size detection method utilized to detect a focus error signal is described as an example of a detecting method of a focus error signal. The method is proposed in Japanese Patent Application No. 185722 of 1990. In short, in cases where the method is adopted, an allowable assembly error in an optical head apparatus can be remarkably enlarged, and the servo signal such as a focus error signal can be stably obtained to adjust the position of the compound objective lens even though the wavelength of the incident light **L3** varies.

In detail, as shown in FIG. **23**, the grating pattern **P4** is designed to change the transmitted light **L4R** (or the diffracted light **L5R**) transmitting through the diffracted light generating region **56*a*** of the wavefront changing unit **56** to a beam of first-order diffracted light **L7** and a beam of minus first-order diffracted light **L8**. The diffracted light **L7, L8** are expressed by two types of spherical waves having different curvatures. That is, interference fringes are produced by actually interfering a spherical wave having a focal point **FP1** in the front of the photo detector **57** with another spherical wave diverging from the converging spot **S7** according to a two-beam interferometric process, so that the grating pattern **P4** agreeing with the interference fringes is formed. In other case, the interference fringes are calculated according to a computer generated hologram method. As a result, the transmitted light **L4R** (or the diffracted light **L5R**) transmitting through the diffracted light generating region **56*a*** of the wavefront changing unit **56** is diffracted and changed to beams of conjugate diffracted light such as a beam of first-order diffracted light **L7** and a beam of minus first-order diffracted light **L8**. The beam of first-order diffracted light **L7** has the focal point **FP1** at the front surface of the photo detector **57**, and the beam of minus first-order diffracted light **L8** has a focal point **FP2** in the rear of the photo detector **57**.

As shown in FIG. **24**, the photo detector **57** comprises a sextant photo-detector **59** (or a six-division photo detector) in which six detecting sections **SE1, SE2, SE3, SE4, SE5** and **SE6** are provided. The intensity of the first-order diffracted light **L7** is detected by each of the detecting sections **SE1, SE2** and **SE3** of the sextant photo-detector **59** and is changed to electric current signals **SC1, SC2** and **SC3**. Also, the intensity of the minus first-order diffracted light **L8** is detected by each of the detecting sections **SE4, SE5** and **SE6** of the sextant photo-detector **59** and is changed to electric current signals **SC4, SC5** and **SC6**.

FIG. **25A** and **25C** respectively show a converging spot of the first-order diffracted light **L7** radiated to the detecting sections **SE1, SE2** and **SE3** of the sextant photo-detector **59** and another converging spot of the minus first-order diffracted light **L8** radiated to the detecting sections **SE4, SE5** and **SE6** of the sextant photo-detector **59** on condition that the objective lens **27** is defocused on the information medium **23** or **25**. FIG. **25B** shows a converging spot of the first-order diffracted light **L7** radiated to the detecting sections **SE1, SE2** and **SE3** of the sextant photo-detector **59** and another converging spot of the minus first-order diffracted light **L8** radiated to the detecting sections **SE4, SE5** and **SE6** of the sextant photo-detector **59** on condition that the objective lens **27** is just focused on the information medium **23** or **25**.

As shown in FIGS. **25A** to **25C**, in cases where the transmitted light **L4** (or the diffracted light **L5**) is converged on the information medium **23** (or **25**) on condition that the objective lens **27** is defocused on the information medium **23** (or **25**), a converging spot **S8** of the diffracted light **L7** shown at the left side of FIGS. **25A, 25C** is formed on the sextant photo-detector **59**, and another converging spot **S9** of the diffracted light **L8** shown at the right side of FIG. **25A** or **25C** is formed on the sextant photo-detector **59**. In contrast, in cases where the transmitted light **L4** (or the diffracted light **L5**) is converged on the information medium **23** (or **25**) on condition that the objective lens **27** is just focused on the information medium **23** (or **25**), a converging spot **S8** of the diffracted light **L7** shown at the left side of FIG. **25B** is formed on the sextant photo-detector **59**, and another converging spot **S9** of the diffracted light **L8** shown at the right side of FIG. **25B** is formed on the sextant photo-detector **59**. The intensity of the diffracted light **L7** is detected in each of the detecting sections **SE1, SE2** and **SE3** of the sextant photo-detector **59** and is changed to electric current signals **SC1, SC2, SC3**. Also, the intensity of the diffracted light **L8**

is detected in the detecting sections SE4, SE5 and SE6 of the sextant photo-detector **59** and is changed to electric current signals SC4, SC5 and SC6. Thereafter, a focus error signal S_{fe} is obtained according to the spot size detection method by calculating an equation (5).

$$S_{fe}=(SC1+SC3-SC2)-(SC4+SC6-SC5) \quad (5)$$

Thereafter, the position of the compound objective lens is moved in a direction along an optical axis at high speed so as to minimize the absolute value of the focus error signal S_{fe}.

In the spot size detection method, the diffracted light L7, L8 are expressed by two types of spherical waves having different curvatures to detect the focus error signal S_{fe}. However, two beams of diffracted light L7, L8 radiated to the photo detector **57** are not limited to the spherical waves. That is, because the change of the diffracted light L7, L8 in a Y-direction is detected by the photo detector **57** according to the spot size detection method, it is required that a one-dimensional focal point of the diffracted light L7 is positioned in the front of the photo detector **57** and a one-dimensional focal point of the diffracted light L8 is positioned in the rear of the photo detector **57**. Therefore, it is applicable that diffracted light including astigmatic aberration be radiated to the photo detector **57**.

In addition, an information signal S_{in} is obtained by adding all of the electric current signals according to an equation (6).

$$S_{in}=SC1+SC2+SC3+SC4+SC5+SC6 \quad (6)$$

Because the information medium **23** or **25** is rotated at high speed, a patterned track pit radiated by the converging spots S8, S9 of the diffracted light L7,L8 is rapidly changed one after another, so that the intensity of the information signal S_{in} is changed. Therefore, the information stored in the information medium **23** or **25** can be reproduced according to the information signal S_{in}.

Next, the detection of a tracking error signal depending on a relative position between a converging spot and a patterned track pit on the information medium **23** or **25** is described.

The grating pattern P5 drawn in the diffracted light generating region **56***b* shown in FIG. **22** is designed to change the transmitted light L4R (or the diffracted light L5R) transmitting through the diffracted light generating region **56***b* of the wavefront changing unit **56** to a beam of first-order diffracted light **L9** and a beam of minus first-order diffracted light **L10**. Also, the grating pattern **P6** drawn in the diffracted light generating region **56***c* shown in FIG. **22** is designed to change the transmitted light L4R (or the diffracted light L5R) transmitting through the diffracted light generating region **56***c* of the wavefront changing unit **56** to a beam of first-order diffracted light **L11** and a beam of minus first-order diffracted light **L12**.

As shown in FIG. **24**, the photo detector **57** further comprises four tracking photo-detectors **60***a* to **60***d* for detecting intensities of the diffracted light L9 to L12. As shown in FIG. **26**, the intensity of the diffracted light L9 is detected by the tracking photo-detector **60***a* and is changed to an electric current signal SC7, the intensity of the diffracted light L10 is detected by the tracking photo-detector **60***d* and is changed to an electric current signal SC10, the intensity of the diffracted light L11 is detected by the tracking photo-detector **60***b* and is changed to an electric current signal SC8, and the intensity of the diffracted light L12 is detected by the tracking photo-detector **60***c* and is changed to an electric current signal SC9. A tracking error signal S_{te} is calculated according to an equation (7).

$$S_{te}=SC7-SC8-SC9+SC10 \quad (7)$$

Therefore, the asymmetry of the intensity distribution of the transmitted light L4R (or the diffracted light L5R) incident on the wavefront changing unit **56**, which changes in dependence on the positional relation between the converging spot S1 (or S2) and a patterned track pit radiated by the light L4 or L5, is expressed by the tracking error signal S_{te}.

Thereafter, the objective lens **27** is moved in a radial direction so as to reduce a tracking error indicated by the tracking error signal S_{te}. The radial direction is defined as a direction perpendicular to both the optical axis and a series of patterned track pits. Therefore, the converging spot S1 (or S2) of the transmitted light L4 (or the diffracted light L5) on the information medium **23** (or **25**) can be formed in the middle of the patterned track pit, so that the tracking error becomes zero.

Accordingly, focus and tracking servo characteristics can be stably obtained in the optical head apparatus **51**. That is, because the wavefront changing unit **56** has a wavefront changing function, a focus error signal can be easily obtained. Also, because the diffracted light generating regions **56***b*, **56***c* are provided in the wavefront changing unit **56**, a tracking error signal can be easily obtained. Therefore, the number of parts required to manufacture the optical head apparatus **51** can be reduced, and the number of manufacturing steps can be reduced. In addition, the optical head apparatus can be manufactured at a low cost and in light weight.

Also, because the compound objective lens having two focal points is utilized in the optical head apparatus **51**, pieces of information can be reliably recorded or reproduced from an information medium by utilizing the optical head apparatus **51** regardless of whether the information medium is thick or thin.

(Seventh Embodiment)

Next, an optical head apparatus in which servo signals such as a focus error signal and a tracking error signal are detected according to an astigmatic aberration method is described according to a seventh embodiment of the present invention.

FIG. **27** is a constitutional view of an optical head apparatus according to a seventh embodiment.

As shown in FIG. **27**, an optical head apparatus **61** for recording or reproducing pieces of information on or from the information medium **23** or **25**, comprises the light source **52**, the collimator lens **53**, the beam splitter **54**, the compound objective lens **29** (or **29M**, **34**, **43**, **45**, **46** or **47**) composed of the hologram lens **26** (or **26M**, **32**, **33** or **42**) and the objective lens **27**, the actuating unit **58**, the converging lens **55**, an astigmatic aberration generating unit **62** such as a plane parallel plate for generating an astigmatic aberration in the transmitted light L4R or the diffracted light L5R converged by the converging lens **55**, and a photo detector **63** for detecting the intensity of the transmitted light L4R or the diffracted light L5R in which the astigmatic aberration is generated to obtain an information signal and servo signals such as a focus error signal and a tracking error signal.

The astigmatic aberration generating unit **62** is classified into one of the wavefront changing unit **56** because

a wavefront of the transmitted light L4R or the diffracted light L5R is changed by the generating unit **62** to generate the astigmatic aberration in the light L4R or L5R. Also, a normal line of the unit **62** is tilted from an optical axis.

As shown in FIG. **28**, the photo detector **63** comprises a quadrant photo-detector **64** in which four detecting sections SE7, SES, SE9 and SE10 are provided.

In the above configuration, the transmitted light L4R (or the diffracted light L5R) reflected by the information medium **23** (or **25**) is converged by the converging lens **55** in the same manner as in the sixth embodiment. Thereafter, the transmitted light L4R (or the diffracted light L5R) transmits through the astigmatic aberration generating unit **62** and is converged on the photo detector **57** to form a converging spot **S10** on the detecting sections SE7, SE8, SE9 and SE10 of the quadrant photo-detector **64**. In this case, because the transmitted light L4R (or the diffracted light L5R) converged by the converging lens **55** is a spherical wave, an astigmatic aberration is generated in the transmitted light L4R (or the diffracted light L5R) by the astigmatic aberration generating unit **62**. Therefore, as shown in FIGS. **29A** to **29C**, the shape of the converging spot **S10** considerably changes depending on a distance between the compound objective lens **29** and the information medium **23** (or **25**).

For example, in cases where the transmitted light L4 (or the diffracted light L5) is converged on the information medium **23** (or **25**) on condition that the objective lens **27** is defocused on the information medium **23** (or **25**), the converging spot **S10** of the transmitted light L4R (or the diffracted light L5R) is formed on the quadrant photo-detector **64** as shown in FIGS. **29A**, **29C**. In contrast, in cases where the transmitted light L4 (or the diffracted light L5) is converged on the information medium **23** (or **25**) on condition that the objective lens **27** is just focused on the information medium **23** (or **25**), the converging spot **S10** of the transmitted light L4R (or the diffracted light L5R) is formed on the quadrant photo-detector **64** as shown in FIG. **25B**.

The intensity of the transmitted light L4R (or the diffracted light L5R) is detected in the detecting sections SE7, SE8, SE9 and SE10 of the quadrant photo-detector **64** and is changed to electric current signals **SC11**, **SC12**, **SC13** and **SC14**. Thereafter, a focus error signal S_{fe} is obtained according to an astigmatic aberration method by calculating an equation (8).

$$S_{fe}=(SC11+SC14)-(SC12+SC13) \quad (8)$$

Thereafter, the position of the compound objective lens **29** is moved in a direction parallel to an optical axis at high speed so as to minimize the absolute value of the focus error signal S_{fe}.

Also, a tangential direction Dt agreeing with an extending direction of patterned recording pits and a radial direction Dr perpendicular to both the optical axis and the patterned recording pits are defined as shown in FIG. **29D**. In this case, when the quadrant photo-detector **64** is directed as shown in FIGS. **29A** to **29C**, a tracking error signal S_{te} is calculated according to an equation (9) by utilizing an intensity distribution change of the transmitted light L4R (or the diffracted light L5R) which depends on a positional relation between the converging spot **S10** and a recording pit radiated by the light L4 or L5.

$$S_{te}=SC11+SC13-(SC12+SC14) \quad (9)$$

Thereafter, the objective lens **27** is moved in the radial direction so as to reduce a tracking error indicated by the tracking error signal S_te. Therefore, the converging spot S1, (or S2) of the transmitted light L4 (or the diffracted light L5) on the information medium **23** (or **25**) can be formed in the middle of the recording pit, so that the tracking error becomes zero.

In other case, the tracking error signal S_{te} is obtained according to a phase difference method by utilizing the result calculated in the equation (8).

In addition, an information signal S_{in} is obtained by adding all of the electric current signals according to an equation (10).

$$S_{in}=SC11+SC12+SC13+SC14 \quad (10)$$

Accordingly, focus and tracking servo characteristics can be stably obtained in the optical head apparatus **61**. That is, because an astigmatic aberration is generated in the transmitted light L4R (or the diffracted light L5R) by the astigmatic aberration generating unit **62** made of a plane parallel plate, the servo signals such as a focus error signal and a tracking error signal can be easily obtained. Therefore, the number of parts required to manufacture the optical head apparatus **61** can be reduced, and the number of manufacturing steps can be reduced. In addition, the optical head apparatus **61** can be manufactured at a low cost and in light weight.

Also, because the compound objective lens having two focal points is utilized in the optical head apparatus **61**, pieces of information can be reliably recorded or reproduced from an information medium by utilizing the optical head apparatus **61** regardless of whether the information medium is thick or thin.

In the seventh embodiment, the astigmatic aberration generating unit **62** formed out of the plane parallel plate is arranged between the converging lens **55** and the photo detector **63**. However, as an optical head apparatus **65** is shown in FIG. **30**, it is applicable that a cylindrical lens **66** integrally formed with the converging lens **55** be arranged in place of the plane parallel plate to generate an astigmatic aberration in the transmitted light L4R (or the diffracted light L5R). In this case, because the cylindrical lens **66** is integrally formed with the converging lens **55**, the optical head apparatus can be moreover manufactured at low cost. In addition, as shown in FIG. **30**, it is applicable that a normal line of the hologram lens **26** (or **32**, **33**, **42**) be tilted from an optical axis passing through the center of the objective lens **27** by about one degree to prevent stray light reflected in a surface of the hologram lens **26** from being incident on the photo detector **57** or **63**. Also, it is applicable that the hologram lens **26** (or **32**, **33**, **42**) be coated with an anti-reflection coating to prevent the occurrence of stray light.

Also, as an optical head apparatus **67** is shown in FIG. **31**, it is applicable that a polarized beam splitter **68** be arranged in place of the beam splitter **54** to perfectly transmit the incident light L3 and a $\frac{1}{4}$-λ plate **69** be additionally placed between the hologram lens **26** (or **32**, **33**, **42**) and the polarized beam splitter **68**. In this case, because the incident light L3 transmits through the $\frac{1}{4}$-λ plate **69** in an outgoing optical path and because the transmitted light L4R (or the diffracted light L5R) again transmits through the $\frac{1}{4}$-λ plate **69** in an incoming optical path, the transmitted light L4R (or the diffracted light L5R) is perfectly reflected by the polarized

beam splitter **68**. Accordingly, a utilization efficiency of the incident light L3 can be enhanced. Also, a signal-noise ratio of each of the servo signals and the information signal can be enhanced.

Also, as an optical head apparatus **70** is shown in FIG. **32**, it is applicable that the polarized beam splitter **68** be arranged in place of the beam splitter **54** to perfectly transmit the incident light L3 and the $\frac{1}{4}$-λ plate **69** be additionally placed between the hologram lens **26** (or **32, 33, 42**) and the objective lens **27**. In this case, the transmitted light L4R (or the diffracted light L5R) is perfectly reflected by the polarized beam splitter **68** in the same manner as the optical head apparatus shown in FIG. **31**. In addition, because stray light reflected from the hologram lens **26** (or **32, 33, 42**) transmits through the polarized beam splitter **68**, the stray light is not incident on the photo detector **63**. Accordingly, a signal-noise ratio of each of the servo signals and the information signal can be moreover enhanced.

Also, as an optical head apparatus **71** is shown in FIG. **33**, it is applicable that a wedge-like prism **72** for reshaping the incident light L3 radiated from the light source **52** be additionally placed between the collimator lens **53** and the polarized beam splitter **68**. In this case, an elliptic wavefront of the incident light L3 is reshaped to a circular wavefront by the wedge-like prism **72**. Accordingly, a utilization efficiency of the incident light L3 can be enhanced.

In the sixth and seventh embodiments, when the transmitted light L4 (that is, zero-order diffracted light L4) converged on the first information medium **23** is reflected toward the compound objective lens to reproduce a piece of information recorded on the first information medium **23**, a part of the transmitted light L4R is diffracted in the hologram lens **26** (or **32, 33, 42**) on the incoming optical path, so that the part of the transmitted light L4R is changed to a beam of first-order diffracted light L13. Therefore, the first-order diffracted light L13 diverges from the hologram lens **26**, and a converging spot S11 of the diffracted light L13 is formed on the photo detector **57** or **63** in a relatively large size, as shown in FIG. **34**. The size of the converging spot S11 is larger than those of the sextant photo-detector **59** and the quadrant photo-detector **64**. Therefore, there is a drawback that a signal-noise ratio in the information signal deteriorates.

To solve the drawback, it is preferred that the photo detector **57** (or **63**) further comprise an information photo-detector **73** surrounding the sextant photo-detector **59** (or the quadrant photo-detector **64**). The size of the information photo-detector **73** is equal to or larger than a 1 mm square. Therefore, in cases where the information signal is determined by the sum of the intensity of the transmitted light L4 detected in the sextant photo-detector **59** (or the quadrant photo-detector **64**) and the intensity of the diffracted light L13 detected in the information photo-detector **73**, the signal-noise ratio in the information signal can be enhanced, and frequency characteristics of the information signal can be enhanced.

(Eighth Embodiment)

Next, a method of focusing performed in the optical head apparatuses **51, 61, 65, 67, 70** and **71** is described according to an eighth embodiment of the present invention.

FIG. **35A** graphically shows a change of the focus error signal obtained by detecting the intensity of the transmitted light L4 formed in the hologram lens **26, 32** or **33**, the strength of the focus error signal depending on a distance between the objective lens **27** and the first information medium **23**. FIG. **35B** graphically shows a change of the focus error signal obtained by detecting the intensity of the diffracted light L5 formed in the hologram lens **26, 32** or **33**, the strength of the focus error signal depending on a distance between the objective lens **27** and the second information medium **25**.

The intensity of the transmitted light L4 is high because the numerical aperture of the objective lens **27** for the transmitted light L4 is large. Therefore, as shown in FIG. **35A**, a change of a focus error signal FE1 obtained in cases where the objective lens **27** is almost focused on the first information medium **23** is considerably large as compared with a change of an unnecessary focus error signal FE2 obtained in cases where the objective lens **27** is defocused on the first information medium **23**. In addition, in cases where the hologram lens **26, 32** or **33** is utilized in each of the optical head apparatuses **51, 61, 65, 67, 70** and **71**, the unnecessary focus error signal FE2 is generated when the distance between the objective lens **27** and the first information medium **23** is larger than the focal length of the objective lens **27** for the transmitted light L4.

In contrast, the intensity of the diffracted light L5 is comparatively low because the numerical aperture of the objective lens **27** for the diffracted light L5 is comparatively small. Therefore, as shown in FIG. **35B**, a change of a focus error signal FE3 obtained in cases where the objective lens **27** is almost focused on the second information medium **25** is almost the same as that of an unnecessary focus error signal FE4 obtained in cases where the objective lens **27** is defocused on the second information medium **25**. In addition, in cases where the hologram lens **26, 32** or **33** is utilized in each of the optical head apparatuses **51, 61, 65, 67, 70** and **71**, the unnecessary focus error signal FE4 is generated when the distance between the objective lens **27** and the second information medium **25** is smaller than the focal length of the objective lens **27** for the diffracted light L5.

Therefore, in cases where the focusing of the transmitted light L4 on the first information medium **23** is performed, the objective lens **27** placed far from the first information medium **23** is gradually brought near to the first information medium **23**. Thereafter, when the strength of the focus error signal reaches a threshold value, a focus servo loop provided in the photo detector **57** or **63** is set to an operation condition, so that the objective lens **27** is set to be focused on the first information medium **23**. Also, in cases where the focusing of the diffracted light L5 on the second information medium **25** is performed, the objective lens **27** placed far from the second information medium **25** is gradually brought near to the second information medium **25** in the same manner. Thereafter, when the strength of the focus error signal reaches a threshold value, a focus servo loop provided in the photo detector **57** or **63** is set to an operation condition, so that the objective lens **27** is set to be focused on the second information medium **25**.

Accordingly, the inverse influence of the unnecessary focus error signal FE4 on the focusing of the diffracted light L5 can be prevented. Also, because the objective lens **27** placed far from the information medium **23** or **25** is gradually brought near to the information medium **23** or **25** regardless of whether the information medium is T1 or T2 in thickness, a focusing

operation in each of the optical head apparatuses **51**, **61**, **65**, **67**, **70** and **71** with the hologram lens **26**, **32** or **33** can be performed according to a common procedure by changing the threshold value or performing an auto gain control in which the focus error signal is normalized by detecting the total intensity of the transmitted light L4R or the diffracted light L5R. Therefore, a control circuit required to perform the focusing operation can be made at a low cost.

FIG. **36**A graphically shows a change of the focus error signal obtained by detecting the intensity of the diffracted light L6 formed in the hologram lens **42**, the strength of the focus error signal depending on a distance between the objective lens **27** and the first information medium **23**. FIG. **36**B graphically shows a change of the focus error signal obtained by detecting the intensity of the transmitted light L4 formed in the hologram lens **42**, the strength of the focus error signal depending on a distance between the objective lens **27** and the second information medium **25**.

As shown in FIG. **36**A, a change of a focus error signal FE5 obtained in cases where the objective lens **27** is almost focused on the first information medium **23** is considerably large as compared with a change of an unnecessary focus error signal FE6 obtained in cases where the objective lens **27** is defocused on the first information medium **23**. In addition, in cases where the hologram lens **42** is utilized in each of the optical head apparatuses **51**, **61**, **65**, **67**, **70** and **71**, the unnecessary focus error signal FE6 is generated when the distance between the objective lens **27** and the first information medium **23** is smaller than the focal length of the objective lens **27** for the diffracted light L6.

In contrast, as shown in FIG. **36**B, a change of a focus error signal FE7 obtained in cases where the objective lens **27** is almost focused on the second information medium **25** is almost the same as that of an unnecessary focus error signal FE8 obtained in cases where the objective lens **27** is defocused on the second information medium **25**. In addition, in cases where the hologram lens **42** is utilized in each of the optical head apparatuses **51**, **61**, **65**, **67**, **70** and **71**, the unnecessary focus error signal FE8 is generated when the distance between the objective lens **27** and the second information medium **25** is larger than the focal length of the objective lens **27** for the transmitted light L4.

Therefore, in cases where the focusing of the diffracted light L6 on the first information medium **23** is performed, the objective lens **27** placed near to the first information medium **23** is gradually moved away from the first information medium **23**. Thereafter, when the strength of the focus error signal reaches a threshold value, a focus servo loop provided in the photo detector **57** or **63** is set to an operation condition, so that the objective lens **27** is set to be focused on the first information medium **23**. Also, in cases where the focusing of the transmitted light L4 on the second information medium **25** is performed, the objective lens **27** placed near to the second information medium **25** is gradually moved away from the second information medium **25** in the same manner. Thereafter, when the strength of the focus error signal reaches a threshold value, a focus servo loop provided in the photo detector **57** or **63** is set to an operation condition, so that the objective lens **27** is set to be focused on the second information medium **25**.

Accordingly, the inverse influence of the unnecessary focus error signal FEB on the focusing of the transmitted light L4 can be prevented. Also, because the objective lens **27** placed near to the information medium **23** or **25** is gradually moved away from the information medium **23** or **25** regardless of whether the information medium is T1 or T2 in thickness, a focusing operation in each of the optical head apparatuses **51**, **61**, **65**, **67**, **70** and **71** with the hologram lens **42** can be performed according to a common procedure by changing the threshold value or performing the auto gain control. Therefore, a control circuit required to perform the focusing operation can be made at a low cost.

(Ninth Embodiment)

An optical head apparatus with the compound objective lens **29**, **34**, **45**, **46** or **47** in which the incident light L3 is efficiently utilized to obtain an information signal and servo signals is described with reference to FIGS. **29**, **37** according to a ninth embodiment of the present invention.

FIG. **37** is a constitutional view of an optical head apparatus according to a ninth embodiment.

As shown in FIG. **37**, an optical head apparatus **81** for recording or reproducing pieces of information on or from the information medium **23** or **25**, comprises the light source **52**, the collimator lens **53**, the beam splitter **54**, the compound objective lens the compound objective lens **29** (**34**, **45**, **46** or **47**) composed of the hologram lens **26** (or **32** or **33**) and the objective lens **27**, the actuating unit **58**, the converging lens **55**, a beam splitter **82** for transmitting a beam of diffracted light L5R or reflecting a beam of transmitted light L4R, the photo detector **63** for detecting the intensity of the diffracted light L5R transmitting through the beam splitter **82** to obtain servo signals and an information signal recorded on the second information medium **25**, the wavefront changing device **56** such as a hologram for changing a wavefront of the transmitted light L4R reflected by the beam splitter **82**, and the photo detector **57** for detecting the intensity of the transmitted light L4R to obtain servo signals and an information signal recorded on the first information medium **23**. The beam splitter **82** is made of a plane parallel plate of which a normal line is tilted from an optical path, so that an astigmatic aberration is generated in the diffracted light L5R passing through the beam splitter **82**. Also, a coating is applied on a surface of the plane parallel plate.

In the above configuration, the transmitted light L4 (or the diffracted light L5) are converged by the converging lens **27** in the same manner as in the sixth embodiment. Thereafter, in cases where a piece of information is recorded or reproduced on or from the first information medium **23**, the transmitted light L4 is converged on the first information medium **23** to form the first converging spot S1. Thereafter, a beam of transmitted light L4R reflected by the first information medium **23** passes through the same optical path in the reverse direction. That is, a great part of the transmitted light L4R again transmits through the compound objective lens without any diffraction and is reflected by the beam splitter **54**. Thereafter, the transmitted light L4R is converged by the converging lens **55**, and a part of the transmitted light L4R is reflected by the beam splitter **82**. Thereafter, the wavefront of a great part of the transmitted light L4R is changed by the wavefront changing unit **56**, and the great part of the transmitted light L4R is converged on the photo detector **57** to form the converging spots S8, S9. Therefore, an information signal and servo signals such as a focus error

signal and a tracking error signal are obtained in the same manner as in the sixth embodiment. Also, a remaining part of the transmitted light L4R not changed its wavefront is converged on the photo detector 57 to form the converging spot S7.

In contrast, in cases where a piece of information is recorded or reproduced on or from the second information medium 25, the diffracted light L5 is converged on the second information medium 25 to form the second converging spot S2. Thereafter, a beam of diffracted light L5R reflected by the second information medium 25 passes through the same optical path in the reverse direction, and a great part of the diffracted light L5R transmits through the hologram lens 26 without any diffraction. Therefore, the diffracted light L5R passes through the incoming optical path differing from the outgoing optical path. Thereafter, the diffracted light L5R is reflected by the beam splitter 54 and is converged by the converging lens 55. Thereafter, a part of the diffracted light L5R transmits through the beam splitter 82. In this case, an astigmatic aberration is generated in the diffracted light L5R. Thereafter, the diffracted light L5R is converged on the photo detector 63 to form a converging spot S12 of which the shape is the same as the converging spot S10 shown in FIGS. 29A to 29C, and the intensity of the diffracted light L5R is detected in the photo detector 63. Therefore, an information signal and servo signals such as a focus error signal and a tracking error signal are obtained in the same manner as in the seventh embodiment.

In this case, though a remaining part of the transmitted light L4R transmits through the beam splitter 82, the remaining part of the transmitted light L4R is not converged at the converging spot S12 because the transmitted light L4R passes through the same optical path. Also, though a remaining part of the diffracted light L5R is reflected the beam splitter 82, the remaining part of the diffracted light L5R is not converged at the converging spot S7, S8 or S9 because the diffracted light L5R passes through the incoming optical path differing from the outgoing optical path.

In the ninth embodiment, because the diffracted light L5R transmits through the hologram lens 26 without any diffraction, the converging spot S12 formed on the photo detector 63 does not relate to a radiating point of the light source 52 in a mirror image, while the converging spot S7 formed on the photo detector 57 relates to the radiating point of the light source 52 in the mirror image. In other words, a focal point of the diffracted light L5R converged by the converging lens 55 differs from that of the transmitted light L4R converged by the converging lens 55. Therefore, the photo detector 57 for detecting the intensity of the transmitted light L4R and the photo detector 63 for detecting the intensity of the diffracted light L5R are required.

Accordingly, because the compound objective lens having two focal points is utilized in the optical head apparatus 81, pieces of information can be reliably recorded or reproduced on or from an information medium regardless of whether the information medium is thick or thin.

An example of the utilization of the optical head apparatus 81 for various types of optical disks is described.

In cases where the optical head apparatus 81 is utilized for an optical disk device in which pieces of information recorded in a thin type of high density optical disk 23 are recorded or reproduced and pieces of information recorded in a thick type of optical disk 25 are exclusively reproduced, the diffraction efficiency of the hologram lens 26, 32 or 33 in the compound objective lens 29, 34, 45, 46 or 47 for changing a beam of light to a beam of first-order diffracted light is set to a value equal to or lower than 30%. Therefore, in cases where a piece of information recorded on the thick type of optical disk 25 is reproduced in the photo detector 63, a signal-noise ratio of each of the servo signals and the information signal obtained in the photo detector 63 can be enhanced because the diffracted light L5R transmitting through the hologram lens 26, 32 or 33 at a high transmission efficiency is utilized to obtain the servo signals and the information signal. In other words, a utilization efficiency of the incident light L3 can be enhanced when a piece of information recorded on the thick type of optical disk 25 is reproduced, so that the output power of the incident light L3 can be minimized. Also, even though a high intensity of the transmitted light L4 is required to record a piece of information on the high density optical disk 23, the recording of the information can be reliably performed without increasing the intensity of the incident light L3 because a transmission efficiency of the hologram lens 26, 32 or 33 for the incident light L3 is high. Also, in cases where a piece of information recorded on the high density optical disk 23 is reproduced in the photo detector 57, a signal-noise ratio of each signal obtained in the photo detector 57 can be enhanced because the transmission efficiency of the hologram lens 32 or 33 for the light L3, L4R is high.

(Tenth Embodiment)

An optical head apparatus with the compound objective lens 29, 34, 45, 46 or 47 in which the incident light L3 is efficiently utilized to obtain an information signal and servo signals is described with reference to FIGS. 38, 39 according to a tenth embodiment of the present invention. X1 and Y1 coordinates shown in FIGS. 38, 39 are utilized in common.

FIG. 38 is a constitutional view of an optical head apparatus according to a tenth embodiment. FIG. 39 is a plan view of a beam splitter having a reflection type of hologram utilized in the optical head apparatus shown in FIG. 38.

As shown in FIG. 38, an optical head apparatus 91 for recording or reproducing pieces of information on or from the information medium 23 or 25, comprises the light source 52, the collimator lens 53, the beam splitter 54, the compound objective lens 29 (or 34, 45, 46 or 47) composed of the hologram lens 26 (or 32 or 33) and the objective lens 27, the actuating unit 58, the converging lens 55, a beam splitter 92 having a reflection type of hologram 93 for transmitting a large part of the transmitted light L4R or reflecting all of the diffracted light L5R incident on the hologram 93, the photo detector 63 for detecting the intensity of the transmitted light L4R transmitting through the beam splitter 92 to obtain servo signals and an information signal recorded in the first information medium 23, and the photo detector 57 for detecting the intensity of the diffracted light L5R to obtain servo signals and an information signal recorded in the second information medium 25.

The beam splitter 92 is made of a plane parallel plate inclined to an optical path, so that an astigmatic aberration is generated in the transmitted light L4R passing through the beam splitter 92. Also, as shown in FIG. 39, the reflection type of hologram 93 is arranged at a cen-

ter portion of the beam splitter **92**, and a light transmitting region **92***a* is arranged at a peripheral portion of the beam splitter **92** to surround the hologram **93**. Light incident on the light transmitting region **92***a* transmits without any diffraction. The hologram **92** is partitioned into a diffracted light generating region **93***a* in which a grating pattern P7 is drawn and a pair of diffracted light generating regions **93***b*, **93***c* in which a pair of grating patterns P8, P9 are drawn. The diffracted light L5R incident on the diffracted light generating region **93***a* is diffracted to obtain a focus error signal in the photo detector **57**. The diffracted light L5R incident on each of the diffracted light generating regions **93***b*, **93***c* is diffracted to obtain a tracking error signal in the photo detector **57**.

In the above configuration, the transmitted light L4 and the diffracted light L5 are converged by the converging lens **27** in the same manner as in the sixth embodiment. Thereafter, in cases where a piece of information is recorded or reproduced on or from the first information medium **23**, the transmitted light L4 is converged on the first information medium **23** to form the first converging spot S1. Thereafter, a beam of transmitted light L4R reflected by the first information medium **23** passes through the same optical path in the reverse direction. That is, a large part of the transmitted light L4R again transmits through the compound objective lens **29** without any diffraction and is reflected by the beam splitter **54**. Thereafter, the transmitted light L4R is converged by the converging lens **55**, and a large part of the transmitted light L4R transmits through the beam splitter **92**. In this case, an astigmatic aberration is generated in the transmitted light L4R. Thereafter, the transmitted light L4R is converged on the photo detector **63** to form a converging spot S13 of which the shape is the same as the converging spot S10 shown in FIGS. **29**A to **29**C, and the intensity of the transmitted light L4R is detected in the photo detector **63**. Therefore, an information signal and servo signals such as a focus error signal and a tracking error signal are obtained in the same manner as in the seventh embodiment.

In contrast, in cases where a piece of information is recorded or reproduced on or from the second information medium **25**, the diffracted light L5 is converged on the second information medium **25** to form the second converging spot S2. Thereafter, a beam of diffracted light L5R reflected by the second information medium **25** passes through the same optical path in the reverse direction, and a large part of the diffracted light L5R transmits through the hologram lens **26** without any diffraction. Therefore, the diffracted light L5R transmits on the incoming optical path differing from the outgoing optical path in the same manner as in the ninth embodiment. Thereafter, the diffracted light L5R is reflected by the beam splitter **54** and is converged by the converging lens **55** on the beam splitter **92** to form a converging spot on the reflection type of hologram **93** of the beam splitter **92**. Therefore, all of the diffracted light L5R is diffracted and reflected by the hologram **93** to be converged on the photo detector **57**. That is, the diffracted light L5R diffracted and reflected in the diffracted light generating region **93***a* of the hologram **93** is splitted into two beams and is converged on the detecting sections SE1 to SE6 of the sextant photo-detector **59** in the photo detector **57** in the same manner as in the sixth embodiment. Also, the diffracted light L5R diffracted and reflected in the diffracted light generating region **93***b* of the hologram **93** is splitted into two beams, and the intensity of the diffracted light L5R is detected in the tracking photo-detectors **60***a* and **60***d*. Also, the diffracted light L5R diffracted and reflected in the diffracted light generating region **93***c* of the hologram **93** is splitted into two beams, and the intensity of the diffracted light L5R is detected in the tracking photo-detectors **60***b* and **60***c*. Therefore, an information signal and servo signals such as a focus error signal and a tracking error signal are obtained in the same manner as in the sixth embodiment.

In the tenth embodiment, because the transmitted light L4R transmits through the hologram lens **26** without any diffraction, the converging spot S13 formed on the photo detector **63** does not relate to a radiating point of the light source **52** in a mirror image. Therefore, the photo detector **57** for detecting the intensity of the diffracted light L5R and the photo detector **63** for detecting the intensity of the transmitted light L4R are required.

Accordingly, because the compound objective lens having two focal points is utilized in the optical head apparatus **91**, pieces of information can be reliably recorded or reproduced on or from an information medium regardless of whether the information medium is thick or thin.

Also, because all of the diffracted light L5R is completely diffracted and reflected by the hologram **93** of the beam splitter **92**, the diffracted light L5R can be utilized at high efficiency. Therefore, a signal-noise ratio of the signals obtained in the photo detector **57** can be enhanced.

An example of the utilization of the optical head apparatus **91** for various types of optical disks is described.

In cases where the optical head apparatus **91** is utilized for an optical disk device in which pieces of information recorded in a thin type of high density optical disk **23** are recorded or reproduced and pieces of information recorded in a thick type of optical disk **25** are exclusively reproduced, the diffraction efficiency of the hologram lens **26**, **32** or **33** in the compound objective lens **29**, **34**, **45**, **46** or **47** for changing a beam of light to a beam of first-order diffracted light is set to a value equal to or lower than 30%. Therefore, in cases where a piece of information recorded on the thick type of optical disk **25** is reproduced in the photo detector **57**, a signal-noise ratio of each of the servo signals and the information signal obtained in the photo detector **57** can be enhanced because the diffracted light L5R transmitting through the hologram lens **26**, **32** or **33** at a high transmission efficiency is utilized to obtain the servo signals and the information signal. In other words, a utilization efficiency of the incident light L3 can be enhanced when a piece of information recorded on the thick type of optical disk **25** is reproduced, so that the output power of the incident light L3 can be minimized. Also, even though a high intensity of the transmitted light L4 is required to record a piece of information on the high density optical disk **23**, the recording of the information can be reliably performed without increasing the intensity of the incident light L3 because a transmission efficiency of the hologram lens **26**, **32** or **33** for the incident light L3 is high. Also, in cases where a piece of information recorded on the high density optical disk **23** is reproduced in the photo detector **63**, a signal-noise ratio of each signal obtained in the photo detector **63** can be enhanced because the transmission

efficiency of the hologram lens **26**, **32** or **33** for the light L3, L4R is high.

(Eleventh Embodiment)

An optical head apparatus with the compound objective lens **29**, **34**, **45**, **46** or **47** in which the incident light L3 is efficiently utilized to obtain an information signal and servo signals is described with reference to FIGS. **40** to **42** according to an eleventh embodiment of the present invention. X1 and Y1 co-ordinates shown in FIGS. **40**, **41** are utilized in common, and X, Y and Z co-ordinates shown in FIGS. **40**, **42** are utilized in common.

FIGS. **40**A, **40**B are respectively a constitutional view of an optical head apparatus according an eleventh embodiment. FIG. **41** is a plan view of a beam splitter having a reflection type of hologram utilized in the optical head apparatus shown in FIG. **38**.

As shown in FIGS. **40**A, **40**B, an optical head apparatus **101** for recording or reproducing pieces of information on or from the information medium **23** or **25**, comprises the light source **52**, the collimator lens **53**, the beam splitter **54**, the compound objective lens **29** (or **34**, **45**, **46** or **47**) composed of the hologram lens **26** (or **32** or **33**) and the objective lens **27**, the actuating unit **58**, the converging lens **55**, a beam splitter **102** having a transmission type of hologram **103** for transmitting the transmitted light L4R converged on the first information medium **23** and the diffracted light L5R converged on the second information medium **25** and diffracting the transmitted light L4R which is converged on the second information medium **25** in defocus, a photo detector **104** for detecting the intensity of the transmitted light L4R converged on the first information medium **23** to obtain servo signals and an information signal recorded in the first information medium **23**, detecting in defocus the intensity of the diffracted light L5R to obtain an information signal recorded in the second information medium **25**, and detecting the intensity of the transmitted light L4R converged on the second information medium **25** in defocus to obtain a focus error signal.

The beam splitter **102** is made of a plane parallel plate inclined to an optical path, so that an astigmatic aberration is generated in the light L4R, L5R passing through the beam splitter **102**. Also, as shown in FIG. **41**, the transmission type of hologram **103** is arranged at a center portion of the beam splitter **102**, and a light transmitting region **102***a* is arranged at a peripheral portion of the beam splitter **102** to surround the hologram **103**. The transmitted light L4R incident on the light transmitting region **102***a* transmits without any diffraction. The hologram **102** is partitioned into diffracted light generating regions **103***a*, **103***b* alternately arranged to detect a focus error signal according to the spot size detection method described in the sixth embodiment. That is, a grating pattern **P10** is drawn in each of the diffracted light generating regions **103***a*, and a converging spot is formed by the transmitted light L4R diffracted in the regions **103***a*. Also, a grating pattern **P11** is drawn in each of the diffracted light generating regions **103***b*, and another converging spot is formed by the transmitted light L4R diffracted in the regions **103***b*.

The photo detector **104** comprises the sextant photodetector **59** in which the detecting sections SE1, SE2, SE3, SE4, SE5 and SE6 are provided in the same manner as the photo detector **57**.

In the above configuration, the transmitted light L4 and the diffracted light L5 are converged by the converging lens **27** in the same manner as in the sixth embodiment. Thereafter, in cases where a piece of information is recorded or reproduced on or from the first information medium **23**, as shown in FIG. **40**A, the transmitted light L4 is converged on the first information medium **23** to form the first converging spot **S1**. Thereafter, a beam of transmitted light L4R reflected by the first information medium **23** passes through the same optical path in the reverse direction. That is, the transmitted light L4R again transmits through the compound objective lens without any diffraction and is reflected by the beam splitter **54**. Thereafter, the transmitted light L4R is converged by the converging lens **55**, and a major part of the transmitted light L4R transmits through the beam splitter **103**. In this case, an astigmatic aberration is generated in the transmitted light L4R. Thereafter, the transmitted light L4R is converged on the photo detector **104** to form a converging spot **S14** of which the shape is the same as the converging spot **S10** shown in FIGS. **29**A to **29**C, and the intensity of the transmitted light L4R is detected in the photo detector **104**. Therefore, an information signal and servo signals such as a focus error signal and a tracking error signal are obtained in the same manner as in the seventh embodiment. In this case, because the position of the photo detector **104** detecting the transmitted light L4R relates to a radiation point of the light source **52** in a mirror image, the transmitted light L4R is converged on the photo detector **104** just in focus.

In contrast, in cases where a piece of information is recorded or reproduced on or from the second information medium **25**, as shown in FIG. **40**B, the diffracted light L5 is converged on the second information medium **25** to form the second converging spot **S2**. Thereafter, a beam of diffracted light L5R reflected by the second information medium **25** passes through the same optical path in the reverse direction and transmits through the hologram lens **26** without any diffraction. Therefore, the diffracted light L5R transmits on the incoming optical path differing from the outgoing optical path in the same manner as in the ninth embodiment. Thereafter, the diffracted light L5R is reflected by the beam splitter **54** and is converged by the converging lens **55**. Thereafter, a major part of the diffracted light L5R transmits through the beam splitter **102**, and the diffracted light L5R is converged on the photo detector **57**. In this case, an astigmatic aberration is generated in the diffracted light L5R. Also, because the diffracted light L5R is not diffracted by the hologram lens **26** on the incoming optical path, the position of the photo detector **104** detecting the diffracted light L5R does not relate to the radiation point of the light source **52** in the mirror image. Therefore, the diffracted light L5R is converged on the photo detector **104** in defocus. However, because the entire intensity of the diffracted light L5R converged in defocus is detected in the photo detector **104**, an information signal is obtained in the same manner as in the seventh embodiment.

Also, the transmitted light L4 is converged on the second information medium **25** in defocus as shown in FIG. **40**B. That is, the transmitted light L4 incident on the rear surface of the second information medium **25** is converged at the front surface of the second information medium **25**. Thereafter, a beam of transmitted light L4R reflected at the front surface of the second information medium **25** again transmits through the compound objective lens without any diffraction and is reflected by the beam splitter **54**. Thereafter, the trans-

mitted light L4R is converged by the converging lens **55** on the beam splitter **102** to form a converging spot on the of hologram **103** of the beam splitter **102**. Therefore, all of the transmitted light L4R is diffracted by the hologram **103** and is converged on the photo detector **104**. That is, the transmitted light L4R diffracted in the diffracted light generating regions **103***a* of the hologram **103** is changed to a first spherical wave SW1 of which a focal point is placed at the front of the photo detector **104**, and the transmitted light L4R diffracted in the diffracted light generating regions **103***b* of the hologram **103** is changed to a second spherical wave SW2 of which a focal point is placed at the rear of the photo detector **104**. Thereafter, as shown in FIGS. **42**A to **42**C, the first spherical wave SW1 is converged on the detecting sections SE1 to SE3 of the sextant photo-detector **59** in the photo detector **104** to form a converging spot S15A, and the second spherical wave SW2 is converged on the detecting sections SE4 to SE6 of the sextant photo-detector **59** to form a converging spot S15B. Because the regions **103***a*, **103***b* are divided into many pieces, the converging spots S15A, S15B are respectively divided into many pieces.

In cases where the diffracted light L5 is converged on the information medium **25** in defocus, the converging spots S15A, S15B of the transmitted light L4R shown in FIGS. **42**A, **42**C are formed on the sextant photo-detector **59**. In contrast, in cases where the diffracted light L5 is converged on the information medium **25** in focus, the converging spots S15A, S15B of the transmitted light L4R shown in FIG. **42**B are formed on the sextant photo-detector **59**. The intensity of the transmitted light L4R is detected in each of the detecting sections SE1 to SE6 of the sextant photo-detector **59** and is changed to electric current signals SC15 to SC20. Thereafter, a focus error signal S_{fe} is obtained according to the spot size detection method by calculating an equation (11).

$$S_{fe}=(SC15+SC17-SC16)-(SC18+SC20-SC19) \quad (11)$$

Thereafter, the position of the compound objective lens is moved in a direction along an optical axis at high speed so as to minimize the absolute value of the focus error signal S_{fe}. Therefore, the focus error signal is obtained in the same manner as in the sixth embodiment.

Accordingly, because the compound objective lens having two focal points is utilized in the optical head apparatus **101**, pieces of information can be reliably recorded or reproduced on or from an information medium regardless of whether the information medium is thick or thin.

Also, because all of the transmitted light L4R reflected by the second information medium **25** is completely diffracted by the hologram **103** of the beam splitter **102** to detect the focus error signal, the transmitted light L4R can be utilized at high efficiency. Therefore, a signal-noise ratio of the focus error signal obtained in the photo detector **104** can be enhanced.

Also, the information signal and the servo signals can be obtained in the photo detector **104** regardless of whether the information medium **23** or **25** is thin or thick. Therefore, the number of parts required to manufacture the optical head apparatus **101** can be reduced, and a small sized optical head apparatus can be manufactured at a low cost and in light weight even though pieces of information are recorded or reproduced on or from an information medium by utilizing the optical head apparatus **101** regardless of whether the information medium is thick or thin.

An example of the utilization of the optical head apparatus **101** for various types of optical disks is described.

In cases where the optical head apparatus **101** is utilized for an optical disk device in which pieces of information recorded in a thin type of high density optical disk **23** are recorded or reproduced and pieces of information recorded in a thick type of optical disk **25** are exclusively reproduced, the diffraction efficiency of the hologram lens **26**, **32** or **33** in the compound objective lens **29**, **34**, **45**, **46** or **47** is set to a value equal to or lower than 30%. Therefore, in cases where a piece of information recorded on the thick type of optical disk **25** is reproduced in the photo detector **104**, a signal-noise ratio of each of the servo signals and the information signal obtained in the photo detector **104** can be enhanced because the diffracted light L5R transmitting through the hologram lens **26**, **32** or **33** at a high transmission efficiency is utilized to obtain the information signal. In other words, a utilization efficiency of the incident light L3 can be enhanced when a piece of information recorded on the thick type of optical disk **25** is reproduced, so that the output power of the incident light L3 can be minimized. Also, even though a high intensity of the transmitted light L4 is required to record a piece of information on the high density optical disk **23**, the recording of the information can be reliably performed without increasing the intensity of the incident light L3 because a transmission efficiency of the hologram lens **26**, **32** or **33** for the incident light L3 is high. Also, in cases where a piece of information recorded on the high density optical disk **23** is reproduced in the photo detector **63**, a signal-noise ratio of each signal obtained in the photo detector **63** can be enhanced because the transmission efficiency of the hologram lens **26**, **32** or **33** for the light L3, L4R is high.

(Twelfth Embodiment)

An optical head apparatus with the compound objective lens **29**M, **43**, **45**, **46** or **47** in which the incident light L3 is efficiently utilized to obtain an information signal and servo signals is described with reference to FIG. **43** according to a twelfth embodiment of the present invention.

FIG. **43** is a constitutional view of an optical head apparatus according to a twelfth embodiment.

As shown in FIG. **43**, an optical head apparatus **111** for recording or reproducing pieces of information on or from the information medium **23** or **25**, comprises the light source **52**, the collimator lens **53**, the beam splitter **54**, the compound objective lens **29**M (or **43**, **45**, **46** or **47**) composed of the hologram lens **42** (or **26**M or **32**) and the objective lens **27**, the actuating unit **58**, the converging lens **55**, the beam splitter **82**, the photo detector **63**, the wavefront changing device **56**, and the photo detector **57**.

In the above configuration, a beam of incident light L3 radiated from the light source **52** is collimated in the collimator lens **53** and transmits through the beam splitter **54**. Thereafter, a part of the incident light L3 transmits through the compound objective lens **29** without any diffraction, and a remaining part of the incident light L3 is diffracted.

Thereafter, in cases where a piece of information is recorded or reproduced on or from the first information medium **23**, the diffracted light L6 is converged on the

first information medium **23** to form the converging spot **S5**. That is, the diffracted light **L6** is incident on the rear surface of the first information medium **23**, and the converging spot **S5** is formed on the front surface of the first information medium **23**. Thereafter, a beam of diffracted light **L6R** reflected at the front surface of the first information medium **23** passes through the same optical path in the reverse direction, and a great part of the diffracted light **L6R** is again diffracted by the hologram lens **42**. Therefore, the diffracted light **L6R** transmits on the incoming optical path agreeing with the outgoing optical path. Thereafter, the diffracted light **L6R** is reflected by the beam splitter **54** and is converged by the converging lens **55**. Thereafter, a part of the diffracted light **L6R** transmits through the beam splitter **82**. In this case, an astigmatic aberration is generated in the diffracted light **L6R**. Thereafter, the diffracted light **L6R** is converged on the photo detector **63** to form the converging spot **S10** of which the shape is shown in FIGS. **29A** to **29C**, and the intensity of the diffracted light **L6R** is detected in the photo detector **63**. Therefore, an information signal and servo signals such as a focus error signal and a tracking error signal are obtained in the same manner as in the seventh embodiment.

In contrast, in cases where a piece of information is recorded or reproduced on or from the second information medium **25**, the transmitted light **L4** is converged on the second information medium **25** to form the converging spot **S6**. That is, the transmitted light **L4** is incident on the rear surface of the second information medium **25**, and the converging spot **S6** is formed on the front surface of the second information medium **25**. Thereafter, a beam of transmitted light **L4R** reflected at the front surface of the second information medium **25** passes through the same optical path in the reverse direction. That is, the transmitted light **L4R** is collimated by the objective lens **27** on the incoming optical path. Thereafter, a great part of the transmitted light **L4R** is diffracted by the hologram lens **42**. Therefore, the transmitted light **L4R** transmits on the incoming optical path differing from the outgoing optical path. Thereafter, the transmitted light **L4R** is reflected by the beam splitter **54** and is converged by the converging lens **55**. Thereafter, a part of the transmitted light **L4R** is reflected by the beam splitter **82**. Thereafter, the wavefront of a great part of the transmitted light **L4R** is changed by the wavefront changing unit **56**, and the great part of the transmitted light **L4R** is converged on the photo detector **57** to form converging spots **S16**, **S17**. Therefore, an information signal and servo signals such as a focus error signal and a tracking error signal are obtained in the same manner as in the sixth embodiment. Also, a remaining part of the transmitted light **L4R** not changed its wavefront by the wavefront changing unit **56** is converged on the photo detector **57** to form the converging spot **S18**.

In the twelfth embodiment, because the transmitted light **L4R** is diffracted by the hologram lens **42** on the incoming optical path, the converging spot **S18** formed on the photo detector **57** does not relate to a radiation point of the light source **52** in a mirror image, while the converging spot **S10** formed on the photo detector **63** relates to the radiation point of the light source **52** in the mirror image. In other words, a focal point of the transmitted light **L4R** converged by the converging lens **55** differs from that of the diffracted light **L6R** converged by the converging lens **55**. Therefore, the photo detector **57** for detecting the intensity of the transmitted light **L4R** and the photo detector **63** for detecting the intensity of the diffracted light **L6R** are required.

Accordingly, even though pieces of information are recorded or reproduced on or from an information medium, the information can be reliably recorded or reproduced on or from the information medium regardless of whether the information medium is thick or thin.

Also, because the diffracted light **L6** formed in the hologram lens **42** converges before the diffracted light **L6** is incident on the objective lens **27**, the distance in an optical axis direction between the converging spots **S5**, **S6** can be lengthened to about 1 mm. Therefore, even though the transmitted light **L4** (or the diffracted light **L6**) is converged on the converging spot **S6** (or **S5**) in focus to record or read a piece of information, the light **L6** (or **L4**) is not converged on the converging spot **S6** (or **S5**) in focus to reduce the intensity of the light **L6** (or **L4**) at the converging spot **S6** (or **S5**). Accordingly, no adverse influence is exerted on the recording or reproduction of the information

Also, because the hologram lens **42** functions as a convex lens for the first-order diffracted light **L6**, the occurrence of a chromatic aberration can be prevented in the optical head apparatus **111**.

An example of the utilization of the optical head apparatus **111** for various types of optical disks is described.

In cases where the optical head apparatus **111** is utilized for an optical disk device in which pieces of information recorded in a thin type of high density optical disk **23** are recorded or reproduced and pieces of information recorded in a thick type of optical disk **25** are exclusively reproduced, the diffraction efficiency of the hologram lens **26M** or **42** in the compound objective lens **29M**, **43**, **45**, **46** or **47** for changing a beam of light to a beam of first-order diffracted light is set to a value equal to or higher than 55%. Therefore, in cases where a piece of information recorded on the thick type of optical disk **25** is reproduced in the photo detector **57**, a signal-noise ratio of each of the servo signals and the information signal obtained in the photo detector **57** can be enhanced because the transmitted light **L4R** diffracted by the hologram lens **26M** or **42** at a high diffraction efficiency is utilized to obtain the servo signals and the information signal. In other words, a utilization efficiency of the incident light **L3** can be enhanced when a piece of information recorded on the thick type of optical disk **25** is reproduced, so that the output power of the incident light **L3** can be minimized. Also, even though a high intensity of the diffracted light **L6** is required to record a piece of information on the high density optical disk **23**, the recording of the information can be reliably performed without increasing the intensity of the incident light **L3** because the diffraction efficiency of the hologram lens **26M** or **42** for the incident light **L3** and the diffracted light **L6R** is high. Also, in cases where a piece of information recorded on the high density optical disk **23** is reproduced in the photo detector **63**, a signal-noise ratio of each signal obtained in the photo detector **63** can be enhanced because the diffraction efficiency of the hologram lens **26M** or **42** for the light **L3**, **L6R** is high.

(Thirteenth Embodiment)

An optical head apparatus with the compound objective lens **29M**, **43**, **45**, **46** or **47** in which the incident light **L3** is efficiently utilized to obtain an information

signal and servo signals is described with reference to FIG. **44** according to a thirteenth embodiment of the present invention.

FIG. **44** is a constitutional view of an optical head apparatus according to a thirteenth embodiment.

As shown in FIG. **44**, an optical head apparatus **121** for recording or reproducing pieces of information on or from the information medium **23** or **25**, comprises the light source **52**, the collimator lens **53**, the beam splitter **54**, the compound objective lens **43** (or **29M**, **45**, **46** or **47**) composed of the hologram lens **42** (or **26M** or **32**) and the objective lens **27**, the actuating unit **58**, the converging lens **55**, the beam splitter **92** having the reflection type of hologram **93**, the photo-detector **63**, and the photo detector **57**.

In the above configuration, the transmitted light L4 and the diffracted light L6 are converged by the converging lens **27** in the same manner as in the twelfth embodiment. Thereafter, in cases where a piece of information is recorded or reproduced on or from the first information medium **23**, the diffracted light L6 is converged on the first information medium **23** to form the converging spot S5. Thereafter, a beam of diffracted light L6R reflected by the first information medium **23** passes through the same optical path in the reverse direction, and a large part of the diffracted light L6R is diffracted by the hologram lens **42**. Therefore, the diffracted light L6R transmits on the incoming optical path agreeing with the outgoing optical path in the same manner as in the twelfth embodiment. Thereafter, the diffracted light L6R is reflected by the beam splitter **54** and is converged by the converging lens **55** on the beam splitter **92** to form a converging spot on the reflection type of hologram **93** of the beam splitter **92**. Therefore, all of the diffracted light L6R is diffracted and reflected by the hologram **93** to be converged on the photo detector **57** in the same manner as in the tenth embodiment. Therefore, an information signal and servo signals such as a focus error signal and a tracking error signal are obtained in the same manner as in the sixth embodiment.

In contrast, in cases where a piece of information is recorded or reproduced on or from the second information medium **25**, the transmitted light L4 is converged on the second information medium **25** to form the converging spot S6. Thereafter, a beam of transmitted light L4R reflected by the second information medium **25** passes through the same optical path in the reverse direction. That is, a large part of the transmitted light L4R is collimated by the objective lens **27** on the incoming optical path. Thereafter, a great part of the transmitted light L4R is diffracted by the hologram lens **42**. Therefore, the transmitted light L4R transmits on the incoming optical path differing from the outgoing optical path in the same manner as in the twelfth embodiment. Thereafter, the transmitted light L4R is reflected by the beam splitter **54** and is converged by the converging lens **55**. Thereafter, a large part of the transmitted light L4R transmits through the beam splitter **92**. In this case, an astigmatic aberration is generated in the transmitted light L4R. Thereafter, the transmitted light L4R is converged on the photo detector **63** to form a converging spot **S19** of which the shape is the same as the converging spot **S10** shown in FIGS. **29A** to **29C**, and the intensity of the transmitted light L4R is detected in the photo detector **63**. Therefore, an information signal and servo signals such as a focus error signal and a tracking error signal are obtained in the same manner as in the seventh embodiment.

In the thirteenth embodiment, because the transmitted light L4R is diffracted by the hologram lens **42**, the converging spot **S19** formed on the photo detector **63** does not relate to a radiation point of the light source **52** in a mirror image. Therefore, the photo detector **57** for detecting the intensity of the diffracted light L6R and the photo detector **63** for detecting the intensity of the transmitted light L4R are required.

Accordingly, because the compound objective lens having two focal points is utilized in the optical head apparatus **121**, pieces of information can be reliably recorded or reproduced on or from an information medium regardless of whether the information medium is thick or thin.

Also, because the diffracted light L6 formed in the hologram lens **42** converges before the diffracted light L6 is incident on the objective lens **27**, the distance in an optical axis direction between the converging spots S5, S6 can be lengthened to about 1 mm. Therefore, even though the transmitted light L4 (or the diffracted light L6) is converged on the converging spot S6 (or S5) in focus to record or read a piece of information, the light L6 (or L4) is not converged on the converging spot S6 (or S5) in focus to reduce the intensity of the light L6 (or L4) at the converging spot S6 (or S5). Accordingly, no adverse influence is exerted on the recording or reproduction of the information

Also, because the hologram lens **42** functions as a convex lens for the first-order diffracted light L6, the occurrence of a chromatic aberration can be prevented in the optical head apparatus **121**.

An example of the utilization of the optical head apparatus **121** for various types of optical disks is described.

In cases where the optical head apparatus **121** is utilized for an optical disk device in which pieces of information recorded in a thin type of high density optical disk **23** are recorded or reproduced and pieces of information recorded in a thick type of optical disk **25** are exclusively reproduced, the diffraction efficiency of the hologram lens **26M** or **42** in the compound objective lens **29M**, **43**, **45**, **46** or **47** for changing a beam of light to a beam of first-order diffracted light is set to a value equal to or higher than 70%. Therefore, in cases where a piece of information recorded on the thick type of optical disk **25** is reproduced in the photo detector **57**, a signal-noise ratio of each of the servo signals and the information signal obtained in the photo detector **57** can be enhanced because the transmitted light L4R diffracted by the hologram lens **26M** or **42** at a high diffraction efficiency is utilized to obtain the servo signals and the information signal. In other words, a utilization efficiency of the incident light L3 can be enhanced when a piece of information recorded on the thick type of optical disk **25** is reproduced, so that the output power of the incident light L3 can be minimized. Also, even though a high intensity of the diffracted light L6 is required to record a piece of information on the high density optical disk **23**, the recording of the information can be reliably performed without increasing the intensity of the incident light L3 because the diffraction efficiency of the hologram lens **26M** or **42** for the incident light L3 and the diffracted light L6R is high. Also, in cases where a piece of information recorded on the high density optical disk **23** is reproduced in the photo detector **63**, a signal-noise ratio of each signal obtained

in the photo detector **63** can be enhanced because the diffraction efficiency of the hologram lens **26M** or **42** for the light L3, L6R is high.

(Fourteenth Embodiment)

An optical head apparatus in which noises included in an information signal are reduced is described with reference to FIGS. **45**, **46** according to a fourteenth embodiment of the present invention.

FIG. **45** is a constitutional view of an optical head apparatus according to a fourteenth embodiment. FIG. **46** is a plan view of a hologram lens utilized in the optical head apparatus shown in FIG. **45**.

As shown in FIG. **45**, an optical head apparatus **131** for recording or reproducing pieces of information on or from the information medium **23** or **25**, comprises the light source **52**, a beam splitter **132** having a polarizing separation film **133** on its surface for reflecting the incident light L3 radiated from the light source **52** on an outgoing optical path and transmitting through the light L4R or L5R reflected on the information medium **23** or **25** on an incoming optical path, a collimator lens **134** for collimating the incident light L3 on the outgoing optical path and converging the light L4R or L5R on the incoming optical path, a hologram lens **135** for transmitting a part of the incident light L3 without any diffraction and diffracting a remaining part of the incident light L3, the $\frac{1}{4}$-λ plate **69**, the objective lens **27**, the actuating unit **58**, and a photo detector **136** for detecting the light transmitting through or diffracted by the hologram lens **135** on the incoming optical path.

As shown in FIG. **46**, the hologram lens **135** is formed by drawing the grating pattern P1 in a central region **135***a* of the transparent substrate **28** and a grating pattern P12 in a peripheral region **135***b* surrounding the central region **135***a*. The grating pattern P12 is drawn in a non-concentric shape. Because the grating pattern P1 are drawn in the hologram lens **135**, a compound objective lens **137** having two focal points is composed of the hologram lens **135** and the objective lens **27**. Light passing through the peripheral region **135***b* of the hologram lens **135** is detected by the photo detector **136** to cancel noises included in an information signal. An optical axis of the optical head apparatus **131** passes through a central point of the grating pattern P1 and a central axis of the objective lens **27**.

The photo detector **136** comprises the quadrant photo-detector **64** having the detecting sections SE7 to SE10 and a noise cancelling photo detector **138** for detecting the intensity of light passing through the peripheral region **135***b* of the hologram lens **135**. Because the grating pattern P12 of the peripheral region **135***b* is drawn in the non-concentric shape, light diffracted in the peripheral region **135***b* is not converged on the detecting sections SE7 to SE10.

In the above configuration, the incident light L3 linearly polarized in a first direction is radiated from the light source **52** and is reflected by the beam splitter **132** because the polarizing separation film **133** functions as a mirror for the incident light L3 linearly polarized in the first direction. Therefore, the incident light L3 is directed in an upper direction and is collimated by the collimator lens **134**. Thereafter, a part of the incident light L3 incident on the central region **135***a* of the hologram lens **135** transmits through the central region **135***a* without any diffraction to form the transmitted light L4, and a remaining part of the incident light L3 incident on the central region **135***a* of the hologram lens **135** is diffracted in the central region **135***a* to form the diffracted light L5. Also, a part of the incident light L3 incident on the peripheral region **135***b* of the hologram lens **135** transmits through the peripheral region **135***b* without any diffraction to form a beam of noise cancelling light L14. Thereafter, the light L4, L5 and L14 pass through the $\frac{1}{4}$-λ plates so that the light L4, L5 and L14 linearly polarized in the first direction is changed to the light L4, L5 and L14 circularly polarized. Thereafter, the light L4, L5 and L14 are converged by the converging lens **27**.

Thereafter, in cases where a piece of information is recorded or reproduced on or from the first information medium **23** (or the second information medium **25**), the transmitted light L4 (or the diffracted light L5) is converged on the information medium **23** (or **25**) to form the converging spot S1 (or S2). Thereafter, a beam of transmitted light L4R (or a beam of diffracted light L5R) reflected by the information medium **23** (or **25**) passes through the same optical path in the reverse direction. That is, the transmitted light L4R (or the diffracted light L5R) is circularly polarized in reverse and again passes through the converging lens **27** and the $\frac{1}{4}$-λ plate **69**. Therefore, the light L4R (or L5R) is linearly polarized in a second direction perpendicular to the first direction. Thereafter, a part of the transmitted light L4R transmits through the central region **135***a* of the hologram lens **135** without any diffraction, or a part of the diffracted light L5R is again diffracted in the central region **135***a*. Thereafter, the transmitted light L4R (or the diffracted light L5R) is converged by the collimator lens **134** and passes through the beam splitter **132** without any reflection because the polarizing separation film **133** functions as a transparent plate for the light L4R (or L5R) linearly polarized in the second direction. In this case, an astigmatic aberration is generated in the transmitted light L4R (or the diffracted light L5R) in the same manner as in the seventh embodiment. Thereafter, the transmitted light L4R (or the diffracted light L5R) is incident on the detecting sections SE7 to SE10 of the photo detector **136** to form a converging spot S20 of which the shape is the same as the converging spot S10 shown in FIGS. **29A** to **29C**. The intensity of the transmitted light L4R (or the diffracted light L5R) is changed to electric current signals SC21 to SC24 in the detecting sections SE7 to SE10. Therefore, servo signals such as a focus error signal and a tracking error signal are obtained in the same manner as in the seventh embodiment, so that the position of the compound objective lens **137** is adjusted to converge the transmitted light L4 (or the diffracted light L5) on the information medium **23** (or **25**) in focus. Also, an information signal expressing a piece of information recorded on the information medium **23** (or **25**) is obtained according to an equation (12).

$$S_{in}=SC21+SC22+SC23+SC24 \quad (12)$$

Also, the noise cancelling light L14 is converged on the information medium **23** to form a converging spot surrounding the converging spot S1. Thereafter, a beam of noise cancelling light L14R reflected by the first information medium **23** passes through the same optical path in the reverse direction. That is, the noise cancelling light L14R again passes through the converging lens **27** and the $\frac{1}{4}$-λ plate **69**, and a part of the noise cancelling light L14R is diffracted and converged in the peripheral region **135***b* of the hologram lens **135** and is

incident on the noise cancelling photo detector **138**. In the photo detector **138**, an output signal SC25 is generated according to the intensity of the noise cancelling light L14R. Thereafter, a noise cancelled information signal S_{nc} expressing a piece of information recorded on the first information medium **23** is obtained by adding all of the signals according to an equation (13):

$$S_{nc}=(SC21+SC22+SC23+SC24)+R\times SC25 \quad (13),$$

where the symbol R is a weighting factor.

In this case, because the term R×SC25 is added to obtain the information signal S_{nc}, inverse influence of noises included in the term (SC21+SC22+SC23+SC24) on the noise cancelled information signal S_{nc} can be reduced. The reason is described.

As is well known (for example, Japanese Patent Gazette No. 22452 of 1990 laid open to public inspection on Jul. 23, 1985 under Provisional Publication No. 138748 of 1985 and Published Unexamined Patent Application No. 131245 of 1986), signals expressing pieces of information recorded on an optical disk shifts to a higher frequency as the density of the information recorded becomes high. Also, the amplitude of a signal having a high frequency becomes low as compared with that of a signal having a low frequency in cases where the signals are produced according to light passing through a central region of a hologram lens. In contrast, the amplitude of a signal having a high frequency is emphasized in cases where the signal is produced according to light passing through a peripheral region of the hologram lens. Therefore, in cases where the information signal S_{nc} is obtained according to the equation (13), high frequency components included in the information signal She is emphasized, and low frequency noise components included in the term (SC21+SC22+SC23+SC24) are comparatively reduced. As a result, a signal-noise ratio in the information signal S_{nc} can be enhanced.

Accordingly, because the compound objective lens having two focal points is utilized in the optical head apparatus **131**, pieces of information can be reliably recorded or reproduced or or from an information medium regardless of whether the information medium is thick or thin.

Also, even though pieces of information are densely recorded in a thin type of high density optical disk represented by the first information medium **23**, the information signal S_{nc} can be reliably reproduced at a high signal-noise ratio.

Also, because the intensity of the light L4R or L5R incident on the detecting sections SE7 to SE10 of the photo detector **136** is reduced by converging the noise cancelling light L14R on the photo detector **138**, a positioning accuracy of the photo detector **136** can be coarsely lowered to 1/100.

Also, in cases where the grating pattern P12 of the peripheral region **135***b* functions as a lens for the incident light L3 diffracted in the peripheral region **135***b*, unnecessary diffracted light generated in the peripheral region **135***b* on the outgoing optical path forms a comparatively large converging spot in defocus on the first information medium **23**. Therefore, pieces of information recorded on the first information medium **23** are read by the unnecessary diffracted light, and the information are treated as a piece of averaged information in the photo detector **136** even though the unnecessary diffracted light is incident on the photo detector **136**. Accordingly, the information read by the unnecessary diffracted light does not adversely influence on the information signal S_{nc} as a noise.

Also, in cases where a transmission efficiency of the peripheral region **135***b* of the hologram lens **135** is set to agree with another transmission efficiency of the central region **135***a*, secondary maxima (or side lobes) occurring around the converging spot S1 can be lowered as compared with the first embodiment. Accordingly, a signal-noise ratio in the information signal S_{nc} can be enhanced.

(Fifteenth Embodiment)

An optical head apparatus in which noises included in an information signal are reduced is described with reference to FIGS. **47** to **49** according to a fifteenth embodiment of the present invention.

FIG. **47** is a constitutional view of an optical head apparatus according to a fifteenth embodiment. FIG. **48** is a plan view of a hologram lens utilized in the optical head apparatus shown in FIG. **47**.

As shown in FIG. **47**, an optical head apparatus **141** for recording or reproducing pieces of information on or from the information medium **23** or **25**, comprises the light source **52**, the beam splitter **82**, the collimator lens **134**, a hologram lens **142** for transmitting a part of the incident light L3 without any diffraction and diffracting a remaining part of the incident light L3, the objective lens **27**, the actuating unit **58**, and a photo detector **143** for detecting the light transmitting through or diffracted by the hologram lens **142** on the incoming optical path.

As shown in FIG. **48**, the hologram lens **142** is partitioned into a central region **142***a* in which the grating pattern P1 is drawn, a pair of side peripheral regions **142***b*, **142***c* in which grating patterns P13, P14 are drawn to cancel noises included in an information signal, and a pair of no-designed regions **142***d*, **142***e* in which no grating pattern is drawn not to reduce the intensity of light. Because the grating pattern P1 are drawn in the hologram lens **135**, a compound objective lens **144** having two focal points is composed of the hologram lens **142** and the objective lens **27**. An optical axis of the optical head apparatus **141** passes through a central point of the grating pattern P1 and a central axis of the objective lens **27**.

The photo detector **143** comprises the quadrant photo-detector **64** having the detecting sections SE7 to SE10, a pair of noise cancelling photo detector **138***a*, **138***b* for detecting the intensity of light passing through the peripheral region **142***b*, **142***c* of the hologram lens **142**.

In the above configuration, the transmitted light L4 (or the diffracted light L5) generated in the central region **142**a of the hologram lens **142** is converged on the first information medium **23** (or the second information medium **25**) in an outgoing optical path to form the converging spot S1 (or S2). Thereafter, the transmitted light L4R (or the diffracted light L5R) passes through the same optical path in the reverse direction. That is, the transmitted light L4R (or the diffracted light L5R) again passes through the converging lens **27**, and a part of the transmitted light L4R transmits through the central region **142***a* of the hologram lens **142** without any diffraction or a part of the diffracted light L5R is again diffracted in the central region **142***a*. Thereafter, the transmitted light L4R (or the diffracted light L5R) is

converged by the collimator lens **134** and passes through the beam splitter **82**. In this case, an astigmatic aberration is generated in the transmitted light L4R (or the diffracted light L5R) in the same manner as in the seventh embodiment. Thereafter, the transmitted light L4R (or the diffracted light L5R) is incident on the detecting sections SE7 to SE10 of the photo detector **143** to form a converging spot S21 of which the shape is the same as the converging spot S10 shown in FIGS. **29**A to **29**C. The intensity of the transmitted light L4R (or the diffracted light L5R) is changed to electric current signals SC26 to SC29 in the detecting sections SE7 to SE10. Therefore, servo signals such as a focus error signal and a tracking error signal are obtained in the same manner as in the seventh embodiment, so that the position of the compound objective lens **144** is adjusted to converge the transmitted light L4 (or the diffracted light L5) on the information medium **23** (or **25**) in focus. Also, an information signal recorded on the second information medium **25** is obtained according to an equation (14).

$$S_{in}=SC26+SC27+SC28+SC29 \quad (14)$$

Also, a part of the incident light L3 incident on the peripheral region **142***b* of the hologram lens **142** transmits through the peripheral region **142***b* without any diffraction to form a beam of noise cancelling light L15, and a part of the incident light L3 incident on the peripheral region **142***c* of the hologram lens **142** transmits through the peripheral region **142***c* without any diffraction to form a beam of noise cancelling light L16. Thereafter, the noise cancelling light L15, L16 are converged on the information medium **23** to form a converging spot surrounding the converging spot S1. Thereafter, beams of noise cancelling light L15R, L16R reflected by the first information medium **23** passes through the same optical path in the reverse direction. That is, the noise cancelling light L15R, L16R again passes through the converging lens **27**. A part of the noise cancelling light L15R is diffracted and converged in the peripheral region **142***b* of the hologram lens **142** and is incident on the noise cancelling photo detector **138***a*, and a part of the noise cancelling light L16R is diffracted and converged in the peripheral region **142***c* of the hologram lens **142** and is incident on the noise cancelling photo detector **138***b*. In the photo detector **138***a*, an output signal SC30 is generated according to the intensity of the noise cancelling light L15R. Also, an output signal SC31 is generated according to the intensity of the noise cancelling light L16R in the photo detector **138***b*. Thereafter, a noise cancelled information signal S_{nc} expressing the information recorded on the first information medium **23** is obtained by adding all of the signals according to an equation (15):

$$S_{nc}=(SC26+SC27+SC28+SC29)+R\times(SC30+SC31) \quad (15),$$

where the symbol R is a weighting factor.

Accordingly, because the compound objective lens having two focal points is utilized in the optical head apparatus **141**, pieces of information can be reliably recorded or reproduced from an information medium regardless of whether the information medium is thick or thin.

Also, a signal-noise ratio in the information signal S_{nc} can be enhanced in the same manner as in the fourteenth embodiment.

Also, even though pieces of information are densely recorded in a thin type of high density optical disk represented by the first information medium **23**, the information signal S_{nc} can be reliably reproduced at a high signal-noise ratio.

Also, because the intensity of the light L4R or L5R incident on the detecting sections SE7 to SE10 of the photo detector **143** is reduced by converging the noise cancelling light L15R, L16R on the photo detectors **138***a*, **138***b*, a positioning accuracy of the photo detector **143** can be coarsely lowered to 1/100.

Also, in cases where the grating patterns P13, P14 of the peripheral regions **142***b*, **142***c* functions as a lens for the incident light L3 diffracted in the peripheral region **142***b*, **142***c*, unnecessary diffracted light generated by diffracting the incident light L3 in the peripheral regions **142***b*, **142***c* on the outgoing optical path forms a comparatively large converging spot in defocus on the first information medium **23**. Also, an numerical number of each of the peripheral regions **142***b*, **142***c* is lowered as compared with that of the region **135***b* in the fourteenth embodiment because the hologram lens **142** are partitioned into many fields. Therefore, the size of the converging spot of the unnecessary diffracted light formed in defocus on the first information medium **23** becomes larger than that in the fourteenth embodiment. As a result, more pieces of information recorded on the first information medium **23** are read by the unnecessary diffracted light, and the information are treated as a piece of averaged information in the photo detector **143** even though the unnecessary diffracted light is incident on the photo detector **143**. Accordingly, the information read by the unnecessary diffracted light is moreover averaged, and the averaged information does not adversely influence on the information signal S_{nc} as a noise.

Also, as shown in FIGS. **49**A, **49**B, the unnecessary diffracted light can be prevented from being incident on the photo detector **64** in which each of the detecting sections SE7 to SE10 has SL0 square in size. In detail, in cases where light generated in the peripheral region **142***c* on the outgoing optical path is again diffracted in the peripheral region **142***b* to form a beam of unnecessary diffracted light Lu_1, the light Lu_1 is converged on a first position PT1 spaced SP1 (SP1>SL0) from the center of the photo detector **64**. In cases where light generated in the peripheral region **142***b* on the outgoing optical path is again diffracted in the peripheral region **142***c* to form a beam of unnecessary diffracted light Lu_2, the light Lu_2 is converged on a second position PT2 spaced SP2 (SP2>SL0) from the center of the photo detector **64**. In cases where light generated in the peripheral regions **142***b*, **142***c* on the outgoing optical path are again diffracted in the same peripheral regions **142***b*, **142***c* to form beams of unnecessary diffracted light Lu_3, Lu_4, the light Lu_3, Lu_4 are converged on third and fourth position PT3, PT4 spaced SP3 (SP3>SL0), SP4 (SP4>SL0) from the center of the photo detector **64**. Accordingly, the adverse influence of the unnecessary diffracted light Lu_1 to Lu_4 can be prevented.

In cases where the light source **52** is formed of a semiconductor laser, a far field pattern of the incident light L3 incident on the hologram lens **142** is distributed in the Gaussian distribution as shown in FIG. **13**A, and a cross-sectional beam profile of the incident light L3

distributed in the Gaussian distribution is in an elliptic shape. That is, a beam divergent angle (or a full angle at half maximum) of the incident light L3 in a perpendicular direction is larger than that in a horizontal direction. In this embodiment, the perpendicular direction of the incident light L3 is directed in an X2 direction shown in FIG. **48**, and the horizontal direction of the incident light L3 is directed in a Y2 direction shown in FIG. **48**. In this case, because a transmission efficiency of the regions **142***b*, **142***c* for the incident light L3 is smaller than that of the regions **142***d*, **142***e*, the intensity of the incident light L3 transmitting through the hologram lens **142** without any diffraction is largely reduced in the perpendicular direction as compared with that in the horizontal direction. Therefore, the cross-sectional beam profile of the incident light L3 is corrected to a circular shape in the hologram lens **142**. That is, the converging spot S1 formed on the first information medium **23** is corrected to the circular shape. Accordingly, secondary maxima (or side lobes) occurring around the converging spot S1 can be lowered, and a signal-noise ratio of the information signal S_{nc} can be enhanced.

In the fifteenth embodiment, the noise cancelled information signal S_{nc} is obtained according to the equation (15). However, it is preferred that the noise cancelled information signal S_{nc} be obtained according to the equation (16):

$$S_{nc}=(SC26+SC27+SC28+SC29)+(R1\times SC30+-R2\times SC31) \quad (16),$$

where the symbols R1,R2 are weighting factors. In this case, the noises included in the information can be moreover reduced.

(Sixteenth Embodiment)

An optical head apparatus manufactured in a small size and stably operated is described with reference to FIGS. **50**, **51** according to a sixteenth embodiment of the present invention.

FIG. **50** is a constitutional view of an optical head apparatus according to a sixteenth embodiment. FIG. **51** is a diagonal view of a light source and photo detectors utilized in the optical head apparatus shown in FIG. **50**.

As shown in FIG. **50**, an optical head apparatus **151** for recording or reproducing pieces of information on or from the information medium **23** or **25**, comprises the light source **52** for radiating the incident light L3 linearly polarized in a non-diffracting direction parallel to an X3 axis, an holographic element **152** for transmitting through the incident light L3 without any diffraction on an outgoing optical path and diffracting the transmitted light L4R or the diffracted light L5R linearly polarized in a diffracting direction parallel to a Y3 axis on an incoming optical path, the collimator lens **53**, the $\frac{1}{4}$-λ plate **69**, the hologram lens **26** (or **26M**, **32**, **33**, **42**, **135** or **142**), the objective lens **27**, the actuating unit **58**, and a photo detector **153** for detecting the intensity of the light L4R or L5R diffracted by the holographic element **152**.

As shown in FIG. **51**, the light source **52** and the photo detector **153** are located on a substrate **154** to precisely fix a relative position between the light source **52** and the photo detector **153**. The photo detector **153** comprises the sextant photo-detector **59** having the detecting sections SE1 to SE6 and the tracking photo-detectors **60***a* to **60***d*. Also, a mirror element **155** is located on the substrate **154** to direct the incident light L3 radiated from the light source **52** in a Z3 direction.

The holographic element **152** is produced by proton-exchanging surface parts of a lithium niobate substrate or by utilizing a liquid crystal cell, as is described in Provisional Publication No. 189504/86 (S61-189504) and Provisional Publication No. 241735/88 (S63-241735). Therefore, light linearly polarized in a non-diffracting direction parallel to an X3 axis transmits through the holographic element **152** without any diffraction. In contrast, light linearly polarized in a diffracting direction parallel to a Y3 axis which is perpendicular to the X3 axis is diffracted by the holographic element **152**.

In the above configuration, the incident light L3 linearly polarized in a non-diffracting direction parallel to an X3 axis is radiated from the light source **52** and transmits through the holographic element **152** without any diffraction. Thereafter, the incident light L3 is collimated by the collimator lens **53**, and the incident light L3 linearly polarized is changed to the incident light L3 circularly polarized by the $\frac{1}{4}$-λ plate **69**. Thereafter, a part of the incident light L3 transmits through the hologram lens **26** without any diffraction to form the transmitted light L4, and a remaining part of the incident light L3 is diffracted by the hologram lens **26** to form the diffracted light L5. Thereafter, the light L4, L5 are converged by the objective lens **27**, and the converging spot S1 of the transmitted light L4 (or the converging spot S2 of the diffracted light L5) is formed on the first information medium **23** (or the second information medium **25**). When the light L4 or L5 is reflected by the information medium **23** (or **25**) and is changed to the light L4R (or L5R), a rotational direction of the circular polarization in the light L4 is reversed. Therefore, the light L4R (or L5R) having the reversed circular polarization passes through the same optical path in the opposite direction. That is, the transmitted light L4R (or the diffracted light L5R) again passes through the converging lens **27**, and a part of the transmitted light L4R transmits through the hologram lens **142** without any diffraction or a part of the diffracted light L5R is again diffracted by the hologram lens **142**. Thereafter, the transmitted light L4R (or the diffracted light L5R) circularly polarized in reverse is changed to the light L4R (or L5R) linearly polarized in a diffracting direction parallel to a Y3 axis by the $\frac{1}{4}$-λ plate **69**. Thereafter, the light L4R (or L5R) is converged by the collimator lens **53** and is diffracted by the holographic element **152** to form a plurality of converging spots on the photo detectors **153**. Therefore, an information signal expressing a piece of information recorded on the information medium **23** (or **25**) and servo signals such as a focus error signal and a tracking error signal are obtained in the photo detector **153** in the same manner as in the sixth embodiment.

Accordingly, because the compound objective lens having two focal points is utilized in the optical head apparatus **151**, pieces of information can be reliably recorded or reproduced or or from an information medium regardless of whether the information medium is thick or thin.

Also, because all of the incident light L3 transmits through the holographic element **152** on the outgoing optical path and because all of the light L4R or L5R is diffracted by the holographic element **152** on the incoming optical path, a utilization efficiency of the inci-

dent light L3 can be enhanced. Therefore, even though a radiation intensity of the incident light L3 in the light source **52** is low, the information signal and the servo signals having a high signal-noise ratio can be reliably obtained.

Also, because no beam splitter is utilized in the optical head apparatus **151**, the optical head apparatus **151** can be manufactured at a small size, in a light weight, and at a low cost.

Also, because optical parts of the optical head apparatus **151** are located along its optical axis, the optical head apparatus **151** stably operated can be obtained even though a circumstance temperature largely varies and the apparatus is operated for a long time.

Also, because the light L4R or L5R transmitting through the holographic element **152** without any diffraction on the incoming optical path is not required, it is preferred that a diffraction efficiency of the holographic element **152** be heightened to set a transmission efficiency of the holographic element **152** to almost zero. In this case, a combination of the holographic element **152** and the $\frac{1}{4}$-λ plate **69** function functions as an isolator to prevent the light L4R or L5R from returning to the light source **52**. Therefore, in cases where a semiconductor laser is utilized as the light source **52**, any light does not return to an active layer of the semiconductor laser. Accordingly, noises induced by the light returning to the semiconductor laser can be prevented.

Also, because the light source **52** and the photo detector **153** are located on the same substrate **154**, the light source **52** and the photo detector **153** can be closely arranged each other. Therefore, a relative position between the light source **52** and the photo detector **153** can be easily set at a high accuracy. For example, the relative position can be set at an accuracy within several μm. Accordingly, a manufacturing cost of the optical head apparatus **151** can be lowered, and the optical head apparatus **151** can be moreover manufactured at a small size, in a light weight, and at a low cost.

Also, the light source **52** is electrically connected with an external circuit through first wirings, and the photo detector **153** is electrically connected with another external circuit through second wirings. In this case, because the light source **52** and the photo detector **153** are located on the same substrate **154**, the first and second wirings can pass on an X3-Y3 plane in common. Therefore, the light source **52** and the photo detector **153** can be easily and automatically connected with the external circuits. In addition, because reference lines required to connect the light source **52** and the photo detector **153** with the external circuits are only drawn on the X3-Y3 plane, the relative position between the light source **52** and the photo detector **153** can be easily set at a high accuracy.

In the sixteenth embodiment, the optical head apparatus **151** with the holographic element **152** is described. However, in cases where the intensity of the incident light L3 is sufficient, it is applicable that a hologram having a small grating pitch or a blazed hologram be utilized in place of the holographic element **152**. In this case, pieces of information can be reliably recorded or reproduced on or from an information medium regardless of whether the information medium is thick or thin. Also, because no beam splitter is utilized in the optical head apparatus **151**, the optical head apparatus **151** can be manufactured at a small size, in a light weight, and at a low cost. Also, because optical parts of the optical head apparatus **151** are located along its optical axis, the optical head apparatus **151** stably operated can be obtained even though a circumstance temperature largely varies and the apparatus is operated for a long time.

(Seventeenth Embodiment)

An optical head apparatus manufactured in a small size and stably operated is described with reference to FIG. **52** according to a seventeenth embodiment of the present invention.

FIG. **52** is a constitutional view of an optical head apparatus according to a seventeenth embodiment.

As shown in FIG. **52**, an optical head apparatus **161** for recording or reproducing pieces of information on or from the information medium **23** or **25**, comprises the light source **52** for radiating the incident light L3 linearly polarized in a first direction, the collimator lens **53**, a polarizing separation film **162** formed on a front surface of a transparent substrate **162** for reflecting the incident light L3 linearly polarized in the first direction and transmitting light linearly polarized in a second direction perpendicular to the first direction, the $\frac{1}{4}$-λ plate **69**, the hologram lens **26** (or **26M**, **32**, **33**, **42**, **135** or **142**), the objective lens **27**, the actuating unit **58**, a reflection-type hologram **164** formed on a rear surface of the transparent substrate **162** for diffracting and reflecting the light L4R, L5R, and the photo detector **57**.

In the above configuration, the incident light L3 linearly polarized in a first direction is radiated from the light source **52** and is collimated by the collimator lens **53**. Thereafter, all of the incident light L3 is reflected by the polarizing separation film **162** because the incident light L3 is linearly polarized in the first direction. Therefore, the incident light L3 is directed in an upper direction. Thereafter, the linear polarization of the incident light L3 is changed to a circular polarization in the $\frac{1}{4}$-λ plate **69**, and a part of the incident light L3 transmits through the hologram lens **26** to form the transmitted light L4. Also, a remaining part of the incident light L3 is diffracted by the hologram lens **26** to form the diffracted light L5. Thereafter, the light L4, L5 are converged by the objective lens **27**, and the converging spot S1 of the transmitted light L4 (or the converging spot S2 of the diffracted light L5) is formed on the first information medium **23** (or the second information medium **25**). Thereafter, the transmitted light L4R (or the diffracted light L5R) circularly polarized in reverse again passes through the converging lens **27** in the same manner as in the sixteenth embodiment, and a part of the transmitted light L4R transmits through the hologram lens **26** without any diffraction or a part of the diffracted light L5R is again diffracted by the hologram lens **26**. Thereafter, the transmitted light L4R (or the diffracted light L5R) circularly polarized in reverse is changed to the light L4R (or L5R) linearly polarized in a second direction perpendicular to the first direction by the $\frac{1}{4}$-λ plate **69**. Thereafter, all of the light L4R (or L5R) is refracted by the polarizing separation film **162** and is diffracted and reflected by the hologram **164**. Thereafter, the light L4R (or L5R) transmits through the polarizing separation film **162** and is converged by the collimator lens **53** to form a plurality of converging spots on the photo detector **57**. Therefore, an information signal expressing a piece of information recorded on the information medium **23** (or **25**) and servo signals such as a focus error signal and a tracking error signal are obtained in the photo detector **57** in the same manner as in the sixth embodiment.

Accordingly, because the compound objective lens having two focal points is utilized in the optical head apparatus **161**, pieces of information can be reliably recorded or reproduced on or from an information medium regardless of whether the information medium is thick or thin.

Also, because the incident light L3 incident on the polarizing separation film **162** is collimated, a reflectivity for the incident light L3 is uniform over the entire film **162**. Therefore, a diffraction-limited spot of the light L4 or L5 can be easily formed on the information medium **23** or **25**. Also, because the light L4R, L5R incident on the polarizing separation film **162** are collimated, a transmissivity for the light L4R, L5R is uniform over the entire film **162**. Therefore, an offset occurring in the servo signals can be prevented.

Also, because all of the incident light L3 transmits through the hologram **164** on the outgoing optical path and because all of the light L4R or L5R is diffracted by the hologram **164** on the incoming optical path, a utilization efficiency of the incident light L3 can be enhanced. Therefore, even though a radiation intensity of the incident light L3 in the light source **52** is low, the information signal and the servo signals having a high signal-noise ratio can be reliably obtained.

Also, because a hybrid element composed of the film **162**, the substrate **163** and the hologram **164** functions as a beam splitter and a rising mirror, the optical head apparatus **161** can be manufactured at a small size, in a light weight, and at a low cost.

Also, because optical parts of the optical head apparatus **161** are located along its optical axis, the optical head apparatus **161** stably operated can be obtained even though a circumstance temperature largely varies and the apparatus is operated for a long time.

Also, a combination of the film **162** and the $\frac{1}{4}$-λ plate **69** function functions as an isolator to prevent the light L4R or L5R from returning to the light source **52**. Therefore, in cases where a semiconductor laser is utilized as the light source **52**, any light does not return to an active layer of the semiconductor laser. Accordingly, noises induced by the light returning to the semiconductor laser can be prevented.

Also, it is preferred that the hologram **164** be blazed. In this case, because the generation of unnecessary diffracted light such as minus first-order diffracted light in the hologram **164** is prevented, a diffraction efficiency of the hologram **164** for changing light to first-order diffracted light can be set to almost 100%. Therefore, the incident light L3 can be efficiently utilized to obtain the signals.

Also, because light incident on the hologram **164** is diffracted to first-order diffracted light, a chromatic aberration occurring in the light L4R, L5R can be compensated in the hologram **164**. Therefore, the servo signals can be stably obtained.

In the seventeenth embodiment, the collimator lens **53** is located between the light source **52** and the film **162**. However, the collimator lens **53** is not necessary in the optical head apparatus **161**.

Also, the optical head apparatus **161** with the film **162** and the $\frac{1}{4}$-λ plate **69** is described. However, in cases where the intensity of the incident light L3 is sufficient, it is applicable that a reflection film having a reflectivity of almost $\frac{1}{3}$ be utilized in place of the film **162** and the $\frac{1}{4}$-λ plate **69** be omitted. In this case, pieces of information can be reliably recorded or reproduced on or from an information medium regardless of whether the information medium is thick or thin. Also, because a hybrid element composed of the film **162**, the substrate **163** and the hologram **164** functions as a beam splitter and a rising mirror, the optical head apparatus **161** can be manufactured at a small size, in a light weight, and at a low cost. Also, because optical parts of the optical head apparatus **161** are located along its optical axis, the optical head apparatus **161** stably operated can be obtained even though a circumstance temperature largely varies and the apparatus is operated for a long time.

In the sixth to seventeenth embodiments, pieces of information can be reliably recorded or reproduced on or from an information medium regardless of whether the information medium represents a conventional optical disk such as a compact disk having a thickness T2 of about 1.2 mm or a prospective high density optical disk having a thickness T1 ranging from 0.4 mm to 0.8 mm. However, when the information recorded or reproduced on or from the information medium, it is required to examine the thickness of the information medium in advance. Therefore, in cases where a piece of distinguishing information is recorded on the information medium in advance to distinguish the thickness of the information medium, it is convenient for a user. Because no distinguishing information is recorded on the conventional optical disk, it is preferred that the distinguishing information be recorded on the prospective high density optical disk appearing on the market in the future. Therefore, a high density optical disk with the distinguishing information is described according to eighteenth and nineteenth embodiments.

(Eighteenth Embodiment)

FIG. **53** is a diagonal view of a high density optical disk according to an eighteenth embodiment, a cross sectional view of the disk being partially shown.

As shown in FIG. **53**, a high density optical disk **171** is partitioned into an outer region **171***a* and an inner region **171***b*. The outer region **171***a* occupies a large part of the optical disk **171**, and an information recording substrate **171***c* of the outer region **171***a* has the thickness T1, and the information recording substrate **171***c* of the inner region **171***b* has the thickness T2. A plurality of first recording pits **172** are formed on the information recording substrate **171***c* of the outer region **171***a* at narrow intervals in series to record pieces of information at a high density. Also, a plurality of second recording pits **173** are formed on the information recording substrate **171***c* of the inner region **171***b* at ordinary intervals in series to record pieces of distinguishing information at an ordinary density of a compact disk. The distinguishing information inform that the optical disk **171** has the thickness T1. The thickness T1 of the outer region **171***a*, for example, ranges from 0.4 mm to 0.8 mm, and the thickness T2 of the inner region is, for example, about 1.2 mm.

In the above configuration, the diffracted light L5 according to the first or second embodiment (or the transmitted light L4 according to the third embodiment) is initially converged on an inner region of the information medium **23**, **25** while performing a focus control corresponding to the second information medium **25** having the thickness T2. In cases where the information medium **23** or **25** is the optical disk **171**, a piece of distinguishing information informing that the optical disk **171** having the thickness T1 is converged by the light L5 (or L4) is detected. Thereafter, the transmitted light L4 (or the diffracted light L6) is auto-

matically converged on the outer region **171***a* of the optical disk **171** while performing a focus control corresponding to the first information medium **23** having the thickness T1.

In contrast, in cases where the information medium **23** or **25** is a thick type of conventional optical disk having a thickness T2, no distinguishing information is detected when the light L5 (or L4) is converged on the inner region **171***b* of the conventional optical disk. In this case, the focus control corresponding to the second information medium **25** is continued to detect an information signal expressing a piece of information recorded on the conventional optical disk.

Accordingly, in cases where one of the optical head apparatuses shown in FIGS. **21, 27, 30, 31, 32, 33, 37, 38, 40A, 43, 44, 50** and **52** is utilized, pieces of information can be automatically recorded or reproduced on or from an information medium regardless of whether the information medium is thin or thick.

Also, because only the distinguishing information is recorded in the inner region, the inner region can be small. Therefore, a memory capacity of the optical disk **171** is not lowered by the addition of the second recording pit **173**.

(Nineteenth Embodiment)

FIG. **54** is a diagonal view of a high density optical disk according to a nineteenth embodiment, a cross sectional view of the disk being partially shown.

As shown in FIG. **54**, a high density optical disk **174** is partitioned into an outer region **174***a* and an inner region **174***b*. The outer region **174***a* occupies a large part of the optical disk **174**. The optical disk **174** has a uniform thickness of T1. The first recording pits **172** are formed on an information recording substrate **174***c* of the outer region **174***a* to record pieces of information at a high density. Also, a plurality of second recording pits **175** having a large size are formed on the information recording substrate **174***c* of the inner region **174***b* at wide intervals to record pieces of distinguishing information at a lower density than the ordinary density. The distinguishing information inform that the entire optical disk **174** has the thickness T1. The thickness T1 of the optical disk **174**, for example, ranges from 0.4 mm to 0.8 mm.

In the above configuration, the diffracted light L5 according to the first or second embodiment (or the transmitted light L4 according to the third embodiment) is initially converged on an inner region of the information medium **23** or **25** while performing a focus control corresponding to the second information medium **25** having the thickness T2. In cases where the information medium **23** or **25** is the optical disk **174**, the light L5 (or L4) is converged on each of the second recording pits **175** in defocus. However, because each of the second recording pits **175** is large in size, a converging spot of the light L5 (or L4) is reliably formed in one of the second recording pits **175**. Therefore, a piece of distinguishing information, which informs that the optical disk **174** having the thickness T1 is converged by the light L5 (or L4), is detected. Thereafter, the transmitted light L4 (or the diffracted light L6) is automatically converged on the outer region **174***a* of the optical disk **174** while performing a focus control corresponding to the first information medium **23** having the thickness T1.

In contrast, in cases where the information medium **23** or **25** is a thick type of conventional optical disk having a thickness T2, no distinguishing information is detected when the light L5 (or L4) is converged on the inner region **174***b* of the conventional optical disk. In this case, the focus control corresponding to the second information medium **25** is continued to detect an information signal expressing a piece of information recorded on the conventional optical disk.

Accordingly, in cases where one of the optical head apparatuses shown in FIGS. **21, 27, 30, 31, 32, 33, 37, 38, 40A, 43, 44, 50** and **52** is utilized, pieces of information can be automatically recorded or reproduced on or from an information medium regardless of whether the information medium is thin or thick.

Also, because only the distinguishing information is recorded in the inner region of the optical disk **174**, the inner region can be small. Therefore, a memory capacity of the optical disk **174** is not lowered by the addition of the second recording pit **173**.

Also, because the thickness of the optical disk **174** is uniform, the optical disk **174** can be easily manufactured at a low cost. Also, the optical disk **174** can be thinned.

(Twentieth Embodiment)

An optical disk apparatus with one of the optical head apparatuses in which it is automatically judged whether a high density optical disk having the thickness T1 or a conventional optical disk having the thickness T2 is utilized is described.

FIG. **55** is a block diagram of an optical disk apparatus with one of the optical head apparatuses shown in FIGS. **21, 27, 30, 31, 32, 33, 37, 38, 40A, 43, 44, 50** and **52** according to a twentieth embodiment. FIG. **56** is a flow chart showing the operation of the optical disk apparatus shown in FIG. **55**.

As shown in FIG. **55**, an optical disk apparatus **176** for recording or reproducing pieces of information on or from the high density optical disk **171** (or **174**) or the conventional optical disk **25**, comprises the optical head apparatus **51** (or **61, 65, 67, 70, 71, 81, 91, 101, 111, 121, 151** or **161**), a moving means **177** such as a feed mechanism for moving the optical head apparatus **51** to a prescribed position, and a rotating means **178** such as a spindle motor for rotating the high density optical disk **171** (or **174**) or the conventional optical disk **25**.

In the above configuration, the high density optical disk **171** or the conventional optical disk **25** is set to a prescribed position of the optical disk apparatus **176**, and the optical disk **171** or **25** is rotated by the rotating means **178**. Thereafter, the optical head apparatus **51** is moved to a position just under an innermost recording track of the optical disk **171** or **25** in a step **211**, and the diffracted light L5 is converged on the innermost recording track of the optical disk **171** or **25** while performing a focus control corresponding to the conventional optical disk **25** of the thickness T2 in a step **212**. Thereafter, a tracking control is performed, and a piece of information recorded on the innermost recording track of the optical disk **171** or **25** is detected in a step **213**. Thereafter, it is judged in a step **214** whether the information agrees with a piece of distinguishing information informing that the optical disk **171** having the thickness T1 is set to the optical disk apparatus **176**.

In cases where the high density optical disk **171** is set to the optical disk apparatus **176**, the distinguishing information is detected. Thereafter, the transmitted light L4 is automatically converged on the optical disk **171** while performing a focus control corresponding to the optical disk **171** of the thickness T1 in a step **215**.

Therefore, pieces of information are recorded or reproduced on or from the optical disk **171**.

In contrast, in cases where the conventional optical head **25** is set to the optical disk apparatus **176**, the distinguishing information is not detected. In this case, the convergence of the diffracted light L5 on the conventional optical disk **25** is continued while performing the focus control and the tracking control corresponding to the conventional optical disk **25** in a step **216**. Therefore, pieces of information are recorded or reproduced on or from the conventional optical disk **25**.

Accordingly, the thickness of the optical disk set in the optical disk apparatus **176** can be rapidly judged at a high accuracy. Also, pieces of information can be stably recorded or reproduced on or from an optical disk regardless of whether the optical disk is the high density optical disk **171** (or **174**) or the conventional optical disk **25**.

(Twenty-first Embodiment)

An optical disk apparatus with one of the optical head apparatuses in which it is automatically judged whether a high density optical disk having the thickness T1 or a conventional optical disk having the thickness T2 is utilized is described.

FIG. **57** is a block diagram of an optical disk apparatus with one of the optical head apparatuses shown in FIGS. **21**, **27**, **30**, **31**, **32**, **33**, **37**, **38**, **40A**, **43**, **44**, **50** and **52** according to a twenty-first embodiment. FIG. **58** is a flow chart showing the operation of the optical disk apparatus shown in FIG. **57**.

As shown in FIG. **57**, an optical disk apparatus **176** for recording or reproducing pieces of information on or from a high density optical disk **182** or the conventional optical disk **25**, comprises the optical head apparatus **51** (or **61**, **65**, **67**, **70**, **71**, **81**, **91**,**101**, **111**, **121**, **151** or **161**), the moving means **177**, and a rotating means **182** such as a spindle motor for rotating the high density optical disk **182** or the conventional optical disk **25**. The high density optical disk **182** has no distinguishing information and has the thickness T1.

In the above configuration, the high density optical disk **182** or the conventional optical disk **25** is set to a prescribed position of the optical disk apparatus **181**, and the optical disk **182** or **25** is rotated by the rotating means **182**. Thereafter, the optical head apparatus **51** is moved to a position just under an innermost recording track of the optical disk **182** or **25** in a step **221** because a piece of information is reliably recorded on the innermost recording track, and the diffracted light L5 is converged on the innermost recording track of the optical disk **182** or **25** while performing a focus control corresponding to the conventional optical disk **25** of the thickness T2 in a step **222**. Thereafter, a tracking control is performed, and a piece of information recorded on the innermost recording track of the optical disk **182** or **25** is detected in a step **223**. Thereafter, it is judged in a step **224** whether the intensity of an information signal expressing the information detected is more than a threshold value. That is, the intensity of the information signal more than the threshold value denotes that the diffracted light L5 is converged in focus on the optical disk **182** or **25**, and the intensity of the information signal not more than the threshold value denotes that the diffracted light L5 is converged in defocus on the optical disk **182** or **25**.

In cases where the high density optical disk **182** is set to the optical disk apparatus **181**, the intensity of the information signal not more than the threshold value is detected. In this case, the transmitted light L4 is automatically converged on the optical disk **182** while performing a focus control corresponding to the high density optical disk **182** of the thickness T1 in a step **225**. Therefore, pieces of information are recorded or reproduced on or from the optical disk **182**.

In contrast, in cases where the conventional optical head **25** is set to the optical disk apparatus **181**, the intensity of the information signal more than the threshold value is detected. In this case, the convergence of the diffracted light L5 on the conventional optical disk **25** is continued while performing the focus control and the tracking control corresponding to the conventional optical disk **25** in a step **26**. Therefore, pieces of information are recorded or reproduced on or from the conventional optical disk **25**.

Accordingly, the thickness of the optical disk set in the optical disk apparatus **181** can be judged even though the optical disk **171** or **174** is not utilized. Also, pieces of information can be stably recorded or reproduced on or from an optical disk regardless of whether the optical disk is the high density optical disk **182** or the conventional optical disk **25**.

(Twenty-second Embodiment)

A binary focus microscope having two focal points in which two images formed on different planes are simultaneously observed is described according to a twenty-second embodiment.

FIG. **59** is a constitutional view of a binary focus microscope according to a twenty-second embodiment.

As shown in FIG. **59**, a binary focus microscope **191** for simultaneously observing a first image of a first sample SP1 put on a first sample plane PL1 and a second image of a second sample SP2 put on a second sample plane PL2, comprises an objective lens **192** having a first focal length F1 for refracting a beam of first light L17 diverging from the first image and refracting a beam of second light L18 diverging from the second image, the hologram lens **26** (or **26M**, **32**, **33** or **42**) for transmitting through a part of the first light L17 without any diffraction and diffracting a part of the second light L18 to pass the second light L18 through the same optical path as the first light L17 passes through, an inner lens **193** for converging a beam of superposed light L19 formed of the first and second light L17, L18 at an inner focal point Pf1, an ocular lens **194** for simultaneously forming the first and second images by converging the superposed light L19 diverging from the inner focal point Pf1, an inner lens-barrel **195** for moving a combination element of the inner lens **193** and the hologram lens **26** along an optical axis to adjust a distance between the combination element and the ocular lens **194**, and an outer lens-barrel **196** for moving the objective lens **192** along the optical axis to set the distance between the first sample plane PL1 and the objective lens **192** to the focal length F1 of the objective lens **192**.

The optical axis passes through the centers of the objective lens **192**, the hologram lens **26**, the inner lens **195** and the ocular lens **194**. The position of the first sample plane PL1 differs from that of the second sample plane PL2 along the optical axis.

In the above configuration, the position of the objective lens **192** is adjusted to set the distance between the first sample plane PL1 and the objective lens **192** to the first focal length F1 of the objective lens **192**. In this

case, the distance between the second sample plane PL2 and the objective lens **192** is set to a second focal length F2. Also, the position of the combination element is adjusted to clearly view the first and second images. That is, a beam of first light L17 diverging from the first image on the first sample plane PL1 is collimated in the objective lens **192**, and a part of the first light L17 transmits through the hologram lens **26**. Also, a beam of second light L18 diverging from the second image on the second sample plane PL2 is refracted in the objective lens **192**, and a part of the second light L18 is diffracted in the hologram lens **26** to pass the second light L18 through the same optical path as the first light L17 passes through. Therefore, a beam of superposed light L19 is formed of the first and second light L17, L18. Thereafter, the superposed light L19 is converged by the inner lens **193** at an inner focal point Pf1 to simultaneously form the first and second images enlarged on an image plane PL3, and the superposed light L19 diverging from the point Pf1 is converged by the ocular lens **194** to simultaneously form the first and second images moreover enlarged on an operator's eye.

Accordingly, because the hologram lens **26**, **26M**, **32**, **33** or **42** is utilized to form the superposed light L19, the first image of the first sample SP1 put on the first sample plane PL1 and the second image of the second sample SP2 put on the second sample plane PL2 can be simultaneously observed by simultaneously focusing the binary focus microscope **191** on the first and second samples SP1, SP2.

Also, even though the intensities of the first and second light L17, L18 are reduced when the light L17, L18 pass through the hologram lens **26**, the intensity of the superposed light L19 is sufficient to observe the first and second images because the intensity of the superposed light L19 is determined by adding the intensities of the first and second light L17, L18.

Also, because the hologram lens **26** is blazed as shown in FIG. **6**, the generation of unnecessary diffracted light such as minus first-order diffracted light is reduced when the second light L18 is diffracted in the hologram lens **26**. Therefore, the intensity of the superposed light L19 can be increased, so that first and second images observed can be moreover brightened.

Also, as shown in FIG. **60**, in cases where the first sample SP1 is placed at a bottom of a first sample holder **197** and in cases where the second sample SP2 is placed at a bottom of a second sample holder **198** located under the first sample holder **197**, aberration such as a chromatic aberration is generated in the first and second light L17, L18 incident on the objective lens **192** because an optical path length in the first sample holder **197** for the first light L17 differs from that in the first and second sample holders **197**, **198** for the second light L18. However, the aberration can disappear in the hologram lens **26** by excessively correcting the chromatic aberration in the hologram lens **26** as is described in the first embodiment.

Also, the difference between the first and second focal lengths can be changed by moving the inner and outer lensbarrels **195**, **196** because the distance between the hologram lens **26** and the objective lens **192** is changed. Therefore, even though the thickness of the second sample holder **198** is changed, the first and second images can be reliably observed.

In the twenty-second embodiment, the ocular lens **194** is utilized in the binary focus microscope **191**. However, the ocular lens **194** is not necessarily required. Also, as shown in FIG. **61**, it is applicable that a camera **199** such as a chargecoupled device (CCD) camera be placed on the image plane PL3 in place of the ocular lens **194**. In this case, a superposed image formed of the first and second images enlarged can be photographed with the CCD camera **199**, so that the first and second images can be simultaneously recorded.

(Twenty-third Embodiment)

In cases where a minute circuit is formed on a semiconductor wafer, a photosensitive material is coated on the semiconductor wafer, and the photosensitive material covering the semiconductor wafer is exposed to ultraviolet light through a photomask having a mask pattern in an exposure process. Therefore, the mask pattern of the photomask is transferred to the photosensitive material. In this case, the semiconductor wafer is required to be aligned with the photomask at a high accuracy in an alignment process performed prior to the exposure process. Therefore, a reference image drawn on the semiconductor wafer and the mask pattern drawn on the photomask are simultaneously observed with a conventional microscope having a deep focal depth. However, because the magnification of the conventional microscope having a deep focal depth is low, it is impossible to align the reference image and the mask pattern at an accuracy within 5 μm.

To solve the above drawback in the present invention, an alignment apparatus utilized in the alignment process in which the semiconductor wafer is aligned with the photomask at a high accuracy while simultaneously observing a reference image drawn on the semiconductor wafer and the mask pattern drawn on the photomask is described according to a twenty-third embodiment.

FIG. **62** is a constitutional view of an alignment apparatus according to a twenty-third embodiment.

As shown in FIG. **62**, an alignment apparatus **201** for aligning a first reference image RF1 of a mask pattern drawn on a bottom surface of a photomask **202** with a second reference image RF2 drawn on a bottom surface of a sample such as a semiconductor substrate **203**, comprises a light source **204** for radiating beams of alignment light having a particular wavelength to illuminate the first and second reference images RF1, RF2, the objective lens **192** for receiving a beam of first alignment light L20 diverging from the first reference image RF1 illuminated with the alignment light and receiving a beam of second alignment light L21 diverging from the second reference image RF2 illuminated with the alignment light, the hologram lens **26** (or **26M**, **32**, **33** or **42**) for transmitting through a part of the first alignment light L20 without any diffraction and diffracting a part of the second alignment light L21 to pass the second alignment light L21 through the same optical path as the first alignment light L20 passes through, the inner lens **193** for converging a beam of superposed alignment light L22 formed of the first and second alignment light L20, L21 at an inner focal point Pf2, a camera **205** such as a charge-coupled device (CCD) camera placed at the inner focal point Pf2 for simultaneously photographing and recording the first and second reference images RF1, RF2, the inner lens-barrel **195**, the outer lens-barrel **196**, a moving means **206** for moving the photomask **202** in a horizontal direction perpendicular to an optical axis to align the first reference image RF1 with the second reference image RF2 along the optical axis, and a control means **207** for controlling the movement of

the photomask **202** according to the first and second reference images RF1, RF2 recorded in the camera **205**.

The particular wavelength of the alignment light is determined on condition that a transmissivity of the semiconductor substrate **203** for the alignment light is sufficiently high. The optical axis passes through the centers of the objective lens **192**, the hologram lens **26** and the inner lens **193**.

A binary microscope **208** is composed of the objective lens **192**, the hologram lens **26** (or **26M**, **32**, **33** or **42**), the inner lens **193**, the inner lens-barrel **195** and the outer lens-barrel **196** in the same manner as in the twenty-second embodiment.

In the above configuration, a beam of first alignment light L20 diverging from the first reference image RF1 is collimated in the objective lens **192**, and a part of the first alignment light L20 transmits through the hologram lens **26**. Also, a beam of second alignment light L21 diverging from the second reference image RF2 is refracted in the objective lens **192**, and a part of the second alignment light L21 is diffracted by the hologram lens **26** to pass the second alignment light L21 through the same optical path as the first alignment light L20 passes through. Therefore, a beam of superposed alignment light L22 is formed of the first and second alignment light L20, L21. Thereafter, the superposed alignment light L22 is converged at an inner focal point Pf2 to simultaneously form the first and second reference images RF1, RF2 enlarged. Thereafter, the first and second reference images RF1, RF2 enlarged are photographed and recorded by the camera **205**. Thereafter, a relative position between the first and second reference images RF1, RF2 is examined in the control means **207**, and the photomask **202** is moved in a horizontal direction by the moving means **206** under control of the control means **207** to align the first reference image RF1 with the second reference image RF2.

Accordingly, because the hologram lens **26**, **26M**, **32**, **33** or **42** is utilized to form the binary microscope **208** having two focal points, the first reference image RF1 and the second reference image RF2 can be simultaneously observed even though a focal depth of the binary microscope **208** is low. Also, because the focal depth of the binary microscope **208** can be lowered, the magnification of the binary microscope **208** can be heightened. Therefore, the first reference image RF1 of the photomask **202** can be aligned with the second reference image RF2 of the semiconductor substrate **203** at a high accuracy.

Having illustrated and described the principles of our invention in a preferred embodiment thereof, it should be readily apparent to those skilled in the art that the invention can be modified in arrangement and detail without departing from such principles. We claim all modifications coming within the spirit and scope of the accompanying claims.

What is claimed is:

1. An optical head apparatus for recording or reproducing a piece of information on or from a first information medium having a first thickness or a second information medium having a second thickness, comprising:

a light source for radiating a beam of incident light;

hologram means for transmitting a part of the incident light radiated from the light source without any diffraction on an outgoing path to form a beam of transmitted light and diffracting a remaining part of the incident light radiated from the light source on the outgoing path to form a beam of diffracted light, the hologram means functioning as a lens for the diffracted light to diverge the diffracted light from the hologram means or converge the diffracted light;

lens means for converging the transmitted light formed in the hologram means at a first focal length on the outgoing path to form a first converging spot at a front surface of the first information medium or converging the diffracted light formed in the hologram means at a second focal length on the outgoing path to form a second converging spot at a front surface of the second information medium, the transmitted light passing through the first information medium from its rear surface, the transmitted light being reflected at the front surface of the first information medium and again passing through the lens means and the hologram means on an incoming path, the diffracted light passing through the second information medium from its rear surface, and the diffracted light being reflected at the front surface of the second information medium and again passing through the lens means and the hologram means on the incoming path;

wavefront changing means for changing a wavefront of the transmitted light or the diffracted light passing through the lens means and the hologram means on the incoming path to form one or more beams of information light; and

detecting means for detecting intensities of the information light formed by the wavefront changing means and generating an information signal according to the intensities of the information light, the information signal expressing a piece of information recorded on the first information medium or the second information medium.

2. An optical head apparatus according to claim **1** in which

a grating pattern is drawn in the hologram means in a concentric circle shape,

the grating pattern of the hologram means is formed in relief to concentrically form alternating rows of bottom portions and top portions,

a height H of relief in the grating pattern is set to:

$$H<\lambda/(n(\lambda)-1),$$

where a symbol λ denotes a wavelength of the incident light and a symbol $n(\lambda)$ denotes a refractive index of the hologram means made of a glass material for the incident light having the wavelength λ, and

a difference in phase modulation degree between the incident light passing through the bottom portions of the grating pattern and the incident light passing through the top portions of the grating pattern is lower than 2π radians to set a diffraction efficiency of the hologram means to a value lower than 100%.

3. An optical head apparatus according to claim **1** in which

a far field pattern of the incident light radiated from the light source is distributed to decrease intensity of the incident light toward a peripheral portion of its beam, and

a diffraction efficiency of the hologram means for the incident light is gradually lowered toward an outer direction of the hologram means to distribute intensity of the transmitted light in a gently-sloping shape.

4. An optical head apparatus according to claim 1 in which

a far field pattern of the incident light radiated from the light source is distributed to decrease intensity of the incident light toward a peripheral portion of its beam, and

a diffraction efficiency of the hologram means for the incident light is gradually lowered toward an inner direction of the hologram means to distribute intensity of the diffracted light in a gently-sloping shape.

5. An optical head apparatus according to claim 1 in which

the hologram means functions as a concave lens for the diffracted light to diverge the diffracted light from the hologram means, and

the first thickness of the first information medium is smaller than the second thickness of the second information medium.

6. An optical head apparatus according to claim 1 in which

the hologram means functions as a convex lens for the diffracted light to converge the diffracted light diffracted by the hologram means, and

the first thickness of the first information medium is larger than the second thickness of the second information medium.

7. An optical head apparatus according to claim 2 in which

the grating pattern of the hologram means is partitioned into a plurality of pattern blocks which each are composed of one of the bottom portions and one of the top portions, and

each block of the grating pattern is formed in a stepwise shape to blaze the grating pattern.

8. An optical head apparatus according to claim 1 in which

the hologram means is partitioned into a pattern region and a no-pattern region surrounding the pattern region,

a grating pattern is drawn in the pattern region of the hologram means in a concentric circle shape, and

a diameter of the grating pattern is smaller than an aperture of the lens means to transmit the incident light through the no-pattern region of the hologram means without any diffraction.

9. An optical head apparatus according to claim 8 in which

the grating pattern of the hologram means is formed in relief to concentrically form alternating rows of bottom portions and top portions in the pattern region,

a thickness of the no-pattern region in the hologram means is set to an average value of those of the pattern region, and

a phase of the incident light passing through the no-pattern region of the hologram means agrees with an average value of those of the incident light passing through the pattern region of the hologram means.

10. An optical head apparatus according to claim 2 in which the height H of the relief in the grating pattern is gradually lowered toward an outer direction of a pattern region in which the grating pattern is drawn, and

a diffraction efficiency of the hologram means for the incident light is gradually lowered toward the outer direction of the pattern region.

11. An optical head apparatus according to claim 2 in which the grating pattern of the hologram means is partitioned into a plurality of pattern blocks which each are composed of one of the bottom portions and one of the top portions,

each block of the grating pattern is formed in a stepwise shape and is composed of a flight of stairs,

an inclined angle of the stairs is gradually lowered toward an outer direction of a pattern region in which the grating pattern is drawn to gradually lower the height H of the relief in the grating pattern toward the outer direction of the pattern region, and

a diffraction efficiency of the hologram means for the incident light is gradually lowered toward the outer direction of the pattern region.

12. An optical head apparatus according to claim 2 in which the height H of the relief in the grating pattern is gradually lowered toward an inner direction of a pattern region in which the grating pattern is drawn, and

a diffraction efficiency of the hologram means for the incident light is gradually lowered toward the inner direction of the pattern region.

13. An optical head apparatus according to claim 2 in which the grating pattern of the hologram means is partitioned into a plurality of pattern blocks which each are composed of a bottom portion and a top portion,

each block of the grating pattern is formed in a stepwise shape and is composed of a flight of stairs,

an inclined angle of the stairs is gradually lowered toward an inner direction of a pattern region in which the grating pattern is drawn to gradually lower the height H of the relief in the grating pattern toward the inner direction of the pattern region, and

a diffraction efficiency of the hologram means for the incident light is gradually lowered toward the inner direction of the pattern region.

14. An optical head apparatus according to claim 1 in which

the detecting means comprises a pair of focus error detectors for detecting intensities of two beams of first information light selected among the information light to generate the information signal and a focus error signal, and four tracking error detectors for detecting intensities of four beams of second information light selected among the information light to generate a tracking error signal, a position of the lens means being adjusted according to the focus error signal and the tracking error signal to focus the transmitted light or the diffracted light on the first information medium or the second information medium.

15. An optical head apparatus according to claim 1 in which

a beam of first information light is generated in the wavefront changing means to have a first focal point in the front of the detecting means,

a beam of second information light is generated in the wavefront changing means to have a second focal point in the rear of the detecting means, and

the detecting means comprises a pair of focus error detectors for detecting an intensity of the first information light and an intensity of the second information light to generate a focus error signal, a position of the lens means being adjusted according to the focus error signal to focus the transmitted light or the diffracted light on the first information medium or the second information medium, and

the information signal being detected in the focus error detectors.

16. An optical head apparatus according to claim 1 in which

the wavefront changing means is a hologram having a plurality types of grating patterns, and

the transmitted light or the diffracted light passing through one of the grating patterns of the hologram means is changed to one of the information light.

17. An optical head apparatus according to claim 1 in which

the wavefront changing means is an astigmatic aberration generating unit for generating an astigmatic aberration in the information light, and

the detecting means comprises a quadrant photodetector having four detecting sections for detecting an intensity of the information light having the astigmatic aberration to generate the information signal and servo signals such as a focus error signal and a tracking error signal, a position of the lens means being adjusted according to the servo signals to focus the transmitted light or the diffracted light on the first information medium or the second information medium.

18. An optical head apparatus according to claim 17 in which

the astigmatic aberration generating unit is formed of a plane parallel plate of which a normal line is tilted from an optical axis.

19. An optical head apparatus according to claim 17 in which

the astigmatic aberration generating unit is formed of a cylindrical lens.

20. An optical head apparatus according to claim 1 in which

a grating pattern is drawn on a flat surface of the hologram means, and

a normal line of the flat surface of the hologram means is tilted from an optical axis of the lens means.

21. An optical head apparatus according to claim 1, additionally including:

a polarized beam splitter for totally transmitting the incident light which is radiated from the light source and is linearly polarized in a first direction and totally reflecting light linearly polarized at a second direction perpendicular to the first direction; and

a $\frac{1}{4}$-λ plate for forming the transmitted light or the diffracted light linearly polarized in the second direction by passing the incident light transmitting through the polarized beam splitter or a pair of the transmitted light and the diffracted light on the outgoing path and passing the transmitted light or the diffracted light on the incoming path, the transmitted light or the diffracted light linearly polarized in the second direction by the $\frac{1}{4}$-λ plate being reflected by the polarized beam splitter on the outgoing path and being incident on the wavefront converging means.

22. An optical head apparatus according to claim 1, additionally including a wedge-like prism for reshaping the incident light radiated from the light source, the incident light reshaped being incident on the hologram means.

23. An optical head apparatus according to claim 1 in which

the first thickness of the first information medium is smaller than the second thickness of the second information medium,

the wavefront changing means comprises a beam splitter for transmitting the diffracted light which transmits through the hologram means without any diffraction on the incoming path to form a beam of first information light having an astigmatic aberration and reflecting the transmitted light which transmits through the hologram means without any diffraction on the incoming path, and a wavefront changing unit for changing a wavefront of the transmitted light reflected by the beam splitter to form a plurality of beams of second information light, and

the detecting means comprises a quadrant photodetector having four detecting sections for detecting an intensity of the first information light transmitting through the beam splitter to generate a first information signal and servo signals such as a first focus error signal and a first tracking error signal, a pair of focus error detectors for detecting intensities of two beams of second information light formed in the wavefront changing unit to generate a second information signal and a second focus error signal, and four tracking error detectors for detecting intensities of four beams of second information light formed in the wavefront changing unit to generate a second tracking error signal, a positional relation between the lens means and the second information medium being adjusted according to the servo signals to focus the diffracted light on the second information medium, a positional relation between the lens means and the first information medium being adjusted according to the second focus error signal and the second tracking error signal to focus the transmitted light on the first information medium, the first information signal expressing the information recorded on the second information medium, and the second information signal expressing the information recorded on the first information medium.

24. An optical head apparatus according to claim 1 in which

the first thickness of the first information medium is smaller than the second thickness of the second information medium,

the wavefront changing means comprises a beam splitter having a wavefront changing unit for transmitting the transmitted light which transmits through the hologram means without any diffraction on the incoming path to form a beam of first information light having an astigmatic aberration and diffracting and reflecting the diffracted light which transmits through the hologram means without any diffraction on the incoming path and is incident on the wavefront changing unit to form a plurality of beams of second information light, and

the detecting means comprises a quadrant photodetector having four detecting sections for detecting an intensity of the first information light transmitting through the beam splitter to generate a first information signal and servo signals such as a first focus error signal and a first tracking error signal, a pair of focus error detectors for detecting intensities of two beams of second information light formed in the wavefront changing unit to generate a second information signal and a second focus

error signal, and four tracking error detectors for detecting intensities of four beams of second information light formed in the wavefront changing unit to generate a second tracking error signal, a positional relation between the lens means and the first information medium being adjusted according to the servo signals to focus the transmitted light on the first information medium, a positional relation between the lens means and the second information medium being adjusted according to the second focus error signal and the second tracking error signal to focus the diffracted light on the second information medium, the first information signal expressing the information recorded on the first information medium, and the second information signal expressing the information recorded on the second information medium.

25. An optical head apparatus according to claim **1** in which

the first thickness of the first information medium is smaller than the second thickness of the second information medium,

the transmitted light converged by the lens means on the outgoing path is also converged at the front surface of the second information medium in defocus and is reflected to again pass through the lens means and the hologram means without any diffraction on the incoming path,

the wavefront changing means comprises a beam splitter having a wavefront changing unit for transmitting the diffracted light which transmits through the hologram means without any diffraction on the incoming path to form a beam of first information light having an astigmatic aberration and diffracting the transmitted light which is converged on the second information medium in defocus and is incident on the wavefront changing unit to form a plurality of beams of second information light, and

the detecting means comprises a quadrant photodetector having four detecting sections for detecting in defocus an intensity of the first information light transmitting through the beam splitter to generate a first information signal expressing the information recorded on the second information medium and detecting in focus intensities of the second information light diffracted in the wavefront changing unit to generate a focus error signal, a positional relation between the lens means and the second information medium being adjusted according to the focus error signal to focus the diffracted light on the second information medium.

26. An optical head apparatus according to claim **1** in which

the first thickness of the first information medium is larger than the second thickness of the second information medium,

the wavefront changing means comprises a beam splitter for transmitting the diffracted light again diffracted by the hologram means on the incoming path to form a beam of first information light having an astigmatic aberration and reflecting the transmitted light diffracted by the hologram means on the incoming path, and a wavefront changing unit for changing a wavefront of the transmitted light reflected by the beam splitter to form a plurality of beams of second information light, and

the detecting means comprises a quadrant photodetector having four detecting sections for detecting an intensity of the first information light transmitting through the beam splitter to generate a first information signal and servo signals such as a first focus error signal and a first tracking error signal, a pair of focus error detectors for detecting intensities of two beams of second information light formed in the wavefront changing unit to generate a second information signal and a second focus error signal, and four tracking error detectors for detecting intensities of four beams of second information light formed in the wavefront changing unit to generate a second tracking error signal, a positional relation between the lens means and the second information medium being adjusted according to the servo signals to focus the diffracted light on the second information medium, a positional relation between the lens means and the first information medium being adjusted according to the second focus error signal and the second tracking error signal to focus the transmitted light on the first information medium, the first information signal expressing the information recorded on the second information medium, and the second information signal expressing the information recorded on the first information medium.

27. An optical head apparatus according to claim **1** in which

the first thickness of the first information medium is larger than the second thickness of the second information medium,

the wavefront changing means comprises a beam splitter having a wavefront changing unit for transmitting the transmitted light diffracted by the hologram means on the incoming path to form a beam of first information light having an astigmatic aberration and diffracting and reflecting the diffracted light which is again diffracted by the hologram means on the incoming path and is incident on the wavefront changing unit to form a plurality of beams of second information light, and

the detecting means comprises a quadrant photodetector having four detecting sections for detecting an intensity of the first information light transmitting through the beam splitter to generate a first information signal and servo signals such as a first focus error signal and a first tracking error signal, a pair of focus error detectors for detecting intensities of two beams of second information light formed in the wavefront changing unit to generate a second information signal and a second focus error signal, and four tracking error detectors for detecting intensities of four beams of second information light formed in the wavefront changing unit to generate a second tracking error signal, a positional relation between the lens means and the first information medium being adjusted according to the servo signals to focus the transmitted light on the first information medium, a positional relation between the lens means and the second information medium being adjusted according to the second focus error signal and the second tracking error signal to focus the diffracted light on the second information medium, the first information signal expressing the information recorded on the first information medium, and the second information

signal expressing the information recorded on the second information medium.

28. An optical head apparatus according to claim **1** in which

the hologram means is partitioned into a central region and a peripheral region surrounding the central region,

a first grating pattern is drawn in the central region of the hologram means in a concentric circle shape,

a second grating pattern is drawn in the peripheral region of the hologram means in a non-concentric shape,

the transmitted light transmits through the central region of the hologram means without any diffraction on the outgoing and incoming paths,

a part of the incident light radiated from the light source transmits through the peripheral region of the hologram means on the outgoing path to form a beam of noise cancelling light which is converged by the lens means to form a third converging spot surrounding the first converging spot,

the noise cancelling light forming the third converging spot passes through the lens means and is diffracted in the peripheral region of the hologram means on the incoming path,

the detecting means comprises a first photo detector for detecting an intensity of the transmitted light transmitting through the central region of the hologram means without any diffraction on the incoming path to generate a first information signal component **SC1** expressing a piece of information recorded on the first information medium, and a second photo detector for detecting an intensity of the noise cancelling light diffracted in the peripheral region of the hologram means on the incoming path to generate a second information signal component SC2 expressing the information, a noise cancelled information signal Snc being obtained by adding the first information signal component **SC1** and a multiplied second information signal component R×SC2 which is obtained by multiplying the second information signal component SC2 by a weighting factor R.

29. An optical head apparatus according to claim **28** in which

the peripheral region of the hologram means is partitioned into a first side peripheral region and a second side peripheral region facing each other with the central region between the first and second side peripheral region,

a far field pattern of the incident light radiated from the light source is distributed to decrease intensity of the incident light toward a peripheral portion of its beam,

a cross-sectional beam profile of the incident light radiated from the light source is in an elliptic shape in which a beam divergent angle of the incident light in a perpendicular direction is larger than that in a horizontal direction,

the incident light placed at one side of its beam in the perpendicular direction passes through the first side peripheral region of the hologram means to form a part of the noise cancelling light,

the incident light placed at the other side of its beam in the perpendicular direction passes through the second side peripheral region of the hologram means to form a remaining part of the noise cancelling light, and

a cross-sectional beam profile of light defined as the combination of the transmitted light and the noise cancelling light is in a circular shape.

30. An optical head apparatus according to claim **28** in which

the peripheral region of the hologram means is partitioned into a first side peripheral region and a second side peripheral region facing each other with the central region between the first and second side peripheral region,

a second photo detector of the detecting means is composed of a first noise cancelling detector for detecting an intensity of the noise cancelling light formed in the first side peripheral region of the hologram means to generate a third information signal component **SC3** expressing the information, and a second noise cancelling detector for detecting an intensity of the noise cancelling light formed in the second side peripheral region of the hologram means to generate a fourth information signal component **SC4** expressing the information, the noise cancelled information signal Snc being obtained according to an equation:

$$Snc=SC1+R1\times SC3+R2\times SC4,$$

where **R1** is a first weighting factor and **R2** is a second weighting factor.

31. An optical head apparatus according to claim **1** in which

the light source and the detecting means are placed on a substrate to fix a relative position between the light source and the detecting means, and

the light source is placed closely to the detecting means.

32. An optical head apparatus according to claim **1** in which

the incident light radiated from the light source is linearly polarized in a first direction,

the wavefront changing means comprises a transparent substrate, a polarizing separation film formed on a front surface of the transparent substrate for reflecting the incident light linearly polarized in the first direction on the outgoing path and refracting the transmitted light or the diffracted light linearly polarized in a second direction perpendicular to the first direction on the incoming path, a hologram formed on a rear surface of the transparent substrate for diffracting the transmitted light or the diffracted light refracted by the polarizing separation film to form the beams of information light, and a $\frac{1}{4}$-λ plate for forming the transmitted light or the diffracted light linearly polarized in the second direction by passing the incident light reflected by the polarizing separation film and passing the transmitted light or the diffracted light on the incoming path.

33. A focusing method for focusing light on a first information medium having a first thickness or a second information medium having a second thickness to record or reproduce a piece of information on or from the first information medium or the second information medium, comprising the steps of:

moving an optical head apparatus in a direction to decrease or increase the distance between the optical head apparatus and the first or second information medium, the optical head apparatus comprising

a light source for radiating a beam of incident light,

hologram means for transmitting a part of the incident light radiated from the light source without any diffraction on an outgoing path to form a beam of transmitted light and diffracting a remaining part of the incident light radiated from the light source on the outgoing path to form a beam of diffracted light, the hologram means functioning as a lens for the diffracted light to diverge the diffracted light from the hologram means or converge the diffracted light,

lens means for converging the transmitted light formed in the hologram means at a first focal length on the outgoing path to form a first converging spot at a front surface of the first information medium or converging the diffracted light formed in the hologram means at a second focal length on the outgoing path to form a second converging spot at a front surface of the second information medium, the transmitted light being incident on a rear surface of the first information medium and being converged at the front surface of the first information medium, the transmitted light being reflected at the rear surface of the first information medium and again passing through the lens means and the hologram means on an incoming path, the diffracted light being incident on a rear surface of the second information medium and being converged at the front surface of the second information medium, and the diffracted light being reflected at the rear surface of the first information medium and again passing through the lens means and the hologram means on the incoming path,

wavefront changing means for changing a wavefront of the transmitted light or the diffracted light passing through the lens means and the hologram means on the incoming path to form one or more beams of information light, and

detecting means for detecting intensities of the information light formed by the wavefront changing means and generating an information signal and a focus error signal according to the intensities of the information light, the information signal expressing a piece of information recorded on the first information medium or the second information medium;

judging whether or not an intensity of the focus error signal generated in the detecting means is larger than a threshold value; and

adjusting the position of the optical head apparatus to decrease the intensity of the focus error signal to zero when the intensity of the focus error signal becomes larger than the threshold value.

34. An information reproducing method for reproducing a piece of recording information from an optical disk in which the recording information are recorded at a high density on a first substrate having a first thickness and a piece of distinguishing information informing that the recording information are recorded on the first substrate is recorded at an ordinary density on a second substrate having a second thickness larger than the first thickness, comprising the step of:

moving an optical disk apparatus under the second substrate of the optical disk, the optical disk comprising

rotating means for rotating the optical disk at a regular speed,

a light source for radiating a beam of incident light;

hologram means for transmitting a part of the incident light radiated from the light source without any diffraction on an outgoing path to form a beam of transmitted light and diffracting a remaining part of the incident light radiated from the light source on the outgoing path to form a beam of diffracted light, the hologram means functioning as a lens for the diffracted light to diverge the diffracted light from the hologram means,

lens means for converging the transmitted light formed in the hologram means on the first substrate of the optical disk rotated by the rotating means to record or reproduce a piece of recording information on or from the optical disk and converging the diffracted light formed in the hologram means on the second substrate of the optical disk rotated by the rotating means to reproduce the distinguishing information from the optical disk, the transmitted light being reflected by the first substrate of the optical disk and again passing through the lens means and the hologram means on an incoming path, and the diffracted light being reflected by the second substrate of the optical disk and again passing through the lens means and the hologram means on the incoming path,

wavefront changing means for changing a wavefront of the transmitted light passing through the lens means and the hologram means on the incoming path to form one or more beams of recording information light and changing a wavefront of the diffracted light passing through the lens means and the hologram means on the incoming path to form one or more beams of distinguishing information light, and

detecting means for detecting intensities of the recording information light formed by the wavefront changing means to generate a recording information signal according to the intensities of the recording information light and detecting intensities of the distinguishing information light formed by the wavefront changing means to generate a distinguishing information signal according to the intensities of the distinguishing information light, the distinguishing information signal expressing the distinguishing information recorded on the second substrate of the optical disk, and the recording information signal expressing the recording information recorded on the first substrate of the optical disk; and

converging the diffracted light on the second substrate of the optical disk to reproduce the distinguishing information;

moving the optical disk apparatus to a position under the first substrate of the optical disk to converge the transmitted light on the first substrate of the optical disk when the distinguishing information is detected in the detecting means; and

reproducing the recording information by generating the recording information signal in the detecting means.

[57] **ABSTRACT**

An apparatus for detecting a rotation operation of revolver is provided with a rotation direction detecting device for detecting a rotation direction of revolver by detecting a displacement of a position indication portion indicating a position of objective mount portion. In case that the rotation of revolver is carried out either in a manual manner or in an automatic manner, an address of mount hole in revolver which is to be next located at the predetermined position may be determined at start of rotation operation of revolver.

OBJECTIVE REPLACING APPARATUS HAVING OBJECTIVE POSITION, DISPLACEMENT AND ADDRESS DETECTING MEANS AND MICROSCOPE USING IT

This is a continuation of application Ser. No. 08,069,399, filed Jun. 1, 1993, now abandoned.

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to an objective replacing apparatus and a microscope using the apparatus. The objective replacing apparatus has a device for detecting an objective replacing operation. When the replacing apparatus, for example a revolver, is moved (rotated) to replace an objective with another, the detection device detects the rotation operation of revolver at rotation start. The microscope automatically controls adjustment of light quantity and adjustment of aperture diameter of aperture diaphragm with the detection device so that the illumination condition is adjusted suitable for a next coming objective being to be set in an optical path of microscope.

2. Related Background Art

There are microscopes provided with an objective replacing apparatus, a light control apparatus, and/or an aperture diaphragm apparatus, which are conventionally arranged as follows. A revolver is known as a conventional objective replacing apparatus. The revolver is held rotatable on a microscope and has a plurality of mount holes concentrically disposed around the rotation center of revolver. An objective is set in each mount hole. The revolver is rotated by an operator in a manual operation or by an automatic mechanism such as a motor, so that an arbitrary objective may be positioned in the optical path of microscope out of a plurality of objectives.

The conventional revolver had a device for detecting an address of each mount hole. There are various devices known for detecting an address of mount hole, for example as disclosed in Japanese Laid-open Utility Model Application No. 56-93713 or in Japanese Laid-open Patent Application No. 62-218915.

Such address detection devices are arranged such that when a desired mount hole is located in the optical path an address of the mount hole is then detected.

Accordingly, the conventional detection devices could not identify during movement of revolver an address of a next coming mount hole being to be set in the optical path, nor an objective set in the mount hole.

Conventional light control apparatuses are arranged such that a photo receptor is located in an observation path of microscope or in a photographic light path of TV camera or the like, that a light quantity of light from a source is detected by the photo receptor, and that the light quantity is adjusted to proper brightness by manually or automatically operating light quantity adjusting means such as a continuously variable ND filter to carry out a light control.

Such light control apparatuses, however, detect a light quantity of light emitted from the source and then passed through an objective, and then adjust the light quantity by operating the ND filter in accordance with the detected light quantity.

When the currently set objective is replaced with another objective having a different magnification by rotating the revolver, light is once shut in the field, because the objective is deviated from the optical path during rotation of revolver. The conventional light control apparatuses respond to this state with a decreased light quantity being detected by the photo receptor so that the ND filter is adjusted to become brighter.

Since brightness is detected after the next objective is located in the optical path and then the ND filter is operated in the conventional light control apparatuses, the apparatuses need a considerable time to obtain a proper light quantity, which interferes smooth observation.

In a microscope provided with such a light control apparatus, excessively bright light suddenly enters the optical path at the moment that the objective enters the optical path, which would cause eye fatigue of observer or which could deteriorate the photo receptor of TV camera. The influence appears great especially when a dark objective is replaced with a bright objective.

In addition, microscopes having an aperture diaphragm in the vicinity of condenser lens are arranged such that a resolution of image by objective, a contrast, a field of depth, and brightness may be adjusted through the aperture diaphragm. In the conventional microscopes an aperture ratio most appropriate to look could be set according to a sort of objective while an observer manually adjusts an opening diameter of aperture diaphragm. A technology was recently developed to automatically adjust the opening diameter of aperture diaphragm.

For example, often used is such an arrangement that the aperture diameter of aperture diaphragm is automatically adjusted in accordance with an objective set in a mount hole located at a stop position of revolver, using the aforementioned address detection device of mount hole in revolver.

The automatic adjusting device, however, starts the adjusting operation to optimize the opening diameter of aperture diaphragm after the revolver is stopped. Accordingly, the conventional microscopes permit no observation before the diameter of aperture diaphragm is adjusted, providing a problem of waiting time.

SUMMARY OF THE INVENTION

The first object of the present invention is to obtain an apparatus for detecting a rotation operation of revolver, which can determine a next objective being to be located at a predetermined position at an early stage of rotation of revolver. The second object of the invention is to obtain a microscope with the apparatus for detecting the rotation operation of revolver, which can start adjustment of light quantity, diameter of aperture diaphragm, or the like concomitant with replacement of objective early.

An apparatus for detecting a rotation operation of revolver according to the present invention is provided with rotation direction detecting means for detecting the rotation direction of the revolver by detecting a displacement of position indication part indicating a position of an objective mount portion.

The conventional microscopes can determine an address of next mount hole or an objective mounted in the next mount hole only either by a command signal of controller of motor-operated revolver in case that the revolver is automatically rotated or by detecting an address of mount hole after rotation in case that the revolver is manually rotated, whereas the apparatus of the present invention can determine an address of next

mount hole in revolver being to be located at a predetermined position at the start of rotation operation of revolver when the revolver is manually or automatically rotated.

A microscope of the present invention is provided with the apparatus for detecting the rotation operation of revolver as described, so that the rotation direction of revolver may be identified thereby to enable determination of next objective being to be located in the optical path of microscope, whereby various adjustments may be early conducted based on the thus determined objective.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a drawing to show a main part of apparatus for detecting a rotation operation of revolver in an embodiment;

FIG. **2** is a drawing to show a state after the revolver **21** of FIG. **1** is rotated;

FIG. **3** is a drawing to show signals of respective sensors in holder H in FIG. **1**;

FIG. **4** is a drawing to show the construction of embodiment of a light control apparatus for microscope using the apparatus of FIG. **1**;

FIG. **5** and FIG. **6** are drawings to show a flowchart for the apparatus of FIG. **4**;

FIG. **7** is a drawing to show the construction of embodiment of an aperture diaphragm apparatus for microscope using the apparatus of FIG. **1**; and

FIG. **8**, FIG. **9**, and FIG. **10** are drawings to show a flowchart for the apparatus of FIG. **7**.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

There will be described referring to FIG. **1** to FIG. **10** an apparatus for detecting the rotation operation of revolver, and a light control apparatus and an aperture diaphragm apparatus for microscope.

FIG. **1** and FIG. **2** show an embodiment of the apparatus for detecting the rotation operation of revolver.

In FIG. **1** reference numeral **21** designates a revolver, which is rotatably held on a fixed portion fixed in a microscope body. A plurality of objectives not shown are mounted at respectively predetermined positions in the revolver **21**.

FIG. **1** shows objective mount holes **21A**, **21B**, **21C** representing the predetermined positions.

Small disk permanent magnets **22A**, **22B**, **22C** are attached to the revolver **21** at peripheral positions radially outside the objective mount holes **21A**, **21B**, **21C**. These small permanent magnets **22A**, **22B**, **22C** are for identifying a reference stop position of objective mount hole **21A**, **21B**, **21C**. Each of the small permanent magnets is disposed on an intersection between an imaginary circumference **C1** with the center at the rotation center **0** of revolver **21** and a straight line passing through the center of each objective lens mount hole and the rotation center **0** of revolver.

A plurality of small disk permanent magnets **23A**, **23B**, **23C** (as will be collectively referred to as an address indication part) each for identifying an address of each mount hole **21A**, **21B**, **21C** are mounted at peripheral positions further radially outside the imaginary circle **C1**. The address indication part **23** indicates an address of each mount hole by arranging the magnets among three locations, which can indicate eight (**23**) addresses at most.

A holder H is fixed at the position F (which is a part of the fixed portion) where it is kept as not interfering with the revolver **21** upon rotation. Hall IC sensors **19*a***, **19*b***, **19*c*** (which will be collectively denoted by numeral **19**) are mounted on the holder H. The Hall IC sensors **19*a***, **19*b***, **19*c*** are located at superposing positions over the imaginary circumference **C1**, and are connected to a position/rotation direction detection part **8** for electrically converting a detection signal. The sensors **19*a*** and **19*c*** are used for rotation direction detection. The IC sensor **19*b*** is used for detecting whether the mount hole is located at the predetermined position.

Hall IC sensors **20*a***, **20*b***, **20*c*** (as will be collectively denoted by numeral **20**) are disposed outside the Hall IC sensor series **19**. The Hall IC sensors **20*a***, **20*b***, **20*c*** are superposedly arranged over an imaginary circumference **C2**. A spacing between the Hall IC sensors is equal to a mount pitch of the magnets **23A**, **23B**, **23C**. The Hall IC sensors **20*a***, **20*b***, **20*c*** are connected to the address detection circuit **9** for electrically converting a detection signal.

Next described are the address detection and the position/rotation direction detection with the Hall IC sensors **19**, **20**.

The address detection circuit **9** outputs an address signal of mount hole, based on the predetermined arrangement pattern of small permanent magnets **23A**, **23B**, **23C** detected by the Hall IC sensors **20*a***, **20*b***, **20*c***.

The position/rotation direction detection part **28** detects the position and the rotation direction by reading the position of small permanent magnet **22A**, **22B**, **22C** through the Hall IC sensors **19*a***, **19*b***, **19*c***.

The logic of revolver position detection and rotation direction detection is described referring to FIG. **2** and FIG. **3**. The detection operation of rotation direction will be described with an example in which the objective mount hole **21B** is set in the optical path, as shown in FIG. **2**.

When the Hall IC sensor **19*b*** at the objective mount hole **21B** is on (active LOW) as in the LOW part of letter P in FIG. **3**, the objective lens is in the optical path (only the optical axis Z of which is shown). Address data detected by the Hall IC sensors **20*a***, **20*b***, **20*c*** become effective only in that state. Accordingly, the Hall IC sensor. **19*b*** functions as a reference position sensor to define the stop position of revolver.

In FIG. **3**, the Hall IC sensors **20*a***, **20*b***, **20*c*** detect on, off, and on, respectively, during ON (active LOW) of the reference position sensor **19*b*** to detect the predetermined revolver address.

The Hall IC sensors **19*a***, **19*c*** are located on either side of the reference position sensor **19*b***. When the revolver **21** is rotated, the small permanent magnet **22B** is slightly deviated in the direction of rotation to enter a sensitive range of either one of the Hall IC sensors **19*a***, **19*c*** located along the rotation direction. This permits one to know in which direction the revolver **21** is rotated.

The reference position signal and the rotation direction signal detected by these detection parts **8**, **9** are output to a rotation direction identification circuit **10** provided inside the microscope, and the rotation direction identification circuit **10** outputs a revolver rotation direction signal and a revolver rotation start signal (see FIG. **4**).

The position/rotation direction identification circuit **10** determines the rotation direction by detecting which sensor **19*a*** or **19*c*** in the rotation direction becomes

LOW after the signal of the reference position sensor **19***b* is turned from LOW to HIGH as shown in FIG. **3**.

This permits one to know an address of next mount hole, or a next objective being to be next set into the optical path at the same time with the rotation of revolver **21**. Consequently, necessary data such as a light quantity suitable for the next objective may be known Substantially at the same time with the start of rotation operation of revolver.

Next described referring to FIG. **4** and FIG. **5** is a light control apparatus for performing a light control for the objective specified by the revolver rotation operation detection apparatus as described.

In FIG. **4** the above-described revolver rotation operation detection apparatus comprises the position/rotation direction detection part **8** enclosed in the revolver part **1**, the address detection circuit **9**, and the rotation direction identification circuit **10** incorporated in a control part **3** in a light control part **2**.

The light control part **2** comprises an ND filter drive part **14**, **16** for driving a continuously variable ND filter, which is variable light control means for adjusting a proper light quantity for an objective, an ND rotation amount storing part **12** storing rotation operation amounts of ND filter corresponding to respective objectives, and an ND rotation amount detection sensor part **13**, **18** for feeding back the rotation amount of ND filter.

Further connected is a manual operation part **15** for inputting initial setting or change setting of proper light quantity data or the like for objective.

An operation of the light control apparatus is now described.

First described is the change-over of objective by manually rotating the revolver.

Suppose the reference position **22**B of the current revolver is known through the sensor **19***b* and the revolver address is read by the address detection part **9**, as described with FIG. **2**. When the revolver **21** is rotated from this state in a certain direction (for example in the direction of L in FIG. **1**), the position/rotation direction detection part **8** outputs a rotation direction detection signal (an output signal of IC sensor **19**C) to the rotation direction identification circuit **10** (Step **100**). The rotation direction identification circuit determines the rotation direction with the detection signal, and outputs a rotation start signal and a rotation direction signal. A CPU **11** reads these signals and the address signal from the detection part **9** (Step **110**), and then identifies an address of next coming mount hole, that is, next objective (Step **120**).

Then, the CPU **11** reads out from the ND rotation amount storing part **12** relative movement data about rotation direction and rotation amount of the continuously variable ND filter **17** from the present position in order to equalize a light quantity through the next objective being to be set into the optical path to the light quantity through the objective set in the optical path before start of rotation (Step **130**).

The CPU **11** then writes the read relative movement data in the counter circuit **13**, and gives the motor rotation direction and a command of rotation start to the motor drive control circuit **14** (Steps **140**, **150**). A DC motor **16** starts rotating with this rotation command signal, and the continuously variable ND filter **17** attached to the rotation shaft of DC motor **16** starts rotating in the predetermined direction (Step **160**). While the continuously variable ND filter **17** is rotated, a slit counting sensor **18** detects slits formed on the peripheral edge of filter to generate count pulses (Step **170**). The count pulses are then counted by the counter circuit **13**, and a movement completion signal is output to the CPU. **11** when the movement count number and the counter pulse number set by the CPU **11** in the counter circuit **13** at Step **140** are coincident with each other (Step **180**). This signal is read by the CPU **11**, and then a motor stop signal is output to the motor drive control circuit **14** (Step **190**). Receiving this stop signal, the motor is stopped and the revolver address detection signal is simultaneously read. It is checked whether the address is coincident with the revolver position anticipated as next (Step **200**).

Next described is the change-over of objective by rotating the revolver **21** by means of motor. The revolver **21** is driven by a motor **4**. The CPU **11** controls the motor **4**, based on the operation of revolver rotation command switch provided in the manual operation part **15**. The CPU **11** outputs a drive signal to the motor **4** when either a forward/backward rotation command signal of motor-operated revolver or an objective address assignment signal is output by operating the switch of the operation part **15**. At the same time, the input signals are read to directly determine a next coming revolver address, or next objective (Step **210**). Namely, data of rotation direction and rotation start can be obtained from the command signal or the assignment signal, and a next objective can be determined simply by reading an address from the detection part **9**. Once the next objective is determined, the CPU **11** executes the light control in the same manner as in the manual rotation. The Hall IC sensor **19***b* may be omitted in case of motor-operated revolver, because it can be detected by another means whether a desired mount hole is located in the optical path.

The another means is as follows. Click grooves are formed at positions corresponding to the respective mount holes on the revolver **21**. An engagement member such as a ball urged by a spring is provided on the fixed portion of revolver, which engages with a click groove when a desired mount hole is coincident with the optical path. When the revolver is rotated, a load on the motor **4** differs depending on whether the mount portion is located in the optical path or at a position other than the optical path. Thus, the another means is one to detect whether the desired mount hole is located in the optical path by detecting the difference of load.

Also, there may be a case that a light amount Passing through the objective is desired to be changed without changing the objective. In this case, the forward rotation/backward rotation switch in the manual operation part **15** is operated to rotation-adjust the aforementioned continuously variable ND filter **17** as to secure a determined light quantity.

When the objective is replaced with another after the continuously variable ND filter **17** was adjusted by such a manual operation, the CPU **11** adjusts the continuously variable ND filter **17** by a relative movement amount corresponding to a light amount difference between proper light quantities for old and new objectives from the position set by the manual operation. In other words, the amount set by the manual operation is kept as an offset. This arrangement assures a proper light quantity for each objective before and after replacement thereof.

Next described referring to the flowchart shown in FIG. **6** is a process for storing relative movement data

of the continuously variable ND filter for objectives set in the respective mount holes in revolver.

The manual operation part **15** has an initial setting switch (for reset and data setting) and the forward-/backward rotation command switch. The storage of relative movement data is carried out with these switches.

When the reset switch of initial setting switch is turned on, the CPU **11** clears movement data stored in the ND rotation amount storing part **12** (Step **300**). Specifically, it writes initial value data in the counter circuit **13**. A desired objective is then set in the optical path of microscope, and the forward/backward rotation switch in the manual operation part **15** is operated to rotate the continuously variable ND filter **17**. By this operation, the light quantity is adjusted to be suitable for an observation optical path or a photographic optical path for example for TV camera (Step **310**). When a suitable light amount is set, the data setting switch in the manual operation part **15** is pressed to write the movement count value of counter circuit **13** at this moment in the ND rotation amount storing part **12** (Step **320**). Similarly, relative movement data for all objectives set in the revolver may be consecutively stored in the storing part **12** (Steps **330**, **340**). A difference between objectives may be calculated with absolute count value as read value to obtain the data.

There is another method for inputting the relative movement data for each objective different from the above method. The another method is as follows. Information (magnification, NA, etc.) on objectives set in the respective mount holes is input from the outside. A difference of proper light quantity is calculated between objectives, based on the Objective information. The data is converted into a corresponding rotation direction movement amount (count value) of continuously variable ND filter **17**, and stored in the ND rotation amount storing part **12**. This data input method has an advantage that there is no need to store the relative movement data, based on brightness adjustment with the continuously variable ND filter **17** for respective objectives prior to observation.

A pulse motor may be employed as the driving motor **16** in place of DC motor. Such a modification may obviate the rotation angle detection sensor such as the slit counting sensor **18**. Namely, the continuously variable ND filter may be rotation-adjusted in open-loop control by inputting pulse string for drive control directly into the counter circuit **13** and counting it.

In contrast, the aforementioned light control apparatus performs a semi-closed loop control to detect a rotation amount of continuously variable ND filter **17**. The light control apparatus of the present invention may also employ a closed-loop control to obtain the proper light quantity by detecting a light quantity of light from a source having passed through the ND filter, and feeding back the state to the set value in order to Judge if the set density of ND filter is appropriate.

Since the Hall IC sensor series **19** for detecting the position of objective mount hole, which is used in the revolver rotation operation detection apparatus as described, is for use in detection of rotation direction, it may be omitted if the revolver is manually rotated. Also, although the rotation direction is determined with the three Hall IC sensors **19***a*, **19***b*, **19***c* in the above embodiment, the rotation direction of revolver may be detected by a phase difference of generated signals. In this case, the number of sensors may be decreased. Further, although the above embodiment employs the Hall IC sensors to detect the position and the address, position detecting means such as the photoelectric transmission slit sensor or the reflection type photo interrupter may be set on the revolver.

The construction of an aperture diaphragm apparatus is next described referring to FIG. 7.

In FIG. 7 a control circuit **30** for aperture diaphragm adjustment is composed mainly of an automatic/manual change-Over switch **34**, a manual aperture diaphragm switch **36**, a D-A converter **31**, a differential amplifier **32**, a drive circuit **33**, an A-D converter **38**, a memory (RAM) **39**, a memory (ROM) **40**, and a CPU **41**. The automatic/manual change-over switch **34** is for change-over between an automatic setting mode in which the aperture diaphragm is automatically set in response to the rotation of revolver **52** and a manual setting mode in which the opening degree of aperture diaphragm may be freely set by motor drive upon setting an arbitrary aperture ratio. The manual aperture diaphragm switch **36** performs an open or close operation of diaphragm while switching an applying voltage (+V, −V) of the source **35** by change-over of switch in the manual setting mode. The D-A converter **31** converts the aperture ratio data of digital signal output through a data bus into an analog signal in the automatic setting mode. The differential amplifier **32** compares an output signal of the D-A converter **31** with a feedback voltage signal obtained by amplifying a signal from a potentiometer **43** of an aperture diaphragm motor **42** through an amplifier **37**. The drive circuit **33** drives the aperture diaphragm motor **42** with this comparison signal. The A-D converter **38** performs the analog-to-digital conversion of the value of the potentiometer **43** obtained at the time of setting of aperture ratio. The memory **39** stores the digital data after the A-D conversion. The memory **40** stores the initially set aperture rate of aperture diaphragm. The CPU **41** controls data transmission between the memories **39**, **40** through the data bus.

A motor-operated revolver drive control circuit **53** for switching objectives includes an objective change-over switch **51**, a part of CPU **41**, a drive circuit **44**, a motor **45**, and a position sensor **46**. The objective change-over switch **51** is disposed on an operation part of microscope, and an observer operates the revolver **52** through this switch **51**. The part of CPU **41** receives an operation signal from the switch **51** and outputs a control signal after a process of predetermined feedback. The drive circuit **44** controls the motor **45**, based on the control signal. The position sensor **16** feeds the position of the revolver motor **15** back to the CPU **41**. The control circuit **53** further has an address detection part **53A** of objective mount hole in revolver **52** and a position/rotation direction detection part **54**.

Moreover, a light/dark field change-over switch control circuit **56** has a light/dark field change-over switch **47**, a part of CPU **41**, a drive circuit **48**, a motor **49**, and a position sensor **50**. The switch **47** is provided on the operation part of microscope as to allow the observer to change over the observation method. The CPU **41** receives an operation signal from the light-/dark field change-over switch **47** and controls the drive circuit **48** with the predetermined feedback. The drive circuit **48** drives the motor **49** under the control of CPU **41** to effect the change-over between a light field and a dark field. The position sensor **50** feeds the position of the light/dark field change-over motor **49** back to the CPU **41**.

Operations of the circuits in the aperture diaphragm apparatus so arranged will be described referring to FIG. 7 to FIG. 10.

A standard change-over operation of objective is first explained.

After the observer sets a plurality of objectives (not shown) in the motor-operated revolver **52**, he or she conducts an operation to store a relation between the respective lenses and the revolver mount positions in the memory **40**. This operation is sequentially carried out according to an instruction on an instruction screen of display provided on a panel having the operation switch of microscope.

After that, when the observer operates the objective change-over switch **51** on the operation part to change the objective for example into one having **20** magnifications during observation (Step **400**), the CPU **41** calculates a mount hole in which the objective of **20** magnifications is set, from a signal of switch **51** and an address of address detection part **53** (Step **410**).

After that, the rotation operation of revolver **52** and the aperture diaphragm rotation operation are carried out in parallel. In the revolver rotation operation the CPU **41** first calculates a rotation direction and a rotation amount from the present position of revolver **52** to the position of mount hole for the objective of 20 magnifications (Step **420**). The CPU **41** outputs a drive signal based on the calculated value to the drive circuit **44**, and the drive circuit **44** rotates the revolver motor **45** based on the drive signal. The revolver is rotated up to a desired magnification position to set the objective of 20 magnifications while the rotation amount of motor **45** is fed back from the position sensor **46** to the CPU **41** (Step **430**).

The open-close operation of aperture diaphragm **55** is also carried out simultaneously with the above operation. The CPU **41** first reads out from the memory (ROM) **40** rotation amount data of motor **49** for obtaining an aperture diameter of aperture diaphragm corresponding to a standard aperture ratio (for example 75%) of objective of 20 magnifications (Step **440**). The data signal is subjected to the digital-to-analog conversion in the D-A converter **31** and then to a predetermined control, and the thus converted signal is output through the drive circuit **33** to the aperture diaphragm motor **42** to conduct the open/close operation of aperture diaphragm **55**. An output of the aperture diaphragm motor **42** is fed back to the potentiometer **43** connected thereto, a difference from the command value of the CPU **41** is obtained, a deviation signal is again output to the aperture diaphragm motor **42**, and the aperture diaphragm motor **42** is stopped at the position of standard aperture ratio (Step **410**). In case that the operation time of aperture diaphragm is shorter than the change-over time of objective, a waiting time of user is just the change-over time of objective. On the other hand, if the relation is reversed, the waiting time is just the operation time of aperture diaphragm.

Adjustment of aperture diaphragm in light/dark field change-over is next described with reference to FIG. 7 and FIG. **9**.

The following example illustrates a case of change-over from a light field to a dark field.

When the light/dark field change-over switch **47** is operated, a field change-over operation signal is output to the CPU **41** (Step **500**).

After that, the light/dark field change-over operation and the aperture diaphragm rotation operation are carried out in parallel. In the light/dark field change-over operation, when the CPU **41** receives a change-over command, it outputs a dark field changeover command to the drive circuit **48** and carries out the field change-over operation by the light/dark field change-over motor **49** through the drive circuit **48** (Step **510**). The field change-over operation is an exchange operation of the light field diaphragm **57***a* and a dark field diaphragm **57***b* as shown in FIG. 7.

Also simultaneously with this operation, the aperture diaphragm positioning operation similar to that as described above is carried out to set an aperture ratio of the aperture diaphragm **55** suitable for the dark field (normally full open). Namely, a present field state is first identified (Step **520**); a desired field is determined from this result (Step **530**); an operation amount of aperture diaphragm corresponding to the aperture ratio fit for the desired field is read out from the memory (ROM) **40** (Step **540**); and after conversion it is output to the drive circuit **3** to set the aperture at the desired aperture ratio (Step **550**).

In case that the operation time of aperture diaphragm is shorter than the change-over time of light/dark field, a waiting time of user is just the change-over time of light/dark-field. In case that the relation is reversed, the waiting time is just the operation time of aperture diaphragm.

Next explained with FIG. **10** is a case that the light-/dark field change-over is manually carried out.

Generally in case of manual light/dark field change-over, the field State is switched by operating a change-over lever (not shown) and moving a field diaphragm plate to a predetermined position (Step **600**). Thus, it is judged in case of manual change-over whether the change-over is carried out, using a current position sensor for detecting a current field diaphragm plate position (Step **610**). The current position sensor is for example a micro switch. The switch is so arranged that it outputs an off signal when the diaphragm **57***a* of field diaphragm plate **57** is set in the optical path and that it outputs an on signal when the diaphragm **57***b* is located in the optical path. Accordingly, a field state desired to be changed may be discriminated from that before change, using the operation state of this switch.

Also in this case, the manual light/dark field change-over operation and the aperture diaphragm open/close operation are carried out in parallel. First, in the light-/dark field change-over operation, when the field diaphragm is set in the other field state, the current position sensor is operated to identify the change-over completion (Step **620**).

Additionally, the aperture diaphragm open/close operation is carried out at the same time with this operation. The previous field state before change-over and a desired field are determined with the sensor change-over operation (Steps **630**, **640**). An operation amount of aperture diaphragm corresponding to an aperture ratio fit for the desired field is read out from the memory (ROM) **40** (Step **650**), and after conversion it is output to the drive circuit **33** to set the diaphragm at the predetermined aperture ratio (Step **660**).

Next explained with FIG. 7 is the procedure for setting an arbitrary aperture ratio and storing it in memory with necessity.

First, the automatic/manual change-over switch **34** is turned into the manual side and the manual aperture diaphragm switch **36** is operated for example to open the aperture diaphragm **55**, whereby a voltage +V is

applied from the power source **35**. The drive voltage is output through the drive circuit **33** to the aperture diaphragm motor **42** to rotate the aperture diaphragm **55** in the opening direction. When the observer Judges that the image contrast is proper for example in observation of 10 magnifications in this state, the switch **36** is made open to stop the opening operation of aperture diaphragm. An output of the potentiometer **43** at this moment is subjected to-the analog-to-digital conversion through the A-D converter **38** and the converted signal is then stored as digital data in the memory (RAM) **39**. since the standard aperture ratio preliminarily set in the apparatus is stored in the memory (ROM) **40**, the arbitrary aperture ratio will never be overwritten on the standard aperture ratio in this occasion. The arbitrary aperture ratio is thus set by the user's setting for 10 magnifications.

Since then, the CPU **41** will read the arbitrary aperture ratio stored in the memory (RAM) **39** and automatically set it as the initial value for objective of 10 magnifications. In case that the aperture ratio is temporarily changed for observation, an instruction may be given to withhold the arbitrarily set aperture ratio from being stored in the memory (RAM) **39**. In this case, the standard aperture ratio in the memory (ROM) **40** will be read out upon next revolver rotation operation or next light/dark field change-over operation.

As described, an optimum aperture ratio may be readily selected while looking at an image through the microscope, and the selected aperture ratio may be stored in the memory. Since the memory used in this operation is RAM, a very high degree of freedom is secured for erasure and rewriting of data. Also, a plurality of aperture ratio data may be stored for respective observers or for respective samples. The data representing the relation between the objectives and the aperture ratios, stored in the memory (RAM) **39** and the memory (ROM) **40** through the data of CPU **41**, may be transferred to various record media or to an external memory device through a personal computer.

For example in an application of microscope for inspection of products, the same inspection standard may be set for a plurality of inspection instruments while enjoying the advantage that a difference between the instruments may be obviated in inspection.

In the above embodiment (FIG. 7–FIG. 10), the CPU **41** read the rotation instruction of revolver through the switch **51** and preliminarily identified the next objective being to be set. However, the present embodiment includes the detection part **53, 54**, so that as in the embodiment detailed with FIGS. **4–6** the aperture diaphragm open/close operation may be carried out in parallel with the rotation operation of revolver even if the revolver is manually rotated. The detection part **53, 54** is constructed and operated in the same manner as the holder H and the detection circuits **8, 9** as described in FIGS. **1–3** and FIGS. **4–6**, and therefore is omitted to explain here.

In the above embodiment, the trigger of aperture diaphragm open/close operation was the start of objective change-over or light/dark field changeover, but the operation may be started with a command from an independent change-over switch or from an external operation device through a certain input/output interface by a software installed in a personal computer.

For example, if numerous combination data of users, samples, and objects with aperture ratios are preliminarily stored in a memory, optimum combination data may be instructed from an external computer in accordance with a user actually using the microscope or a sample to be inspected, or the data may be freely selected.

Although the embodiment is fully equipped, the switch **51**, the motor **45**, the drive circuit **44**, and the position sensor **46** may be omitted in case of manual revolver.

In the above description of the embodiments, the revolver was employed as an example of objective change-over part. In the present invention, however, the objective change-over means may be so arranged that objectives are arranged on a line, as in the field diaphragm of FIG. 7, and that the change-over means is translationally moved to replace an object with another.

Although the apparatus for detecting the rotation operation of revolver is separately described from the light control apparatus and the aperture diaphragm apparatus for easy understanding in the description of the embodiments, the microscope equipped with all apparatuses is the best.

Further, the embodiments using the apparatus for detecting the rotation operation of revolver were shown as applications for the light control apparatus and the aperture diaphragm apparatus, but it may be applied for another apparatus, for example for the field diaphragm apparatus. In addition, the light source may be controlled to increase or decrease the light quantity. Further, the stage may be controlled to move vertically to avoid the interference between the objective and the stage.

What is claimed is:

1. An objective replacing apparatus comprising:

objective replacing means having a plurality of objective mount portions and selectively positioning at a predetermined position a desired objective out of a plurality of objectives set in said mount portions;

a position indication portion for indicating respective positions of said plurality of mount portions, said position indication portion being disposed on said objective replacing means as to be formed corresponding to said respective mount portions;

an address indication portion indicating respective addresses of said plurality of mount portions, said address indication portion being disposed on said objective replacing means as to be formed corresponding to said respective mount portions;

means for detecting, when said desired objective is located at said predetermined position, an address of a mount portion in which the desired objective is set, from said address indication portion;

means for detecting a displacement of said position indication portion after said desired objective is located at said predetermined position thereby to detect a movement direction of said objective replacing means; and

means for determining an address of another desired mount portion which is to be next located at said predetermined position, based on the address of said desired mount portion from said address detecting means and on the movement direction of said objective replacing means from said movement direction detecting means.

2. An objective replacing apparatus according to claim **1**, wherein said objective replacing means further comprises means for detecting said position indication portion thereby to detect that the objective is located at said predetermined position.

3. An objective replacing apparatus according to claim 2, further comprising means for outputting, when an operator assigns another desired objective or another mount portion of said objective replacing means corresponding to said another desired objective, an assignment signal corresponding to said assigned another objective or another mount portion;

wherein said objective replacing means moves based on the assignment signal thereby to position the assigned another objective or another mount portion at said predetermined position; and

wherein said determining means determines the address of the another desired mount portion being to be next located at the predetermined position, based on the assignment signal from said assignment signal output means and the address of said desired mount portion from said address detecting means, or based on the address of said desired mount portion from said address detecting means and the movement direction of said objective replacing means from said movement direction detecting means.

4. An objective replacing apparatus according to claim 3, wherein said determining means includes memory for storing relative positions of addresses of said plurality of mount portions, and determines the address of said another desired mount portion to be next located at the predetermined position based on the assignment signal from said assignment signal output means, the address of said desired mount portion from said address detecting means and said relative positions of addresses of said plurality of mount portions from said memory, or based on the address of said desired mount portion from said address detecting means, the movement direction of said objective replacing means from said movement direction detecting means and said relative positions of addresses of said plurality of mount portions from said memory.

5. An objective replacing apparatus according to claim 1, wherein said objective replacing means is a revolver for selectively positioning the desired objective at the predetermined position by rotation.

6. An objective replacing apparatus according to claim 1, wherein said determining means includes memory for storing relative positions of addresses of said plurality of mount portions, and determines the address of said another desired mount portion to be next located at the predetermined position, based on the address of said desired mount portion from said address detecting means, the movement direction of said objective replacing means from said movement direction detecting means and said relative positions of addresses of said plurality of mount portions from said memory.

7. A microscope comprising:

objective replacing means having a plurality of objective mount portions and selectively positioning at a predetermined position a desired objective out of a plurality of objectives set in said mount portions;

a position indication portion for indicating respective positions of said plurality of mount portions, said position indication portion being disposed on said objective replacing means as to be formed corresponding to said respective mount portions;

an address indication portion indicating respective addresses of said plurality of mount portions, said address indication portion being disposed on said objective replacing means as to be formed corresponding to said respective mount portions;

means for detecting, when said desired objective is located at said predetermined position, an address of a mount portion in which the desired objective is set, from said address indication portion;

means for detecting a displacement of said position indication portion after said desired objective is located at said predetermined position thereby to detect a movement direction of said objective replacing means;

a memory for storing information of the objectives set in the respective mount portions;

means for determining an objective set in another desired mount portion which is to be next located at the predetermined position, based on the address of said desired mount portion from said address detecting means, the movement direction of said objective replacing means from said movement direction detecting means, and the information of objectives from said memory; and

means for controlling a part of the microscope other than the objectives, based on the objective determined by said determining means.

8. A microscope according to claim 7, wherein said objective replacing means further comprises means for detecting said position indication portion thereby to detect that the objective is located at said predetermined position.

9. A microscope according to claim 7, wherein said part of microscope is light control means located in an optical path of the microscope and controlling a light quantity of light from a .light source; and

wherein said control means controls said light control means as to control the light quantity as suitable for the objective determined by said determining means.

10. A microscope according to claim 7, wherein said part of microscope is means for changing an aperture diameter of an aperture diaphragm located in an optical path of the microscope; and

wherein said control means controls said aperture diameter changing means as to adjust the aperture diameter of aperture diaphragm as suitable for the objective determined by said determining means.

11. A microscope according to claim 7, further comprising means for outputting, when an operator assigns a desired objective or a mount portion of said objective replacing means corresponding to said desired objective, a signal corresponding to said assigned objective or mount portion;

wherein said determining means determines the objective set in the another desired mount portion being to be next located at the predetermined position, based on the signal from the assigning means and the information of objectives from said memory, or based on the address of said desired mount portion from said address detecting means, the movement direction of said objective replacing means from said movement direction detecting means, and the information of objectives from said memory.

12. A microscope according to claim 7, wherein said objective replacing means is a revolver for selectively positioning the desired objective at the predetermined position by rotation.

13. A microscope according to claim 7, wherein said determining means includes memory for storing relative positions of addresses of said plurality of mount portions, and determines the address of said another desired

mount portion to be next located at the predetermined position based on the address of said desired mount portion from said address detecting means, the movement direction of said objective replacing means from said movement direction detecting means and said relative positions of addresses of said plurality of mount portions from said memory.

14. A microscope according to claim **7**, further comprising means for outputting, when an operator assigns another desired objective or another desired mount portion of said objective replacing means corresponding to said another desired objective, a signal corresponding to said assigned another objective or another mount portion;

wherein said determining means includes memory for storing relative positions of addresses of said plurality of mount portions, and determines the address of said another desired mount portion to be next located at the predetermined position based on the assignment signal from said assignment signal output means, the address of said desired mount portion from said address detecting means and said relative positions of addresses of said plurality of mount portions, or based on the address of said desired mount portion from said address detecting means, the movement direction of said objective replacing means from said movement direction detecting means and said relative positions of addresses of said plurality of mount portions.

[57] **ABSTRACT**

A focus detection apparatus includes an optical system for forming first and second optical distributions associated with object images whose relative positional relationship is changed in accordance with an imaging state of an imaging optical system subjected to focus detection, a photoelectric conversion element, having a plurality of picture elements, for outputting first and second signals respectively corresponding to the first and second optical distributions, and a calculating unit for performing filter processing of the first and second signals, sequentially displacing the first and second signals relative to each other on the calculation basis, calculating an evaluation amount representing a coincidence between the first and second signals at the relatively displaced positions, obtaining positional deviations between the first and second object images on the basis of a change in evaluation amount, and detecting the imaging state of the imaging optical system on the basis of the deviations. The filter processing is performed using a filter determined by the relatively displaced positions.

APPARATUS FOR DETECTING THE FOCUS ADJUSTING STATE OF AN OBJECTIVE LENS BY PERFORMING FILTER PROCESSING

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to a focus detection apparatus and, more particularly, to an improvement in a focus detection apparatus suitable for a photographic camera, a video camera, or the like to detect the imaging state of an imaging optical system in accordance with the relative positional relationship between two object images formed by a distance measuring optical system using a beam passing through a phototaking lens (imaging optical system).

2. Related Background Art

A focus detection apparatus of a so-called image correlation scheme as a conventional method of performing focus detection in a focus detection apparatus is disclosed in U.S. Pat. Nos. 4,559,446, 4,833,313, and many other patents. This scheme has an assumption that two object images (secondary images) to be compared with each other are identical images laterally deviated from each other. For this reason, the aperture ratio of the imaging optical system or the location of the distance measuring field is limited so as not to vignette a distance measuring beam.

High-pass filter processing is known to effectively improve precision of an image signal degraded by vignetting of the distance measuring beam. However, this processing mainly aims at eliminating small adverse influences of vignetting caused by manufacturing errors. The effect of high-pass filter processing cannot perfectly eliminate the limitations of the open f-number or allow free layout of the distance measuring field.

In a camera system obtained by applying this focus detection apparatus to, e.g., a single-lens reflex camera, open f-numbers of various phototaking lenses are assumed to be generally set to fall within the range from F1.0 to F8. For this reason, when this camera system is to be arranged as an auto-focus camera system, the open f-numbers of phototaking lenses used in the auto-focus operation are limited to ones smaller than F5.6. Alternatively, the distance measuring field is located at a position near the optical axis, e.g., a position within the range of 5 mm from the optical axis so as to reduce vignetting of the distance measuring beam. It is, therefore, very difficult to realize a camera system having an auto-focus mode which can use any kind of phototaking lens and can operate (distance measurement) in any area of the finder field.

The present invention is related to an improvement of the invention of U.S. Ser. No. 723,962 filed by the present applicant.

SUMMARY OF THE INVENTION

It is an object of the present invention to allow good focus detection by an apparatus for detecting the focus adjusting state of an objective lens on the basis of a relative positional deviation between a pair of optical distributions even if a detection beam is vignetted. In the present specification, the beam represents an invisible beam as well as a visible beam.

It is another object of the present invention to reduce limitations required to reduce the f-number of the objective lens in accordance with the f-number of a beam incident on a focus detection apparatus.

It is still another object of the present invention to provide a focus detection apparatus capable of reducing the aperture ratio of an imaging optical system, eliminating the limitations of the distance measuring field location, and performing high-precision focus detection by employing a filter having an appropriate arrangement although the distance measuring beam is slightly vignetted in focus detection using an image deviation scheme.

It is still another object of the present invention to provide a focus detection apparatus comprising a reimaging optical system for forming first and second object images whose relative positional relationship is changed in accordance with an imaging state of an imaging optical system subjected to focus detection, photoelectric converting means, having a plurality of picture elements, for outputting first and second signals respectively corresponding to the first and second object images, and calculating means for performing filter processing of the first and second signals, sequentially displacing the first and second signals relative to each other on the calculation basis, calculating an evaluation amount representing a coincidence between the first and second signals at the relatively displaced positions, obtaining positional deviations between the first and second object images on the basis of a change in evaluation amount, and detecting the imaging state of the imaging optical system on the basis of the deviations, the filter processing being performed using a filter determined by the relatively displaced positions.

It is still another object of the present invention to provide a focus detection apparatus comprising a reimaging optical system for forming first and second object images whose relative positional relationship is changed in accordance with an imaging state of an objective optical system subjected to focus detection, photoelectric converting means, having a plurality of picture elements, for outputting first and second signals respectively corresponding to the first and second object images, and calculating means for, when the first and second signals are sequentially displaced relative to each other on the calculation basis and an evaluation amount representing a coincidence between the first and second signals at the relatively displaced positions is calculated, performing filter processing of the first and second signals using a filter determined by the relatively displaced positions, obtaining deviations between the first and second object images on the basis of a change in evaluation amount, and detecting the imaging state of the imaging optical system, wherein

(a) the calculating means has a first processing step of producing the filter from first original filter information and a second processing step for producing the filter from second original filter information, and further comprises selecting means for selecting one of the first and second processing steps in accordance with the relative displacement of the first and second signals,

(b) the filter corrects the first and second signals even if the relative displacement is zero,

(c) the filter has only a positive component in one direction and positive and negative components in the other direction with respect to an origin, and

(d) the photoelectric converting means has picture elements used for the filter processing outside pic-

ture elements whose outputs are used to calculate the evaluation amount.

It is still another object of the present invention to provide a focus detection apparatus comprising a reimaging optical system for forming first and second object images whose relative positional relationship is changed in accordance with an imaging state of an imaging optical system subjected to focus detection, photoelectric converting means, having a plurality of picture elements, for outputting first and second signals respectively corresponding to the first and second object images, and calculating means for, when the first and second signals are sequentially displaced relative to each other on the calculation basis and an evaluation amount representing a coincidence between the first and second signals at the relatively displaced positions is calculated, performing filter processing of the first and second signals, obtaining deviations between the first and second object images on the basis of a change in evaluation amount, and detecting the imaging state of the imaging optical system, wherein

(e) the filter processing is performed using a filter determined in accordance with an aperture ratio of the imaging optical system subjected to focus detection,

(f) the filter processing is performed using a filter determined in accordance with an exit pupil position of the imaging optical system subjected to focus detection,

(g) the calculating means has the filter processing having an (A1)th processing process performed using the filter determined by the relative displacement and an (A2)th processing step performed next to the (A1)th processing step by using a specific filter without depending on the relative displacement, the specific filter in the (A2)th processing step being determined on the basis of the deviations obtained in the (A1)th processing step,

(h) the calculating means has the filter processing having a (B1)th processing process performed using the filter determined by the relative displacement and a (B2)th processing step performed using a specific filter without depending on the relative displacement and comprises selecting means for selecting one of the (B1)th and (B2)th processing steps,

(i) the filter processing is performed using a filter determined by a distance from an optical axis of the imaging optical system subjected to focus detection to a distance measuring field determined by the photoelectric converting means, and

(j) the calculating means has a (C1)th processing step of performing filter processing of the first signal and a (C2)th processing step of performing filter processing of the second signal, the filter used in the (C2)th processing step being constituted by characteristics obtained by inverting the filter used in the (C1)th processing step.

FIG. **59** is a view of a correction filter corresponding to a bright phototaking lens having a small f-number when this bright phototaking lens is mounted on a camera body.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

FIG. **1** shows the basic arrangement of a focus detection system in a focus detection apparatus according to the present invention. This embodiment is characterized in that a phototaking beam is aligned with a distance measuring beam to obtain an optimal in-focus position and is also in consideration of a spatial frequency included in an object image.

The arrangement of the focus detection system will be described below. Referring to FIG. **1**, the object has an object surface **40**. A diffusion plate **42** has a mat surface **42***a* having a fine three-dimensional pattern located near a prospective imaging plane of a phototaking lens **41**. A field lens (condenser lens) **43** is located on the exit side of the diffusion plate **42**. An aperture **48** has two openings **48***a* and **48***b*. A re-imaging lens (secondary imaging lens) **44** has two lens portions **44***a* and **44***b* located symmetrically about an optical axis L2 of the phototaking lens **41**. The re-imaging lens **44** converges beams passing through the two aperture openings **48***a* and **48***b* to form secondary object images of the object on photoelectric element arrays **46** and **47** located behind the re-imaging lens **44**. Photoelectric conversion outputs from the photoelectric conversion element arrays **46** and **47** are input to a microcomputer (to be described later) and used for focus detection of the phototaking lens.

The field lens **43** has a projection function for establishing a conjugate relationship between the aperture **48** and the exit pupil of the phototaking lens **41** if diffusion in the diffusion plate **42** is neglected. The diffusion characteristics of the diffusion plate **42** and the converging characteristics of the field lens **43** determine the area of the distance measuring beam passing through the exit pupil of the phototaking lens.

FIG. **2** is a view for explaining the diffusion characteristics of the diffusion plate **42**. A beam L vertically incident from the phototaking lens **41** is diffused by the mat surface **42***a* on the re-imaging lens side. A straight incident component, which emerges at the same angle as the incident angle, is the strongest, and the intensity of light components is decreased away from the straight incident component. A beam incident from the phototaking lens side is readily understood to have a spread on the aperture **48** to some extent. A beam focused on a given point on the aperture **48** has a spread on the exit pupil to some extent in accordance with the principle of reverse light propagation.

FIGS. **3** and **4** are views for explaining the above phenomenon. FIG. **3** is a plan view of the aperture **48**, and FIG. **4** is a view showing an image of the aperture **48** on the exit pupil of the phototaking lens **41**. As shown in FIG. **3**, the two aperture openings **48***a* and **48***b* have a shape obtained by dividing one circle into halves. The images of the aperture openings **48***a* and **48***b* are formed on the exit pupil of the phototaking lens **41**. In this case, the resultant image has a blurred peripheral portion by the behavior of the diffusion plate **42**. FIG. **4** schematically illustrates the blurred state.

Two opening images **49***a* and **49***b* in FIG. **4** are represented by lines hatched from the upper right side to the lower left side and lines hatched from the upper left side to the lower right side, respectively. These opening images partially overlap each other due to blurring. These two images spread entirely within the exit pupil. As a result, the distance between the centers of gravity of the aperture opening images **49***a* and **49***b* is set relatively small, and distance measuring beams can be incident from the large area of the exit pupil.

The principle of distance measurement in the focus detection apparatus having the above arrangement will be described below.

FIGS. **5**A and **5**B are views for explaining the above principle, showing the detailed arrangement from the

phototaking lens **41** to the aperture **48**. Strictly speaking, analysis by wave optics is required for diffusion on the mat surface **42***a* of the diffusion plate **42**. However, an opto-geometric description will be made as an explanation similar to the analysis by wave optics.

Assume two beams A and B passing through optical paths connect points G and H in the aperture openings **48***a* and **48***b* and a point E on the optical axis of the mat surface **42***a* in FIG. **5**A. For descriptive convenience, assume that the condenser lens **43** is thin and is adjacent to the mat surface **42***a*. An angle defined by lines connecting the point E to the points G and H on the openings of the aperture **48** is defined as $\theta 1$. Since the mat surface **42***a* is a diffusion surface, it is a continuous, fine three-dimensional pattern. If a plane tangential to the point E of the mat surface **42***a* is defined as a plane P1, the beams A and B are refracted at the point E into beams A′ and B′. Points at which the two diffracted beams reach on the exit pupil of the phototaking lens **41** are defined as I and J, respectively.

A point F is set very close to a point E on the optical axis of the mat surface **42***a* in FIG. **5**B, and the behavior of the beam at the point F will be taken into consideration in the same manner as in FIG. **5**A. A plane tangent to the point F is defined as a plane P2, and an angle defined by lines connecting the point F to points G and H on the aperture openings is defined as $\theta 2$. Two beams C and D passing through the lines connecting the point F to the points G and H on the openings of the aperture **48** are diffracted into beams C′ and D′ in the same manner as in FIG. **5**A. Points at which the two diffracted beams reach on the exit pupil of the phototaking lens **41** are defined as K and M, respectively.

The thickness of the focusing screen **42** is neglected, and angles between the points I and J and between the points K and M on the exit pupil of the phototaking lens **41** with respect to the points E and F are respectively defined as $\theta 1'$ and $\theta 2'$ The point E is very close to the point F. If the angles $\theta 1'$ and $\theta 2'$ and the inclination angles of the tangential planes are very small, the following relation can be approximated:

$$\theta 1' \simeq \theta 2'$$

When the angle defined by the lines connecting the intersection between the optical axis and the mat surface **42***a* to the points on the two aperture openings is small, the lengths of the distance measuring base lines of the beams diffracted within a given range are identical. The diffusion characteristics (FIG. **2**) of the mat surface indicate that various planes tangent to the point E are opto-geometrically present, and the diffusion characteristics are the total characteristics obtained from the various planes. The diffusion characteristics of the mat surface fall within a given range in relation to the light amount, and explanation with reference to FIGS. **5**A and **5**B can be applied to all these tangential planes.

For the sake of descriptive simplicity, the description of FIGS. **5**A and **5**B has been made for distance measurement of a point on the optical axis. It is apparent that the same description as for FIGS. **5**A and **5**B can be applied to any point outside the optical axis. The distance measuring base line length in the focus detection apparatus of the present invention is determined by the distance between the openings of the aperture **48** and is not influenced by the characteristics of the diffusion plate.

The focus detection operation is basically identical to that of the conventional focus detection apparatus having no diffusion plate due to the above nature. For example, when the phototaking lens **41** is extended to the left in FIG. **1** to set a so-called front-focus state, the object images projected on the light-receiving surfaces of the photoelectric conversion element arrays **46** and **47** by the re-imaging lenses **44***a* and **44***b* are deviated in a direction indicated by an arrow. The front-focus state and its amount can be detected in accordance with changes in outputs from the photoelectric conversion element arrays **46** and **47**, which changes correspond to a relative deviation between the object images. In the rear-focus state, the object images are deviated in a direction opposite to that in the front-focus state. The rear-focus state and its amount can be detected in the same manner as described above.

As described above, in the focus detection apparatus, by using the diffusion plate, a distance measuring beam having an intensity corresponding to a small f-number can be received without excessively increasing the distance measuring base line length. An optimal focus position corresponding to the spatial frequency of the object image can be detected. As will be described below, the focusing screen of a single-lens reflex camera can be used as the diffusion plate.

FIG. **6** is a schematic view showing the main part of a single-lens reflex camera which employs the focus detection apparatus according to the present invention.

The camera has a single-lens reflex camera body **80**. A phototaking lens **81** is mounted to be movable in a direction of the optical axis of a lens barrel **82**. A movable mirror **83** is set in a mirror down state when the photographer observes an object. In this state, a beam from the phototaking lens **81** is deflected upward and guided to a finder and a focus detection system of the present invention. The movable mirror **83** is set in a mirror up state immediately before the start of exposure of a photographing film **92** in the phototaking mode so as not to vignet the beam from the phototaking lens. At the end of exposure, the movable mirror **83** returns to the mirror down state shown in FIG. **6**.

The finder and the focus detection system will be described below. An object image is projected from the phototaking lens **81** on a focusing screen **84**. The focusing screen **84** diffuses the distance measuring beam. The camera also includes a condenser lens (field lens) **85**, a pentagonal prism **86**, a beam splitter **87** for splitting the beam toward the focus detection system, and an eyepiece lens **88**. A spherical surface portion **84***a* is formed on the beam incident surface of the focusing screen **84** to cause the beam to impinge, at almost a right angle, on a mat surface **84***c* foraged on the light exit surface of the focusing screen **84**. A Fresnel lens **84***b* is formed in the peripheral portion serving as the range outside the distance measuring field. The mat surface **84***c* has a convex surface portion corresponding to the spherical surface portion **84***a* to correct the curvature of a prospective imaging plane. The beam diffused by the mat surface **84***c* is diffracted by the condenser lens **85** located behind the mat surface **84***c* so as to match the location of the eyepiece lens **88**. The beam passes through the pentagonal prism **86** and a half mirror surface **87***a* of the beam splitter **87** and is deflected in a direction toward the eyepiece lens **88**. The beam passing through the eyepiece lens **88** reaches eyes of the observer.

The beam splitter **87**, located in front of the eyepiece lens **88**, causes the half mirror surface **87***a* to reflect part of the beam supposed to reach the eyepiece lens **88**

upward. The reflected beam is utilized for focus detection. The components from a light-shielding mask **89** belong to the focus detection system. The focus detection system includes a secondary imaging lens (re-imaging lens) **90** comprising a transparent plastic material, an aperture **93**, a light guide prism **94**, and photoelectric conversion element (picture element) arrays **108**, **108*h*1** and **108*h*2** each made of a large number of picture elements. These picture element arrays are held by a transparent plastic package **95**. The aperture **93** is projected on the exit pupil of the phototaking lens **81** by the secondary imaging lens **90**, the condenser lens **85**, and the spherical surface portion **84*a*** of the focusing screen **84**. The secondary imaging lens **90** serves to project the mat surface **84*c*** of the focusing screen on the photoelectric transducer element arrays **108*h*1** and **108*h*2**. The projected image of the object spreads and is blurred by the diffusion behavior of the mat surface **84*c*** in the same manner as described with reference to FIG. **1**.

FIGS. **7** and **8** are developed views of the focus detection optical system having the above structure along the optical axis. FIG. **7** shows the section in the short-side direction of the finder field, whereas FIG. **8** shows the section in the long-side direction of the finder field. Equivalent flat parallel members **186** and **187** have optical path lengths equal to that obtained by developing the pentagonal prism **86** and the beam splitter **87** along the optical paths, respectively.

The condenser lens **85** has a function of brightening the entire finder field by establishing the relationship of mutual projection between the exit pupils of the eyepiece lens **88** and the phototaking lens **81** with respect to the observation system and a function of widening the distance measuring field by establishing the relationship of mutual projection between the exit pupils of the aperture **93** and the phototaking lens **81** with respect to the focus detection system. These functions can be achieved by locating the eyepiece lens **88** and the aperture **93** at almost optically equivalent positions.

Upon establishment of these two functions, in the relationship of mutual projection with respect to the focus detection system, the distortion of the detection system adversely affects detection precision. Therefore, it is difficult to limit the curvature of each of the surfaces of the condenser lens **85**. On the other hand, in the relationship of mutual projection with respect to the observation system, the curvature may be limited to some extent if a predetermined power can be obtained, thereby intentionally obtaining an arbitrary value. In order to arrange a compact camera by utilizing this characteristic, the first surface of the condenser lens **85** is constituted by two curvature portions.

FIG. **9** is a plan view showing this state when the condenser lens **85** is observed from the light incident direction. The condenser lens **85** has a spherical surface portion **85*a*** and a flat surface portion **85*b***. The diameter of the spherical surface portion **85*a*** is determined so that the distance measuring beam passes through the range defined by this diameter. The outer flat surface portion is obtained by limiting the surface in view of the observation system. When the flat surface portion is formed in the peripheral portion of the condenser lens **85** as described above, the thickness of the condenser lens can be much smaller than that of a condenser lens having a curvature on the entire light incident surface. In this case, although the boundary between the spherical surface portion **85*a*** and the flat surface portion **85*b*** becomes discontinuous, discontinuity of refracting powers is different depending on areas can be eliminated by properly selecting the shape of the focusing screen **84**. FIG. **10A** is a plan view of the focusing screen **84** when viewed from the light incident direction, and FIG. **10B** is a sectional view thereof. As shown in FIG. **10A**, the focusing screen **84** is also constituted by two areas, i.e., the spherical surface portion **84*a*** and the Fresnel lens portion **84*b***. The boundary between the two areas of the condenser lens **85** overlaps that of the focusing screen **84** when the photographer observes an image in the finder through the eyepiece lens **88** from the reference position on the optical axis.

FIG. **10B** shows the section of the focusing screen **84**, as described above. As can be apparent from two tangents V and W in FIG. **10B**, the Fresnel portion **84*b*** is added to the spherical surface portion **84*a***. For this reason, the refracting power of the Fresnel portion **84*b*** is higher than that of the spherical surface portion **84*a***. As a result, a decrease in refracting power of the flat surface portion **85*b*** of the condenser lens **85** in correspondence with the spherical surface portion **85*a*** can be compensated. That is, in order to satisfy the relationship of mutual projection in the observation system with respect to the eyepiece lens system in the entire field, a total refracting power of the spherical surface portion **84*a*** of the focusing screen **84** and the corresponding spherical surface portion **85*b*** of the condenser lens **85** is set equal to that of the Fresnel portion **84*b*** of the focusing screen **84** and the flat surface portion **85*b*** of the condenser lens **85** with respect to the exit surface of the condenser lens **85**.

The imaging relationship of the focus detection system will be supplementarily described with reference to FIGS. **7** and **8** again. The secondary imaging lens **90** is a kind of double-convex multilens obtained such that two pairs of lens portions are integrally formed to constitute a light incident surface and a light exit surface has a curved surface coaxial with the optical axis of the phototaking lens. FIG. **11** shows the shape of the secondary imaging lens **90** when viewed from the light incident direction. Upper and lower lens portions **90*a*** and **90*b*** are located to sandwich central lens portions **90*c*** and **90*d***. The lens portions **90*a*** and **90*b*** and the lens portions **90*c*** and **90*d*** are paired in the multilens to form two pairs of object images whose relative positions are changed in correspondence with an imaging state of the phototaking lens **81**. These lens portions of the multilens are entirely constituted by spherical surfaces. The center of sphere is set such that beams passing through the centers of gravity of the four openings of the aperture **93** from the optical axis position of the mat surface **84*c*** of the focusing screen **84** are incident almost perpendicularly to the lens portions respectively corresponding to the openings.

A light exit surface **90*e*** of the secondary imaging lens **90** is a spherical surface common to the lens portions **90*a*** to **90*d***. The optical axis of the light exit surface **90*e*** is common to the phototaking lens **81**. The center of sphere of the light exit surface **90*e*** is located at an optically equivalent position close to the mat surface **84*c*** of the focusing screen **84** serving as the object plane with respect to the secondary imaging lens **90**. When the optical path length between the pentagonal prism **86** and the beam splitter **87** is measured in air, the center of the mat surface **84*c*** almost coincides with the center of sphere of the light exit surface **90*e*** of the secondary imaging lens **90**. As described above, the four beams entering from the optical axis position of the mat surface

94c of the focusing screen 84 are vertically incident on the lens portions 90a to 90d even on the incident side in the secondary imaging lens 90, thereby obtaining an optical system wherein the four beams almost vertically emerge from the exit surface 90e as the main characteristic feature of this embodiment.

As described above, the secondary imaging lens 90 is arranged such that rays entering from the center of the focusing screen 84 and passing through the centers of gravity of the openings of the aperture 93, that is, rays passing through the centers of gravity of the beams passing through the lens portions 90a to 90d are guided to the photoelectric conversion element arrays 108. This indicates that the distance between two images constituting a pair can be very small even if the wavelength of light from the object is variously changed. Therefore, detection errors corresponding to the colors of the object, which are caused by influences of the chromatic aberration of the focus detection system can be almost eliminated.

When the optical system having the arrangement according to the present invention is employed, it is preferable to set an imaging magnification of the secondary imaging lens 90 within the range of about −0.2 to −0.5 so as to increase the distance measuring field while the chip area of the photoelectric conversion element arrays 108 is kept small. The arrangement shown in FIGS. 7 and 8 has an imaging magnification of about −0.2. In order to generally arrange this reduction imaging system by one convex lens, it is known that the curvature of the light incident surface is increased and the curvature of the light exit surface is decreased according to the aberration sharing rule, thereby reducing the size of a projected point image with a small aberration. As shown in FIGS. 7 and 8, the light exit surface 90e of the secondary imaging lens 90 is common to the lens portions on the incident side. In addition, since the center of sphere of the light exit surface 90e is optically very close to the mat surface 84c, the light exit surface 90e can have only a small curvature. On the other hand, the curvature of the small-diameter lens portions of the multilens is increased to compensate for a small curvature thereof on the exit side so as to maintain a given imaging magnification. In this sense, the embodiment shown in FIGS. 7 and 8 is based on the aberration sharing rule, thereby realizing a small point image. The small point image in the focus detection optical system indicates that distance measurement of a finer pattern can be performed, thereby contributing to the improvement of the detection performance.

The two pairs of positions of the light amount distributions of the object and the positions of the photoelectric conversion element (pixel element) arrays must be aligned with a precision of several μm or less so as to satisfy the distance measuring precision of the camera. The most important problem in the manufacture of a system using the secondary imaging lens integrally having the two pairs of lens portions and the photoelectric conversion element arrays arranged on a single chip is concentrated on the optical axis alignment within the secondary imaging lens. According to this embodiment, the light exit surface of the secondary imaging surface is constituted by a single spherical surface common to the two pairs of lens portions, thereby solving the above problem.

The plastic secondary imaging lens is manufactured by injection molding or compression molding. In this case, deviations between the light incident surface and the light exit surface of each secondary imaging lens element, and deviations between the secondary imaging lens elements cause a serious problem. In particular, when two pairs of second imaging lens elements are used as in the present invention, and the optical axes of the four secondary imaging lens elements are different on both the incident and exit sides, it is very difficult to achieve given alignment precision between the incident and exit sides. Components of mutual rotation of the portions constituting the light incident and exit surface portions of the molds require strict precision. If errors occur in these components, deformation of images of the secondary imaging lens elements is complicated by the aberration. As a result, point images of the secondary imaging lens elements for forming paired images cannot be similar to each other.

Upon focus detection, the object image from the phototaking lens 81 is formed as pairs of images respectively on the photoelectric conversion element arrays by the system through the secondary imaging lens 90. When the phototaking lens 81 is extended to the left in FIGS. 7 and 8 to set a front-focus state, the pair of object images formed on the light-receiving surfaces of the photoelectric conversion element arrays are deviated to come close to each other. The front-focus state and its amount are detected in accordance with changes in outputs from the photoelectric conversion element arrays in correspondence with the relative deviation between the images. In the rear-focus state, the pair of images are deviated in the direction opposite to that in the front-focus state. The rear-focus state and its amount can be detected in the same manner as in the front-focus state.

As described above, focus state detection is performed in accordance with the distance between the pair of images. This distance between the pair of images is directly represented as a distance measuring error. As in this embodiment, when the light exit surface is a spherical surface common to all the beams, mutual rotation does not adversely affect the precision, thereby facilitating its manufacture.

The beams passing through the secondary imaging lens 90 are incident on the aperture 93 located behind the secondary imaging lens 90. As shown in FIGS. 7 and 8, the aperture 93 is located to be slightly spaced apart from the secondary imaging lens 90 and has two pairs of openings corresponding to the lens portions constituting the secondary imaging lens 90. FIG. 12 is a plan view of the aperture 93, showing the shapes of the openings. Openings 93a and 93b and openings 93c and 93d of the aperture 93 are paired to respectively correspond to the secondary imaging lens portions 90a and 90b and the secondary imaging lens portions 90c and 90d. The distance between the centers of gravity of the openings corresponds to the distance measuring base line length. As is apparent from FIG. 12, the distance measuring base line length determined by the openings 93a and 93b is larger than that determined by the openings 93c and 93d according to the characteristic feature of this embodiment. By utilizing this, the chip area of the photoelectric transducer element arrays can be reduced, and the system can be made compact as a whole.

Each of the four openings 93a to 93d has a shape surrounded by two arcs. The shape of the outer arc is set such that an image thereof projected on the exit pupil of the phototaking lens 81 through the spherical surface portion 84a, the condenser lens 85, and the secondary imaging lens 90 has the shape of an arc having

its center on the optical axis of the phototaking lens **81**. The inner arc is determined by translating the outer arc of one opening of the paired openings toward the other opening of the paired openings, thereby obtaining identical shapes of the paired openings. The shapes of the effective diameters of the paired secondary imaging lens portions coincide with each other on the phototaking lens **81**. Even if the object image is defocused within the range in which the distance measuring beam is not vignetted, the similarity of the light amount distributions is not disturbed.

The shape of the outer arc of the aperture **93** should be noted. Since the secondary imaging lens **90** is a decentered system with respect to the phototaking lens **81**, the center of the outer arc of the aperture **93** is different from the point Q at which the optical axis of the phototaking lens **81** crosses the aperture **93**. Referring to FIG. **12**, the center of the outer arc R of the opening **93***a* is given as P and is deviated from the intersection Q with the optical axis of the phototaking lens **81** by a length S. The outer arc is so decentered that an image thereof projected on the exit pupil of the phototaking lens **81** through the lens portion (spherical portion) **90***a* or the like of the secondary imaging lens **90** has a shape having its center on the optical axis of the phototaking lens **81**, thereby most effectively receiving the beam. FIG. **13** is a view for explaining projected images of the aperture openings. The phototaking lens **81** has an exit pupil **101**, and projected images **102***a* to **102***d* of the aperture openings **93***a* to **93***d* are formed. The distance between the paired aperture openings corresponds to the distance measuring base line length. Since the mat surface **84***c* of the focusing screen **84** is located within the optical path, the images of the openings of the aperture **93** are blurred and spread in accordance with the diffusion characteristics shown in FIG. **2**. The hatched portions in FIG. **13** represent blurring. The aperture **93** is located behind the secondary imaging lens **90** to improve uniformity of the field angle of the point image.

FIG. **14** shows the shape of the light-shielding mask **89** located immediately before the secondary imaging lens **90**. The light-shielding mask **89** has three openings **89***a* to **89***c*, and the remaining portion of the mask **89** serves as a light-shielding portion. The light-shielding effect of the light-shielding mask **89** can prevent production of ghosts caused by the bonding portions of the lens portions **90***a* to **90***d* of the secondary imaging lens **90**.

Since the focus detection optical system described in this embodiment is arranged through the pentagonal prism **86**, the overall length of the focus detection optical system is large, as described above. On the other hand, in order to improve distance measuring precision, the distance between the centers of gravity of the openings **93***a* to **93***d* must be large. As a result, a pair of light amount distributions corresponding to an object are formed to be spaced apart from each other. FIG. **15** shows the relationship between the distance measuring field and the phototaking frame. When distance measuring fields **104***a* to **104***j* are arranged in a crossed shape in a phototaking frame **103** and are simply projected by the secondary imaging lens **90**, secondary object images are formed to be considerably spaced apart from each other, thus requiring a large space for the arrangement of picture elements.

In the embodiment shown in FIGS. **6**, **7**, and **8**, the above problem is taken into consideration to reduce the chip size of the photoelectric conversion element arrays by using the light guide prism **94**. FIGS. **17** and **18** are a partial enlarged view and a perspective view, respectively, of the light guide prism **94**. FIG. **17** shows the section corresponding to that in FIG. **7**. In this section, the light guide prism **94** made of a transparent plastic member has six optical surfaces **94***a* to **94***f*. These six optical surfaces have a function of folding the optical path in the optical axis direction of the phototaking lens **81** and a function of cutting off unnecessary light components.

The beams passing through the openings **93***a* and **93***b* in FIG. **17** are incident on the incident surface **94***a*. The beams are reflected twice by the total reflection surfaces **94***b* and **94***c* and the total reflection surfaces **94***d* and **94***e* and emerge from the light exit surface **94***f* toward a photoelectric conversion element **107**. On the other hand, as can be apparent from FIG. **18**, the beams passing through the aperture openings **93***c* and **93***d* pass through openings **94***g* and **94***h* formed in the light guide prism **94** and reach the photoelectric conversion element **107**. The optical distance between the secondary imaging lens **90** and the photoelectric conversion element **107** has a difference in accordance with whether the beam is reflected by the light guide prism **94**. Since the reflection optical path is present in the plastic component, the optical length is substantially decreased. Therefore, the optical path distance obtained with reflection by the light guide prism **94** is slightly different from that without reflection by the light guide prism **94**. In addition, since the curvature values of the two pairs of lens portions of the multilens as the secondary imaging lens **90** can be independently selected, optimal imaging for the two different optical paths can be realized.

The photoelectric conversion element **107** can be made compact by using the above light guide prism **94**. FIG. **16** shows this state of the photoelectric conversion element **107**. Picture element arrays **108***a***1** to **108***e***2** correspond to the distance measuring fields **104***a* to **104***e*, and picture element arrays **108***f***1** to **108***j***2** correspond to the distance measuring fields **104***f* to **104***j*. The suffixes indicate the correspondence of two images formed through the secondary imaging lens **90** even if the same distance measuring field is used. The picture element arrays **108***f***1** to **108***j***1** and **108***f***2** to **108***j***2**, corresponding to the distance measuring fields **104***f* to **104***j*, are located in the area defined between the picture element arrays **108***a***1** to **108***e***1** and **108***a***2** to **108***e***2** corresponding to the distance measuring fields **104***a* to **104***e*, thereby eliminating wasteful areas. The economical advantage obtained by a decrease in the photoelectric conversion element is apparent, and the camera body itself can be made compact due to the folded optical path with use of the light guide prism **94**.

In particular, since the picture element arrays of the distance measuring fields having the large distance measuring base line length are located inside, and the picture element arrays of the distance measuring fields having the short distance measuring base line length are located outside, compactness of the camera body can be further enhanced. This arrangement is advantageous not only in terms of economy but also in terms of compactness of the camera.

The focus detection apparatus described above is effective for a bright lens having a small f-number (aperture ratio), which requires strict focusing. However, in a system such as a single-lens reflex camera system using interchangeable lenses, a dark lens having a large f-number may be mounted on the camera body. The f-number

may be increased in a zoom lens upon zooming. In this case, the distance measuring beam may be vignetted by the phototaking lens. A focus detection method corresponding to various types of phototaking lenses will be described below.

FIG. **19** is a perspective view for explaining the vignetting state of the distance measuring beam. Only a distance measuring beam to be incident on the distance measuring field **104***j* of all the distance measuring fields shown in FIG. **15** is illustrated. Referring to FIG. **19**, each of the projected images **102***a* and **102***b* shown in FIG. **13** has an outermost shape **150***a*. Relatively dark phototaking lenses have exit windows **151** and **152**.

In general, a decrease in pupil area, which is called "vignetting", occurs at a portion except for the central portion of the phototaking lens. This is caused by the fact that the number of surfaces for determining the width of the beam in an open aperture state is two or more when viewed from a given point on the image plane. These surfaces are called exit windows. For example, these surfaces are the frontmost and rearmost lenses. The two exit windows **151** and **152** exemplify this case. Judging from the degree of vignetting of the distance measuring beam, these exit windows may be represented by an intermediate exit pupil (to be described later).

Assume that a beam reaches the distance measuring field **104***j* through two circles slightly spaced apart from each other in a space in FIG. **19**. In this case, the passing range of the distance measuring beam is fixed even at other distance measuring field positions, and the passing range of the phototaking beam is considered on the image formation plane of the aperture opening of the focus detection optical system. A region in which light actually pass through the above range is limited to the inside of a region **153**. The presence of the aperture opening image outside the region **153** indicates that the distance measuring beam is vignetted. FIG. **19** shows only the distance measuring beam in the distance measuring field **104***j*. When the exit pupil is projected in the same manner as described above, the vignetting degree of light for other distance measuring fields can also be determined. Therefore, the beam tends to be vignetted in the peripheral portion of the phototaking frame **103**, but not to be vignetted in the central portion thereof.

When the defocus amount of an image formed by the phototaking lens and the re-imaging lens is increased, the point image on the photoelectric conversion element has a shape close to that of the aperture. When the distance measuring beam is vignetted in this manner, the degree of blurring of the point image is asymmetrical about the vertical axis. Blurring is reversed in a pair of secondary object images, and symmetry of the two images is disturbed. As described above, the relative distance between the pair of secondary object images is obtained to calculate the defocus amount. The calculation precision of two images which are not similar to each other is low. For this reason, blurred images asymmetrical about the vertical axis are corrected for a dark phototaking lens having a large open f-number, thereby preventing degradation of image deviation calculation precision. This correction means will be described below after a description of vibrations of the light beam.

FIGS. **20**A to **20**C and **21**A to **21**C are views for explaining changes in vignetting of the distance measuring beam, depending on the characteristics of the phototaking lenses. FIGS. **20**A to **20**C are plan views illustrated when the optical path to the distance measuring field **104***j* of the distance measuring fields shown in FIG. **15** is viewed from the top. FIGS. **21**A to **21**C are views showing the range of phototaking beams passing on the aperture image formation surface of the distance measuring optical system.

Referring to FIGS. **20**A to **20**C, an alternate long and short dashed line **169** represents an optical axis of the phototaking lens. A broken line **156** represents a projection plane of the aperture opening image. A broken line **155** represents a distance measuring beam. The optical axis **169**, the projection plane **156**, and the distance measuring beam **155** are common in FIGS. **20**A to **20**C. A phototaking lens is located at positions corresponding to exit pupils **157**, **158**, and **159** in FIGS. **20**A, **20**B, and **20**C. Each exit pupil represents a middle position of the two exit windows shown in FIG. **19**. FIG. **20**A shows a state in which the exit pupil position is relatively close to the phototaking frame, FIG. **20**B shows a state in which the exit pupil coincides with the projection plane **156** of the aperture image, and FIG. **20**C shows a state in which the exit pupil position is relatively away from the phototaking frame. The beams passing through each exit pupil are represented by solid lines **160** to **168**. The innermost beam is obtained in a case for an f-number (aperture ratio) of 5.6, the middle beam is obtained in a case for an f-number of 4, and the outermost beam is obtained in a case for an f-number of 2.8. For illustrative convenience, the size in the vertical direction is increased. When a region common to the distance measuring beam **155** and the beam passing through each exit pupil on the projection plane **156** is measured, the degree of vignetting of the distance measuring beam can be detected.

As described above, since the distance measuring beam passes through the diffusion plate, its intensity distribution on the pupil plane is not uniform. In order to more accurately determine the degree of vignetting including this intensity distribution, the projection plane of the aperture opening image as in FIG. **19** is taken into consideration, and the relationship between the distance measuring beam and the phototaking beam on this plane is shown in FIGS. **21**A to **21**C. FIGS. **21**A to **21**C correspond to FIGS. **20**A to **20**C, respectively. FIG. **21**A shows a state in which the exit pupil position is relatively close to the phototaking frame, FIG. **21**B shows a state in which the exit pupil position coincides with the projection plane **156** of the aperture image, and FIG. **21**C shows a state in which the exit pupil position is relatively away from the phototaking frame.

Referring to FIGS. **21**A to **21**C, a point **180** represents a position corresponding to the optical axis **169** of the phototaking lens. For illustrative convenience, spreading of one distance measuring beam **181** of the pair of distance measuring beams is illustrated. The size of the point indicates the density of the effective beam. Circles **183** to **191** drawn on the distance measuring beam **181** indicate the exit pupils of the phototaking lens. The innermost exit pupil indicates a case for an f-number of 5.6, the middle exit pupil indicates a case for an f-number of 4, and the outermost exit pupil indicates a case for an f-number of 2.8. The actual distance measuring beam is also distributed at a position symmetrical about an axis **182**. Vignetting of the distance measuring beams occurs in a shape symmetrical about the axis **182**.

Referring to FIGS. **20**A to **20**C and **21**A to **21**C, when the brightness of the phototaking beam is increased, and the projection plane **156** of the aperture

opening image is closer to the exit pupil plane, it is understood that vignetting tends not to occur.

FIGS. **22A** to **22C** show states in which the distance measuring field is changed. The beam incident on the distance measuring field **104***i* shown in FIG. **15** will be exemplified.

Referring to FIGS. **22A** to **22C**, an alternate long and short dashed line **169** represents an optical axis of the phototaking lens, and a broken line **156** represents a projection plane of the aperture opening image as in FIGS. **20A** to **20C**. A broken line **200** represents a distance measuring beam in this distance measuring field. Beams passing through exit pupils **157**, **158**, and **159** of the phototaking lens are represented by solid lines **201** to **209**. The innermost beam indicates a case for an f-number of 5.6, the middle beam indicates a case for an f-number of 4, and the outermost beam indicates a case for an f-number of 2.8.

As is apparent from comparison between FIGS. **20A** to **20C** and FIGS. **22A** to **22C**, when the exit pupil diameter is decreased and the exit pupil position is farther away from the aperture image formation plane, the degree of vignetting of the distance measuring beam is increased regardless of the position of the distance measuring field. The degree of vignetting is small when the distance measuring field position is closer to the optical axis **169** of the phototaking lens.

As described above, since vignetting occurs in the distance measuring beam, a pair of images on the photoelectric conversion element have characteristic shapes depending on the imaging state. The shapes are defined as a function of the exit pupil diameter, the exit pupil position, the distance measuring field position, and the aberration of the re-imaging lens. The shape of the blurred image adversely affects the conventional defocus calculation. In order to maintain high detection precision, some correction means is required. Note that the aberration of the phototaking lens is not taken into consideration because the re-imaging lens is generally constituted by a single lens and the aberration of the re-imaging lens is greatly smaller than that of the phototaking lens. For this reason, the aberration of the phototaking lens can be neglected.

The method of correcting a blurred image in this embodiment will be described below. An object image by an optical system is generally given as a convolution integral between the point image determined by the characteristics of the optical system and the brightness distribution of the object. The point image corresponds to an impulse response of the optical system. An adaptive inverse filter is produced on the basis of a transfer function serving as a Fourier transfer of the impulse response and is operated for the point image, thereby restoring the point image into the original point. When the inverse filter acts on a general object image, the brightness distribution of the original object can be obtained. When this principle is applied to the focus detection optical system described herein, the object image formed on the photoelectric conversion element is given by a convolution integral between the point image of the object image and the brightness distribution of the object. In addition, the original object brightness distribution can be restored by an appropriate inverse filter.

In this case, since focus detection is performed by examining the relative distance between images, the photoelectric conversion element is a one-dimensional line sensor. Image data correction performed for the sensor outputs can be correction of a line image obtained by integrating the point image in a direction perpendicular to the picture element array. The correction of the blurred image need not "restore" the line image to a perfect line. If the line images asymmetrical about the vertical axis, which are caused by vignetting of the distance measuring beams, are restored to have at least a symmetrical shape about the vertical axis, the relative distance between the two images can be obtained with high precision.

This operation will be described in more detail with reference to FIGS. **23A** to **23C** and **24A** to **24C**. FIGS. **23A** to **23C** and **24A** to **24C** show blurred images and their correction filters. FIGS. **23A** to **23C** or **24A** to **24C** show a correction filter, image data, and corrected image data, respectively. A pair of secondary object images formed by the focus detection optical system are defined as OA(i) and OB(i), respectively, and corrected image data are represented by A(i) and B(i), respectively. Since the distance measuring beams are incident on the re-imaging optical system through the diffusion plate, vignetting occurs depending on the open f-number (aperture ratio) of the phototaking lens. As a result, line images asymmetrical about the vertical axis are formed, as shown in FIGS. **23B** and **24B**. Since the two distance measuring beams are vignetted symmetrically about the optical axis of the phototaking lens, the resultant line images are reversed to each other. The line images spread to some extent because the phototaking lens is set in a defocus state. The distance between the two images is different from that in the in-focus state. The image OA(i) in FIG. **23B** is deviated to the left and the image OB(i) in FIG. **24B** is deviated to the right due to this reason. The distance between the two images is smaller than that in a case wherein the distance measuring beams are not vignetted. This must be taken into consideration in the calculation of the sensitivity of image deviation (to be described later).

The filters for correcting these line images are shown in FIGS. **23A** and **24A**. Each correction filter has an origin FOF in the abscissa. The origin FOF is also used for inverting the correction filter (to be described later).

The algorithm performed in the calculating means has a "**C1**" processing step for performing filter processing of the first signal and a "**C2**" processing step for performing filter processing of the second signal. The filter used in the "**C2**" processing step is obtained by inverting the filter used in the "**C1**" processing step.

The filter component values are plotted with reference to an origin AXX. Since the two line images are reversed to each other, as described above, the characteristics of the filter in FIG. **23A** are reversed from the characteristics of the filter in FIG. **24A**. For this reason, one of the shapes of the filter can be stored in the camera, and original filter information (to be described later) can be efficiently utilized. The shape of the correction filter is determined to eliminate asymmetry of the line images and not to excessively restore the corrected images to the original line due to the following reason. A correction filter for faithfully restoring an image to the original line must have characteristics for greatly amplifying a high frequency. This correction filter is easily affected by random noise (particularly, a high-frequency component) caused by thermal noise of the photoelectric conversion element. When high-frequency noise superposed on the original image data is excessively amplified, the correlation between the two images is degraded to impair distance measuring preci-

sion. The shape of this filter will be described with reference to FIG. 23A. The right portion of the filter acts to shorten the bottom of the image OA(i) extending to the right, whereas the left portion of the filter acts to extend the left short bottom. In order to facilitate a subsequent description, a restoration portion is referred to as a ZR portion (e.g., the right portion in FIG. 23A with respect to the origin FOF) and the diffusion portion is referred to as a ZS portion (e.g., the left portion in FIG. 23A with respect to the origin FOF). When the ZS portion is constituted by only the positive component, and the ZR portion is constituted by positive and negative components, the image is not faithfully restored to the original line and the lengths of the right and left bottoms can be uniformed.

That is, the filter has only the positive component in one direction and both the positive and negative components in the other direction with respect to the origin.

In order to correct the images, the lines shown in FIGS. 23B and 24B are subjected to the convolution integral using the correction filters in FIGS. 23A and 24A. The results are the corrected image data in FIGS. 23C and 24C. As shown in FIGS. 23C and 24C, the corrected image data represent images symmetrical about the vertical axis. Therefore, the relative distance between the images represented in FIGS. 23C and 24C can be calculated with high precision.

The line image correction has been described above. Correction of a general object image as a result of convolution integral between line images and the object brightness distributions will be described below, as shown in FIGS. 25A and 25B. The black edge of a monochrome pattern is selected as an object and is located at the center of the distance measuring field. FIG. 25A is a view showing overlapping image data of a pair of secondary images, and FIG. 25B shows corrected image data. The image data represented by the solid line is overlapping data of the point image of FIG. 23B, and the image data represented by the broken line is overlapping data of the point image of FIG. 24B. Since the shapes of the point images are different from each other, the shapes of the two images are different from each other.

The result obtained by causing the correction filters to act on these image data is shown in FIG. 25B. The correction filter shown in FIG. 23A is used for the image data represented by the solid line, while the correction filter shown in FIG. 24A is used for the image data represented by the broken line. The corrected images have the same shape, and the distance between the images can be calculated.

When the phototaking lens has a small defocus amount, image data shown in FIGS. 26A and 26B are obtained. Since the point images have a small size, the resultant images are sharp. In addition, the relative distance between the two images is different from that in FIGS. 25A and 25B. In this case, since the size of the blurred image on the primary imaging plane of the phototaking lens changes almost in proportion to the defocus amount, the magnification of the horizontal axis or abscissa is changed in accordance with the defocus amount to perform correction in the same manner as in FIGS. 25A and 25B. More specifically, the filters shown in FIGS. 23A and 24A are used such that they are compressed in the horizontal axis direction, the corrected images shown in FIG. 26B are obtained. This will be repeatedly described in a flow chart (to be described later). Prior to this description, the control system of the camera will be described below.

FIG. 27 is a block diagram of the camera focus detection apparatus suitably embodying the present invention.

Referring to FIG. 27, a central processing circuit PRS is a one-chip microcomputer including a CPU, a RAM, a ROM, an ADC (A/D converter), and I/O ports. Software and parameters for controlling a series of camera operations including AF control are stored in the ROM. The central processing circuit PRS constitutes part of an arithmetic operating means.

The central processing circuit PRS is connected to a data bus DBUS. A shutter control circuit SHT receives data supplied through the data bus DBUS during reception of a control signal CSH from the central processing circuit PRS and controls to cause the front and rear curtains of a shutter (not shown) to run on the basis of the input data. An aperture control circuit APR receives data through the data bus DBUS during reception of a control signal CAPR and controls an aperture control mechanism (not shown) on the basis of the input data. A switch group SWS includes a release switch, a continuous photographic mode switch, various information setting switches, and a switch for selecting whether focus detection is performed in consideration of only the central portion of the frame or both the central and peripheral portions of the frame. A lens communication circuit LCOM receives data through the data bus DBUS during reception of a control signal CLCOM and performs serial communication with a lens control signal circuit LNSU on the basis of the input data. In synchronism with a clock signal LCK, the lens communication circuit LCOM supplies lens drive data DCL to a lens control circuit LNSU, and at the same time serially receives lens information DLC.

A signal BSY is used to inform the camera side that a focus adjusting lens (not shown) is being moved. During generation of this signal, the serial communication is prohibited. A photometry circuit SPC sends a photometry output SSPC to the central processing circuit PRS upon reception of a control signal CSPC from the control circuit. The photometry output SSPC is A/D-converted in an ADC in the central processing circuit PRS and is used as data for controlling the shutter control circuit SHT and the aperture control circuit APR.

A projection circuit **220** projects an auxiliary focus detection beam to drive an LED and cause the LED to emit light in accordance with a control circuit ACT and a clock signal LCK.

A distance measuring light-receiving circuit SNS has pairs of line sensors **108***a***1** and **108***a***2**, . . . **108***j***1** and **108***j***2**. The distance measuring light-receiving circuit SNS is arranged to cause the pairs of line sensors **108***a***1** and **108***a***2**, . . . , **108***j***1** and **108***j***2** to receive images at positions corresponding to the distance measuring fields **104***a* to **104***j* of the frame. A sensor driving circuit SDR controls light-receiving circuits **1** to **10** (i.e., the pairs of **108***a***1** and **108***a***2** to **108***j***1** and **108***j***2**) in accordance with a signal STR and the clock signal LCK supplied from the central processing circuit PRS. The light-receiving circuits **1** to **10** are controlled in accordance with control signals ϕ**1** and ϕ**2** and the control signals CL and SH, and one of the light-receiving circuits **1** to **10** is selected in accordance with selection signals SEL1 to SEL**10**. An image signal SSNS from the selected light-receiving circuit is transmitted from the sensor driving circuit SDR to the central processing circuit PRS.

FIG. **28** shows the operation of the lens control circuit LNSU to obtain lens focal length information and distance ring information. The distance ring position, the zoom ring position, the defocus amount vs. focus adjusting lens extension coefficients are converted into 5-bit signals by a brush. The 5-bit signals are calculated in the CPU in the lens control circuit LNSU as the lens information DLC. The lens information DLC is input to the central processing circuit PRS through the lens communication circuit LCOM. In this case, since the distance ring position information is not directly used in an in-focus operation, high precision is not required.

The operations of the camera having the above arrangement will be described with reference to a flow chart in FIG. **29**.

When a power switch (not shown) is turned on, the central processing circuit PRS is powered on to start executing a sequence program stored in the ROM.

FIG. **29** is the flow chart showing the overall flow of the program. When execution of the program is started by the above operation, the flow advances to step **002** through step **001**. In step **002**, the ON/OFF state of a switch SW1 turned on upon depression of the release button up to the first stroke is detected. If the switch SW1 is set in an OFF state, the flow advances to step **003** to clear all the control flags and variables set in the RAM in the central processing circuit PRS, thereby initializing the RAM. Steps **002** and **003** are repeated until the switch SW1 is turned on or the power switch is turned off. When the switch SW1 is turned on, the flow advances from step **002** to step **011**. In step **011**, a timer interruption operation is allowed. In this case, the timer interruption operation is periodically performed in steps from step **012** to detect various states. In step **012**, the "photometry" subroutine for exposure control is executed. The analog input terminal of the central processing circuit PRS receives the photometry output SSPC from the photometry circuit or sensor SPC. The photometry output SSPC is converted into a digital signal to calculate an optimal shutter control value and an optimal aperture control value from the digital photometry value. The calculated values are stored at predetermined addresses of the RAM. The shutter and the aperture are controlled on the basis of the stored values during a release operation.

Step **014** is a subroutine for receiving an image signal and calculating a defocus amount. After the central processing circuit PRS receives the image signal from the distance measuring light-receiving circuit SNS, the central processing circuit PRS filters this image signal and performs a predetermined calculation on the basis of the image deviation scheme, thereby calculating a defocus amount of the phototaking lens. The detailed contents of this step will be described later.

Step **015** is a subroutine for driving the lens on the basis of the detected defocus amount DEF. This subroutine will also be described in detail later.

In step **016**, the timer interruption allowed in step **011** is prohibited, and the timer interruption is kept prohibited in steps **017** to **019**. In step **017**, the ON/OFF state of a switch SW2 turned on upon depression of the release button up to the second stroke is detected. If the switch SW2 is set in an OFF state, the flow advances to step **018**. Otherwise, the flow advances to step **019**. A flag AFFLG in steps **018** and **019** defines whether AF control in steps **012** to **015** is completed in the ON state of only the switch SW1 or in the ON state of the switch SW2. The AF control is completed when the switch SW2 is OFF, i.e., only the switch SW1 is ON, the flag AFFLG is set at logic "0". If the AF control is completed when the switch SW2 is ON, the flag AFFLG is set at logic "1". In this case, since the switch SW2 is kept off, the flag AFFLG is set at logic "0".

A timer interruption operation in steps **012** to **015** executed if AF control is performed in steps **011** to **018** when only the switch SW1 is ON will be described below.

The timer interruption in step **021** has an interruption function of periodically monitoring the state of the switch SW2, the charge/feed state, and the AF history to detect whether a release operation is started. The interruption is performed every, e.g., 5 msec during execution of steps **012** to **015**.

The respective steps will be described below.

The flow advances to step **022** through step **021** to determine the state of the switch SW2. If the switch SW2 is determined to be OFF, the interruption is ended in step **023** and the flow returns to the main routine. That is, even if an interruption is performed every 5 msec during AF repetition while only the switch SW1 is kept on, the subroutine immediately returns to the main routine because the switch SW2 is kept off.

If the switch SW2 is ON in step **022**, the flow advances to step **024** to determine whether a switch SWCH is ON/OFF. If the switch SWCH is OFF, since the charge/feed operation upon completion of the release operation is still continued, the next release operation cannot be performed. Therefore, the flow returns to the main routine in step **023** to continue the AF operation. At the same time, the charge operation is also continued.

If the switch SWCH is determined to be ON in step **024**, since the charge/feed operation is completed, a charge/feed stop signal is output in step **025** to stop a motor MTR1, and the flow returns to step **026**.

In step **026**, the logic state of the flag AFFLG is determined. If AFFLG=1 in step **026**, it is determined that the AF operation is completed once upon the ON operation of the switch SW2. The flow advances to step **027** to perform a release operation. If AFFLG≠1, i.e., if the flag AFFLG is set at "0", since the AF operation is completed only one upon the ON operation of the switch SW2, the flow returns to the main routine in step **023**, and the release operation is not performed.

The flag AFFLG is set to "0" in step **028** to start the charge/feed operation in step **029** (this operation is performed by one revolution of the motor MTR1). The flow returns to step **002** while the start of the charge/-feed operation is being performed. The next focus detection operation is started from step **011**.

The flow chart of the "AF" subroutine is shown in FIG. **30**.

It is determined in step **402** whether an entire field detection mode for performing focus adjustment in accordance with distance measuring information of the entire distance measuring field or a specific field detection mode for performing focus adjustment in only a distance measuring field at the central portion of the frame is set. If the entire field detection mode is set, the flow advances to step **403**. However, if the specific field detection mode is set, the flow advances to step **405**. Note that the mode can be set by a photographer using the switch group SWS shown in FIG. **27**.

In step **403**, a flag SPF is reset. In step **404**, the entire distance measuring field is set as a detection distance measuring field. In step **405**, the flag SPF is set at "1".

In step **406**, the distance measuring fields **104***c* and **104***h* shown in FIG. **15** are set as detection distance measuring fields.

In step **407** as the step next to step **404** or **406**, the distance measuring light-receiving circuit (line sensors) SNS is driven through the sensor driving circuit SDR in FIG. **27**. Analog output signals of the detection distance measuring field are converted into digital signals, and the digital signals are stored at predetermined addresses in the RAM.

In step **408**, defocus detection is performed on the basis of the image signals stored in the RAM in the previous step. This subroutine will be described in detail later.

It is determined in step **409** whether defocus detection can be performed in the entire distance measuring field. If YES in step **409**, the flow advances to step **410** to perform focus detection incomplete processing such as a search operation and a detection incomplete display. If any one of the measuring fields can be detected, the flow advances to step **412**.

In step **412**, the state of the flag SPF set in step **403** or **405** is checked. If the logic state of the flag SPF is zero, the flow advances to step **413**. If NO in step **412**, the flow advances to step **415**.

In step **413**, the nearest point among the detectable measuring fields is selected. In step **414**, the defocus amount of the nearest point is stored in DEF. In step **415**, an average defocus of the detectable measuring fields is calculated. In step **416**, the average defocus is stored in the DEF. The subroutine returns to the main routine in step **418**.

The "focus detection" subroutine is shown in FIG. **31**.

In the defocus detection subroutine, it is determined in step **502** whether the calculation of the entire detection distance measuring field is completed. If YES in step **502**, the flow advances to step **503**, and this subroutine returns to the main routine. However, if any distance measuring field whose defocus calculation is not completed is present, the flow advances to step **504**.

In step **504**, a new measuring field for the subject of calculation is set. In step **505**, the defocus amount of the distance measuring field for the subject of calculation set in step **504** is calculated. The flow then returns to step **502**. The calculation of defocus will be described in detail later.

FIG. **32** shows a flow chart of a "lens driving" subroutine.

When this subroutine is executed, the central processing circuit PRS communicates with the lens in step **202** in FIG. **32** to receive data "S" and "PTH". The "S" is a "coefficient of the defocus amount vs. focus adjusting lens extension amount" inherent to the phototaking lens. For example, when the phototaking lens is an entire extension type single lens, since the phototaking lens as a whole is a focus adjusting lens, condition "S=1" is established. When the phototaking lens is a zoom lens, the value of "S" is changed at each zoom position. The "PTH" is a focus adjusting lens extension amount per pulse from an encoder ENCF interlocked with movement of a focus adjusting lens LNS in the optical axis direction.

A value (i.e., a lens driving amount FP) of the focus adjusting lens extension amount as an output pulse count of the encoder ENCF in accordance with the defocus amount DEF to be focus-adjusted, and the coefficient S and the amount PTH can be given as follows.

$$FP=DEF\times S/PTH$$

The operation in step **203** is a direct calculation of the above equation.

In step **204**, the amount FP obtained in step **203** is sent to a lens FLNS to command driving of the focus adjusting lens (the entire phototaking lens when the lens is the entire extension type single lens).

In step **205**, the central processing circuit PRS communicates with the lens FLNS to determine whether driving of the lens by the lens driving amount FP commanded in step **204** is completed. If YES in step **205**, the flow advances to step **206**, and the "lens driving" subroutine returns to the main routine.

FIG. **33** shows a flow chart of a "release" subroutine.

In step **302**, the quick return mirror of the camera is pivoted upward. This is performed by controlling a mirror driving motor (not shown) through the motor control circuit shown in FIG. **27**.

In step **303**, the aperture control value already stored in the "photometry" subroutine in step **012** is sent to the lens FLNS to cause the lens FLNS to perform aperture control.

It is determined in step **304** whether the mirror up operation and the aperture control in steps **302** and **303** are completed. Whether or not the mirror up operation is completed can be confirmed by a detection switch (not shown) attached to the mirror. Whether or not the aperture control is completed is confirmed in accordance with whether or not the lens FLNS is driven to the predetermined aperture value.

When either the mirror up operation or the aperture control is not completed, the central processing circuit PRS waits in step **304** and continues state detection. When both the mirror up operation and the aperture control are completed, the flow advances to step **305**. At this time, preparation for exposure is completed.

In step **305**, shutter control is performed using the shutter control value already stored in the "photometry" subroutine in step **012**, thereby exposing the film.

When the shutter control is completed, a command for obtaining an open aperture state is supplied to the lens FLNS in step **306**. A mirror down operation is performed in step **307**. The mirror down operation is performed by controlling a mirror driving motor (not shown) as in the mirror up operation.

In step **308**, the central processing circuit PRS waits for the completion of the mirror down operation and the open aperture control as in step **304**. When both the mirror down operation and the open aperture control are completed, the flow advances to step **309**, and the subroutine returns to the main routine.

The above flow will be summarized with reference to FIG. **29**.

When only the switch SW1 is ON, steps **002**, **011** to **017**, and **018** are repeated. During execution in steps **012** to **015**, an interruption from step **021** is executed every 5 msec. The switch SW2 is determined to be turned off in step **022**, and the interruption returns to the main routine.

When the switch SW2 is turned on during the above cycle, the ON operation of the switch SW2 is determined by the first timer interruption upon the ON operation of the switch SW2 in step **022**, and the flow advances to step **024**. This flow is based on an assumption

that the release operation will be performed for the first time. For this reason, the charge/feed operation has been completed. The ON state of the switch SWCH is determined in step **024**, and the flow advances to step **025**. However, execution of step **025** is meaningless, so that the flow advances to step **026**. When the flow advances to step **026** for the first time, the flag AFFLG is set at "0", and the flow returns to step **023**. When the AF operation and the timer interruption are alternately performed, and the AF operation is completed, the flow advances from step **017** to step **019**. The flag AFFLG is set at "1", and the flow returns to step **002**. In the first timer interruption upon advance from step **011** to step **012**, the flow reaches steps **022** to **026**. In step **026**, the flag AFFLG=1 is determined, and the flow is allowed to advance to step **027** to perform the release operation.

Upon completion of the release operation, the flag AFFLG is reset to "0". While the charge/feed operation is started in step **026**, the flow returns to step **023**. The flow advances from step **011** to step **012** to start the next AF operation.

In the timer interruption during the initial period of the ON state of the switch SW2, since the switch SWCH is kept off, and the flag AFFLG is set at "0", the AF operation is repeated. When the switch SWCH is turned on first, the charge/feed operation is stopped. The central processing circuit PRS waits for the flag AFFLG=1, i.e., completion of one AF cycle. When the flag AFFLG is set at "1", the release operation is performed.

On the other hand, when the flag AFFLG is set at "1" first, the AF operation is repeated, and the central processing circuit PRS waits for the ON operation of the switch SWCH. When the switch SWCH is turned on, a film feed motor (not shown) is stopped, and the release operation is started.

FIGS. **34** and **35** are flow charts of a "defocus calculation" subroutine. Correlation operations used in this subroutine and then the processing steps will be described in detail below.

Signal processing methods for detecting image deviation amounts from image signals output from arrays each consisting of a pair of sensor elements are disclosed in Japanese Laid-Open Patent Application Nos. 58-142306, 59-107313, and 60-101513. More specifically, assume that the number of picture elements constituting the sensor array is defined as N, and that image signals from the ith (i=0, . . . , N-1) sensor array are defined as A(i) and B(i), the following equation is calculated for $k_1 \leqq k \leqq k_2$:

$$\begin{aligned} X(k) &= \sum_{i=1}^{M-1} \max\{A(i),B(i+|k|+1\} - \\ &\quad \sum_{i=0}^{M-1} \max\{A(i+1),B(i+|k|)\}\ (k<0) \\ &= \sum_{i=0}^{M-1} \max\{A(i+k),B(i+1)\} - \\ &\quad \sum_{i=0}^{M-1} \max\{A(i+k+1),B(i)\}\ (k \geqq 0) \\ &= X_1(k) - X_2(k) \end{aligned} \tag{1}$$

or

$$\begin{aligned} X(k) &= \sum_{i=1}^{M-1} \min\{A(i),B(i+|k|+1\} - \\ &\quad \sum_{i=0}^{M-1} \min\{A(i+1),B(i+|k|)\}\ (k<0) \end{aligned} \tag{2}$$

-continued

$$\begin{aligned} &= \sum_{i=0}^{M-1} \min\{A(i+k),B(i+1)\} - \\ &\quad \sum_{i=0}^{M-1} \min\{A(i+k+1),B(i)\}\ (k \geqq 0) \\ &= X_1(k) - X_2(k) \end{aligned}$$

where M is the number of calculation picture elements represented by M=N−|k|−1, k is called the relative displacement amount, so that k_1 and k_2 are often defined as −N/2 and N/2, max{a,b} is an operator for extracting a larger one of a and b, and min{a,b} is an operator for extracting a smaller one of a and b. Terms $X_1(k)$, $X_2(k)$, $Y_1(k)$, and $Y_2(k)$ in equations (1) and (2) can be defined as broad correlation amounts. When equations (1) and (2) are examined in detail, $X_1(k)$ and $Y_1(k)$ represent correlation amounts by a (k−1) displacement, and $X_2(k)$ and $Y_2(k)$ represent correlation amounts by a (k+1) displacement. Therefore, an evaluation amount X(k) as a difference between the amounts $X_1(k)$ and $X_2(k)$ represents an amount of change in correlation amount of each of the image signals A(i) and B(i) by a relative displacement amount k.

As can be apparent from the above definitions, the correlation amounts $X_1(k)$ and $X_2(k)$ become minimum when the correlation between the two images is maximum. The amount of change X(k) as the correlation amount is "0" when the correlation between the two images is maximum, and has a negative slope. However, since X(k) is discrete data, actually, the peak of the correlation amount is assumed to be present in an interval [kp·kp+1] under the following conditions:

$$X(kp) \geqq 0,\ X(kp+1)<0 \tag{3}$$

and X(kp)−X(kp+1) is maximum.

For this reason, the following interpolation is performed to detect the image deviation amount PR in units of sub-picture elements:

$$PR = kp + \frac{X(kp)}{X(kp) - X(kp+1)} \tag{4}$$

On the other hand, the correlation amounts $Y_1(k)$ and $Y_2(k)$ are maximum when the correlation between the two images is maximum according to the above definitions. The amount of change Y(k) as the correlation amount is "0" when the correlation between the two images is maximum, and has a positive slope. The peak of the correlation amount is assumed to be present in an interval [kp·kp+1] under the following conditions:

$$Y(kp) \leqq 0,\ Y(kp+1)>0 \tag{6}$$

and Y(kp)−Y(kp+1) is maximum.

For this reason, the following interpolation is performed to detect the image deviation amount PR in units of sub-picture elements:

$$PR = kp + \left| \frac{Y(kp)}{Y(kp) - Y(kp+1)} \right| \tag{7}$$

The image deviation amount can be detected regardless of whether the focus evaluation amount X(k) or Y(k) is used. As can be apparent from U.S. Pat. No. 4,618,236, the focus evaluation amount X(k) is used for |X(kp)−X(kp+1)| > |Y(kp+1)−Y(kp)|, and the

focus evaluation amount Y(k) is used for $|X(kp)-X(kp+1)| > |Y(kp+1)-Y(kp)|$ to obtain the image deviation amount PR with a higher S/N ratio.

Referring back to the flow chart in FIGS. **34** and **35**, step **100** represents an "**A1**" processing step in this embodiment. In steps **100** to **105**, the focus evaluation amount X(k) is obtained when the relative displacement amount k is changed within the range of "−20 to 20". The range of the relative displacement amount k is defined to be −20 to 20 because the number of picture elements of the sensor array is assumed to be "40". The range of processing target picture elements may be set variable in accordance with the focal length of the phototaking lens.

In step **150**, image correction is performed to eliminate the influence of vignetting of the distance measuring beam. The "image correction" subroutine will be described in detail later. The image-corrected data can restore the similarity of the pair of images, and the precision of the correlation calculation is improved.

In step **101**, the calculation picture element count M is calculated by $M=39-|k|$. The calculation picture element count M is set variable in accordance with the relative displacement amount k. The count M is decreased as the absolute value of the relative displacement amount k is increased. This is because when the relative displacement amount k is increased, the outputs from the corresponding sensors are omitted from the end. The sign (positive or negative) of the relative displacement amount k is checked in step **102**. A start picture element position PA or PB for starting the calculation of the A or B image in accordance with the sign is calculated in step **103** or **104**. The focus evaluation amount X(k) is calculated in step **105**.

Processing in steps **100** to **105** will be described with reference to FIGS. **36**A to **36**D. FIG. **36**A represents the two image signals A(i) and B(i). FIG. **36**B represents a corresponding relationship of sensor arrays at k=−20. At this time, when $M=39-|20|=19$, PA is "0" and PB="20".

Since the relative displacement amount k is a negative value, the B image is relatively displaced to the left by k picture elements (−20 picture elements). The value calculated by the relationship obtained by displacing the B image by one picture element to the left from the above corresponding relationship is the first term of the equation for obtaining X(−20). The value calculated by the relationship obtained by displacing the A image by one picture element to the left from the above corresponding relationship is the first term.

Since the A and B images are displaced every picture element to the left in the first and second terms, the calculation picture element count M is not defined as $M=40-|k|$ but as $M=39-|k|$. FIG. **36**C shows a corresponding relationship at k=0. FIG. **36**D shows a corresponding relationship of the correlation calculation at k=20 and represents the A image displaced by 20 picture elements to the left, unlike the case in FIG. **36**B.

FIG. **37** is a graph obtained by plotting the focus evaluation values X(k) as described above.

Referring back to the flows in FIGS. **34** and **35**, the peak value kp of the image deviation amount between two images, the A and B images in units of picture elements is detected. In steps **120** to **146**, the image deviation amount PR in units of sub-picture elements is obtained. In steps **120** to **135**, the two focus evaluation amounts X(k) and Y(k) are calculated again in steps **120** to **135** on the basis of the peak value kp obtained in step **110**.

The above re-calculation is performed due to the following two reasons. According to one reason, in the step of calculating the peak value kp, the calculation picture element count M is set variable in accordance with the relative displacement amount k. When the focus evaluation amount X(k) calculated within the variable calculation range is interpolated to obtain the image deviation amount PR in units of sub-picture elements, an error caused by the non-coincidence of the calculation picture element count M may be included. The other reason lies in that a combination of X(k) and Y(k) is better than only the focus evaluation amount X(k) to obtain the image deviation amount PR so as to obtain a higher S/N ratio depending on the signal patterns of the object, as described in U.S. Pat. No. 4,618,236. Judging from the above, the focus evaluation amounts X(k) and Y(k) are simultaneously obtained on the basis of the peak value kp in steps **120** to **135** while the calculation picture element count M is kept constant (step **120**).

The image deviation calculation using the constant calculation picture element count M is called a re-correlation calculation.

As will be described in an "image correction" subroutine in detail, the image correction filters used in step **150** are determined as a function of the relative displacement amount k. However, since the re-correlation calculation aims at obtaining the image deviation amount in units of sub-picture elements, the image correction filter must be set more strictly. For this purpose, processing in steps **151** to **153** is performed to obtain the relative displacement amount k for producing the image correction filters at a resolution of less than the units of picture elements.

In step **151**, kz, z_1, and z_2 are set from the value kp obtained in the above step. In steps **152** and **153**, $ZD=|z_1-z_2|$ and $PR'=kz+|z_1/ZD|$ are calculated. Note that this indicates that the "**A2**" processing step is performed using the fixed filter regardless of the relative displacement amount.

In step **120**, $M=38-|kp|$ is calculated to obtain the value of the calculation picture element count M. In steps **130** to **135**, the focus evaluation amounts X(k) and Y(k) are obtained at three points, i.e., k=kp−1, kp, and kp+1 using the kp as the center in the same manner as described above. In the calculation of the calculation picture element count M, the absolute value of each of the three points k=kp−1, kp, kp+1 is fixed to the calculation picture element count M at the maximum relative displacement amount.

Step **130** corresponds to the "**A2**" processing step.

In step **154**, each image correction filter is produced using the value PR', and the corresponding image is corrected with high precision. In step **130**, the operation in step **154** is repeated three times. In this case, the image correction using the same correction filter is performed three times.

In this embodiment, the calculating means has the "**A1**" processing step performed using the filter determined in accordance with the relative displacement amount and the "**A2**" processing step performed next to the "**A1**" processing step, using the fixed filter regardless of the relative displacement amount. The filter in the "**A2**" processing step is determined on the basis of the image deviation amount obtained in the "**A1**" processing step.

The image deviation amounts kpx and kpy based on the focus evaluation amounts in units of picture elements are detected from the focus evaluation amounts X(k) and Y(k) (steps **140** and **141**). At this time, XD (XD=(X(kpx)−X(kpx+1)) and YD (YD=Y(kpx+1-)−Y(kpx)) roughly representing the contrast evaluation amounts of the focus evaluation amounts X(k) and Y(k) are also calculated due to the following reason. If a non-in-focus amount is large, the contrast evaluation amounts XD and YD obtained in consideration of the image information at the end portions are checked to obtain information as if the image signals at the end portions are checked every relative displacement. When the contrast evaluation amounts XD and YD are larger, the S/N ratio is higher. When the two contrast evaluation amounts XD and YD are compared and XD≧YD is satisfied in step **142**, the focus evaluation amount X(k) is employed (step **143**). However, if XD<YD is satisfied, the focus evaluation amount Y(k) is employed (step **144**). In steps **145** and **146**, an interpolation calculation is performed by PR=kz+|z_1/ZD| using the employed ZD(z_1-z_2) and kz, thereby obtaining the image deviation amount PR in units of sub-picture elements. This process is shown in FIG. **38**. In this case, since condition XD<YD is established, the focus evaluation amount Y(k) is employed. kz=kpy, z_1=(kP), and z_2=Y(kp+1) are used in the calculation of the image deviation amount PR in units of sub-picture elements. In step **130**, since filter processing using a predetermined correction filter is performed, the meanings of the focus evaluation amounts at kpx and kp(x+1) are identical.

When the image deviation amount in units of sub-picture elements is obtained, the defocus amount is calculated on the basis of this image deviation amount. An "image deviation sensitivity calculation" subroutine for obtaining a defocus amount conversion coefficient α from the required image deviation amount is executed in step **155**.

In step **156**, by using the defocus conversion coefficient α, the image deviation amount PR, and a constant G determined by the re-imaging optical system, the following calculations are performed to determine the DEF value as the output of this subroutine:

$$DEF = \begin{cases} \alpha \times PR/(1 - \alpha \times PR/G) & (PR \geqq 0) \\ \alpha \times PR/(1 + \alpha \times PR/G) & (PR < 0) \end{cases}$$

The subroutine returns to the main routine in step **157**.

The "image correction" subroutine will be described below. As described above, an image on the photoelectric conversion element is defined as an optical convolution integral between an object and a point image. That is, the optical impulse response is a point image, the input is the brightness distribution of the object, and the output is an image. On the other hand, when any digital filter is determined and is subjected to the convolution integral with the image signal, the shape of the blurred image can be changed by software. This digital filter is determined in accordance with the condition of the optical system, and the total result of the two convolution integral cycles is set equivalent to one transfer function symmetrical about the vertical axis. Even if line image data represents an image asymmetrical about the vertical axis due to vignetting of the distance measuring beams, the image data can be restored to represent an object shape upon filter processing.

In particular, the similarity of the image is important in the defocus calculation. A digital filter to be selected need not be an inverse filter for restoring the asymmetrical line image caused by the optical system, but can be a filter for restoring a symmetrical image with respect to the vertical axis, as previously described.

FIG. **39** shows the "image correction" subroutine. The blurred image is corrected such that a correction filter is produced in accordance with the state of the phototaking lens, the convolution integral between the image data and the correction filter is performed to correct the image, the corrected image data is filtered through a high-pass filter, and finally normalization is performed. The shape of the blurred image correction filter described with reference to FIG. **39** is changed in accordance with the state of the distance measuring optical system, the type of phototaking lens, its distance ring position, and the zoom position. For this reason, it is difficult to store all the data in the ROM. Only original data of the filter is stored in the ROM and is processed in accordance with the above conditions.

In step **601**, information such as an open f-number, the exit pupil position, and the like of the phototaking lens is fetched.

In step **603**, a "correction filter magnification" subroutine for determining parameters for producing the image correction filter is executed. The information fetched in the previous step is used in this subroutine.

In step **604**, an "execution filter production" subroutine for producing a correction filter actually used in image correction is executed in accordance with the parameters. Steps **603** and **604** will be described later.

In step **605**, in order to minimize the error caused particularly in peripheral image correction, both the peripheral image data are elongated in opposite sides to produce a hypothetical image signal. FIG. **40** is a view for explaining production of the hypothetical image signal. Signals having the same level as that of the peripheral value are added to both the sides of the actual central image signal.

As will be described later, this processing is required to perform image correction as the convolution integral with the image correction filter. That is, since a signal of a given picture element is corrected upon reception of an influence of a noncorrected signal located at a location remote by the image correction filter, the end portions of the actual image signal are not strictly corrected. If only a perfectly corrected image is used in focus detection, a considerably large number of image correction picture elements must be added in as the peripheral picture elements of the picture element used in the defocus calculation. However, when the defocus amount of the phototaking lens is considerably large, i.e., when the defocus amount is 5 mm or more, strict image correction precision need not be required. For this reason, the correction processing operation of the entire image signal can be performed. In order to minimize the image correction error, the peripheral image data are elongated, as illustrated in FIG. **40**.

On the other hand, when the defocus amount is less than several millimeters, the image signal must be strictly corrected. The number of picture elements used in the defocus calculation is set to be smaller than 5 picture elements at each peripheral portion of the actual image signal. The length of a correction filter suitable for a given defocus amount is smaller as the defocus

amount is decreased. By this characteristic, correction picture elements corresponding to the given defocus amount are arranged to cause a filter corresponding to a small defocus amount to operate without any error.

In this embodiment, the photoelectric conversion element has picture elements used for the filter processing, which elements are located outside the picture elements whose outputs are used to calculate the evaluation amounts.

Note that image data A(i) and B(i) represent data falling within the defocus calculation range, unless otherwise specified.

In step **606**, the image correction filter obtained in step **604** and the hypothetical image signal obtained in step **605** are subjected to the convolution integral. By this processing, the image signal is restored to have a shape as if the distance measuring beam is not vignetted, thereby restoring the similarity between the two images. The "convolution integral" subroutine will be described in detail later.

In step **607**, high-pass filter processing for eliminating a low-frequency component contained in the image signal is performed. When a strong beam spot is incident on the phototaking lens, a low-frequency ghost component may be contained in the image signal. For this reason, in order to improve the precision of the defocus calculation described with reference to FIGS. **34** and **35**, a low-frequency component must be cut off.

FIG. **41B** shows a state in which a low-frequency component is superposed on the image signal in FIG. **41A**. The filter processing of this image signal is performed as follows:

$$HA(i) = -A(i-2) + 2 \times A(i) - A(i+2)$$

where A(i) is the corrected image data, HA(i) is the high-pass filtered image data, and i is the sensor picture element position. If A(i) is substituted with HA(i) again, image data shown in FIG. **41C** is obtained, and an accurate image deviation amount can be detected.

In step **608**, the image data is normalized into 8-bit data, and the subroutine returns to the main routine in step **609**.

The filter processing using the filter determined in accordance with the aperture ratio of the imaging optical system subjected to focus detection and the filer determined in accordance with the exit pupil position of the imaging optical system subjected to focus detection will be described below with reference to FIGS. **42** to **44D**.

FIG. **42** shows the "correction filter magnification" subroutine. This subroutine is the preparation for producing a correction filter actually used in image correction from the original filter information of the correction filter. More specifically, a horizontal axis magnification **1FGR**, a horizontal axis magnification **2FGL**, a vertical axis magnification **1YGR**, and a vertical axis magnification **2YGL** used in the next "execution filter production" subroutine are determined. The horizontal axis magnification and the vertical axis magnification are axis magnifications for producing the correction filters by reducing or enlarging the original filter stored in the ROM.

F-number (aperture ratio) correction coefficients **1HVR** to **4HVR**, **1HVL** to **4HVL**, **1LVR** to **4LVR**, and **1LVL** to **4LVL** and pupil position correction coefficients **1KVFR** to **4KVR**, **1KV3L** to **4KVL**, **1MVR** to **4MVR**, and **1MVL** to **4MVL** used in the subsequent steps are shown in FIGS. **43A** to **43D** and FIGS. **44A** to **44D**. The f-number correction coefficients **1HVR** to **4HVR**, **1HVL** to **4HVL**, **1LVR** to **4LVR**, and **1LVL** to **4LVL** are functions of an open f-number FNO of the phototaking lens. The pupil position correction coefficients **1KVR** to **4KVR**, **1KVL** to **4KVL**, **1MVR** to **4MVR**, and **1MVL** to **4MVL** are functions of a distance PD between the exit pupil of the phototaking lens and a prospective imaging plane. These relationships are determined in accordance with the diffusion characteristics of the diffusion plate inserted in the optical path of the distance measuring optical system.

A description will be made from a re-correlation calculation in step **702** in FIG. **42**. It is determined in step **702** whether this subroutine in step **100** ("**A1**" processing step) of the "defocus calculation" subroutine shown in FIGS. **34** and **35** is called, or this subroutine is called in step **130** ("**A2**" processing step). If this subroutine is called in step **100**, the flow advances to step **703** (i.e., the "**B1**" processing step). If this subroutine is called in step **130** (i.e., the re-correlation calculation ("**A2**" processing step)), the flow advances to step **704** ("**B2**" processing step).

The calculating means of this embodiment has the "**B1**" processing step performed using the filter determined in accordance with the relative displacement amount and the "**B2**" processing step performed using the fixed filter regardless of the relative displacement amount and includes a selecting means for selecting one of the "**B1**" and "**B2**" processing steps.

In step **703**, the relative displacement amount k is stored as a parameter MKFS for determining the length of the correction filter. In the "defocus calculation" subroutine described above, the value k is changed to shift the image data because the defocus amount every k is assumed. In this case, the value k is used to set the length of the correction filter on the basis of the assumed defocus amount. On the other hand, PR' having a resolution less than the units of picture elements is stored in step **704**.

This step is executed when this subroutine is called in re-correlation. In this case, since the image deviation amount is almost known, MKFS=PR' is set to fix the correction filter for each relative displacement amount. This operation is performed to perform more accurate correction filtering and to improve linear interpolation precision in step **146** of the "defocus calculation" subroutine by determining a predetermined correlation evaluation amount regardless of the value of the relative displacement amount k when an image deviation amount which is less than the units of picture elements is calculated in step **146** of the "defocus calculation" subroutine in FIG. **35**.

In step **705**, a parameter NV determined by the defocus amount of the assumed phototaking lens is stored as the horizontal axis magnification **1FGR** and the horizontal axis magnification **2FGL**. This parameter NV is a function of MKFS-FDLT shown in FIG. **45**. FDLT is the correction term for operating the correction filter to some extent even if the image becomes asymmetrical due to the aberration of the phototaking lens and vignetting of the beam in the zero defocus state of the phototaking lens.

The filter corrects the first and second signals even if the relative displacement amount is zero.

The parameter NV generally assumes a value of 1 or less, and the original filter is enlarged to produce an execution filter, thereby preventing degradation of pre-

cision. Since the defocus amount of the phototaking lens is almost proportional to the size of the blurred image, NV has characteristics almost proportional to the absolute value of the MKFS-FDLT. Note that the parameter NV is not perfectly proportional due to the aberration of the re-imaging lens. The secondary term is added in consideration of the above aberration to determine the MKFS-FDLT in FIG. **45**.

The FDLT used herein will be described in more detail. When the distance measuring beam is vignetted in the in-focus state of the phototaking lens, a point image on the photoelectric conversion element is not symmetrical about the vertical axis, as will be described with reference to FIG. **46**. FIG. **46** shows a spot diagram on the photoelectric conversion element in the in-focus state. The direction of an arrow is the line-up direction of the picture elements. Asymmetry of the light amount distribution is found in this direction. By setting the FDLT, this asymmetry can be eliminated. A slight image noncoincidence in the in-focus state can be corrected. The FDLT value is stored in the ROM in the phototaking lens and is properly fetched in the RAM in the microcomputer through the communication between the phototaking lens and the camera body.

In step **706**, the product of the horizontal magnification 1FGR, the distance measuring field position PF, and a proportional constant CV is stored as the horizontal axis magnification 1FGR. The product of the horizontal axis magnification 2FGL, the distance measuring field position PF, and the proportional constant CV is stored as the horizontal axis magnification 2FGL. These storage operations can be performed since the degree of vignetting of the distance measuring beam is approximately proportional to the distance from the optical axis of the phototaking lens to the distance measuring field.

That is, the filter processing is performed using a filter determined by the distance from the optical axis of the imaging optical system subjected to focus detection to the distance measuring distance determined in accordance with the photoelectric converting means.

In particular, in this embodiment, when the defocus amount conversion calculation of the image deviation amount is performed to detect the imaging state of the imaging optical system, the defocus conversion calculation of the image deviation amount is set as a function of a representative distance from the optical axis of the imaging optical system subjected to focus detection to the distance measuring field determined by the photoelectric converting means comprising a plurality of picture elements.

In step **707**, the product of the horizontal axis magnification 1FGR, the f-number correction coefficient 1HVR, and the pupil position correction coefficient 1KVR is stored as the horizontal axis magnification 1FGR, and the product of the horizontal axis magnification 2FGL, the f-number correction coefficient 2HVL, and the pupil position correction coefficient 2KVL is stored as the horizontal axis magnification 2FGL.

The product of the f-number correction coefficient 3LVR and the pupil position correction coefficient 3MVR is stored as the vertical axis magnification 1YGR, and the product of the f-number correction coefficient 4LVL and the pupil position correction coefficient 4MVL is stored as the vertical axis magnification 2YGR, thereby specifying all the final correction coefficients.

The subroutine returns to the main routine in final step **708**.

FIG. **47** shows the "execution filter production" subroutine. In this subroutine, a correction filter is produced from the original filter in accordance with the axis magnifications determined in the previous "correction filter magnification" subroutine. Two different original filters are stored in the ROM and are selectively used in accordance with the positive or negative sign of the MKFS-FDLT due to the following reason. The shape of a line image is determined by mainly the re-imaging lens regardless of the type of phototaking lens. In addition, the sign of the MKFS-FDLT can be determined in accordance with the front-focus and rear-focus states. In other words, since the re-imaging lens comprises a single lens, the aberration of the single lens is considerably larger than that of the phototaking lens.

FIG. **48** is a view for explaining this, showing a spot diagram when the object distance is shifted between the front and rear sides of the in-focus position. The primary image of the object is set on three points on the optical axis of the phototaking lens. A beam reaching the photoelectric conversion element through a dark phototaking lens is traced. When the distance measuring beam is vignetted in this manner, the right side of the point image is omitted in the front-focus state. Similarly, the left side of the point image is omitted in the rear-focus state. This indicates that the direction of tailing of the point image in the front-focus state is opposite to that in the rear-focus state. In addition, since the shape of the point image in the front-focus state is entirely different from that in the rear-focus state, it is apparent that the correction filters suitable for these states are not identical even if one of the filters is reversed.

The "execution filter production" subroutine will be described with reference to FIG. **47**.

In step **802**, the sign of the MSFS-FDLT is checked. If the sign is positive or zero, the flow advances to step **803**. However, if the sign is negative, the flow advances to step **805**.

In step **803**, a "first original filter 1" shown in FIG. **49A** is selected as the original filter and stored as the correction filter in the RAM. In step **804**, **10** is stored in the FOF. In step **805**, a "second original filter 2" shown in FIG. **49B** is selected from the original filters and stored as the correction filter in the RAM. In step **806**, **30** is stored in the FOF. Note that each original filter comprises **41** 8-bit data. The FOF is a variable representing the position of origin of the original filter data. The FOF is set as a variable because the original filter is elongated in one direction with respect to the origin.

Steps **807** to **810** are executed to produce a target correction filter by compressing or expanding the original filter data stored in the RAM as the correction filter in each previous step.

More specifically, in step **807**, the ZR portion of the filter data having an effect for reducing tailing is multiplied with FGR times in the horizontal axis direction. In step **808**, the ZS portion having a function of increasing tailing is multiplied with FGL times in the horizontal axis direction.

When the filter lengths are determined, the data of the ZR portion is compressed by YGR times in the vertical axis direction in step **809**. In step **810**, the data of the ZS portion is compressed by YGL times. Note that the data of the origin FOF is not subjected to compression.

In final step **811**, this subroutine returns to the main routine.

In this embodiment, as described above, the calculating means has the first processing step of producing the filter from the first original filter information and the second processing step of producing the filter from the second original filter information and includes a selecting means for selecting one of the first and second processing steps in accordance with the relative displacement amount between the first and second signals.

The correction filter is thus produced.

In this embodiment, as described above, the first or second original filter is used in accordance with the relative displacement amount. For example, the "filter **1**" mainly corresponding to the rear-focus state and the "filter **2**" mainly corresponding to the front-focus state are used to produce an appropriate correction filter corresponding to any focus state.

As described in the "correction filter magnification" subroutine, the horizontal axis magnification **1**FGR, the horizontal axis magnification **2**FGL, the vertical axis magnification **1**YGR, and the vertical axis magnification **2**YGL are set as a function of the open f-number FNO of the phototaking lens, the distance PD between the exit pupil of the phototaking lens and the prospective imaging plane, and the distance measuring field position PF. Therefore, an appropriate correction filter can be formed for any distance measuring field regardless of the type of phototaking lens.

The shape of the correction filter is changed in accordance with changes in horizontal axis magnifications **1**FGR and **2**FGL and vertical axis magnifications **1**YGR and **2**YGL as follows. When the f-number of the phototaking lens is decreased, the f-number correction coefficient **2**LVL and the pupil position correction coefficient **1**MVL shown in FIGS. **43**B and **43**C come close to zero, and the vertical axis value of the ZR portion of the image correction filter comes close to zero. On the other hand, the image correction capacity of the ZS portion is gradually decreased as the filter length comes close to zero.

Since all the correction filters used for image correction are produced by using one of the two different original filters, the volume of information stored in the ROM can be small.

FIG. **50** shows the "convolution integral" subroutine. The convolution integral equation for discrete data is given as follows for two series D(i) and E(i):

$$S(i) = \sum_h D(h) \times E(i - h)$$

and S(i) is the output of this equation. If D(i) is defined as image data, and E(i) is a correction filter, S(i) is defined as the corrected image data. In this subroutine, a pair of secondary images are set as the image data. As previously described, since two blurred images have symmetry about the optical axis of the phototaking lens, the correction filter is reversed, and the reversed correction filter is operated for one image data, thereby obtaining corrected images.

The "convolution integral" subroutine in FIG. **50** will be described below. A pair of image data are called images OA(i) and OB(i).

In step **902**, i.e., the "**C1**" processing step, the image OA(i) and a correction filter F(i) produced in the "execution filter production" subroutine are subjected to the convolution integral as follows:

$$A(i) = \sum_h OA(h) \times F(i - h)$$

thereby obtaining a corrected image A(i).

In step **903**, i.e., the "**C2**" processing step, the image OB(i) and a correction filter F(-i) obtained by reversing the above filter about the origin FOF are subjected to the convolution integral as follows:

$$B(i) = \sum_h OB(h) \times F(-i - h)$$

thereby obtaining a corrected image B(i). In this manner, a single corrected filter is used in two ways, i.e., with and without a reverse operation. In the "execution filter production" subroutine described above, only one filter is produced. Therefore, the calculation time for producing the correction filter can be almost halved, and the volume of the original filter information stored in the ROM can also be reduced.

This subroutine returns to the main routine in step **904**.

When the imaging state of the imaging optical system is to be detected by performing a defocus amount conversion calculation of the image deviation amount, the defocus conversion calculation of the image deviation amount is a function of the aperture ratio or exit pupil position of the imaging optical system subjected to focus detection. This will be described below.

FIG. **51** shows a "sensitivity of image deviation" subroutine. This subroutine is to calculate the defocus conversion coefficient α from the image deviation amount. The shape of an appropriate correction filter is changed in accordance with not only the defocus amount of the phototaking lens but also the degree of vignetting of the distance measuring beam. The sensitivity of image deviation is also a function of the open f-number, the exit pupil position, and the distance measuring distance position.

When the defocus amount conversion calculation of the image deviation amount is to be performed to detect the imaging state of the imaging optical system, the defocus conversion calculation is a function of the aperture ratio or exit pupil position of the imaging optical system subjected to focus detection, or a representative distance from the optical axis of the imaging optical system to the distance measuring field.

In step **1001**, the sign of the MKFS-FDLT is checked. If the sign is positive or zero, the flow advances to step **1003**. However, if the sign is negative, the flow advances to step **1004**. This determination is branched in accordance with the original filter used.

In step **1003**, an image deviation sensitivity AP free from vignetting of the distance measuring beam is corrected using the f-number correction coefficients **1**HVR to **4**HVR, **1**HVL to **4**HVL, **1**LVR to **4**LVR, and **1**LVL to **4**LVL, the pupil position correction coefficients **1**KVR to **4**KVR, **1**KVL to **4**KVL, **1**MVR to **4**MVR, and **1**MVL to **4**MVL, and the distance measuring field position PF. The correction equation is given as follows:

$$a = AP + PF \times (H1 \times HVL \times LVL \times KVL \times MVL \times H2 \times HVR \times LVR \times KVR \times MVR)$$

where H1 and H2 are correction coefficients by the shape of the correction filter.

Similarly, in step **1004**, the image deviation sensitivity is determined using correction coefficients H3 and H4 as follows:

$$\alpha = AP + PF \times (H3 \times HVL \times LVL \times KVL \times MVL + H4 \times HVR \times LVR \times KVR \times MVR)$$

In final step **1005**, this subroutine returns to the main routine.

As described above, the image deviation sensitivity α of each correction filter is prepared on the basis of the corresponding equation as a function of the open f-number FNO of the phototaking lens, the distance PD between the exit pupil of the phototaking lens and the prospective imaging plane, and the distance measuring field position PF. An accurate defocus calculation of each distance measuring field can be performed regardless of the type of phototaking lens.

The above equations will be described below. According to the characteristic features of the image correction filters, the ZS portion has a function of increasing the tails of the image, and the ZR portion has a function of decreasing the tails of the image, as described previously with reference to FIGS. **23A** to **23C**. These functions will be taken into consideration in view of image movement. The ZS and ZR portions in FIG. **23A** have a function of moving the center of gravity of the line image in FIG. **23B** to the left. The ZS and ZR portions in FIG. **24A** have a function of moving the center of gravity of the line image in FIG. **24B** to the right. Therefore, it is understood that the centers of gravity of two images are separated from each other by this filter processing. In this case, since the distance measuring beam is vignetted from its peripheral portion, the distance between the images is smaller than a case in which the distance measuring beam is not vignetted. Therefore, even if the two images are separated from each other, it can be said that the state of the two images comes closer to a state free from vignetting.

Judging from the above characteristics of the filter, in order to convert an image deviation amount into a defocus amount, it is understood that this conversion function must be set as a function of the correction filter. The correction term of the filter for the image deviation sensitivity is defined as the sum of the function of the ZS portion and the function of the ZR portion in accordance with the characteristics of the ZS and ZR portions of the filter. More specifically, the image deviation sensitivity AP free from vignetting of the distance measuring beam is corrected by using the f-number correction coefficients, the pupil position correction coefficients, and the distance measuring field position for determining a correction filter required for image correction, i.e., by obtaining the sum of the product of the f-number correction coefficients 2HVL, 4HVL, 2LVL, and 4LVL and the pupil position correction coefficients 2KVL, 4KVL, 2MVL, and 4MVL and the product of the f-number correction coefficients 1HVR, 3HVR, 1LVR, and 3LVR and the pupil position correction coefficients 1KVR, 3KVR, 1MVR, and 3MVR, and multiplying the resultant sum with the distance measuring field position PF. Therefore, the image deviation sensitivity suitable for this correction filter can be obtained. By these calculations, the image deviation sensitivity can be obtained in consideration of:

(1) vignetting of the distance measuring beam occurs more easily when the position of the distance measuring field is farther away from the optical axis of the phototaking lens;

(2) vignetting of the beam occurs more easily when the aperture ratio is increased; and

(3) vignetting of the beam occurs more easily when the exit pupil position of the phototaking lens is farther away from the set pupil position of the focus detection optical system.

The description of this subroutine has thus been made. The operation of the defocus detection in FIG. **34** will be described again below.

If a diffusion plate is located on the prospective imaging plane of the phototaking lens in the optical path of the focus detection optical system, distance measuring precision is improved for a bright lens having a small f-number. When a dark phototaking lens having a large f-number is mounted on the camera incorporating this focus detection apparatus, the distance measuring beam is vignetted. For example, image data shown in FIGS. **52A** to **52C** are obtained as outputs from the photoelectric conversion element.

FIGS. **52A** to **52C** and FIGS. **53A** and **53B** show imaging states of a phototaking lens. The phototaking lens is changed in an order of a front-focus state (FIGS. **52A** and **52B**), an in-focus state (FIG. **52C**), and a rear-focus state (FIGS. **53A** and **53B**), and line images in the respective states are illustrated. Line images OA(i) and OB(i) are obtained from a pair of picture element arrays. Since the line images are impulse responses of the composite system of the phototaking lens and the distance measuring optical system and can be restored to be symmetrical about the vertical axis, the shapes of the pair of object images formed by the distance measuring optical system can be restored to have a similarity, thereby detecting a relative distance between the two images.

The pair of illustrated line images are reserved from each other, and their shapes can be classified into front- and rear-focus shapes. The degree of spreading of each line image changes in almost proportion to the image deviation amount. Front- and rear-focus blurred image correction filters shown in FIGS. **49A** and **49B** are prepared, and the filter length is appropriately adjusted in accordance with the corresponding defocus amount. Therefore, the line images can be restored to be symmetrical about the vertical axis.

A method of filtering image data through a correction filter while an image deviation amount is unknown is the "defocus calculation" subroutine shown in FIGS. **34** and **35**. In this subroutine, in step **100**, the value of the relative displacement amount k is sequentially changed, and the correlation evaluation amounts (equations (1) and (2)) of the paired images are obtained while image correction is being performed using the correction filters as a function of the amount k.

FIGS. **54A** to **54C** and FIGS. **55A** and **55B** are views showing the shapes of correction filters for various k values. FIGS. **54A** to **54C** and FIGS. **55A** and **55B** show filters for appropriately correcting the line images in FIGS. **52A** to **52C** and FIGS. **53A** and **53B**. The relative evaluation amount is obtained for one line image by causing such a filter to act on this line image. When the relative displacement amount k is different from the actual image deviation amount, image correction becomes inappropriate. However, when the relative displacement amount k is gradually changed to

come close to the actual image deviation amount, image correction comes close to an appropriate state accordingly. An optimal image correction state can be obtained when the relative displacement amount k is closest to the actual image deviation amount. Therefore, to find a relative displacement amount k corresponding to the zero relative evaluation amount is to find an optimal image correction filter. When appropriate correction filters act on line images, the line images are obtained as shown in FIGS. **56**A to **56**C and FIGS. **57**A and **57**B, thereby satisfactorily achieving symmetry of the line images about the vertical axis. As a result, each pair of images are similar to each other, and it is possible to obtain a distance between the two images with high precision. As previously described, if the line images are corrected in this manner, a general object image can also be corrected to two similar images.

On the other hand, FIGS. **58**A to **58**D show states in which inappropriate correction filters act on the line images shown in FIG. **53**B when the relative displacement amount k is sequentially changed. FIGS. **58**A and **58**C show correction filters different from that of FIG. **55**B, and FIGS. **58**B and **58**D show images corrected by these correction filters. In this manner, when the relative displacement amount k is greatly different from the deviation amounts of the two images, the corrected images have a small degree of similarity. A change in relative evaluation amount with a relative displacement of the image becomes conspicuous.

In step **130** of the "defocus calculation" subroutine in FIGS. **34** and **35**, a more accurate correction filter is produced using the relative displacement amount PR' in units of sub-picture elements obtained in interpolation, and the final image deviation amount is calculated by the most correlation calculation while the shape of the correction filter is fixed.

In order to obtain a correction filter suitable for various conditions for determining the degree of vignetting of the distance measuring beam, the horizonal and vertical axes of the original filter are enlarged or reduced ("execution filter production" subroutine) on the basis of the f-number correction coefficients **1**HVR to **4**HVR, **1**HVL to **4**HVL, **1**LVR to **4**LVR, and **1**LVL to **4**LVL and the pupil position correction coefficients **1**KVR to **4**KVR, **1**KVL to **4**KVL, **1**MVR to **4**MVR, and **1**MVL to **4**MVL which are obtained as a function of the open f-number, the exit pupil positions, and the distance measuring field position. For example, FIG. **59** shows a correction filter corresponding to a bright phototaking lens having a small f-number. In this case, slight vignetting is still present, and the relative displacement amount in FIG. **57**B is assumed. This filter is obtained such that the length of the original filter is caused to correspond to the relative displacement amount, the ZR portion is enlarged in the horizontal axis direction and reduced in the vertical axis direction, and the ZS portion is reduced in the horizontal axis direction.

The above description exemplifies the defocus detection method utilizing image correction in the distance measuring optical system having the diffusion plate in the optical path. This defocus detection method is not limited to this distance measuring optical system, but is applicable to various other distance measuring optical systems.

For example, in the conventional distance measuring optical system obtained by omitting the diffusion plate **42** from the distance measuring optical system shown in FIG. **1**, this defocus detection is effective when a considerably dark phototaking lens is mounted and the distance measuring beam is vignetted. For this reason, the following combination may be proposed. That is, a distance measuring optical system is arranged such that a distance measuring beam is not vignetted by a phototaking lens having an open f-number of 5.6 or less. The conventional distance measurement is performed for a phototaking lens having an open f-number of 5.6 or less. However, when a phototaking lens having an open f-number of more than 5.6 is mounted, the above image correction is performed to detect a defocus amount.

If this conventional distance measuring optical system has an aperture as shown in FIG. **3**, strictly speaking, the shapes of two pairs of blurred images are not symmetrical with each other due to the following reason. The shapes of the aperture openings **48***a* and **48***b* do not overlap each other when one of the openings is translated to the other. The blurred images behave as if the outer side of the rectangular opening is vignetted in an arcuated shape. Therefore, as described above, the image can be corrected later in the filter processing. Note that the correction filter is different from that described above except that the correction filter is formed not as a function of the f-number and exit pupil position of the phototaking lens, and the distance measuring field position.

According to the embodiment described above,

(a) since vignetting of the distance measuring beam is allowed, the limitations of the aperture ratio of the imaging optical system in the conventional focus detection apparatus can be relaxed, and focus detection of a dark imaging lens having a large f-number can be performed.

In particular, in a focus detection apparatus having an improved distance measuring optical system having a diffusion plate in the optical path of a distance measuring optical system, distance measuring precision as the characteristic feature of this apparatus can be achieved for a bright imaging lens. At the same time, focus detection can be performed for even a dark imaging lens in which the distance measuring beam is conventionally vignetted.

(b) Even if the distance measuring beam is vignetted, distance measurement can be performed. The distance measuring field can be located at an arbitrary position within the phototaking frame without darkening the beam incident on the focus detection optical system.

(c) Accurate image correction can be performed even if the imaging lens is set in the front- or rear-focus state. As a result, focus detection precision can be remarkably improved.

Accurate defocus detection can be performed regardless of the imaging states of the imaging optical system. The nun%bet of times of driving the lens to achieve the in-focus state can be reduced.

(d) All the correction filters can be produced in accordance with the aperture ratios of phototaking lenses on the basis of two original filters.

Accurate defocus detection can be performed regardless of the aperture ratio of the imaging optical system. The number of times of driving the lens to achieve the in-focus state can be reduced.

In addition, if the correction filter is calculated as a function of the aperture ratio, the volume of information required to be stored in the focus detection apparatus can be minimized, and a small ROM can be used,

resulting in low cost. In particular, a great effect can be obtained for industrial equipment such as cameras having restricted costs.

(e) Since all the correction filters can be produced in accordance with the exit pupil position of the phototaking lens on the basis of the two original filters, focus detection can be performed for imaging lenses having different exit pupil positions.

Accurate defocus detection can be performed regardless of the exit pupil position of the imaging optical system. The number of times of driving the lens to achieve the in-focus state can be reduced.

In addition, if the correction filter is calculated as a function of the exit pupil position, the volume of information required to be stored in the focus detection apparatus can be minimized, and a small ROM can be used, resulting in low cost. In particular, a great effect can be obtained for industrial equipment such as cameras having restricted costs.

(f) In focus detection of a dark imaging lens having a large f-number, the filter in the "A2" processing step is determined on the basis of the image deviation amount obtained in the "A1" processing step. The accurate correction filter can be produced in the "A2" processing step. The image deviation amount can be calculated with high precision. Therefore, the restrictions as to the aperture ratio of the imaging optical system can be relaxed, unlike the conventional focus detection apparatus.

(g) Even if the relative displacement amount is zero, the digital filter is arranged to correct the first and second signals. A slight image noncoincidence in the in-focus state can be corrected. In the focus detection of a dark imaging lens having a large f-number and a large vignetting amount of the distance measuring beam, the images can coincide with each other with high precision.

As a result, the restrictions as to the aperture ratio of the imaging optical system can be relaxed, unlike the conventional focus detection apparatus, and focus detection of a dark imaging lens having a large f-number can be performed.

An accurate defocus amount of the imaging optical system can be detected regardless of whether the in-focus state is obtained. The number of times of driving the lens to achieve the in-focus state can be reduced.

(h) In focus detection of a dark imaging lens having a large f-number, the filter in the "B2" processing step is determined on the basis of the image deviation amount obtained in the "B1" processing step. In addition, the correction filter is fixed in the "B2" processing step regardless of the relative displacement of the image signal. The weighting coefficients of the evaluation amounts at the respective relative displacements obtained by interpolation of the evaluation amounts representing the coincidence between the signals in units of sub-picture elements do not change, and high-precision evaluation amounts can be obtained. Therefore, the restrictions as to the aperture ratio of the imaging optical system can be relaxed, unlike the conventional focus detection apparatus, and focus detection of a dark imaging lens having a large f-number can be performed.

Accurate defocus detection can be performed regardless of the aperture ratio of the imaging optical system. The number of times of driving the lens to achieve the in-focus state can be reduced.

(i) All the correction filters can be produced in accordance with the distance measuring field positions of phototaking lenses on the basis of two original filters. Focus detection in a plurality of distance measuring fields can be performed for imaging lenses having different aperture ratios.

In addition, if the correction filter is calculated as a function of the distance measuring field position, the volume of information required to be stored in the focus detection apparatus can be minimized, and a small ROM can be used, resulting in low cost. In particular, a great effect can be obtained for industrial equipment such as cameras having restricted costs.

(j) Since the length of the correction filter adaptive to a given focus amount is decreased when the defocus amount is decreased, the number of picture elements used in the defocus calculation is smaller than that of the actual image signal by five picture elements at each end of the actual image signal. When the defocus amount is several millimeters or less, a filter corresponding to a small defocus amount can be operated without any error. Therefore, accurate defocus detection can be performed, and the number of times of driving the lens to achieve the in-focus state can be reduced.

Since vignetting of the distance measuring beam is allowed, the limitations of the aperture ratio of the imaging optical system in the conventional focus detection apparatus can be relaxed, and focus detection of a dark imaging lens having a large f-number can be performed.

(k) Since the correction filter having the above-mentioned arrangement is used, the corrected images do not excessively come close to the original line. The high-frequency component of the original image data is not excessively amplified, and the right and left tails of the image signal can be set equal to each other. Therefore, even if random noise caused by thermal noise is superposed on image data, distance measuring precision is rarely degraded.

Since vignetting of the distance measuring beam is allowed, the limitations of the aperture ratio of the imaging optical system in the conventional focus detection apparatus can be relaxed, and focus detection of a dark imaging lens having a large f-number can be performed.

(l) The calculation time for producing the correction filters can be halved as compared with a case in which correction filters for the two images are independently produced.

Since vignetting of the distance measuring beam is allowed, the limitations of the aperture ratio of the imaging optical system in the conventional focus detection apparatus can be relaxed, and focus detection of a dark imaging lens having a large f-number can be performed.

In addition, since the correction filter for one image can be produced from that for the other image, the volume of information required to be stored in the focus detection apparatus can be minimized, and a small ROM can be used, resulting in low cost. In particular, a great effect can be obtained for industrial equipment such as cameras having restricted costs.

What is claimed is:

1. A focus detection apparatus comprising an optical system for forming first and second optical distributions associated with object images whose relative positional

relationship is changed in accordance with an imaging state of an imaging optical system subjected to focus detection, photoelectric converting means, having a plurality of picture elements, for outputting first and second signals respectively corresponding to the first and second optical distributions, and calculating means for performing filter processing of the first and second signals, wherein the first and second signals are respectively processed through filters having mutually different characteristics, processed sequentially displacing the first and second signals relative to each other, calculating an evaluation amount representing a coincidence between the first and second signals at the relatively displaced positions, obtaining positional deviations between the first and second object images on the basis of a change in evaluation amount, and detecting the imaging state of the imaging optical system on the basis of the deviations, the filter processing being performed using a filter determined by the relatively displaced positions.

2. An apparatus according to claim 1, wherein said calculating means has a first processing step of producing said filter from first original filter information and a second processing step for producing said filter from second original filter information, and further comprises selecting means for selecting one of the first and second processing steps in accordance with the relative displacement of the first and second signals.

3. A focus detection apparatus comprising an optical system for forming first and second optical distributions associated with object images whose relative positional relationship is changed in accordance with an imaging state of an imaging optical system subjected to focus detection, photoelectric converting means, having a plurality of picture elements, for outputting first and second signals respectively corresponding to the first and second optical distributions, and calculating means for, when the first and second signals are sequentially displaced relative to each other, and an evaluation amount representing a coincidence between the first and second signals at the relatively displaced positions is calculated, performing filter processing of the first and second signals, obtaining deviations between the first and second object images on the basis of a change in evaluation amount, and detecting the imaging state of the imaging optical system, the filter processing, wherein the first and second signals are respectively processed through filters having mutually different characteristics, being performed using a filter determined by an aperture ratio of said imaging optical system subjected to focus detection.

4. A focus detection apparatus comprising an optical system for forming first and second optical distributions associated with object images whose relative positional relationship is changed in accordance with an imaging state of an imaging optical system subjected to focus detection, photoelectric converting means, having a plurality of picture elements, for outputting first and second signals respectively corresponding to the first and second optical distributions, and calculating means for, when the first and second signals are sequentially displaced relative to each other, and an evaluation amount representing a coincidence between the first and second signals, obtaining deviations between the first and second object images on the basis of a change in evaluation amount, and detecting the imaging state of the imaging optical system, the filter processing, wherein the first and second signals are respectively processed through filters having mutually different characteristics, being performed using a filter determined by an exit pupil position of said imaging optical system subjected to focus detection.

5. A focus detection apparatus comprising an optical system for forming first and second optical distributions associated with object images whose relative positional relationship is changed in accordance with an imaging state of an imaging optical system subjected to focus detection, photoelectric converting means, having a plurality of picture elements, for outputting first and second signals respectively corresponding to the first and second optical distributions, and calculating means for, when the first and second signals are sequentially displaced relative to each other, and an evaluation amount representing a coincidence between the first and second signals at the relatively displaced positions is calculated, performing filter processing of the first and second signals, obtaining deviations between the first and second object images on the basis of a change in evaluation amount, and detecting the imaging state of the imaging optical system, wherein said calculating means has a first processing step of performing the filter processing using a filter determined by the relative displacement and a second processing step, performed next to the first processing step, of performing the filter processing using a fixed filter regardless of the relative displacement, and said filter in the second processing step is determined on the basis of the image deviation obtained in the first processing step.

6. A focus detection apparatus comprising an optical system for forming first and second optical distributions associated with object images whose relative positional relationship is changed in accordance with an imaging state of an imaging optical system subjected to focus detection, photoelectric converting means, having a plurality of picture elements, for outputting first and second signals respectively corresponding to the first and second optical distributions, and calculating means for, when the first and second signals are sequentially displaced relative to each other, and an evaluation amount representing a coincidence between the first and second signals at the relatively displaced positions is calculated, performing filter processing of the first and second signals, Wherein the first and second signals are respectively processed through filters having mutually different characteristics, using a filter determined by the relative displacement, obtaining deviations between the first and second object images on the basis of a change in evaluation amount, and detecting the imaging state of the imaging optical system, wherein said filter corrects the first and second signals even when the relative displacement is zero.

7. A focus detection apparatus comprising an optical system for forming first and second optical distributions associated with object images whose relative positional relationship is changed in accordance with an imaging state of an imaging optical system subjected to focus detection, photoelectric converting means, having a plurality of picture elements, for outputting first and second signals respectively corresponding to the first and second optical distributions, and calculating means for, when the first and second signals are sequentially displaced relative to each other, and an evaluation amount representing a coincidence between the first and second signals at the relatively displaced positions is calculated, performing filter processing of the first and second signals, obtaining deviations between the

first and second object images on the basis of a change in evaluation amount, and detecting the imaging state of the imaging optical system, wherein said calculating means has a first processing step of performing the filter processing using a filter determined by the relative displacement and a second processing step, performed next to the first processing step, of performing the filter processing using a fixed filter regardless of the relative displacement, and further comprises selecting means for selecting one of the first and second processing steps.

8. A focus detection apparatus comprising an optical system for forming first and second optical distributions associated with object images whose relative positional relationship is changed in accordance with an imaging state of an imaging optical system subjected to focus detection, photoelectric converting means, having a plurality of picture elements, for outputting first and second signals respectively corresponding to the first and second optical distributions, and calculating means for, when the first and second signals are sequentially displaced relative to each other, and an evaluation amount representing a coincidence between the first and second signals at the relatively displaced positions is calculated, performing filter processing of the first and second signals, obtaining deviations between the first and second object images on the basis of a change in evaluation amount, and detecting the imaging state of the imaging optical system, the filter processing being performed using a filter determined by a distance from an optical axis of the imaging optical system subjected to focus detection to a distance measuring field determined by said photoelectric converting means.

9. A focus detection apparatus comprising an optical system for forming first and second optical distributions associated with object images whose relative positional relationship is changed in accordance with an imaging state of an imaging optical system subjected to focus detection, photoelectric converting means, having a plurality of picture elements, for outputting first and second signals respectively corresponding to the first and second optical distributions, and calculating means for, when the first and second signals are sequentially displaced relative to each other, and an evaluation amount representing a coincidence between the first and second signals at the relatively displaced positions is calculated, performing filter processing of the first and second signals using a filter determined by the relatively displaced positions, obtaining image deviations between the first and second object images on the basis of a change in evaluation amount, and detecting the imaging state of the imaging optical system, wherein said filter has only a positive component in one direction and positive and negative components in the other direction with respect to an origin.

10. A focus detection apparatus comprising an optical system for forming first and second optical distributions associated with object images whose relative positional relationship is changed in accordance with an imaging state of an imaging optical system subjected to focus detection, photoelectric converting means, having a plurality of picture elements, for outputting first and second signals respectively corresponding to the first and second optical distributions, and calculating means for, when the first and second signals are sequentially displaced relative to each other, and an evaluation amount representing a coincidence between the first and second signals at the relatively displaced positions is calculated, performing filter processing of the first and second signals, obtaining deviations between the first and second object images on the basis of a change in evaluation amount, and detecting the imaging state of the imaging optical system, wherein said calculating means has a first processing step of performing filter processing of the first signal and a second processing step of performing filter processing of the second signal, and a filter used in the second processing step has characteristics obtained by inverting a filter used in the first processing step.

11. A focus detection apparatus comprising an optical system for forming first and second optical distributions associated with object images whose relative positional relationship is changed in accordance with an imaging state of an imaging optical system subjected to focus detection, photoelectric converting means, having a plurality of picture elements, for outputting first and second signals respectively corresponding to the first and second optical distributions, and calculating means for, when the first and second signals are sequentially displaced relative to each other, and an evaluation amount representing a coincidence between the first and second signals the relatively displaced positions is calculated, performing filter processing of the first and second signals using a filter determined by the relatively displaced positions, obtaining image deviations between the first and second object images on the basis of a change in evaluation amount, and detecting the imaging state of the imaging optical system, wherein said photoelectric converting means has picture elements used in the filter processing, which are located outside picture elements whose outputs are used to calculate the evaluation amounts.

12. A focus detection apparatus comprising an optical system for forming first and second optical distributions associated with object images whose relative positional relationship is changed in accordance with an imaging state of an imaging optical system subjected to focus detection, photoelectric converting means, having a plurality of picture elements, for outputting first and second signals respectively corresponding to the first and second optical distributions, and calculating means for, when the first and second signals are sequentially displaced relative to each other, and an evaluation amount representing a coincidence between the first and second signals at the relatively displaced positions is calculated, performing filter processing of the first and second signals using a filter determined by the relatively displaced positions, obtaining image deviations between the first and second object images on the basis of a change in evaluation amount, and performing a defocus conversion calculation of the image deviation to form a signal representing the imaging state of the imaging optical system, wherein the defocus conversion calculation of the image deviation is a function of an aperture ratio of the imaging optical system subjected to focus detection.

13. A focus detection apparatus comprising an optical system for forming first and second optical distributions associated with object images whose relative positional relationship is changed in accordance with an imaging state of an imaging optical system subjected to focus detection, photoelectric converting means, having a plurality of picture elements, for outputting first and second signals respectively corresponding to the first and second optical distributions, and calculating means for, when the first and second signals are sequentially displaced relative to each other, and an evaluation

amount representing a coincidence between the first and second signals at the relatively displaced positions is calculated, performing filter processing of the first and second signals using a filter determined by the relatively displaced positions, obtaining image deviations between the first and second object images on the basis of a change in evaluation amount, and performing a defocus conversion calculation of the image deviation to form a signal representing the imaging state of the imaging optical system, wherein the defocus conversion calculation of the image deviation is a function of an exit pupil position of the imaging optical system subjected to focus detection.

14. A focus detection apparatus comprising an optical system for forming first and second optical distributions associated with object images whose relative positional relationship is changed in accordance with an imaging state of an imaging optical system subjected to focus detection, photoelectric converting means, having a plurality of picture elements, for outputting first and second signals respectively corresponding to the first and second optical distributions, and calculating means for, when the first and second signals are sequentially displaced relative to each other, and an evaluation amount representing a coincidence between the first and second signals at the relatively displaced positions is calculated, performing filter processing of the first and second signals using a filter determined by the relatively displaced positions, obtaining image deviations between the first and second object images on the basis of a change in evaluation amount, and performing a defocus conversion calculation of the image deviation to form a signal representing the imaging state of the imaging optical system, wherein the defocus conversion calculation of the image deviation is a function of a representative distance from an optical axis of said imaging optical system subjected to focus detection to a distance measuring field determined by said photoelectric converting means comprising the plurality of picture elements.

15. A focus detection apparatus comprising:

an optical system for forming first and second optical distributions associated with object images whose relative positional relationship is changed in accordance with an imaging state of an imaging optical system;

photoelectric converting means, having a plurality of picture elements, for outputting first and second signals respectively corresponding to the first and second optical distributions;

filter processing means for employing filter-processing wherein the first and second signals are respectively processed through filters having mutually different characteristics; and

detection means for detecting a focal point state of said imaging optical system on the basis of the first and second signals to which said filter-processing is applied.

[57] **ABSTRACT**

There is provided a multifunction coaxial objective system (**16**) for a laser rangefinder (**10**). The transmitter, receiver, and viewing optical systems have a common, coaxial optical axis (**48**). The multifunction coaxial objective system (**16**) includes lenses (**28**), (**30**) and mirror (**32**) each having a central obscuration therein. The multifunction coaxial objective system (**16**) further includes a lens (**34**) having a dichroic coating on one surface (**50**). The dichroic coated lens (**34**) transmits visible and near infrared light and reflects light of the wavelength transmitted by a laser emitter (**18**). The viewing optical system includes a pair of focusing wedges (**42**), (**44**) for adjusting the focus of the viewing optical system. Each focusing wedge (**42**), (**44**) is a wedge-shaped optical flat. The pair of focusing wedges (**42**), (**44**) are disposed against one another along a plane inclined with respect to the coaxial optical axis (**48**) of the multifunction coaxial objective system (**16**). Focus adjustment is achieved by relative movement between the focusing wedges (**42**), (**44**) along the inclined plane. The multifunction coaxial objective system (**16**) of the present invention may alternatively be incorporated into a rangefinder and camera for example.

FIG. 2

MULTIFUNCTION COAXIAL OBJECTIVE SYSTEM FOR A RANGEFINDER

TECHNICAL FIELD OF THE INVENTION

The present invention relates to optical systems and, more particularly to an improved optical system for a laser rangefinder having coaxial viewing, transmitting, and receiving channels.

BACKGROUND OF THE INVENTION

Laser rangefinders are well known in the rangefinding art. A laser rangefinder emits one or more laser pulses toward an object the range of which is to be determined. The laser pulses reflect from the object back to the rangefinder, and are detected by a laser detector. The length of time between emission of each laser pulse and its detection by the laser detector is measured by a timer clock, and the range is determined from this time period. A numerical range figure may be displayed on a suitable electronic display on the rangefinder, or may be printed on a remote paper printer, for example.

Typical laser rangefinders of the prior art have three separate optical channels: a channel for the transmitting optics, a channel for the receiving optics, and a channel for the viewing optics. Each of these optical channels typically has its own distinct optical axis. A few laser rangefinders have been designed in which the receiving and viewing channels are coaxial. However, there are no known laser rangefinders with coaxial transmitting, receiving and night viewing channels. Such a rangefinder having coaxial optics for all three functions is highly desirable for reducing size, weight, and cost of the rangefinder.

A second disadvantage with laser rangefinders of the prior art resides in the lens system for focusing the viewing optics. A typical focusing system requires relative movement between the viewing lens and the transmitter and receiver optics. This relative movement between the viewing and the rangefinder optics contributes to boresight loss, parallax, and alignment stability problems in the rangefinder.

Consequently, a need exists for a laser rangefinder with an improved optical system which uses a single optical channel for transmitting, receiving and viewing functions. Preferably, such an improved laser rangefinder will have an optical system which permits focus adjustment for the viewing system without relative movement between the viewing lens and the transmitter or receiver optics. Such an improved laser rangefinder will further preferably have night vision capability.

SUMMARY OF THE INVENTION

The present invention provides a laser rangefinder and night vision goggle having an improved optical system. The transmitter, receiver, and viewing optical systems have coaxial optical axes. The improved optical system includes at least one optical element having a central obscuration therein. The improved optical system further includes a lens having a dichroic coating on one surface for transmitting visible and near infrared light and for reflecting light of the wavelength transmitted by the laser emitter. The viewing optical system includes a pair of focusing wedges for adjusting the focus of the viewing optical system. Each focusing wedge is a wedge-shaped optical flat, the pair of focusing wedges being disposed against one another along a plane inclined with respect to the optical axis of the viewing optical system, whereby focus adjustment is achieved by relative movement between the focusing wedges along the inclined plane.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a top, cross-sectional schematic view of a laser rangefinder and night vision goggle of the present invention.

FIG. **2** is an enlarged schematic view of the improved optical system of the present invention, illustrating the path of representative rays through the optical system.

DETAILED DESCRIPTION OF THE INVENTION

The preferred embodiment of the present invention and its advantages are best understood by referring to the drawings, like numerals being used for like and corresponding parts of the various drawings.

Referring now to the drawings, and more particularly to FIG. **1**, there is shown a top, cross-sectional view of a laser rangefinder and night vision goggle, generally designated **10**, which incorporates the preferred embodiment of the present invention. Rangefinder and night vision goggle **10** comprises a housing **12** having on its rear a pair of eyepieces **14**. The front portion of housing **12** contains the improved optical system or multifunction coaxial objective system, generally designated **16**, of the present invention. Improved optical system **16** includes a transmitter optical system, a receiver optical system, and a viewing or imaging optical system.

The transmitter optical system includes laser emitter **18**, folding mirror **20**, lens **22**, folding mirror **24**, and lens **26**. Laser emitter **18** is preferably a triple emitting region, pulsed output, semiconductor laser diode. The preferred commercially available laser diode that may be used for laser emitter **18** is the EG&G Model C86091E which emits laser energy of 1.55 μm wavelength. Alternatively, the Stantel LE Series Type LE25-02 diode, having a 905 nm pulsed output, may be used for emitter **18**. Mirrors **20** and **24** are commercially available, optical grade, flat mirrors which are well known in the art. The lens prescription and mounting distance data for lenses **22** and **26** are listed in Table I. Listed in order from left to right are: (1) the lens surface number; (2) the radius of curvature of the surface (mm) (positive (+) radii for centers of curvature to right of lens surface, and negative (−) radii for centers to left of surfaces); (3) the lens axial thickness, or distance to the next surface (mm); (4) the clear aperture radius (mm); and (5) the lens material.

TABLE I

SURFACE NO.	RADIUS OF CURVATURE (mm)	THICKNESS (mm)	CLEAR APERTURE RADIUS (mm)	MATERIAL
93	70.75	5.73	22.0	BK7
94	∞	74.83	21.7	AIR
95	−41.32	3.10	9.5	SFL6
96	−68.89	110.82	9.5	AIR
97	∞	—	—	AIR

The receiver optical system includes lens **28**, lens **30**, mirror **32**, lens **34**, lens **36**, and laser detector **38**. Table II lists the preferred lens prescription and mounting distance data for the receiver optical system. Listed in

order from left to right are: (1) the lens surface number; (2) the radius of curvature of the surface (mm) (positive (+) radii for centers of curvature to right of lens surface, and negative (−) radii for centers to left of surface); (3) the lens axial thickness, or distance to the next surface (mm); (4) the lens material; (5) the clear aperture radius (mm); and (6) the central obscuration radius (mm), if any.

TABLE II

SURFACE NO.	RADIUS OF CURVATURE (mm)	THICKNESS (mm)	MATERIAL	CLEAR APERTURE RADIUS (mm)	CENTRAL OBSCURATION RADIUS (mm)

The viewing optical system includes lens **28**, lens **30**, mirror **32**, lens **34**, lens **40**, focusing wedges or optical flats **42** and **44**, and image intensifier tube **46**. Table III lists the preferred lens prescription and mounting distance data for the viewing optical system. Listed in order from left to right are: (1) the lens surface number; (2) the radius of curvature of the surface (mm) (positive (+) radii for centers of curvature to right of lens Surface, and negative (−) radii for centers to left of surface); (3) the lens axial thickness, or distance to the next surface (mm); (4) the lens material; (5) the clear aperture radius (mm); and (6) the central obscuration radius (mm), if any. Image intensifier tube **46** permits night vision when the present invention is incorporated in a night vision goggle.

				IMAGE	

Referring now to FIG. **2**, there is shown an enlarged, cross-sectional view of the improved optical system **16** of the present invention. One of the important features of this invention is that the transmitter, receiver, viewing optical systems are coaxial in object space, sharing a common optical axis **48**. The innovative means by which all three of these optical systems have a common optical axis is another important feature of this invention, and is explained hereinafter.

As seen in FIG. **2**, lenses **28** and **30** and mirror **32** together comprise the major part of a catadioptric lens system. A catadioptric lens system is one in which both reflecting and refracting elements are used to form its focal power. The central portions of these lenses and mirror are not used for imaging. This unused, central area of lenses **28** and **30** and mirror **32** is referred to as the central obscuration or centrally obscured region and is used instead for portions of the transmitter and/or receiver optical systems. The use of these optical elements having central obscurations therein constitutes an important feature of this invention. As seen in FIG. **2**, laser energy transmitted by laser emitter **18** passes through the central obscuration of lens **28**. Laser energy received by lens **28** focuses to laser detector **38** situated within the central obscuration of lens **30**. Finally, the visible image produced by the viewing optical system passes through the central obscuration of mirror **32**. Thus, the central obscuration of each of lenses **28** and **30** and mirror **32** are used by a different optical system of the present invention.

As seen in FIG. **2**, lens **36** of the receiver optical system is located in the central obscuration of lens **30**. Lens **34**, used in both the viewing and receiving optical systems, and lens **40** of the viewing optical system, are located in the central obscuration of mirror **32**. Lens **26** of the transmitting optical system is located adjacent to and within the centrally obscured region of lens **28**. Laser detector **38** is located adjacent to lens **36**, and within the centrally obscured region of lens **30**.

It should be noted that the inner surface **67** of the side of lens **30** which faces lens **34** is mirror coated, whereas the outer surface **65** of this side of lens **30** is uncoated. Surface **67** of lens **30** is mirror coated to reflect light from mirror **32** to lens **34**. Surface **65** of lens **30** is uncoated to permit light to pass through lens **30** to mirror **32**.

A key aspect of this invention resides in the dichroic coating applied to side **50** of lens **34**. The dichroic coating on side **50** of lens **34** transmits visible and near infrared light produced by the viewing optical system to the image intensifier tube **46**, but reflects light or laser energy of the wavelength transmitted by the laser emitter **18** back to laser detector **38**. Dichroic coated lens **34** thus performs a dual function as a short wavelength pass filter in transmitting visible and near infrared light for the viewing optical system and in reflecting laser energy for the receiver optical system.

The wavelength transmitted by the EG&G Model C86091E laser diode, the preferred choice for laser emitter **18**, is 1.55 μm. Dichroic coatings suitable for this application are well known in the art, and are commercially available. Dichroic coated lens **34** is preferably located at least partially within the central obscuration of mirror **32**. Alternatively, dichroic coated lens **34** may be located adjacent to and near the central obscuration of mirror **32**.

FIG. **2** also illustrates another important feature of this invention: The viewing optical system includes a

pair of focusing wedges **42** and **44** for adjusting the focus of visual images transmitted to image intensifier tube **46**. Each focusing wedge **42** and **44** is a wedge-shaped optical flat. The two optical flats **42** and **44** are disposed against one another along a plane **52** which is inclined with respect to the common optical axis **48**. Focus adjustment for the viewing optical system is achieved by relative movement between focusing wedges **42** and **44** along inclined plane **52**. This relative movement changes the combined optical thickness of the pair of focusing wedges **42** and **44**, thereby adjusting the focus of the viewing optical system.

The relative movement between focusing wedge **42** and **44** may be achieved by one of several alternative means. In the preferred embodiment, focusing wedges **42** and **44** are simultaneously moved along plane **52** in opposite directions by rotating a knob (not illustrated) attached to housing **12**. The rotatable knob is attached to focusing wedges **42** and **44** through a suitable linkage (not illustrated). Alternatively, focusing wedges **42** and **44** may be moved along plane **52** in opposite directions by a pivotable lever (not illustrated) attached to housing **12**. The pivotable lever is attached to focusing wedges **42** and **44** through a suitable linkage (not illustrated). Focus adjustment may also be achieved by moving only one of focusing wedges **42** or **44** along inclined plane **52**, the other focusing wedge **42** or **44** being held stationary. For a handheld rangefinder, displacement of focusing wedge **42** or **44** by approximately $\frac{3}{4}$ inch would be sufficient to adjust the viewing system focus over the required range.

The improved optical system **16** of the present invention has been described and illustrated as it might be incorporated in a handheld laser rangefinder and night vision goggle or viewer. Although not illustrated or described in detail, an alternative embodiment of the improved optical system of the present invention might be a laser rangefinder and camera, for example. In this embodiment, a camera film plane would be substituted for the image plane of the image intensifier tube of the described embodiment. Still another embodiment of this invention might be a laser rangefinder alone. In this embodiment, only the coaxial transmitter and receiver optical systems would be included, without the viewing optical system. Such a rangefinder might be used in a motion detector for a security system, in an aircraft altitude sensor, or in a vehicle separation sensor.

The laser rangefinder multifunction coaxial objective system of the present invention, and many of its intended advantages, will be understood from the foregoing description and it will be apparent that, although the invention and its advantages have been described in detail, various changes, substitutions, and alternations may be made in the manner, procedure, and details thereof without departing from the spirit and scope of the invention, as defined by the appended claims, or sacrificing all of its material advantages. The form hereinbefore described being merely a preferred or exemplary embodiment thereof.

We claim:

1. An improved optical catadioptric lens system for a rangefinder suitable for use as part of a night vision goggles system, comprising:

a transmitter optical system having an optical axis;

a receiver optical system having an optical axis;

an image intensifier; and

a viewing optical system adapted for receiving an image from the image intensifier, the viewing optical system having an optical axis, wherein the optical axes of the transmitter optical system, the receiver optical system, and the viewing optical system are coaxial in object space.

2. The improved optical system of claim **1**, wherein the viewing optical system includes a plurality of optical elements having central obscurations therein.

3. The improved optical system of claim **2**, wherein a visible and near infrared image produced by the viewing optical system passes through the central obscuration of a first optical element of the plurality of optical elements.

4. The improved optical system of claim **2**, wherein the rangefinder includes a laser emitter and a laser detector.

5. The improved optical system of claim **4**, wherein the optical axis of the laser emitter of the rangefinder is offset with respect to the coaxial axis of the transmitter, receiver, and viewing optical system, and wherein the transmitter optical system includes at least one folding mirror for reflecting laser energy from the laser emitter into a path concentric with the coaxial axis of the transmitter, receiver, and viewing optical systems.

6. The improved optical system of claim **4**, wherein laser energy transmitted by the laser emitter passes through the central obscuration of a second optical element of the plurality optical elements.

7. The improved optical system of claim **4**, wherein laser energy received by the laser detector passes through the central obscuration of the optical element.

8. The improved optical system of claim **4**, wherein the laser detector is located in the central obscuration of the optical element.

9. The improved optical system of claim **4**, further including a lens having a dichroic coating on one surface for transmitting visible and near infrared light and for reflecting light of the wavelength transmitted by the laser emitter.

10. The improved optical system of claim **9**, wherein the dichroic coated lens is located in the central obscuration of the optical element.

11. The improved optical system of claim **1**, wherein the viewing optical system includes an image intensifier tube for permitting night vision.

12. The improved optical system of claim **1**, wherein the viewing optical system includes a pair of focusing wedges for adjusting the focus of the viewing optical system.

13. The improved optical system of claim **12**, wherein each focusing wedge is a wedge shaped optical flat, the pair of focusing wedges being disposed against one another along a plane inclined with respect to the optical axis of the viewing optical system, whereby focus adjustment is achieved by relative movement between the focusing wedges along the inclined plane.

14. The improved optical system of claim **13**, further including means for moving at least one of the focusing wedges with respect to the other focusing wedge along the inclined plane for changing the optical thickness of the pair of focusing wedges, and thereby adjusting the focus of the viewing optical system.

15. The improved optical system of claim **14**, further including a housing for supporting the improved optical system, and wherein the means for moving at least one of the focusing wedges with respect to the other focusing wedge is a rotatable knob attached to the housing.

16. The improved optical system of claim **14**, further including a housing for supporting the improved optical

system, and wherein the means for moving at least one of the focusing wedges with respect to the other focusing wedge is a pivotable lever attached to the housing.

17. An improved optical catadioptric lens system for a rangefinder suitable for use as part of a night vision goggles system, the improved system including a laser emitter and a laser detector, the improved optical system comprising:

a viewing optical system;

an image intensifier adapted for projecting an image to the viewing optical system for viewing;

a transmitter optical system having an optical axis for transmitting laser energy from the laser emitter;

a receiver optical system having an optical axis for permitting the laser detector to receive laser energy, wherein the optical axes of the transmitter optical system and the receiver optical system are coaxial in object space; and

at least one optical element having a central obscuration therein included within the receiver optical system, wherein laser energy transmitted by the laser emitter passes through the central obscuration of the optical element.

18. The improved optical system of claim 17, wherein the optical axis of the laser emitter of the rangefinder is offset with respect to the coaxial axis of the transmitter and receiver optical systems, and wherein the transmitter optical system includes at least one folding mirror for reflecting laser energy from the laser emitter into a path concentric with the axis of the transmitter and receiver optical systems.

19. The improved optical system of claim 17, wherein laser energy received by the laser detector passes through the central obscuration of the optical element.

20. The improved optical system of claim 17, wherein the laser detector is located in the central obscuration of the optical element.

21. The improved optical system of claim 17, further including a viewing optical system having an optical axis, wherein the optical axes of the transmitter optical system, the receiver optical system, and the viewing optical system are coaxial in object space.

22. The improved optical system of claim 21, wherein at least one of the viewing optical system and the receiver optical system includes a lens having a dichroic coating on one surface, for transmitting visible and near infrared light, and for reflecting light of the wavelength transmitted by the laser emitter.

23. The improved optical system of claim 21, wherein the viewing optical system includes a pair of focusing wedges for adjusting the focus of the viewing optical system.

24. The improved optical system of claim 23, wherein each focusing wedge is a wedge shaped optical flat, the pair of focusing wedges being disposed against one another along a plane inclined with respect to the optical axis of the viewing optical system, whereby focus adjustment is achieved by relative movement between the focusing wedges along the inclined plane.

25. The improved optical system of claim 24, further including means for moving at least one of the focusing wedges with respect to the other focusing wedge along the inclined plane for changing the optical thickness of the pair of focusing wedges, and thereby adjusting the focus of the viewing optical system.

26. The improved optical system of claim 25, further including a housing for supporting the improved optical system, and wherein the means for moving at least one of the focusing wedges with respect to the other focusing wedge is a rotatable knob attached to the housing.

27. The improved optical system of claim 25, further including a housing for supporting the improved optical system, and wherein the means for moving at least one of the focusing wedges with respect to the other focusing wedge is a pivotable lever attached to the housing.

28. The improved optical system of claim 21, wherein the viewing optical system includes an image intensifier tube for permitting night vision.

29. A night vision goggle and rangefinder, comprising:

a housing;

a laser emitter having an optical axis supported within the housing;

a laser detector supported within the housing;

a transmitter optical system having an optical axis supported within the housing;

a receiver optical system having an optical axis supported within the housing;

a viewing optical system having an optical axis supported within the housing, wherein the optical axes of the transmitter optical system, the receiver optical system, and the viewing optical system are coaxial in object space;

an image intensifier tube included within the viewing optical system for permitting night vision;

a first optical element supported within the housing and having a central obscuration therein, wherein a visible image produced by the viewing optical system passes through the central obscuration of the first optical element;

a second optical element supported within the housing and having a central obscuration therein, wherein laser energy received by the laser detector passes through the central obscuration of the second optical element;

a third optical element supported within the housing and having a central obscuration therein, wherein laser energy transmitted by the laser emitter passes through the central obscuration of the third optical element;

a lens having a dichroic coating on one surface in at least one of the viewing optical system and the receiver optical system, for transmitting visible and near infrared light to the image intensifier tube and for reflecting laser energy received by the receiver optical system to the laser detector; and

a pair of focusing wedges for adjusting the focus of the viewing optical system, each focusing wedge being a wedge-shaped optical flat, the pair of focusing wedges being disposed against one another along a plane inclined with respect to the coaxial axis of the transmitter, receiver, and viewing optical systems, whereby focus adjustment is achieved by relative movement between the focusing wedges along the inclined plane.

30. The night vision goggle and rangefinder of claim 29, wherein the optical axis of the laser emitter is offset with respect to the coaxial axis of the transmitter, receiver, and viewing optical systems, and wherein the transmitter optical system includes at least one folding mirror for reflecting laser energy from the laser emitter into a path concentric with the coaxial axis of the transmitter, receiver, and viewing optical systems.

31. The night vision goggle and rangefinder of claim 29, further including means for moving at least one of the focusing wedges with respect to the other focusing

wedge along the inclined plane for changing the optical thickness of the pair of focusing wedges, and thereby adjusting the focus of the viewing optical system.

32. The night vision goggle and rangefinder of claim **31**, wherein the means for moving at least one of the focusing wedges with respect to the other focusing wedge is a rotatable knob attached to the housing.

33. The night vision goggle and rangefinder of claim **31**, wherein the means for moving at least one of the focusing wedges with respect to the other focusing wedge is a pivotable lever attached to the housing.

[57] **ABSTRACT**

A lens system for a folding reflex camera is provided. The system includes: (a) a first group on the object side of the system's stop which (i) has a positive dioptric power, (ii) includes an aspheric surface, and (iii) has a concave surface adjacent to the stop; and (b) a second group on the image side of the stop consisting of either a single positive component or the combination of a single positive component and one or more focusing elements. The system includes at least two elements made of materials differing in dispersive powers where at least one of the elements is of plastic. The system can comprise just two plastic elements and even with such a simple configuration achieves excellent optical performance including a relatively flat field, relatively low distortion, and at least partial correction for lateral chromatic aberration.

COMPACT OBJECTIVE LENS

FIELD OF THE INVENTION

This invention relates to objective lens systems for use in cameras and, in particular, to objective lens systems for use in folding, reflex cameras.

BACKGROUND OF THE INVENTION

1. Description of the Prior Art

Numerous objective lens systems for cameras have been proposed. Examples employing two elements include Simpson, Jr. et al., U.S. Pat. Nos. 4,932,764 and 5,000,552, and Davis, U.S. Pat. No. 2,586,418. See also Aldis, U.S. Pat. No. 682,017, discussed below. A two element lens for use in a copying machine, as opposed to a camera, is disclosed in Japanese Patent Publication No. 3-242608. Similarly, Rothe, U.S. Pat. No. 4,645,311, discloses a two element design including an aspheric surface for use in an optical scanner.

Three element designs include Bertele, U.S. Pat. No. 2,721,501, Grey, U.S. Pat. No. 3,784,287, De Jager, U.S. Pat. No. 3,967,884, and Sato, U.S. Pat. No. 4,542,961 in which an aspheric surface is used, as well as the early Cooke/Taylor triplet and variations thereof. See Kingslake, R., *A History of the Photographic Lens*, Academic Press, New York, 1989, pages 103–115.

The incorporation of a focusing element or group in an objective lens system is disclosed in the following patents: Westphalen, U.S. Pat. Nos. 3,185,061 and 3,388,650, Laurent, U.S. Pat. No. 4,174,153, Yamada, U.S. Pat. No. 4,394,071, Owen, Jr. et al., U.S. Pat. No. 4,443,067, Wakabayashi, U.S. Pat. No. 4,669,848, Nishi et al., U.S. Pat. No. 4,791,441, Nakayama et al., U.S. Pat. No. 4,830,474, Takase, U.S. Pat. No. 4,913,537, and Ogawa et al., U.S. Pat. No. 5,005,038. A construction of this general type for use in a viewfinder is disclosed in Wakamiya, U.S. Pat. No. 4,832,470. A magnifying lens employing an aspheric surface for attachment to the objective of a camera is disclosed in Baker, U.S. Pat. No. 3,604,786, and the use of an auxiliary lens for short range work is disclosed in Noguchi, U.S. Pat. No. 4,505,566.

Also of interest is U.S. Pat. No. 697,959, dated Apr. 22, 1902 to Ernst Abbe. He discusses how an aspheric surface can be used to improve far off-axis performance of a landscape type lens (cemented doublet and stop).

Notwithstanding the variety of objective lens systems which have been previously proposed, there still exists a need for lens systems of relatively simple construction which can be mass produced at low cost. In particular, such systems are needed in the field of multiple purpose hand cameras which are used by individuals and families, as well as for commercial applications, such as in the preparation of advertisements and the like, where small scale photographs of good to excellent quality can be useful and economic.

The present invention addresses this need and provides objective lens systems which 1) contain a minimum number of elements, 2) can be manufactured at low cost, and 3) have optical and physical properties suitable for use in a mass produced camera.

2. Design Principles

As is known from basic optical principles, even a simple, single lens element with spherical surfaces possesses a paraxial image position conjugate to an object distance, and an equivalent focal length, which together comprise the element's "Gaussian" optics of first order magnitude. For a rotational lens system, the usual case for practical objectives intended for mass production, there are no second order aberrations.

The chromatic variations of both image location and image size, that is to say, longitudinal and lateral chromatic aberrations, can be construed as of third order in magnitude. For the monochromatic third order of approximation and, in particular, for the development of a power series which represent the x and y intercepts on the image surface of a light ray from an object point after transit through the optical system, there will be five independent mathematical coefficients of series terms which represent the conditions to be reduced essentially to zero or at least to optimized small non-zero values. These "Seidel" coefficients in physical meaning have to do with spherical aberration, coma, astigmatism, curvature of field, and distortion.

The development of the associated power series can be carried out in explicit formulations of object distance, curvature of the object surface if any, off-axis position of the object point, intercepts of a given ray in the entrance pupil, or the equivalent in image space, and the like. Thus, the x and y intercepts of a given ray on a desired image surface can be given as a power series in 5 variables, one of which is the wavelength, or in 4 variables monochromatically, or even in 3 if rotational relationships are employed. The variables may be simple, as for example the direction of the object point as seen from the center of the entrance pupil (2 variables), and the x and y intercepts of a ray from the object point on the entrance pupil, or in terms of selected functions of the simple variables. The design task if formulated in simplest terms is to bring all rays from an object point into sharp focus at an image point. The location of the image point may not be exactly where desired but may include a displacement in x, y and z according to allowable tolerances. For example, a lateral displacement in the image surface may be permitted to some degree, in the nature of distortion, one of the Seidel conditions.

In the fifth order of approximation one encounters nine monochromatic aberrations, plus chromatic variations of the five Seidel conditions, and secondary chromatic variations of the image position in longitudinal displacement, as well as secondary chromatic variations of magnification, or of the equivalent focal length if the object plane lies at infinity. Higher orders of power series approximation have been worked out by various theorists, but the complexities of solution are such as to confine the higher order formulas generally to analysis rather than to synthesis of optical structures.

The above mentioned power series contain the basic parameters of construction of the optical system, such as the radii of curvature of the multiple surfaces, the axial spacings of the surfaces, the indices of refraction of the media used, including the wavelength dependence in some mathematical form, and if any particular surface is aspheric, that is, nonspherical, the aspheric coefficients that define the shape of the surface according to the order of approximation. The object of the invention is thus to select a set of parameters which can be used to cost-effectively to produce an objective lens system which can be successfully employed for family or general purpose applications and the like.

3. Historic Lens Designs

In the past, so-called landscape lenses have combined a single meniscus lens element with spherical surfaces with a stop at an optimum location in the lens barrel,

such that one can say that the meniscus is curved in a general sense about the stop. Even if the aperture-ratio is quite limited, as for example, f/16 or slower, such a landscape lens is afflicted with distortion. With the stop forward, the distortion is barrel in nature, and if the stop is rearward of the meniscus, the distortion is pin-cushion. If the stop is rearward, the overall length is accordingly reduced. In addition, compromises have to be made with curvature of field, chromatic aberrations, astigmatism and residual aberrations of spherical aberration and coma. Nevertheless, vast numbers of family photographs have been made by means of such simplified objectives, optimized as well as may be from the complex of considerations.

In accordance with the invention, it has been found that the optical performance can be improved even for a plastic material having a relatively low index and moderate dispersion characteristics by means of at least one surface of the meniscus becoming aspheric. Use of an aspheric of optimum shape has been found to reduce distortion and to reduce astigmatism to a level sufficient to flatten the mean image surface. By means of modern manufacturing techniques known in the art the use of at least one aspheric surface per plastic element is practical for mass production.

As discussed in detail below, the photographic objective of the present invention has two lens groups, one before a centrally located stop and one after. Thus, in general terms, it can be considered to resemble that of the Aldis lens (see Aldis, U.S. Pat. No. 682,017, issued Sep. 3, 1901).

Symmetrical or nearly symmetrical objectives of two meniscus elements enclosing a central stop are known in the art and have many uses, particularly for medium to wide angle performance where a "slow" lens may be used. The well-known "Hypergon", U.S. Pat. No. 706,650 by Carl Paul Goerz, which at a high aperture-ratio such as f/60 can cover very wide angle fields on a nearly flat image surface, uses this approach. The symmetry of the arrangement eliminates most of the coma even for an infinite object distance, although not entirely. The very restrictive central stop reduces the spherical aberration and longitudinal chromatic aberrations to manageable proportions and the rest of the residual coma as well. The effectiveness of the thin Hypergon menisci arises from the near optical cancellation of the convex and adjacent concave surfaces of the individual meniscus, the power, though low, coming partly from the separation of the convex and concave surfaces, that is, from the thickness of the individual meniscus. An optimization causes the tangential and radial image surfaces to lie close to a mean nearly flat image surface and to one another as well.

A difficulty with the more or less symmetrical double meniscus form is that the principal points and indeed the perspective center lie more or less within a rather long lens barrel. The overall length of the objective from front surface vertex to the axial point of the image surface is thereby greater than the equivalent focal length, resulting usually in a lack of compactness in the camera itself. Indeed, an important requirement of the modern hand camera is compactness. Another requirement is that the clear apertures of front and rear surfaces be relatively modest which means that the menisci cannot be very far from the central stop, front and rear, if an adequate field of view is to be covered.

Unsymmetrical objectives employing at least one strong meniscus component preceding the stop, which in some cases is only a single element, are also known in the art. This structure enhances several characteristics of the front element of the Hypergon. The inner concave surface opposed to and lying at a moderate axial distance from the stop provides to some extent for a reduced Petzval sum and reduction in astigmatism caused by the meniscus component as a whole, while at the same time a substantial thickness of the meniscus component preserves much of the net lens power needed for focusing the oncoming rays from a distance object. These historic designs, however, have not achieved the optical performance at low cost which the present invention achieves.

SUMMARY OF THE INVENTION

In accordance with certain of its aspects, the invention provides a lens system which comprises:

(a) a first group on the object side of the system's stop or aperture which (i) has a positive dioptric power, (ii) includes a concave surface preceding and adjacent to the stop or aperture, and (iii) includes at least one aspheric surface; and

(b) a second group on the image side of the stop or aperture consisting of a single component having only two air surfaces and a positive power;

the overall system

(i) having a total diagonal field of view not exceeding about 60 degrees;

(ii) having a relatively flat or weakly concave field;

(iii) having relatively low distortion;

(iv) being corrected at least partially for lateral chromatic aberration; and

(v) having at least two elements made of plastic materials differing in dispersive powers, where at least one of the elements is plastic.

In certain embodiments, the second group includes an aspheric surface. In other embodiments, the second group includes means for focusing the system over a range of object distances from infinity down to about 4.0 times the effective focal length of the system.

In its simplest form, the lens system includes just two elements. Even for this level of simplicity, the system achieves excellent performance, particularly with regard to correction of lateral color and distortion (see below). This is, in part, a consequence of the use of a thick front element, the choice of materials for their dispersion, and their sequence.

The thick front element, while appearing strongly positive, actually is not. In fact, it acts much like a Galilean telescope as evidenced by the nearly parallel bundle of rays in the intervening space between it and the second element (see, for example, FIG. 1A). Most of the power in the system is in the second element.

The shape or bending of the thick front element about the real stop, along with the inclusion of an aspheric surface aids in the control of aberrations as does the use of an aspheric surface with the second element. The entire system may be injection molded for mass production, and the placement of the rear element is relatively insensitive to tilt and decentering errors because, while more positive than the thick front element, it is less positive than the system as a whole.

In overview, the two element embodiment of the invention can be considered an asymmetric system comprising a thick front telescopic element bent about a following real stop which in turn is followed by a more dispersive more powerful positive element.

The accompanying drawings, which are incorporated in and constitute part of the specification, illustrate the preferred embodiments of the invention, and together with the description, serve to explain the principles of the invention. It is to be understood, of course, that both the drawings and the description are explanatory only and are not restrictive of the invention.

BRIEF DESCRIPTION OF THE DRAWINGS

FIGS. **1A-7E** show lens systems constructed in accordance with the present invention. In each of these figures, the configuration of the system is shown in the "A" panel of the figure, the residual astigmatism and distortion as a function of field angle is shown in the "B" panel, the ray aberrations (blur) as a function of position over the field at three different wavelengths is shown in the "C" panel, the MTF versus field angle at the paraxial image surface ($r=-80$ inches) is shown in the "D" panel, and the departure in the modulation at 1 cycle/mm with changes in the position of the image surface of best focus from its nominal or paraxial position is shown in the "E" panel.

FIG. **8** is a perspective view of a folding reflex camera with which the lens systems of the present invention can be used. As shown in this figure, the camera is in its folded configuration.

FIGS. **9** and **10** are perspective and side views, respectively, of the camera of FIG. **8** in its unfolded configuration.

FIGS. **11A-11E** are similar to FIGS. **1A-7E** showing the example of FIG. **3** in conjunction with a close-up lens.

BRIEF DESCRIPTION OF THE TABLES

Tables 1-7 give prescriptions for the examples corresponding to FIGS. **1A** through 7E and Table 8 gives the prescription of the example corresponding to FIG. **11A-11E**.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

1. General Principles and Features

In general terms, the objective lens systems of the present invention have moderate speeds, e.g., f/8 or slower, and field angles no larger than 62 degrees relative to the full diagonal of the format.

As can be seen from the Figures and Tables, the systems may include two plastic elements of differing dispersions, one forward and the other to the rear of a central stop, with not more than one aspheric surface per plastic element. When desired, additional elements in glass or plastic can be included or the rear element may be glass. The lens systems are normally used with photographic film, but can be used with other types or kinds of light-sensitive recording media, such as in all-electronic cameras, infra-red detectors, and the like.

The lens systems are intended for use in imaging objects whose distance from the system is at least four equivalent focal lengths. The systems can have internally disposed focusing means immediately following the stop or objective focusing as a whole can be used. Auxiliary lenses can be added externally or within the objective structure to extend the useful range of object distances, such as for a hyperfocal object distance for scenic shots, or for close-up portrait photography, or for even closer technical or artistic applications.

In terms of overall design, the systems have a first (front) lens group forward of the central stop (to the left in the usual lens drawing) such that the surface adjacent to the stop is a concave "air" surface curved about the stop and such that the first lens group has at least some positive focusing power. The axial bundle emerging from the concave surface and about to pass through the stop thus has convergence and of itself is able to produce a real image at some location to the right in the usual convention. For example, in Example 1 discussed below, the equivalent focal length (EFL) of the first lens group (single element in this instance) is 2.556 in units of the focal length of the objective as a whole. The reciprocal gives the dioptric power, namely, 0.391 where the power of the overall system is 1.000.

If in the general case the dioptric power of the front group is made very small, the positive power of the rear group must be correspondingly large. Such a situation leads to imbalance in distortion correction, astigmatism, coma and even spherical aberration. If the power of the first group is too large, there will again be an imbalance among the various corrections. Accordingly, the range of dioptric power for the first group (K_1) should be between about 0.200 and about 0.500 of the total power of the lens system (K_0), corresponding to a range in the equivalent focal length of the front group from about 5.000 down to about 2.000 relative to the EFL of the entire lens system.

The first group with its weak net positive power can be viewed as a corrector for the rearward strongly positive group, the combination by design yielding a flat or nearly flat mean image surface, which can be optimized to conform to a known non-flat film surface such as may exist on the average when cut film is stacked sequentially in a supply pack, or when the sensitive surface is flat, or only relatively flat for any reason.

The first group includes a meniscus component which serves to reduce the diameter of the oncoming axial bundles of rays defined by the entrance pupil. This, in turn, has a telephoto effect which improves the compactness of the imaging system. Thus, if the effective cross-section of the axial bundle is reduced to, for example, 84% of the bundle in object space, the aperture stop is then small, and the optical focusing by the second group operates on a smaller bundle to produce the desired positive focal length for the system as a whole. The back focus is also reduced which provides for compactness in the camera itself.

For example, in Example 1, the overall length from front vertex to focal point for an infinite object distance is only 0.961 times the EFL of the entire lens system, which represents a great improvement in compactness over the symmetrical double meniscus form. The distance of the stop from the focal point is 0.875 times the EFL, which again accentuates the compactness resulting from the use of the compressing front meniscus component.

The front meniscus component, which is relatively thick, is used in combination with the rear positive group to minimize the aberrations of the lens system. The rear positive group of itself makes a strong positive (undercorrected) contribution to the Petzval sum. For example, in Example 1, the rear group by itself leads to a Petzval image surface of curvature -0.461, where a positive Petzval sum corresponds to a negative curvature, that is, to a concave surface curved about the exit pupil with the center of curvature to the left in the usual lens drawing where light travels from left to right. More specifically, the tangential image surface for the

second group has a curvature of −2.437, and the radial surface −1.120.

The correcting front meniscus component has strong negative (over-corrected) astigmatism and indeed a slightly negative Petzval sum contribution. In combination, the mean field is adequately coincident with a desired weakly cylindrical concave image surface (e.g., a radius of approximately −80 inches corresponding to the curvature of the average sheet in a film pack) and the performance is approximately anastigmatic.

In accordance with the invention the front lens group can take on various forms adapted for variables as the size of the format, the focal length of the lens system, the effective lens speed, the desired materials for the lens elements, the overall complexity and thus cost of the lens system, and the like. While the invention permits complexity of construction and multiple components forward of the stop, consistent with the desired weak convergence, the construction rearward of the stop is confined strictly to one component, that is with but two "air" surfaces whatever the internal construction of the component may be. (As used herein a "group" comprises one or more air-spaced "components," where a "component" has two air-contacting surfaces and is composed of one or more "elements".)

As discussed further below, a focusing means can be inserted between the stop and the rear component. Except for minor readjustments caused by interpolation of such focusing means, the rear component otherwise retains its characteristics. Except for the focusing means, the invention is therefore restricted to a single rearward component having a moderate total central thickness for purposes of improving compactness, and an "air" surface adjacent to the stop or interpolated focusing means that is generally convex or at most weakly concave, according to the field angle or other combinations of parameters.

The total thickness of the rearward component must be at least a reasonable value to allow for the curvatures of its "air" surfaces. The lower limit is small if the component lies relatively near the stop and if the aperture-ratio is moderate, such as f/10, e.g., the lower limit is on the order of 0.01 times the EFL of the entire lens system. The upper limit is on the order of 0.05 times the EFL if numerous cemented elements, which would unduly increase the cost of the lens system, are to be avoided. At this upper limit, the air surface adjacent to and opposed to the stop or to the interpolated focusing means, if any, tends toward plano and the final air surface tends to become strongly convex and curved more or less about the exit pupil. Also, at the upper limit, the overall length of the objective tends to become somewhat long for a compact construction for the camera. Accordingly, operating towards the middle to lower end of the range of thicknesses for the rearward component is normally preferred.

Similarly, to achieve compactness, the axial displacements of the last air surface of the first group and the first air surface of the rearward component with respect to the stop are relatively small, that is, the respective surfaces lie close to the stop. For the forward group, the concavity requires enough displacement axially from the stop to prevent interference of the periphery of the lens surface in its cell, if any, with the action of the shutter and stop, the latter usually comprising an iris or similar defining and variable opening. Optimum results are generally obtained if the rear surface of the forward component adjacent to the stop lies at a moderate distance from the stop, owing to the strong negative curvature of the surface, and generally curved about the stop, as is the case for the Hypergon.

Generally, the first group will include at least one plastic element having an aspheric surface. In the simplest case the aspherizing may be confined to the concave surface adjacent to and opposed to the stop, if the associated lens element is made of plastic.

Different considerations apply to the rear group than the front group. There are numerous lens designs that have complex structures following the stop, many with lead-off concave surfaces but the overall length of the objective and the clear apertures of the rearmost surfaces become much increased if wide angle performance is to be achieved. For purposes of the present invention, compactness requires that convergence after the stop be not too long delayed, either by too large an axial displacement from stop to lead-off surface of the rear component, or by use of a lead-off concave surface. The present invention is distinguished from the prior art in part from the fact that well-corrected optical performance is achieved even though the rearward component is relatively thin and relatively near the stop.

In quantitative terms, the axial clearance of the forward surface of the rear component from the stop should have a minimum value of about 0.015 times the EFL of the lens system. To achieve compactness, the upper limit is preferably set at about 0.050. For example, in Example 1, the axial separation between the stop and the front refracting surface of the rearward component is 0.038 times the lens system's EFL, which is within the 0.050 limit. While an even larger value is permissible for some applications, in general, the 0.050 value is appropriate for most applications of the present invention.

With respect to the rear component, there is also another way of looking at the limitations on total thickness and location. It is important as to the location of the convex rear air surface, if the front surface of the rear component tends toward plano. In this instance most of the converging power rests with the convex last refracting surface. The resulting strong curvature about the exit pupil is favorable for reducing the contribution of the surface to the undercorrected astigmatism of the system, particularly if the net convergence of the front component is weak. Conversely, if the element is thin, the axial separation from the stop becomes larger and indeed at or near the upper bound stated above. The refractive power of the component reacts favorably on the correction for distortion, that is, toward an inward or barrel-type refraction which offsets most if not all of the outward or pin-cushion refraction of the forward group. Correction for distortion need not be complete and thus the overall system can be held to a pin-cushion residual acceptable according to the application.

It should be noted that with respect to the off-axis refracting power of the rear component, a larger air space produces a kind of lever arm action which must not be overdone. It should also be noted that, except for wider angle systems, as the air space becomes larger and the rear component thinner, the first air surface of the rear component tends to become more and more convex and the rear surface weaker. This result holds true even if a focusing means is interpolated between the stop and the rear component.

In accordance with the invention, it is preferred to use at least one aspheric surface in the front group and not more than one in the rear component. The aspheric coefficients of power terms in a series expression for the

physical shape of the aspheric surface act as additional parameters, both for the forward group and for the rear component. Optimization procedures then produce favorable compactness, relatively short barrel lengths as an offshoot of compactness, and above all, improved correction for the many lower and higher order aberrations described above. Also, by means of these parameters, as well as the other optical parameters of the system, economy of construction, insensitivity to alignment errors, relative insensitivity to thermal changes of focus, and the like can be achieved to a greater or lesser extent depending upon the particular application.

Prior plastic systems used as camera objectives, including those having aspheric surfaces, have in many cases suffered from uncorrected longitudinal and lateral chromatic aberrations, as indeed have the landscape plastic and glass simple systems described earlier.

While the double meniscus systems with central stop generally have excellent correction for lateral chromatic aberration, that is to say, far off-axis images are more or less point-like rather than short spectra, the double meniscus forms are not short nor even compact. If the design makes use of a relatively short unsymmetrical barrel, as for the present invention, lateral chromatic aberration, if present, may indeed lead to degraded image quality at large off-axis angles. In the case of longitudinal chromatic aberration at f/10 more or less, the situation is much more forgiving. If not overdone, an improvement in depth of focus may even result.

Accordingly, in accordance with certain aspects of the invention, the lens system neglects longitudinal chromatic aberration but corrects for lateral chromatic aberrations. A short lens barrel also is helpful in this respect and may be thought of as a by-product of the designs conforming in other ways to the ranges and limitations expressed in this specification. In addition, a choice of materials front and rear is helpful.

Thus, the front group, at least for the simplest constructions, produces a net outward dispersion of the chief rays (such rays are defined as passing through the axial point of the real stop, one for each field angle), and the rear component, at least for the simplest constructions, an inward net dispersion. By arrangement of materials, lens powers and locations, a quite complete correction for lateral chromatic aberration over the field of view is achieved. A requirement, however, is that the rear component contain a material of strong dispersive power for a positive element in the rear component, which in the simplest case stands alone. This requirement is all the more important if the rear component lies near the stop. Incomplete correction, though a partial improvement, is allowable according to the image quality sought, but in any event, for purposes of this invention, at least some reduction in the lateral chromatic aberration for the system is generally required, as compared to that obtaining for a completely uncorrected system of equivalent monochromatic correction.

Thus, if a weakly dispersive material such as CHM or plexiglas ® is used for the strongest positive element in the rear component, particularly if the rear component is comprised in the simplest form of but a single positive element, the correction for lateral chromatic aberration in the case of the unsymmetrical objective forms outlined above, though partial, is generally inadequate. For purposes of the present invention one generally must resort to some more dispersive material for use as a positive element in the rear component. Viable materials are available, such as AN (acrylonitrile), styrene, or polycarbonate, where a moldable plastic is used. There will also be the cases where the rear component contains a dispersive glass element with spherical surfaces, aided by a thin contact element of plastic, including plexiglas ® or CHM, if only for the purpose of incorporating an aspheric surface on the plastic element or elements. In all these circumstances the design purpose is to achieve some marked reduction of the lateral chromatic aberration. Objectives not having such a reduction are generally not to be considered as part of the present invention.

Moreover, if the rear component is compounded of at least two materials of high and low dispersive powers, which can be called hyperchromatic for the net action resulting, it becomes possible to continue the correction or reduction in lateral chromatic aberration, even if the material of highest dispersive power for the positive element is not as dispersive as for the simpler, non-hyperchromatic combinations. This is true even if the hyperchromatic pairing lies near the stop. It is for this reason, when taken together with the stated bounds on axial location and dioptric power of the rear component that the present invention includes systems with two or more elements bonded together in optical contact to effect the correction and to simulate the action of non-existing single materials.

In summary, it is a purpose of this invention to require that a reduction in lateral chromatic aberration for the system as a whole be effected at least in part, as measured by the spectral spread in the image surface of an otherwise desired image point, according to the off-axis angle and spectral band-width, for uncorrected and totally or partially corrected systems being compared.

Thus, the inventive systems comprise a type of unsymmetrical objective which is compact, in terms of both barrel length and overall length, which provides improved performance for systems of moderate speed, such as f/8 or slower, having only a single rear component or which may incorporate a focusing means between said rear component and stop, such an objective having acceptable correction for distortion not exceeding 5%, according to aspheric powers and complexity of construction.

For practical reasons, any given plastic moldable element should either have spherical surfaces or not more than one of its two surfaces aspheric. To do otherwise, that is to say, if both surfaces were to be made aspheric, one usually will encounter serious misalignment, that is, lateral decentering of the respective aspheric zones, particularly if higher order aspheric terms of significance are present. Similarly, it is not feasible in large production runs for a design to have bonded aspheric surfaces of contact between adjacent elements of different materials. For purposes of the present invention, therefore, one can say that if more than one aspheric surface is used forward of the stop (that is to say, on the long conjugate side of the stop), there will be a corresponding number of plastic elements with any given aspheric at an air surface of the host element. In general, it is sufficient for the purposes of the present invention to limit the number of aspheric surfaces forward of the stop to not more than two. According to the application, the particular aspheric surface may lie either on the forward surface of its host element or on the rear. For the single rear component,

having therefore only two air surfaces, either one of these two surfaces may be aspheric but in general not both.

The objectives can be further modified by interpolation of some form of focusing means immediately following the stop and preceding the above discussed rear component. It is intended that the maximum axial distance between the shutter and rear surface vertex of the rear component not be increased, but that instead, enough space be left between the stop and the front surface vertex of the rear component for the aforesaid interpolation of a focusing means. Further discussion of the focusing means appears below.

Aspheric surfaces that are separated along the optical axis from front to rear of the objective not only have aspheric power zone by zone on the respective surface but also have a lever arm effect on refracted rays in interaction between one another. If the aspheric surfaces are far apart, the aspheric power zone by zone on either surface may be weak but varying in strength of the refractions in interplay over any angular field required. If the aspheric surfaces are close to one another, the respective coefficients often tend to be quite large but usually with less variation over the field. Moreover, higher order aspheric terms that are far apart tend to affect images in the tangential direction more sensitively than at right angles thereto. An image having an ambient aberrational extent in a direction radially outward, particularly if far from the center of the field, may be pulled together to an image core that improves the focusing effect for tangential lines while the skew direction of the image remains only partially improved in focusing effect for radial lines. Sometimes this azimuthal variation in correction may be useful if the uncorrected aberrations have the opposite tendencies, but more often not. If the aspheric surface lies relatively near to the stop, then even the higher order terms may be more tractable in the various azimuths of the image.

In terms of the present invention, the single aspheric of the rearward component, if any, may be on either air surface. Forward of the stop, at least one aspheric air surface preferably lies on the component nearest the stop, whether on the forward or rear surface of this component.

In the text above, the term "air surface" has been used. It is generally true that the hand camera objective is immersed in ordinary air at a density varying with elevation above or below the earth's mean surface. In space technology, however, it may prove necessary to use some other gaseous medium, such as dry nitrogen, or helium, or other gas, at a gas pressure from some maximum value down even to zero if a true vacuum is required. Clearly, the refractive actions of the surfaces of the present invention are not affected substantially thereby, except for a slight refocusing required and calibration of scale, and the governing principles within the scope of this invention remain essentially the same. The term "air" surface is accordingly used herein in a generic sense purely by way of reference, for the case of the vacuum is also included. In particular, in this specification and in the appended claims, the phrases "air surface" and "air-spaced" are to be understood to include a vacuum and media other than air when used in the practice of the invention.

One of the important features of the present invention is that the concave surface adjacent to and forward of the stop is very strongly curved. For Example 1 (FIG. 1 Series and Table 1) the axial curvature (1/R) of this surface is 7.61 in terms of the dioptric power for the system as a whole being taken as 1.000. Such a strong curvature is unusual in camera objectives except for wide angle systems of moderate aperature-ratio, such as f/5 to f/60 or so, the latter as for the Hypergon. Clearly, the front group cannot have the weak net positive power alluded to earlier unless there is at least one strongly positive compensating surface forward of the concave surface adjacent to the stop.

In quantitative terms, the concave surface adjacent to and forward of the stop should in general have a curvature in the range from about 4.0 to about 10.0 without regard to algebraic sign in terms of the dioptric power of the system as a whole being taken as 1.0. In the examples discussed below, the range for this surface is between 5.1 and 7.7. The wider recommended range allows for variations derived from wider field angles, or higher f-numbers, or for some special requirement such as clearance between lens surface and shutter action, where no change in principle occurs.

In the specific instance of Example 1 the lens group forward of the stop is comprised of but a single plastic element of plexiglas ® with the concave surface adjacent to the stop being aspheric. This is about the simplest forms of forward group lying within the scope of the present invention. The element is relatively thick in that the axial thickness is 0.060 of the equivalent focal length, and the forward surface is almost as strongly curved as the rear, the net power arising from the separation of surfaces. As noted above, the net dioptric power of this single element is 0.391 and the equivalent focal length of the element is 2.556. A real image is formed to the right if entered on the usual lens drawing.

For Example 1, the single component lying rearward of the stop is formed of but a single element of styrene and the rear surface of this element is both weakly curved and aspheric, the surface being slightly convex. If plexiglas ® were to be used for this single rear element instead of styrene, the high v-value or low dispersive power of plexiglas ® would have resulted in a marked amount of lateral chromatic aberration. Although a single rear plexiglas ® positive element does in part counteract the opposite contribution to lateral chromatic aberration of the meniscus lens element forward of the stop, the compensation is inadequate. One can take the net lateral chromatic aberration of such an all-plexiglas ® system as defining lateral chromatic aberration in a quantitative sense, e.g., as the radial extent of an image as a short spectrum instead of as the desired point image measured radially at some off-axis angle between red and blue wavelengths. Uncorrected lateral chromatic aberration is a defect for chief rays too, even though the lens aperture may be stopped down nearly to zero. When styrene is used for the rear component as in Example 1, the radial extent of the short spectrum is reduced virtually to zero.

Example 3 (FIG. 3 Series and Table 3) is closely related to Example 1 in general nature except that polycarbonate or PC has been used instead of styrene. The dispersive power of polycarbonate is approximately the same as for styrene, the respective nu-values being 29.9 (PC) and 30.8 (styrene). For comparison, the nu-value for plexiglas ® is 57.2, while that for AN is 34.9 approximately. Thus, any one of the three dispersive plastic materials styrene, PC or AN will reduce lateral chromatic aberration to acceptable residuals, as compared to use of plexiglas ® alone.

It should be noted that use of a very dispersive medium for the positive lens of the rear component, while needed for reducing or eliminating lateral chromatic aberration, increases the undercorrected longitudinal chromatic aberration of the system as a whole. It should also be noted that if elaborate compounding of elements of different dispersive power is employed within the lens group forward of the stop, or if multiple strong elements are used, as for many photographic objectives, it is feasible to reduce the longitudinal chromatic aberration to such a level that use of plexiglas ® for the rear element will lead to correction for lateral chromatic aberration. Such elaborate construction however results in extra costs and complexity, not in keeping with the needs of an economic photographic objective intended for the mass market.

Within the scope of this invention, it is intended that the longitudinal chromatic aberration of the front group is only partially corrected, if at all, and that the use of a dispersive medium for a positive element in the rear component may actually increase the longitudinal chromatic aberration for the system as a whole. The dividing line rests with the choice of dispersive medium for the rear component, where one can take an averaged value for the rear pairings, if of more than one element, or if but a single element, for the one plastic medium, as being not larger than 44.0, about the halfway point for the specific materials already mentioned. At this halfway point either the longitudinal chromatic aberration of the system as a whole, as a result of elaboration of construction and materials in the front group, is about 50% corrected with the effective elimination of lateral chromatic aberration, or else the lateral chromatic aberration is about half corrected, if the group of elements forward of the stop is not at all corrected for longitudinal chromatic aberration.

Apart from considerations of chromatic corrections there is another reason for elaboration of the structure of the front group. Plastic molded elements are economical and well suited for the mass market. However, at least to some extent, a need exists for having a lead-off element made of an optical glass and generally therefore with spherical surfaces. Hand cameras quite often receive rough treatment in the family environment in that the front surface becomes soiled, abraded, or corroded. Accordingly, for some cameras it becomes desirable to have the simple element used in Example 1 or in Example 3 protected by the addition of a front spherically surfaced glass element. For minimization of costs with respect to lens cells, and other mounting details, it is desirable that the one glass element with a single companion plastic element (with one aspheric surface) comprise a more elaborate front lens group fitting the same cell as for the simpler cases of Examples 1 or 3. Such a two-element front group fitting the same cell and mount as for the single element front component may be called a "drop-in" replacement, to be used or not used, as desired. Examples 2 and 4 (Figures and Tables) thus have glass front elements that by design and in combination with suitably shaped plexiglas ® second elements form "drop-in" equivalents of Examples 1 and 3 having glass front surfaces. The optical performances remain very nearly the same and no new principles are introduced affecting the range of parameters already discussed.

It has been mentioned above that the lens systems incorporating the several principles of this invention can be further modified by the interpolation of focusing means between the stop and the front surface of the rear component. Various forms of focusing are known in the art. One of the oldest is physical movement of the objective as a whole along the optical axis until the image conjugate to the object surface is focused as well as need be on the recording surface of the camera. This kind of focusing can be used with the lens systems of this invention to achieve focusing for object planes from 4 equivalent focal lengths of the objective at the near point through a continuous range up to an infinite object distance.

Interpolation of focusing means can be used instead of the above discussed physical movement of the objective as a whole. In particular, compactness and camera construction may preclude any marked change in position of the objective and instead, one may interpolate a much more compact focusing means. Known in the art is the direct interpolation of one or more dioptrically weak elements of glass or plastic, but only one at a time to accord with any given object distance. Such weak dioptric elements can be arranged on an eccentric wheel and if of plastic molded as a unit to accommodate several interchangeable weak elements according to the angular setting of the disc. For any given object distance the corresponding element will be centered in position on the optical axis between stop and rear component. If of plastic, weak aspherics may also be used for each of the weak elements on the disc to improve performance according to the object distance. Such aspherics are permitted and are not to be confused with the aspherics previously described on one of the air surfaces of the rear component.

Another form of focusing known in the art is the interpolation of a pair of plates, each with an external plano optical surface, in close juxtaposition on the optical axis immediately following the stop as, for example, that disclosed in U.S. Pat. No. 3,583,790 issued to James G. Baker on Jun. 8, 1971. The opposed and adjacent internal surfaces of the pair of plates can be of an aspheric shape of analytic mathematical surfaces described in detail by polynomial expressions of non-rotational terms in x and y up to some cutoff term in what may otherwise be a power series that represents the desired analytic surface mathematically to any desired precision. The polynomial terms may include the ordinary second and higher order rotational terms of any dioptric surface and aspherics normally associated with purely rotational aspheric surfaces. Focusing is accomplished by an eccentric rotation of one or both of the plates about axes displaced laterally from the optical axis generally completely outside of the interrupted lens barrel. Another means is to slide one or both of the plates laterally such that the plano surface on each remains in its own plane during the sliding. The quantitative nature of the polynomial terms are optimized throughout the focusing range according to the type of focusing motion of the plates deemed desirable for the application.

2. Specific Embodiments and Applications

FIGS. 1–7 illustrate various lens systems constructed in accordance with the invention. Corresponding prescriptions appear in Tables 1 to 7, respectively. The dimensions given in these tables have been normalized to the EFL of the lens which is nominally 100 mm. The aspheric coefficients set forth in the tables are for use in the following equation:

$$z(r) = \frac{cr^2}{1 + [1 - (1 + K)c^2r^2]^{\frac{1}{2}}} + Ar^4 + Br^6 + Cr^8 + Dr^{10}$$

where $r^2 = x^2 + y^2$, c is the curvature at the pole of the surface, K is a conic constant ($K = -e^2$), which for the lenses of Tables 1-7 is zero, and A, B, C, and D are the 4th, 6th, 8th, and 10th order deformation terms.

In overview, the examples of FIGS. **1** and **3** show the two-component form of the lens system of the invention. Example 1 uses styrene for the rear component, and Example 3 uses PC. Examples 2 and 4 illustrate the use of a "drop-in" plastic-glass combination with the front element being made of glass. Examples 5-7 show further variations embodying the principles of the invention. Example 5 increases the field to 62 degrees; Example 6 has very low distortion as well as a glass front element; and Example 7 includes a focusing means.

A preferred application of the objective lens systems of the present invention is in connection with a folding, reflex camera **10** such as the one illustrated in FIGS. **8-10**. FIG. **8** shows camera **10** in its folded condition and FIG. **9** and **10** in its fully erected, picture taking condition. If the base of camera **10** is placed on the horizontal, the objective "looks" slightly up. The camera preferably accepts instant, or self-processable, film whose format can be, for example, 2.15 by 2.87 inches with a diagonal of 3.586 inches.

Prior to taking a picture, camera **10**, upon actuation by pressing a shutter button, automatically determines which one of two zones the subject is in and then, depending on the zone, sets the objective lens system in one of two possible configurations to assure that the subject will be sharply reproduced (see below).

In both of its configurations, the lens system preferably has a maximum aperture of f/10 with a semi-field coverage of 14.25 by 18.76 degrees with a half diagonal of 23.05 degrees. The effective focal length preferably is 99.1 mm. Preferably, distortion is less than 3%, and the blur diameter due to all aberrations is less than 0.005 inches.

The lens system, here preferably example 7 of FIGS. 7A-7E and Table 7, preferably includes two plastic elements. The first element is molded of plexiglas ® and has an aspheric rear surface. Following the first element is a stop which is preferably oblong in shape being longer along the y-axis, the up and down of the camera, than in the x-axis, the horizontal azimuth of the camera.

Following the stop, adjacent and in alignment with it, are a pair of apertured reciprocating blades (not shown) that open and close to control exposure. In the x-direction, the maximum aperture is f/1 4 while in the y-direction, it is f/10 for an average overall aperture of about f/12. Hence, the f/10 designation has been adopted to go along with the maximum in the y-direction.

Following the reciprocating blades is a second positive lens made of polystyrene having a first surface which is spherical and a second surface which is aspheric.

Following the second element is a plano mirror (not shown) for folding the optical path and following that is the film surface which is slightly curved inwardly, i.e., the ends bend toward the front of the camera **10**. In particular, the film surface is curved in the x-z plane and, as such, must be included in evaluating the overall performance of the camera optical system, i.e., objective plus curved film surface, because it relaxes the demands on the objective for correcting curvature of field.

The second, longer focal length configuration of the lens system is achieved by introducing a supplemental lens in the intervening space between the two elements of the first configuration. This lens is preferably made of plexiglas ®, has a net negative power and is positioned along the optical axis following the stop and shutter blades. This element is preferably all spherical, although an aspheric surface can be included if desired. By introducing this element, the net power of the combination is reduced, nominally focusing it at 11 feet with a range of focus of 8 feet to infinity. A suitable prescription for this focusing lens, focusing to infinity for example, to an image position preset beyond a focal point for alternate usage, for use with the lens system of Table 3 is given in Table 7. The front vertex of the focusing lens is located 0.0128 behind the stop in Table 7.

As discussed above, the lens system's front plastic element can be replaced by a glass-plastic combination. The glass element can be made of BK7 glass from the OHARA glass catalog. In both the near and far configurations, the remainder of the optics following the glass-plastic pair are as before. As also discussed above, the glass-plastic pair is preferably packaged so that its outside shape and dimensions match those of the plastic front element of the all plastic version so that it can be used as a "drop-in" replacement during manufacturing. This is accomplished by encapsulating the outside exterior surfaces of the glass-plastic combination in a casing which closely matches the exterior geometry of the plastic version.

With both the all plastic and glass-plastic version, a close-up lens can be provided. The close-up lens, which is a manual, external attachment, can be made of plexiglas ® and preferably has spherical surfaces. This element is intended to be used at a aperture no larger than f/40 so its shape is not critical, just its power. It can nominally focus the camera at 12 inches and can have a range of focus which is largely dependent on exposure errors rather than optical capability. This is because exposure errors vary as the inverse of the fourth power and are large at this distance range (small changes result in large exposure errors) while focus errors are less sensitive. In other words, the exposure errors will become noticeable so quickly that they will completely overwhelm any blurriness that may be present. A suitable prescription for the close-up lens for use with the lens system of Table 3 is given in Table 8. The rear vertex of the close-up lens is forward of the front vertex of the lens system of Table 3.

Although specific embodiments of the invention have been described and illustrated, it is to be understood that a variety of modifications which do not depart from the scope and spirit of the invention will be evident to persons of ordinary skill in the art from the foregoing disclosure. For example, the front group may be made of glass and the rear moldable plastic with the difference in their Abbé v-values exceeding 10 numerically. The following claims are intended to cover the specific embodiments set forth herein as well as such modifications, variations, and equivalents.

What is claimed is:

1. A lens system for use in forming an image on a flat or weakly concave recording surface which has a half-diagonal length $D_{\frac{1}{2}}$, said lens system (i) having an equivalent focal length f_0, (ii) a diotropic power K_0, and (iii) including a stop or aperture, said lens system comprising:

(a) a first group on the object side of the stop or aperture having a positive dioptric power K_1 which is in the range from about 0.2 to about 0.5 times K_0, said first group comprising a concave surface preceding and adjacent to the stop or aperture, said concave surface having a radius of curvature, if spherical, or a central radius of curvature, if aspheric, lying in the range from about 0.1 to about 0.25 times f_0, the vertex or axial point of said concave surface lying within a distance along the lens system's optical axis from the axial point of the stop or aperture not greater than about 1/20 times f_0; and

(b) a second group on the image side of the stop or aperture consisting of a single component comprising one or more lens elements, said single component having:

(i) only two air surfaces;

(ii) a positive power;

(iii) a front vertex which lies axially to the rear of the axial point of the stop or aperture at a distance not greater than about 1/20 times f_0;

(iv) an axial thickness not greater than about 1/20 times f_0; and

(v) a forward surface adjacent to the stop or aperture having a curvature, if spherical, or an axial or central curvature, if aspheric, lying in the range from about -2.0 to about $+1.5$ times K_0;

said lens system:

(i) having a total diagonal field of view not exceeding about 62 degrees;

(ii) having an average field curvature whose magnitude in any azimuth does not exceed about 0.1 times K_0;

(iii) having a distortion not exceeding about 5% of $D_{\frac{1}{2}}$;

(iv) being corrected at least partially for lateral chromatic aberration; and

(v) having at least two elements made of materials differing in dispersive powers, at least one of the two elements is plastic.

2. The lens system of claim 1 wherein:

(A) the overall axial length from the lens system's first surface vertex to the focal point in image space does not exceed about 1.030 times f_0, external attachments excluded, for an object at infinity; and

(B) the overall axial length from the lens system's first surface vertex to the conjugate focus in image space does not exceed about 1.365 times f_0, external attachments excluded, for object distances down to but not less than about 4 times f_0, object distances being measured from the axial point of the object surface along the axis to the vertex of the first lens surface on the long conjugate side of the lens system.

3. The lens system of claim 2 wherein the overall axial length from the lens system's first surface vertex to its rear surface vertex does not exceed about 0.165 f_0, external attachments excluded.

4. A lens system for use in forming an image on a flat or weakly concave recording surface which has a half-diagonal length $D_{\frac{1}{2}}$, said lens system (i) having an equivalent focal length f_0, (ii) a dioptric power K_0, and (iii) including a stop or aperture, said lens system comprising:

(a) a first group on the object side of the stop or aperture having a positive dioptric power K_1 which is in the range from about 0.2 to about 0.5 times K_0, said first group comprising:

(i) a concave surface preceding and adjacent to the stop or aperture, said concave surface having a radius of curvature, if spherical, or a central radius of curvature, if aspheric lying, in the range from about 0.1 to about 0.25 times f_0, the vertex or axial point of said concave surface lying within a distance along the lens system's optical axis from the axial point of the stop or aperture not greater than about 1/20 times f_0; and

(ii) at least one aspheric surface; and

(b) a second group on the image side of the stop or aperture consisting of two separated subgroups,

the first of said two separated subgroups comprising focusing means for focusing the lens system as a whole over a range of object distances from infinity down to about 4.0 times f_0, object distances being measured from the axial point of the object surface along the axis to the vertex of the first lens surface on the long conjugate side of the lens system, and

the second of said two separated subgroups consisting of a single component comprising one or more lens elements, said single component having:

(i) only two air surfaces;

(ii) a positive power;

(iii) a front vertex which lies axially to the rear of the axial point of the stop or aperture at a distance not greater than about 1/20 times f_0, said distance containing wholly within it said first of said two separated subgroups;

(iv) an axial thickness not greater than about 1/20 times f_0; and

(v) a forward surface having a curvature, if spherical, or an axial or central curvature, if aspheric, lying in the range from about -2.0 to about $+1.5$ times K_0;

said lens system:

(i) having a total diagonal field of view not exceeding about 62 degrees;

(ii) having an average field curvature whose magnitude

in any azimuth does not exceed about 0.1 times K_0;

(iii) having a distortion not exceeding about 5% of $D_{\frac{1}{4}}$;

(iv) being corrected at least partially for lateral chromatic aberration; and

(v) having at least two elements made of plastic materials differing in dispersive powers.

5. The lens system of claim 4 wherein:

(A) the overall axial length from the lens system's first surface vertex to the focal point in image space does not exceed about 1.030 times f_0, external attachments excluded, for an object at infinity; and

(B) the overall axial length from the lens system's first surface vertex to the conjugate focus in image space does not exceed about 1.365 times f_0, external attachments excluded, for object distances down to but not less than about 4 times f_0.

6. The lens system of claim 5 wherein the overall axial length from the lens system's first surface vertex to its rear surface vertex does not exceed about 0.165 f_0, external attachments excluded.

7. The lens system of claim 1, 2, 3, 4, 5, or 6 wherein the first group consists of a single element.

8. The lens system of claim 1, 2, 3, 4, 5, or 6 wherein the single component of the second group has an aspheric surface.

9. The lens system of claim 1, 2, 3, 4, 5, or 6 wherein the forward surface of the single component of the second group is convex in the direction of the stop or aperture.

10. The lens system of claim 1 having at least two elements made of plastic materials differing in dispersive powers.

11. The lens system of claim 1 having the following prescription:

COMPACT PHOTOGRAPHIC OBJECTIVE OF THE TRIPLET TYPE HAVING IMPROVED CHROMATIC AND MONOCHROMATIC CHARACTERISTICS

BACKGROUND

The invention relates to a photographic objective having a relative aperture 3.5 and a focal length 35 of the triplet type with a rear stop, which is provided especially for compact photographic cameras.

A photographic objective of the triplet type having a rear stop is disclosed in DE 24 24 343 C2, which contains three lens elements of which the front element is a positive meniscus lens which is convex on the object side, the central lens element is a hi-concave lens, and the rear lens element is a hi-concave cemented element consisting of two lenses of opposite refractive power.

DE-PS 544,329 discloses a photographic objective comprising a diverging lens and in each case one collecting lens element, arranged in front of and behind it, of which that on the object side is constructed as a cemented element with a positive overall refractive power. This known objective has a focal length of 100 mm; there are no statements on the position of the aperture stop.

SUMMARY OF THE INVENTION

It is an object of the present invention to provide an extremely compact photographic objective of the generic type mentioned initially, having balanced monochromatic correction and a reduction in the chromatic magnification difference, the color coma and the color astigmatism. This photographic objective overall has improved imaging characteristics over known systems of this type. .

In order to achieve the above and other objects of the present invention, the photographic objective has a relative aperture of 3.5 and a focal length of 35 mm and is of the triplet type with a rear aperture stop. The objective further includes: a cemented element, including a first and a second lens element, having a positive overall refractive power on its object side; a bi-concave central lens element; and a bi-convex rear element. In order to achieve the desired objects of the invention, the objective composed of the above elements also meets four design conditions.

BRIEF DESCRIPTION OF THE DRAWINGS

The invention will be described in further detail with reference to the accompanying drawings, in which:

FIG. **1** shows a sectional view of an objective system according to an embodiment of the invention, and

FIGS. **2A–D** show the correction state of the objective according to an embodiment of the invention, where FIG. **2A** is a distortion plot, FIG. **2B** is a relative illumination intensity plot, FIG. **2C** is a transverse aberrations plot, and FIG. **2D** is a field curvature plot.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

The objective shown in FIG. **1** has a first lens element L_1 with surfaces 1 and 2 cemented to a second lens element L_2 with surfaces 2 and 3 as the lens group closest to the object. The objective also has a middle lens element L_3 with surfaces 4 and 5, as well as a back lens element L_5 with surfaces 6 and 7. A rear aperture stop 8 is also shown.

The compactness of the objective is described by the condition $B_L/S' < 0.6$, where $S'_{max} = 0.8 \times f'$, where B_L is the structural length of the objective, S' is the distance between the back lens and the image, and f' is the focal length of the objective. In order to correct for monochromatic aberrations, a high refractive index in the first lens group, corresponding to the condition $n_2 > 1.7$, where n_2 is the refractive index of the second lens element L_2, has been found to be favorable. In order to achieve the desired matching between the lens surfaces 2 and 7 while avoiding higher order aberrations, a large difference $\nu_1 - \nu_2 > 15$, where $\nu_{1,2}$ are the Abbe numbers of the first and second lens elements L_1, L_2, is essential. Finally, as a result of condition $0.7 \times F_2(7) < F_2(2) < 1.3 \times F_2(7)$, where $F_2(2)$ and $F_2(7)$ are the Seidel coefficients for the chromatic magnification difference of the lens elements having the lens surfaces 2 and 7, respectively, the effect of the cemented surface in the first lens group is described, the final surface 7 is compensated for the effect F_2 (chromatic magnification difference) by means of this cemented surface. In addition, relief of stress in the second lens element is thus produced such that, here, a relatively large ν value and a relatively low refractive index are adequate, which has a positive effect on the Petzval sum. In addition, a reduction in the 3rd order aberration coefficient is achieved which has a favorable effect on the higher order monochromatic and chromatic aberrations.

The photographic objective of the present invention also has the following numeric data:

	r	d	n(546)	ν
1	11.0297	2.7300	1.808109	46.34
2	39.1519	2.0219	1.812640	25.23
3	19.1519	0.7000		
4	−40.8013	1.0051	1.652230	33.57
5	10.4692	0.8000		
6	20.7116	3.5430	1.716700	42.89
7	−24.0136	1.2000		
8	Stop	24.5165		

where r(1–7) are the radii of curvature of the individual lens surfaces 1–7, d(1–6) are distances between and thicknesses of same, d(7) is the distance from the rear lens face 7 to the near aperture stop 8, d(8)is the distance from the rear aperture stop 8 to the image plane, n(1,2,4,6) are the refractive indices of the lens elements having the lens surfaces 1,2,4,6 and ν(1,2,4,6) are the corresponding Abbe numbers of these lens elements.

In addition to the numeric data mentioned above, the objective according to the invention has the following paraxial data:

$f' = 33.6323$

$S' = 26.7165$

$\beta ap' = 0.7290$

$SS' = 10.8000$

$Z' = 1.2000$

where S' is the distance between the rear lens and the image, f' is the focal length, $\beta ap'$ is the pupil magnification of the exit pupil, SS' is the structural length be-

tween the first and the last lens vertex, Z' is the distance between the rear shutter and the last lens vertex.

From the correction curves shown in FIG. 2, it is apparent that the objective according to the invention has a favorable monochromatic correction with an extremely compact construction, despite the use of a rear aperture stop. The objective especially has a major reduction in the chromatic magnification difference, the color coma and the color astigmatism.

It is self-evident that the numeric data may differ in the context of normal variations. Other designs within the spirit and scope of the invention will be apparent to those skilled in the field after receiving the above teachings. The invention, therefore, is defined with reference to the following claims.

What is claimed is:

1. A photographic objective having a relative aperture of 3.5 and a focal length of 35 mm, of the triplet type with a rear lens aperture stop, comprising:

a cemented element, including a first and a second lens element, having a positive overall refractive power on its object side;

a bi-concave central lens element; and

a bi-convex rear lens element, wherein said photographic objective satisfies the following conditions:

$$\frac{B_L}{S'} < 0.6, \text{ where } S_{max}' = 0.8 \times f \quad \text{(I)}$$

$$n_2 > 1.7 \quad \text{(II)}$$

$$\nu_1 - \nu_2 > 15 \text{ and} \quad \text{(III)}$$

$$0.7 \times F_2(7) < F_2(2) < 1.3 \times F_2(7), \quad \text{(IV)}$$

where

where

B_L is the structural length of the objective,

S' is its distance between the rear lens and an image formed by said objective,

f' is the focal length of the objective,

S'_{max} is the maximum distance between the rear lens and the image formed by said objective,

n_2 is the refractive index of the second lens element,

$\nu_{1,2}$ are the Abbe numbers of said first and second lens elements, and

$F_2(2)$ and $F_2(7)$ are the Seidel coefficients for the chromatic magnification difference of said cemented element having lens surface 2 and said bi-convex rear lens element having lens surface 7.

2. The photographic objective as claimed in claim 1, wherein said objective has the following numeric data:

	r	d	n(546)	ν
1	11.0297	2.7300	1.808109	46.34
2	39.1519	2.0219	1.812640	25.23
3	19.1519	0.7000		
4	−40.8013	1.0051	1.652230	33.57
5	10.4692	0.8000		
6	20.7116	3.5430	1.716700	42.89
7	−24.0136	1.2000		
8	Stop	24.5165		

where

r(1–7) are the radii of curvature of the individual lens surfaces 1–7,

d(1–6) are distances between the consecutive lens surfaces 1–7,

d(7) is the distance from the final lens surface 7 to said rear aperture stop,

d(8) is the distance from said rear aperture stop to said image formed by the objective,

n(1,2,4,6) are the refractive indices at 546 nm of the lens elements having front lens surfaces 1,2,4,6, and

ν(1,2,4,6) are the corresponding Abbe numbers of the lens elements having front lens surfaces 1,2,4,6.

3. The photographic objective as claimed in claim 2, wherein said objective has the following paraxial data:

$f' = 33.6323$

$S' = 26.7165$

$\beta ap' = 0.7290$

$SS' = 10.8000$

$Z' = 1.2000$

where

βap' is a pupil magnification of an exit pupil,

SS' is a structural length between a first and a last lens vertex, and

Z' is a distance between said rear aperture stop and said last lens vertex.

[57] **ABSTRACT**

The invention is directed to a pancratic mirror objective system for laser focussing and especially for laser machining apparatus. The pancratic mirror objective system preferably includes a convex paraboloid mirror and an ellipsoid mirror. The ellipsoid mirror can be approximated by a toric or spherical form. The focus F_1 of the paraboloid mirror P and the first focus of the ellipsoid mirror E are coincident. By rotating the ellipsoid mirror E about the axis parallel to the incident laser beam through the first focus F_1, the effective image side aperture (for example K=4 to K=8) and the focal length are varied. The track control compensates for the movement of the focus F_2 in laser machining apparatus.

MIRROR OBJECTIVE ARRANGEMENT

FIELD OF THE INVENTION

The invention relates to a mirror objective arrangement having two mirrors. Arrangements of this kind having a fixed geometry and focal length are known in various configurations also with paraboloid and ellipsoid mirrors. The invention also relates to a laser machining apparatus incorporating the mirror objective arrangement.

BACKGROUND OF THE INVENTION

For machining materials with lasers, the machining result is very critically dependent upon the energy distribution at the focus. This applies especially to laser cutting. Here, lasers are preferably utilized which radiate in a low mode and therefore supply an approximately diffraction limited focus distribution. An adaptation of the focus distribution to the requirements (for example, determined by the type of material and the material thickness) can, in this case, be obtained practically only by means of the effective aperture and therefore the focal length of the focussing optics. For this reason, different focal lengths are used depending upon the application. When the requirements change frequently, then the need for focussing optics having a changeable aperture increases in order to reduce the change-over time.

Such systems have long been utilized when using lens optics. Here, complete pancratic focussing units or pancratic expansion or contraction systems in combination with fixed focussing optics are utilized.

Lens systems are only of use to a limited extent when utilizing lasers of high capacity. For this reason, the lens systems are increasingly replaced with mirror optics which can be loaded to a significantly greater extent. However, only embodiments having a fixed aperture are known.

SUMMARY OF THE INVENTION

In view of the foregoing, it is an object of the invention to provide a mirror objective arrangement which is configured as a pancratic system.

The mirror objective arrangement of the invention includes: a first mirror having a shape which at least approximates a paraboloid form and defining a first focus F_1; a second mirror having a shape which at least approximates an ellipsoid form; the second mirror being in a first position wherein the second mirror images the first focus F_1 at an initial second focus F_2; and, pivot means for pivoting the second mirror about a pivot axis passing through the first focus F_1 from the first position to a second position so as to cause the second mirror to image the first focus F_1 at a new second focus F_2'.

The pancratic system of the invention includes two mirrors with one of these mirrors being configured at least approximately as a paraboloid mirror and the other one being configured at least approximately as an ellipsoid mirror. The laser beam is focussed by the paraboloid mirror. This focus is positioned in the one focal point of the ellipsoid mirror and is imaged by the ellipsoid mirror into the other focal point thereof.

The change of the effective aperture does not take place in the manner conventional with lens systems by changing the spacing between the optical elements; instead, by changing the angle between the optical elements, that is, the angle between the paraboloid mirror and ellipsoid mirror.

BRIEF DESCRIPTION OF THE DRAWINGS

The invention will now be described with reference to the drawings wherein:

FIG. **1** is a schematic of the mirror objective arrangement of the invention showing the paraboloid mirror and the ellipsoid mirror thereof disposed in spaced relationship to each other and how the ellipsoid mirror is moved relative to the paraboloid mirror;

FIG. **2** is a section view taken through the axis F_1-S of FIG. **1**; and,

FIG. **3** shows a laser machining arrangement according to an embodiment of the invention.

DESCRIPTION OF THE PREFERRED EMBODIMENTS OF THE INVENTION

In FIG. **1**, a laser beam impinges perpendicularly to the plane of the paper on the convex paraboloid mirror P and is reflected so that a virtual focus at F_1 is formed. The ellipsoid mirror E is first in a position having an image-side aperture $K=8$ and images F_1 at F_2.

As shown in FIG. **2**, a section of paraboloid mirror P is illuminated by the laser **2** at an elevation which corresponds to twice the vertex focal length f_p so that a mean deflection of 90° takes place.

In the embodiment shown, the ellipsoid mirror E is so dimensioned that a variation of the image side aperture by a factor of two is possible between $K=4$ and $K=8$. Preferably, the ellipsoid mirror E is so configured that the end positions (E, E') are symmetrical. Then, the incident beam (generated by paraboloid mirror P) must have an aperture of $K=5.6$ (geometric mean). Thus, for a diameter of the beam of $dp=40$ mm, an effective focal length of the paraboloid mirror P is required which is twice the vertex focal length f_p in the embodiment or $2 \cdot f_p = 225$ mm. A minimum spacing must be maintained between the two mirrors (P, E) so that the reflected beam is not shaded. The spacing F_1-S should be at least 300 mm for the dimensions given above.

The precise form of the ellipsoid mirror E is not yet determined. A further parameter can be arbitrarily selected. In FIG. **1**, the additional requirement is introduced that a primary ray H or H' should be perpendicular to the axis of the ellipsoid mirror E in the extreme positions. With these requirements, an ellipsoid mirror E is obtained having the values $a=362$ mm, $b=329$ mm for the half axes and $c=151$ mm for the half focal point spacing. The minimum length of the mirror necessary for the application is $L=366$ mm.

Changes of the arbitrary parameter have only a slight influence on the required length of the mirror. The dimensions of the arrangement can be varied widely.

If the ellipsoid mirror E is rotated about the axis through the first focus F_1 wherein the holder **8** rotates about the bearing **9**, then the second ellipsoid focus F_2 moves while at the same time the aperture of the beam focussed there changes and therefore the focal length of the entire system. The above-mentioned axis is perpendicular to the plane of the paper but parallel to the incident laser beam. The new position of the ellipsoid mirror is identified by E' and is shown in phantom outline in FIG. **1**. The ellipsoid mirror E' has an aperture $K=4$ and a focus F_2'.

While for camera-related variable-focus lenses with changing focal lengths the image must always be formed on the plane of the film, it is not a problem for

the mirror objective arrangement of the invention for the application to laser machining that the focus F_2, F_2' moves along a circular arc.

A laser machining apparatus often has a track control **4** as shown in FIG. **3** for the movement of a laser head (**1**, **2**) relative to the workpiece (**71**, **72**). The laser head (**1**, **2**) includes the laser **2** and the objective **1**. The track control **4** can be so programmed for the use of the pancratic system **1** of the invention that the position of the machining point **3**, that is the focus (F_2, F_2') is always considered relative to the laser head (**1**, **2**). The position of the machining point **3** is dependent upon the desired focal length or aperture.

The beam direction of the emitted beam is not significantly changed with the variation of the effective focal length. The use of an ellipsoid mirror for forming a finite image achieves a trouble-free joining of beams.

In some cases, slight imaging errors are accepted when in this way, a mirror can be used which is more simple to produce.

In the case of FIG. **1**, the ellipsoid mirror can be replaced, for example, by a toric surface having a primary radius of curvature in the plane of the drawing of:

$$R_1 = a^2/b = 362^2/329 = 398 \text{ mm}$$

and perpendicularly thereto,

$$R_2 = b = 329 \text{ mm}.$$

A still coarser approximation is obtained with a spherical surface. However, the imaging error is significant, especially the astigmatism.

The paraboloid mirror shown in FIG. **1** can be replaced with a surface, which is simpler to produce, when a deterioration of the focus quality is permissible.

A spherical surface would cause very considerable imaging errors in the arrangement shown, that is, with a 90° beam deflection. For this reason, a sphere having the smallest possible deflection angle would be used. The component of the astigmatism can be substantially eliminated by using a toric surface.

It is also plausible to dimension the astigmatic error components of both mirrors so that they compensate when added. However, this appears to be advantageous only in rare cases since modern manufacturing machines are available in most cases with which the ellipsoid and paraboloid surfaces can be produced with no problem and at acceptable cost.

It is understood that the foregoing description is that of the preferred embodiments of the invention and that various changes and modifications may be made thereto without departing from the spirit and scope of the invention as defined in the appended claims.

What is claimed is:

1. A mirror objective arrangement comprising:

a first mirror having a shape which at least approximates a paraboloid form and defining a first focus F_1;

a second mirror having a shape which at least approximates an ellipsoid form;

said second mirror being in a first position wherein said second mirror images said first focus F_1 at an initial second focus F_2; and,

pivot means for pivoting said second mirror about a pivot axis passing through said first focus F_1 from said first position to a second position so as to cause said second mirror to image said first focus F_1 at a new second focus F_2'.

2. The mirror objective arrangement of claim **1**, wherein the effective aperture K of light focussed at said initial second focus F_2 is varied when focussed at said new second focus F_2'.

3. The mirror objective arrangement of claim **2**, wherein the variation of said effective aperture can vary between $K=4$ and $K=8$.

4. The mirror objective arrangement of claim **1**, further comprising a laser light source for supplying a laser beam defining a beam axis parallel to said pivot axis and incident upon said first mirror for focussing at said first focus F_1.

5. The mirror objective arrangement of claim **1**, wherein said first mirror is convex.

6. The mirror objective arrangement of claim **1**, said first mirror being a precision paraboloid mirror and said second mirror being a precision ellipsoid mirror.

7. The mirror objective arrangement of claim **1**, wherein said paraboloid form of said first mirror is approximated by a toric surface and said ellipsoid form of said second mirror is approximated by a toric surface.

8. The mirror objective arrangement of claim **1**, wherein said paraboloid form of said first mirror is approximated by a toric surface.

9. The mirror objective arrangement of claim **1**, wherein said ellipsoid form of said second mirror is approximated by a toric surface.

10. A laser machining apparatus for machining a workpiece, said apparatus comprising:

a laser head including laser means for supplying a laser beam defining a beam axis; and, a mirror objective arrangement mounted on said beam axis for directing said laser beam to a machining point on the workpiece;

said mirror objective arrangement having an adjusted focal length and including: a first mirror having a shape which at least approximates a paraboloid form and defining a first focus F_1; a second mirror having a shape which at least approximates an ellipsoid form; said second mirror being in a first position wherein said second mirror images said first focus F_1 at an initial second focus F_2; and, pivot means for pivoting said second mirror about a pivot axis passing through said first focus F_1 from said first position to a second position so as to cause said second mirror to image said first focus F_1 at a new second focus F_2'; and,

track control means for controlling said laser head to change the location of said machining point relative to said laser head so as to cause said machining point to be coincident with said focus (F_2, F_2').

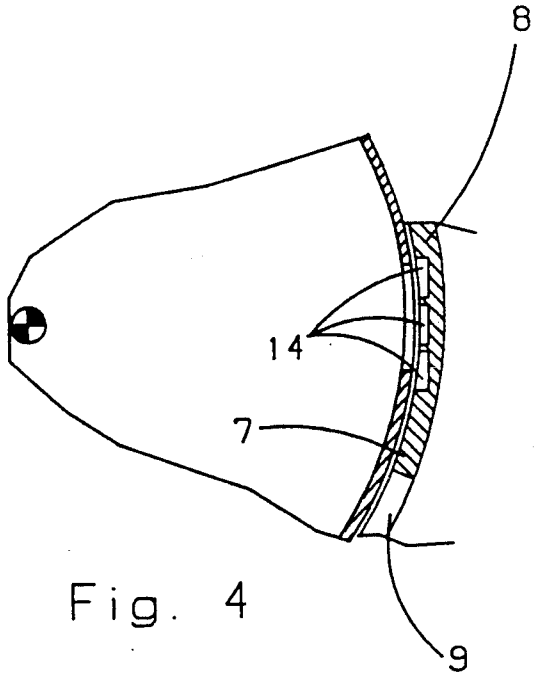

Fig. 4

PANORAMIC CAMERA WITH OBJECTIVE DRUM

BACKGROUND OF THE INVENTION

The present invention relates to a panoramic camera with an objective drum which is rotatable relative to a cylinder segment of the camera housing provided with an image window.

Panoramic cameras of the above-mentioned general type are known in the art. In a known panoramic camera which is disclosed for example in the German document DE-PS 1 173 331, felt inserts are provided for blocking undesired light impingement. The felt inserts mounted in the camera housing rub during the receipt against the casing of the drum and brake the drum turning, which must be compensated by higher force application during driving. Moreover, the felt inserts have a tendency for embedding dust particles which further increase the above-mentioned braking friction and in addition cause scratching traces on the objective drum.

SUMMARY OF THE INVENTION

Accordingly, it is an object of the present invention to provide a panoramic camera which avoids the disadvantages of the prior art.

More particularly, it is an object of the present invention to provide a panoramic camera with improved features for obtaining the required light safety.

In keeping with these objects and with others which will become apparent hereinafter, one feature of the present invention resides, briefly stated, in a panoramic camera with an objective drum in which the cylinder segment is provided laterally near the image window with segment flanks formed with light catching grooves which extend parallel to the rotary axis of the objective drum, and the light catching grooves end at a distance from the outer edges of the cylinder segment, which is covered by the curvature of the objective drum.

When the panoramic camera is designed in accordance with the present invention, it eliminates the disadvantages of the prior art and provides for the above-mentioned highly advantageous results.

In accordance with another feature of the present invention, the light catching groove has a depth which increases relative to the image window in a wedge-shaped manner.

Still a further advantageous feature of the present invention is that the light catching groove is provided with a portion which is deepened in a wedge-shaped manner relative to the image window and a cylindrical portion connected with the image window.

When in accordance with a further feature of the present invention the light catching groove has a rectangular cross-section, it provides for a technologically advantageous solution.

Finally, in accordance still another advantageous feature of the present invention, a light absorbing layer is arranged additionally in the light catching groove.

The novel features which are considered as characteristic for the invention are set forth in particular in the appended claims. The invention itself, however, both as to its construction and its method of operation, together with additional objects and advantages thereof, will be best understood from the following description of specific embodiments when read in connection with the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a view showing a camera housing with an objective drum in accordance with the present invention;

FIG. **2** is a view showing a light catching groove of the inventive panoramic camera;

FIG. **3** is a view showing a further modification of the light catching groove in accordance with the invention;

FIG. **4** is a view showing a technologically favorable further embodiment of the invention; and

FIG. **5** is a view showing a light catching groove with a light absorbing layer in accordance with the invention.

DESCRIPTION OF PREFERRED EMBODIMENTS

A panoramic camera in accordance with the present invention has a camera housing which is identified as a hole with reference numeral **1**. A drum **3** is supported in the camera housing rotatably about an axis **2**, and an objective **4** is arranged in the drum **3**. The camera is provided with a light inlet opening **5** and illuminating slots **6** which extend through the casing of the drum **3** and are located opposite to one another in an objective ray path. A cylinder segment **7** is provided concentrically to the drum **3** in the camera housing **1** and has segment flanks **8** arranged so that an image window **9** is located between the flanks.

Light catching grooves **10** are provided in the segment flanks **8** and extend parallel to the rotary axis **2** of the drum **3**. The light catching grooves **10** are spaced from the outer edges of the cylinder segment **7** at such an angular distance α, that the ends of the light catching grooves **10** which face toward the image window **9** are covered relative to the outer edges of the cylinder segment **7** by the drum **3** as can be seen from FIG. **2**. An imaginary straight line "g" between the outer edge of the cylinder segment **7** and the end of the light catching groove **10** which faces the image window **9**, intersects the outer surface of the drum **3**.

The panoramic camera in accordance with the present invention operates in the following manner:

When undesired light enters through the gap **11** [see FIG. 2]between the drum **3** and the cylinder segment **7**, the light rays reach the light catching groove **10**. If the light rays are not absorbed by the matted walls of the cylinder segment **7** or the light catching groove **10** or the outer surface of the drum **3**, the light rays, directly or after multiple reflection on the outer surface of the drum and the light catching grooves, reach the end which faces the image window **9**. At this end which is located substantially radially to the drum axis **2**, these residual light rays are turned back and guided back directly or after multiple reflection through the gap **11**.

In a further embodiment shown in FIG. **3**, the segment flanks **8** are provided with a light catching groove **12** which has a portion **12*a*** with a depth increasing in a wedge-shaped manner relative to the image window **9** and a portion **12*b*** which is cylindrical and faces the image window **9**. The operation of this embodiment corresponds to the operation of the first embodiment of the invention.

FIG. **4** shows another embodiment which is favorable technologically for manufacturing purposes. In the embodiment shown in FIG. **4** the light catching groove **14** has a rectangular cross-section.

FIG. 5 shows another embodiment of the invention. Here an additional light absorbing layer 13 is inserted in the light catching groove 12. The light absorbing layer 13 can be composed of any suitable material.

In accordance with a further not-shown embodiment of the invention, a light catching groove can be provided with a plurality of saw-tooth-shaped wedge surfaces or with a plurality of rectangular grooves.

It will be understood that each of the elements described above, or two or more together, may also find a useful application in other types of constructions differing from the types described above.

While the invention has been illustrated and described as embodied in a panoramic camera with an objective drum, it is not intended to be limited to the details shown, since various modifications and structural changes may be made without departing in any way from the spirit of the present invention.

Without further analysis, the foregoing will so fully reveal the gist of the present invention that others can, by applying current knowledge, readily adapt it for various applications without omitting features that, from the standpoint of prior art, fairly constitute essential characteristics of the generic or specific aspects of this invention.

What is claimed as new and desired to be protected by Letters Patent is set forth in the appended claims.

We claim:

1. A panoramic camera, comprising a camera housing having a cylinder segment provided with an image window; an objective drum which is rotatable relative to said cylinder segment about a rotary axis, said cylinder segment having segment flanks located laterally near said image window, said segment flanks being provided with light catching grooves extending parallel to said rotary axis of said objective drum and ending at an angular distance from the outer edges of said cylinder segment, covered by a curvature of said drum.

2. A panoramic camera as defined in claim 1, wherein at least one of said light catching grooves has a depth which increases in a wedge-shaped manner relative to said image window.

3. A panoramic camera as defined in claim 1, wherein at least one of said light catching grooves has a first portion which deepens relative to said image window in a wedge shaped manner and a second cylindrical portion which follows said image window.

4. A panoramic camera as defined in claim 1, wherein at least one of said light catching grooves has a rectangular cross-section.

5. A panoramic camera as defined in claim 1; and further comprising at least one light absorbing sheet arranged in at least one of said light catching grooves.

6. A panoramic camera as defined in claim 1, wherein at least one of said light catching grooves has a plurality of partial grooves.

7. A panoramic camera as defined in claim 6, wherein said partial grooves have a rectangular cross-section.

[57] ABSTRACT

A spatially resolved map of the eye's refractive characteristics are provided by measuring the eye's refractive characteristics on a point-by-point basis across the anterior surface of the eye. This spatially resolved refraction data may be obtained subjectively by providing a reference pattern and a measurement beam, by establishing a particular position on the cornea as the location to be measured and manipulating the orientation of the measurement beam at that measurement point to bring the measurement beam to a desired position relative to the reference image. When the patient indicates that the measurement beam is in the desired position relative to the reference pattern, the orientation of the beam is recorded as the refractive data for that measurement point and the process proceeds to another measurement point. This provides relatively rapid, physiologically accurate refractive data on a spatially resolved basis. Alternatively, this spatially resolved refraction data may be obtained objectively by independently controlling the position and orientation of a measurement beam and using a feedback null system to determine the refractive characteristics. This enables rapid, automatic non-subjective determination of the refractive characteristics of the eye and thereby provides the ability to provide improved correction of the eye. This spatially resolved refraction information enables spatially resolved correction of vision by spatially resolved shaping of the anterior surface of the eye.

SPATIALLY RESOLVED OBJECTIVE AUTOREFRACTOMETER

RELATED APPLICATION

This application is related to U.S. patent application Ser. No. 07/402,946, filed Sep. 5, 1989 and entitled, "Laser Shaping With an Area Patterning Mask" by R. M. Levinson et al. now abandoned, which is incorporated herein by reference in its entirety.

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to the field of measurement of the refractive characteristics of an optical system, and more particularly, to automatic measurement of the refractive characteristics of the human or other animal eye and to corrections to the vision thereof.

2. Background Information

The refractive characteristics of individual components of such man-made optical systems as telescopes, microscopes, cameras and so forth are well understood and susceptible to accurate, non-subjective measurement as are the overall characteristics of such systems.

In such optical systems, prior to their assembly, each component of the optical system is individually accessible for shaping, measurement, modification, adjustment and so forth. Further, each of these components is normally extremely stable over time when disposed in a stable environment. In addition, the position and orientation of each component can be carefully selected and accurately adjusted during assembly and/or alignment of the system, if need be. As a result, the physical configuration of each component and the overall effect it produces in that optical system can be accurately controlled and adjusted to meet the system's overall specifications. Thus, the overall optical system may be accurately characterized as the sum of its parts. Further, in most such systems, both the input and the output ends are accessible with the result that accurate measurement of the complete system is possible.

In contrast with such man-made optical systems, human and animal eyes are optical systems in which the individual internal components of a given eye are not normally separately accessible for either direct measurement or adjustment, the output of the optical system is not directly accessible for analysis and the characteristics of individual components change over time with growth, aging and other factors.

The most common reason for measuring the optical characteristics of a human eye is to determine a prescription for corrective lenses to correct vision problems. Such measurements of the optical characteristics of the eye have long been made by the actual or apparent substitution of lenses with various correction factors with the patient indicating the effect of each substitution in terms of the image being clearer or fuzzier. This technique determines an overall correction for the optical characteristics of the eye.

Such determinations are subject to experimental errors and such events as accommodation of the eye to the substituted lens in a manner which gives the impression that a particular correction is desirable, when in fact that correction is not optimum.

Further, these measurement techniques determine corrections which improve overall vision, but are limited in normal practice to prism, cylindrical and spherical corrections which are low order corrections to the patient's actual, detailed vision errors which include higher order terms or characteristics which these measurement techniques cannot determine.

For the most part these prior art measurement systems are subjective and require the active participation of the patient for their success. In such cases the ophthalmologist must rely on the patient to indicate accurately which images are clearer than others as an indication of the appropriate degree of correction. This requirement for active participation of the patient is a disadvantage in a number of circumstances such as in the diagnosis of small children who have difficulty in understanding what is being asked of them and prevents its use for infants who are incapable of indicating the effect of such lens substitutions.

The requirement for the active participation of the patient in the determination of the characteristics of the eye can have unfortunate effects. Some anomalous conditions result in permanent disabilities because they are not detected during infancy because of the inability of infants to communicate with ophthalmologists. For example, if one eye is in focus and the other is severely out of focus during the time the brain is developing its ability to interpret visual signals, then a permanent disability develops in which the out-of-focus eye is never able to contribute usefully to the brain's image recognition because of a lack of proper stimulation during the period in which the brain's image interpretation functions became established. A person suffering from this condition can tell with the affected eye whether the lines in an image are sharp or fuzzy, but cannot assimilate the perceived information into an image. Present subjective refraction measurement systems are incapable of determining the development of this condition in infants because they cannot accurately diagnose the visual acuity of the eye without the active participation of the patient.

A number of objective refractometers have been developed in the hope of overcoming these problems. However, each of these has had problems or deficiencies of its own. One common deficiency is accommodation by the eye being measured. Another common problem is determining and maintaining accurate alignment of the measurement system during the measurement cycle, since any misalignment can cause inaccurate results.

In recent years, substantial interest has developed in using laser sculpturing, i.e. ultraviolet (UV) light laser ablation, to shape the anterior surface of the cornea as a means of providing corrected vision in place of the use of glasses or contact lenses. U.S. Pat. No. 4,665,913, which is incorporated herein by reference, discloses a UV laser scanning ablation technique for shaping a cornea in which a laser beam which produces a small spot is scanned across the cornea to remove a desired thickness of corneal material on each scan. The area scanned is increased or decreased on subsequent passes to scan each portion of the corneal surface a number of times which is proportional to the thickness of material to be removed at that portion of the cornea.

An alternative to the direct shaping of the corneal surface, is to essentially permanently attach a lenticule to the cornea with the lenticule being shaped to provide the desired vision correction. We say "essentially permanent" because the intention is to leave the lenticule in place permanently, unless some problem should develop which requires its removal. Such lenticules them-

selves may be reshaped or reprofiled by laser ablation at the time of installation or subsequent thereto to compensate for changes in the overall characteristics of the eye. Such techniques are disclosed in more detail in U.S. Pat. No. 4,923,467, entitled, "Apparatus and Process for Application and Adjustable Reprofiling of Synthetic Lenticules for Vision Correction" by Keith P. Thompson, which is incorporated herein by reference.

In addition to the advantages provided by eliminating the need for eye glasses or contact lenses, both of these techniques are conceptually capable of providing substantial additional advantages in that each should, under proper control and with sufficiently detailed correction instructions, be able to produce fully asymmetric reshaping of the cornea in a practical manner, rather than being limited to the sphere, cylinder and wedge approximation mentioned previously.

However, in order to provide such detailed correction, there is a need for measurement techniques which measure the shape of the cornea and the existing refraction characteristics of the eye with the same detail and precision as can be provided by the correction modality in order that the errors may be fully corrected in this manner.

U.S. Pat. No. 4,669,466, which is incorporated herein by reference, discloses a system for providing an ophthalmic surgeon with data on the shape and thickness of the cornea to aid in making surgical decisions. That system measures the contour of the anterior surface of the cornea and the thickness of the cornea in order to provide the surgeon with data as to the present configuration and thickness of the cornea. That system is neither intended for nor capable of determining the refractive correction required for that eye. Rather, the surgeon must rely on a separately determined desired correction.

A measurement system providing such a correction measurement should be fast and should measure the eye's detailed refraction characteristics referenced to the cornea as a function of position across the dilated pupil. This position-dependent measurement may be categorized as a spatially resolved refraction measurement because the refraction at each measurement region (point) is determined in that local measurement region independent of the refraction at other, non-overlapping measurement regions.

Ideally, such a spatially resolved measurement system should be operable in both an objective mode which does not require the patient to interpret the quality of images and a subjective mode in which the patient determines the quality of the image. In that way, the best features of both techniques may be employed and the refraction of both cooperative and non-cooperative patients may be measured. As a desirable alternative, separate objective and subjective embodiments may be provided.

OBJECTS OF THE INVENTION

Accordingly, a primary object of the present invention is to provide an optical measurement system suitable for measuring the refractive characteristics of an eye in a spatially resolved manner.

Another object of the present invention is to provide an optical measurement system which relies on patient responses in measuring the refractive characteristics of the eye in a spatially resolved manner with the measurements referenced to the cornea.

Another object of the present invention is to provide an optical measurement system which relies on patient responses in measuring the refractive characteristics of the eye in a manner which minimizes adverse effects which result from accommodation.

Another object of the present invention is to provide an optical measurement system which does not rely on patient responses in measuring the refractive characteristics of the eye in a spatially resolved manner with the measurements referenced to the cornea.

Another object of the present invention is to provide an automatic optical measurement system capable of fully measuring an optical system in a spatially resolved manner in only seconds, and preferably in well under one second where the optical system is an eye.

Still another object of the present invention is to provide an automatic optical measurement system which avoids fatigue, eye motion and accommodation and which permits multiple measurements to be made.

A further object of the present invention is to provide an optical measurement system which provides the capability for automatic alignment.

A still further object of the present invention is to derive spatially resolved correction data from the spatially resolved refraction data.

A still further object of the present invention is to provide spatially resolved correction of vision.

SUMMARY OF THE INVENTION

The above and other objects which will become apparent from the specification as a whole, including the drawings, are accomplished in accordance with the present invention by determining the refractive characteristics of the eye in a spatially resolved manner. In accordance with this invention, these spatially resolved refraction measurements may made by both subjective and objective refractometers.

In accordance with a subjective refractometer embodiment of the present invention, a reference image or pattern and a measurement beam of light which is essentially collimated, are projected into the eye. The reference pattern and the measurement beam are preferably directed into the eye along two initially different optical paths which are merged into a single optical path by an appropriate optical mechanism such as a beam splitter. The patient controls manipulation of the measurement beam to properly position its image with respect to the reference image or pattern. This is preferably done directly by manipulation of a joystick or another input mechanism, but may also be done by verbal instructions to the ophthalmologist. For each measurement point on the cornea, the measurement beam is preferably held stationary at that measurement point while its impingement orientation relative to the optical axis of the refractometer is manipulated until the patient is satisfied that the image of the measurement beam is disposed in the desired relationship to the reference pattern.

During measurements, the eye must be properly aligned with respect to the refractometer. A desirable alignment choice is with the visual axis of the eye aligned with the optical axis of the refraction instrument. For this purpose we define the visual axis as the path of an optical ray that passes through the centroid of the pupil and strikes the fovea centralis. This visual axis may not be a straight line within the eye because this optical ray can bend through refraction at each of the optical surfaces within the eye. The fovea centralis, as is well known in the ophthalmic art, is that portion of

the retina where the clearest image is produced and can be visually located as a substantially featureless depression in the retinal surface.

In this subjective embodiment, after correct alignment is obtained, the collimated measurement light beam projected by the refractometer is directed at a selected measurement point on the cornea. Typically, the beam diameter is chosen to be 1/5 to 1/10 of the diameter of the dilated pupil, such that measurements may be taken at between 25 and 100 separate measurement regions or "measurement points" on the cornea. At each measurement region, the beam direction is varied in response to patient inputs without changing the location at which the beam impinges on the cornea, until the patient sees the measurement beam as being properly aligned with respect to the reference pattern. The beam's angles, with respect to the instrument's optical axis in two perpendicular planes which include the instrument's optical axis describe the deviation of the beam direction from the optical axis. These angles are recorded and constitute the refraction information for that region of the cornea. The beam is then directed to another measurement point and the process of the patient aligning the measurement beam with respect to the reference pattern is repeated until measurements have been obtained at a desired set of measurement points.

A complete refraction measurement produces a record of these angle pairs for each measurement point. This record constitutes a refraction map of the eye which specifies the eye's refraction as a function of position on the cornea. For example, for an ideal or perfect eye which is perfectly aligned to the refractometer, the result for each measurement point would be 0° for each angle or an angle pair of 0,0. I.e., at each measurement point, the beam would strike the fovea centralis when it was parallel to the optical axis of the refractometer. For a real eye, most of the angles are likely to assume differing non-zero values. A conventional correction prescription in terms of prismatic, cylindrical and spherical corrections can be calculated rapidly from this information within a computer. However, considerably more information is contained within the refraction map. Thus, for example, the conventional refractive corrections can be subtracted within the computer from a full correction to indicate how well or poorly the conventional means can correct the eye. Alternatively, the full correction can be used in controlling a refractive correction technique such as a laser ablation to modify the refraction of the eye in a fully asymmetrical manner to produce a better correction than can be produced by conventional means.

In accordance with the invention, these measurements are preferably made by separately varying the location of the measurement point on the cornea and the direction of the beam at that measurement point.

In accordance with one embodiment, the actual or apparent position of the measurement beam light source controls the measurement beam impingement orientation, that is, the direction at which the measurement beam strikes the cornea relative to the optical axis of the refractometer (or the beams angles with respect to the optical axis in two preferably perpendicular planes, each of which includes the optical axis). A system for shifting the position of the light source serves as an impingement orientation imposer, i.e. controls the direction of the measurement beam with respect to the cornea. The beam is then passed through an aperture which narrows the beam and serves as a position shifter, i.e. selects the location on the cornea of the measurement point. That narrow beam is passed through a collimating lens which focuses the position shifting aperture onto the cornea. The aperture and the cornea are placed at conjugate locations with respect to the collimating lens so that the position of the scanning aperture determines the point on the cornea at which the measurement beam impinges independent of the beam orientation established by the orientation imposer. A beam splitter which combines the measurement beam and the reference pattern is preferably disposed between the collimating lens and the cornea. The reference pattern is separately provided, focused by a reference lens and reflected off the beam splitter toward the eye.

In accordance with an objective refractometer embodiment of the invention for use in measuring the eye, a measurement beam of light which is essentially collimated is projected through a measurement point on the cornea onto the retina where it forms a small illuminated spot. The retina of the eye is imaged onto a photosensitive detector which can determine when this small illuminated spot is essentially precisely centered on a target region on the retina. In response to the output of that photosensitive detector, appropriate electronics guide the movement of that illuminated spot to that target retinal region by generating electronic signals which result in the impingement orientation of the projected beam changing to one at which the illuminated spot is centered on the target region. One example of such a detector is a quadrant photodiode on which the retina is centered with its target region imaged on the origin of the quadrant photodiode. Preferably the origin of the quadrant photodiode is shifted into alignment with the image of the illuminated spot on the retina while the measurement beam of light is aimed along the optical axis of the refraction instrument and the visual axis of the eye.

During operation of this objective refractometer, the eye must be aligned and maintained in alignment for the short time (typically 10–30 milliseconds) required to take a complete set of refraction measurements. A desirable alignment choice is with the visual axis of the eye aligned with the optical axis of the refraction instrument. The eye can be aligned subjectively by the patient fixating on a target placed on the optical axis of the refractometer. Alternatively, correct alignment can be sensed objectively, as, for example, by viewing the position at which an undeflected projected beam from the refractometer passing through the pupil's centroid strikes the retina and moving the eye or the refractometer axis until this position coincides with the fovea centralis.

After correct alignment is obtained, the collimated light beam projected by the refractometer is scanned across the cornea. At each measurement region or point, the beam direction is varied without changing the point at which the beam impinges on the cornea until the position sensing detector determines that the beam is striking the fovea centralis. The beam's angles, with respect to the instrument's optical axis in two perpendicular planes constitute the refraction information for that region of the cornea. Using high speed circuit components, approximately 30 to 50 microseconds is required to complete the beam direction variation at each corneal measurement region. In this case, a complete refraction covering 100 distinct corneal regions can be completed in 3 to 5 milliseconds.

As an alternative to this measurement scheme, the beam direction may be set at a particular orientation and the beam scanned to the various measurement points and those measurement points for which the position sensing detector determines that the beam is striking the fovea centralis may be recorded as having that beam direction as their "optimum" orientation. The beam direction is then changed and the process repeated.

Since the refraction can be accomplished so quickly, the complete refraction can be repeated many times within a few seconds and the results compared to evaluate measurement quality.

In accordance with one embodiment, the measurement beam first passes through an orientation imposer which is a two dimensional beam scanner which provides an orientation-selected collimated beam. That beam is then passed through the position shifter which is a scanning aperture to provide a narrow beam. That narrow beam is passed through a collimating lens which focuses the scanning aperture onto the cornea. The scanning aperture and the cornea are placed at conjugate locations with respect to the collimating lens so that the position of the scanning aperture determines the point of impingement on the cornea independent of the beam orientation established by the orientation imposer.

In accordance with another embodiment, the orientation imposer is a first two dimensional beam deflector, the position shifter is a second two dimensional beam deflector effectively positioned at the focal point of the collimating lens. The orientation imposer and the tangent plane to the surface of the cornea are positioned at conjugate locations to the collimating lens, such as at twice the focal length (f) of the collimating lens with the cornea on the side of the collimating lens opposite the orientation imposer and the position shifter. The direction of deflection imposed by the first beam deflector controls the direction relative to the instrument's optical axis at which the measurement beam strikes the cornea. The second beam deflector determines the position (in two dimensions) at which the measurement beam strikes the cornea by displacing the measurement beam at the collimating lens a distance equal to $f\tan\nu$ from the reference position, where ν is the angle of deflection imposed on the beam by the position beam deflector as measured in the plane defined by the optical axis and the beam itself.

In either fully automatic embodiment, an image of the retina is separately formed on a photodetector for the purpose of determining the point on the retina at which the measurement beam strikes the retina. This retina imaging system may preferably comprise (1) a beam splitter (preferably polarizing) through which the measurement beam passes, preferably after passing through the collimating lens, (2) an additional polarizing filter (optional) and (3) a lens which focuses an image of the retina on the photodetector. The polarizing beam splitter and the polarizer in the retina imaging system serve to filter out light from a cross-polarized measurement beam which reflects off the surface of the cornea or the eye's lines. This minimizes the adverse impact of those corneal reflections (which may be brighter than the image of the retina) on the determination of the location of the bright spot on the retina.

The output from the photodetector is used to determine the location of the image of the beam on the retina. The measurement electronics adjust the beam orientation to move the image of the beam to a reference point such as the fovea centralis, without changing the measurement point. The photodetector may preferably be a quadrant detector or other sensor which provides an output which can be used to rapidly adjust the beam orientation to move the beam image to the reference point. Under these conditions, the system operates as a negative feedback loop to maintain the beam image in the null position (at the reference point) as the location of the measurement point is scanned across the eye. When implemented with suitable optics and high speed electronics, this overall system can obtain the data necessary for a hundred point map of the refractive characteristics of the eye in well under one second.

The spatially resolved refraction data, in combination with a measured existing surface contour of the anterior surface of the eye, enable the calculation of a detailed (spatially resolved) new contour for the anterior surface of the eye which will provide corrected vision. This new contour is provided by detailed (spatially resolved) modification of the contour of the anterior surface of the eye, as by laser ablation.

BRIEF DESCRIPTION OF THE DRAWINGS

The subject matter which is regarded as the invention is particularly pointed out and distinctly claimed in the concluding portion of the specification. The invention, however, both as to organization and method of practice, together with further objects and advantages thereof, may best be understood by reference to the following description taken in connection with the accompanying drawings in which:

FIG. **1** is a perspective, schematic illustration of one embodiment of a subjective refractometer in accordance with the present invention;

FIG. **2** is an optical diagram of the subjective refractometer of FIG. **1**;

FIGS. **3A**, **3B** and **3C** illustrate images observed by the patient during the use of the FIG. **1** refractometer;

FIG. **4** is a perspective illustration of an autorefractometer in accordance with the present invention;

FIGS. **5** and **6** comprise optical diagrams of the structure of FIG. **4** under different conditions;

FIG. **7** illustrates conditions at a measurement point;

FIG. **8** is an illustration of a measurement beam scanning pattern produced by the system of FIG. **7**;

FIGS. **9–11** are illustrations of an alternative embodiment of the projection portion of the FIG. **4** system; and

FIGS. **12A** and **12B** are diagrams of geometric relationships at a measurement point.

DETAILED DESCRIPTION

In order to determine the refractive characteristics of an eye, in accordance with the present invention, a narrow, collimated measurement light beam is directed to selected measurement points on the cornea of the eye, one measurement point at a time. While holding the measurement beam to impinging on the cornea at the selected measurement point, the direction or orientation of the measurement beam relative to the refractometer system's axis (that is, the measurement beam's impingement orientation or direction) is adjusted until the measurement beam strikes the retina in a location associated with desired or optimum performance in accordance with the criterion being employed for the refraction measurement. Once that direction or orientation has been determined for a given measurement point, a different measurement point is selected and the process is repeated.

Since vision involves both physical optics within the eye and physiological effects within the image processing portions of the mind, we consider it preferable to involve a cooperative patient in the determination of when the beam is in the position which corresponds to optimum image formation. To this end, in a first, subjective refractometer embodiment of the present invention, we include a reference image generating portion **50** for providing a reference image with respect to which the patient adjusts the measurement beam into a desired optimum relationship. In the refractometer embodiment **8** illustrated in a perspective view in FIG. **1** and as an optical diagram in FIG. **2**, a reference image generation system **50** comprises a source **52** of a reference image **53**, a shaping lens **54**, an opaque member **56** having a beam size restricting aperture **58** therein, a reference collimating lens **64**, a mirror **66** and a beam splitter **68**. The opaque member **56** serves to prevent the light which forms the reference pattern from flooding the cornea and the aperture **58** therein allows the light which forms the reference pattern to enter the eye in the vicinity of the center of the pupil. This is to minimize distortion of the reference pattern as a result of any existing refractive errors. To this end, the opaque member **56** is positioned where reference collimating lens **64** conjugates it to the cornea **42**. The lenses **54** and **64** focus the reference image **53** onto the retina of the eye and are positioned with a common focal plane disposed between them with their axial focal points which are disposed in that focal plane co-incident and respectively conjugate with respect to the image source **52** and the retina **48** whereby the image source **52** is positioned conjugate to the retina **48**. The mirror **66** bends the reference optical path toward the optical axis of the eye and the beam splitter **68** bends the reference optical path into the eye substantially concentric to the eye's optical axis while allowing the measurement beam which is separately provided by a projection portion **10** of the refractometer to pass directly through the beam splitter to reach the eye substantially parallel to the eye's optical axis. Thus, beam splitter **68** preferably merges the reference image and the measurement beam to cause them to appear to the eye as two parts of a single image. In FIG. **1** the distance between the lens **64** and the eye **40** is excessive compared to the distance between the lens **14** (to be discussed subsequently) and the eye. These two distances are preferably the same in the actual system. In the drawing the need to fit all of the elements of the Figure on the drawing sheet results in the lens-**64**-to-eye distance being exaggerated.

A vast number of reference images may be used in accordance with the particular vision characteristics of the patient and the portion of the eye to be measured. For reasons to be discussed subsequently, our preferred reference image comprises an illuminated circular annulus **53** as illustrated in FIG. **3A**. It may be considered desirable to provide a discrete fixation target such as a cross within the reference image **53** in order to aid the patient in maintaining eye fixation throughout the measurement process. However, that is generally unnecessary in this embodiment since the reference pattern itself serves as a fixation target. The pattern shown in FIG. **3A** is the image the patient sees (1) with a reference image which does not include a separate fixation target while (2) the measurement beam **18** (to be discussed subsequently) is turned off or blocked. We prefer to have the patient adjust the focus of the annulus **53** at the beginning of the measurement process so that it appears sharply defined to the patient. This adjustment of the focus of the annulus **53** is to minimize the effect of any existing refractive errors on the measurements to be taken.

This adjustment to sharp focus may be done manually by the patient adjusting the position of the collimating lens **64** or the position of the reference image source **52** with respect to the position of the collimating lens **64**. Alternatively, it may be done under electronic control by the patient manipulating a joy stick **74** which is connected to a control system **80** which then, in turn, controls the position of either the collimating lens **64** or the reference image source **52**, and/or other components of the reference portion of the system. As a further alternative, the adjustment may be done by the ophthalmologist in response to responses from the patient.

The eye is generally properly aligned with respect to the optical axis of the refractometer when the patient is "looking at" the reference pattern.

With these preliminary adjustments completed, the system is ready to perform a refraction on the patient's eye.

A projection portion **10** of the refractometer **8** comprises a point light source **12** which may preferably be a light emitting diode (either an incoherent diode or a laser diode, as may be preferred).

For this subjective refractometry system, the light source **12** provides a beam of visible light which the patient can see in order to make the decisions and/or adjustments required in the process of performing the refraction measurements.

The position of the light source **12** is controlled by an impingement orientation imposer **20** which operates under the control of the control system **80**. A light source **12** should be disposed at a distance from orientation imposer **20** which renders its light rays substantially parallel at the angle imposer. The light source **12** may be mounted on an X-Y table or stage **22** or any other mechanism which is suitable for shifting the position of the light source in the X-Y plane in the FIG. **1** and **2** illustrations. The X-Y stage **22** should be capable of providing accurate, repeatable small changes in the position of the light source **12** in a manner in which the control system **80** is accurately informed of the actual position of that light source. The light emerging from the light source **12** passes through a lens system **24** which focuses that light into a beam which is focused in the focal plane of the lens system **24**. This focus of the beam to a point in the focal plane is provided independent of the setting of the X-Y stage. As an alternative to movement of the light source itself, the position of the light source may be fixed with the light from the light source being reflected by a galvanometer mounted mirror whose orientation is controlled by control system **80** to provide an effect like that produced by moving the light source in the plane in which the X-Y stage is disposed in FIG. **1**.

After passing through the lens system **24**, the light from light source **12** passes through a position shifter **30** whose function is to control the location of the measurement point on the cornea. In the illustrated embodiment, the position shifter **30** comprises an opaque member **32** whose position in the X-Y plane is controlled by control system **80** via a position drive system **36** which may be another X-Y stage. The opaque member **32** has a single, small aperture **34** therein. In FIG. **1**, the full pattern of the measurement light beam is illustrated as though member **32** were transparent. FIG. **2** illustrates

a beam pattern present in the system during actual use, i.e. with the member **32** being treated as being opaque except for its aperture **34**. As will be observed, only a portion of the light from light source **12** passes through the aperture **34** to comprise the beam **18** (FIG. **2**) with the remainder of the light being blocked by the member **32**. In a manner to be discussed subsequently, the position of the aperture **34** controls the location of the measurement point on the cornea. The size of the aperture **34** also controls the size of the portion of the cornea which constitutes a measurement point, that is, the size of the portion of the cornea whose refractive characteristics affect the data at that measurement point. The measurement beam at the cornea is preferably small in diameter compared to the area of the dilated pupil (also referred to as the active portion of the cornea) and preferably has a diameter of about 0.5 to 1 mm or less (about 1/10 to 1/5 of the diameter of the dilated pupil). The dilation of the pupil may be as a result of dark adaptation or medication or other causes. Dilation of the pupil is not essential, but in absence of dilation, measurements are limited to that portion of the corneal surface through which light of the measurement beam can reach the active retina. Such restricted data limits the quality of the correction which can be provided.

After passing through the aperture **34**, the light passes through the focal plane of the lens system **24** at a point whose location is determined by the position of the aperture **34**. Thereafter, the light beam expands until it reaches the collimating lens **14**. The collimating lens **14** is positioned with its focal plane coincident with the focal plane of lens system **24** and with its focal point **16** coincident with the focal point **29** of the lens system **24**. Upon emerging from the collimating lens **14**, the light beam is collimated with parallel rays because the incident light beam was focused in the focal plane of the collimating lens **14**. This narrow beam **18** of parallel light rays (FIG. **2**) then passes through the beam splitter **68**. The beam splitter **68** is not a necessary part of the projection portion **10** of the refractometer, but is present to combine the measurement beam **18** and the reference image **53** into a single image as seen by the eye. The measurement beam enters the eye via the cornea **42** at the selected measurement point and is refracted by the cornea which provides much of the eye's refraction. Thereafter, the measurement light beam is further refracted by the lens **46** of the eye and finally strikes the retina **48** of the eye.

The position shifter **30** and the measurement surface (cornea **42**) of the eye **40** are positioned with respect to the collimating lens **14** so that they are at conjugate surfaces. In general, conjugate surfaces, are paired surfaces associated with a lens. A characteristic of conjugate surfaces for a lens is that any light passing through a given point in the first conjugate surface (on the first side of the lens) will pass through the corresponding or conjugate point in the second conjugate surface (on the second side of the lens). This is true independent of the light's orientation at the first conjugate surface, so long as that light passes through the lens rather than passing beyond its outer edge. Specifically, if the member **32** and the cornea of the eye are disposed on opposite sides of a collimating lens and each is positioned twice the collimating lens' focal length from the collimating lens, then the member **32** and a tangent plane to the cornea (perpendicular to the axis of the projection system) are conjugate surfaces. Consequently, any light passing through an aperture **34** in the member **32** will also pass through the corresponding measurement point on the cornea of the eye. It is in this manner that the position of the aperture **34** determines the location of the measurement point.

The direction of propagation of (also referred to as the orientation of) the measurement beam where it strikes the cornea is determined by the direction or orientation of the measurement beam at the focal plane of the collimating lens. For a properly configured refractometer, if the orientation imposer **20** is set so that the rays emerging from the lens system **24** are focused above the axial focal point **16** of collimating lens **14** (that is, angled upward), then the light rays emerging from collimating lens **14** are disposed parallel to each other, but angled downward at a corresponding angle. If the orientation imposer **20** is not imposing a deflection on the light beam, the light rays emerging from the lens system **24** are focused at the axial focal point of collimating lens **14** (that is, the light rays are parallel to the optical axis), then those light rays are disposed parallel to the axis of the optical system when they emerge from collimating lens **14**. If the orientation imposer is set so that the light rays emerging from the lens system **24** are focused below the axial focal point **16** of collimating lens **14** (that is, angled downward), then those light rays emerge from collimating lens **14** angled upwards relative to the axis of the optical system. As a result, for these three conditions, the light rays at the corresponding measurement point on the cornea are traveling, respectively, downward, parallel to and upward with respect to the optical axis. It will be understood that this type of relationship applies also to beams which are angled relative to the YZ plane, the YZ plane being the plane of the paper in the drawing. In all cases, the beams will impinge on the cornea at the same point because the collimating lens **14** conjugates points on member **32** at the cornea, i.e. it focuses an image of the member **32** onto the cornea. This ability of the imposer to control the orientation at which the light ray impinges on the cornea surface without changing the position where it meets the cornea is important in this technique for measuring the refraction of the eye as is described hereinafter. The impingement orientation or direction is set relative to the optical axis of this refraction instrument (i.e., it is *not* the angle of incidence of the beam on the cornea, that is, it is *not* measured relative to the normal to the cornea surface at the measurement point).

It will be recognized that if the aperture **34** in the member **32** were large enough, the entire active portion of the cornea would be illuminated by the measurement beam. The small size of the aperture **34** serves to block any portion of the light beam emerging from the lens system **24** which would strike the cornea outside the desired measurement point and has no effect on the orientation of the measurement beam at the cornea for a properly focused beam emerging from the lens system **24**.

At a measurement point where the eye exhibits refractive error, a narrow beam of light oriented parallel to the optical axis of the refractometer does not get refracted to the fovea centralis, but rather is refracted to some other location. However, there is another orientation for a narrow light beam at that measurement point which results in the beam being refracted to the fovea centralis. The difference in orientation of these two beams is a measure of the present refractive error at that measurement point. It will be recognized, that the orientation of that off-orientation beam is defined by its

angle with respect to the optical axis of the refractometer system in the Y-Z plane and its angle with respect to that optical axis in the X-Z plane.

For a measurement beam which is oriented parallel to the optical axis of the refraction system at a measurement point where the eye exhibits refractive error, the image seen by the patient will appear in some fashion like that illustrated in FIG. 3B in that the image of the measurement beam **18** will not be centered in the center of the blank (nonilluminated) disk in the middle of the annulus **53**. With the joystick now connected to control the position of the light source **12** by controlling the X-Y stage **22** (or mirror, if used), the patient manipulates joystick **74** to bring the image of the measurement beam **18** into the center of the annulus **53**, as illustrated in FIG. 3C. As is known from target rifle shooting, the human eye and mind together can determine when a small disk is centered within the open center of an annulus with great accuracy. It is for this reason that the annulus **53** is a preferred reference pattern for this subjective refraction measurement. When the patient concludes that the image **18** is centered in the annulus **53**, the patient presses the joystick button **76**. At that point, the control system records or stores the position of the X-Y stage **22** as the measured data for that measurement point. The recorded information may be the physical positioning of the X-Y stage (or mirror or other orientation control structure) or the beam angles in the X-Z and Y-Z planes which result from that position or any other appropriate data. Recording that data completes the process of measuring the refraction of the eye at that measurement point. The control system **80** may be considered as a means for storing data representative of the position and/or orientation of the measurement pattern when said measurement pattern is in the desired relationship centered within the annulus **53**. The control system **80** may also be considered as a means for providing data indicative of the refraction of the eye. The control system **80** then causes the position shifting drive system **36** to shift the member **32** to place the aperture **34** in a new location which corresponds to the next desired measurement point. Once again, the patient manipulates the joystick to center the image **18** in the annulus **53** and presses the joystick button when it is centered.

Use of this reference pattern measurement beam positioning technique minimizes the problem of accommodation because the bulk of the image perceived by the patient remains fixed throughout the measurement process because no lenses are substituted in front of it and only the initial position of the measurement beam changes from measurement point to measurement point.

This process is repeated at each desired measurement point on the cornea until all of the desired measurement data has been taken. This measurement process can include repeating measurements at each measurement point more than once in order to ascertain that the data is accurate, or at least repeatable. Further, substantially identically data for the same measurement point taken at different times provides assurance that the eye was still in the same location and orientation at the time of the repeated measurements as it was at the time of the original measurement. Several substantially identical measurements at each measurement point ensure that the eye has remained stationary during the measurement process and that the data is therefore valid.

One advantage with this subjective system is that the process of making the measurement can help in obtaining and retaining a child's attention by presenting it as being like a video game in which the goal is to center the measurement beam spot in the central disk of the reference pattern.

For use with a non-cooperative patient, an objective, automatic refractometer is preferred. Such an objective, automatic refractometer system **108** in accordance with the present invention is illustrated in a perspective, stylized view in FIG. **4** and in a side view as an optical diagram in FIGS. **5** and **6**. Automatic refractometer system **108** comprises a projection portion **110**, a sensing portion **150** and a control system **180**. In both FIGS. **4** and **5**, the full pattern of the light beam is illustrated as though the scanning disk **132** within the projection portion **110** were transparent. FIG. **6** illustrates a beam pattern present in the system during actual use, i.e. with the scanning disk **132** opaque except for its scanning apertures.

The autorefractometer **108** comprises a light source **112** which provides a narrow collimated beam of light having a frequency to which the components of the eye in front of the retina are transparent and to which the retina is at least partially reflective or scattering. Thus, this light source may preferably be a laser which emits visible, UV or infrared radiation. In this specific embodiment, the laser beam is preferably vertically polarized. The beam from this laser passes through beam impingement orientation imposer **120** which may be an acoustic/optical (A/O) scanner **122** in combination with a lens system **124**. In accordance with control signals applied thereto, the scanner **122** is capable of deflecting the angle of the beam in both the vertical and horizontal directions simultaneously. Other two dimensional beam deflectors such as galvanometer mounted mirrors may also be used.

The light beam emerging from (A/O) scanner **122** passes through the lens system **124** which is shown in this schematic illustration as being a telescope including lenses **126** and **128**. This beam of light, when it emerges from the lens **128**, is converging toward a point in the focal plane of the lens system **124**, independent of the selected measurement beam orientation.

A position shifter **130** comprised of a scanning disk **132** is positioned in the path of the light beam emerging from the orientation imposer for the purpose of establishing the position of the measurement point on the cornea. This is done by restricting the light beam to a small cross-section (narrow beam) (FIG. **6**) which is appropriate for making the desired measurements of the refraction of the eye. The location of the aperture which narrows the beam controls the location in which this narrow light beam strikes the cornea. This narrowed laser beam is preferably small in diameter compared to the area of the optically active portion of the cornea and preferably has a diameter of about 0.5 to 1 mm or less.

This scanning mechanism (rotating disk **132**) scans the measurement beam or measurement point along the surface of the eye in a predetermined pattern. However, we use "scan" as a general term which is free of implications as to the particular type of scan pattern employed. Depending on the scanning mechanism employed, the measurement point may be scanned in a continuous manner or in steps or jumps separated by pauses between such movements along the surface of the eye. Such pauses may be uniform or of varying length. The scan pattern may follow a predetermined path (such as a raster scan), may follow a random path or a path

which is dependent on the results of previous measurements, or any other desired path.

After passing through the scanning disk **132**, the light comes to a point in the focal plane of lens system **124**, after which the light beam expands until it reaches a collimating lens **114** having its focal plane coincident with the focal plane of lens system **124** and its focal point **116** coincident with the focal point **129** of lens system **124**. Upon emerging from the collimating lens **114**, the light beam is collimated with parallel rays because the incident light beam was focused in the focal plane of the collimating lens **114**.

This narrow beam of parallel light rays then passes through a beam splitter **168** which preferably passes vertically polarized light and reflects horizontally polarized light. Substantially all the light in the beam passes through the beam splitter, because none of the operations performed on the beam has the effect of changing its polarization. Beam splitter **168** is part of the sensing portion **150** of the system rather than the projection portion **110**. The light beam is refracted by the cornea **142** of the eye **140**, is further refracted by the eye's lens **146** and finally strikes the eye's retina **148**.

The scanning disk **132** and the measurement surface (cornea **142**) of the eye **140** are positioned with respect to the collimating lens **114** so that they are at conjugate surfaces.

The light beam in FIGS. **4** and **5** subtends, encompasses or spans the entire active part of the cornea at all useful beam impingement orientations in order to ensure than any desired beam impingement orientation (relative to the optical axis) can be provided at any given measurement point.

What is actually present at the measurement surface or cornea is an image of the scanning disk **132**. However, since only the scanning aperture **134** (about 0.5–1 mm in diameter) in the scanning disk transmits light, the rest of the scanning disk's image is dark and we observe the 0.5–1 mm diameter light beam from hole **134** as though it were the entire image.

Together, the position shifter **130** (scanning disk **132**) and the orientation imposer **120** (scanner **122** and lens system **124**), under the control of the control system **180** independently control both the position at which the beam strikes the cornea and the impingement orientation at which it strikes the cornea. This capability is of general utility and not restricted to this particular application.

The measurement region of the cornea at which the measurement beam is directed may be at any desired location on the cornea. For perfect refraction, a measurement beam which is disposed parallel to the visual axis should impinge on the retina at the fovea centralis. If the measurement beam strikes the eye in the center of the fovea centralis, then the eye's refraction at this measurement point is considered optimum.

A fraction of the light which strikes the retina is scattered by the retina. This scattered light leaves the retina in all directions. The portion of this scattered light which strikes the eye's lens **146** is refracted, continues on toward the iris **144** (which blocks any portion outside the pupil), continues on to the cornea **142** where further refraction takes place as the light emerges from the cornea into the ambient atmosphere. On emerging from the cornea, the rays of light will be parallel for an eye having optimum refraction. This emergent beam of light then enters the sensing system **150** by striking the surface of the beam splitter **168** which reflects the horizontally polarized portion of that light toward a photodetector **172**. The beam splitter **168** is preferably chosen to pass one state of polarized light and to reflect the other polarization state. The polarization of the projected laser light is chosen to be in the "pass" state (vertical in this example) so that substantially all of that projected light beam will pass through the beam splitter and strike the cornea. Light reflected off the cornea and the eye's lens back toward the beam splitter will primarily pass through the beam splitter and only be reflected weakly by the beam splitter because reflections off a smooth surface at relatively small angles with respect to the surface normal are by nature so-called Fresnel reflections in which the reflected light is strongly polarized in the same direction as the incident light. However, the light scattered off the cells of the retina is partially-to-completely depolarized and thus will be significantly reflected by the beam splitter. In this way, a clean image of the measurement beam spot on the retina can be obtained without clutter from the reflections off the cornea and lens of the eye. Any remnants of clutter from the Fresnel reflections can be further filtered by a polarization filter **164**. The remaining light is then focused on the photodetector **172** as an image of the retina by a retina imaging lens **166**.

This interaction of the measurement beam with the eye is shown schematically in the optical diagram in FIG. **6**. The incident beam is narrow and collimated because of the nature of its production. In contrast, the light pattern emerging from the eye is substantially wider than the incident beam because of the scattering at the retinal surface which produces that beam.

The position photodetector **172** is preferably composed of four separate quadrants 172_{Q1}–172_{Q4}. Such a quadrant detector provides an output signal indicating which quadrant or quadrants of the detector have the most light impinging on it or them and, therefore, in which quadrants of the detector the image of the illuminated spot on the retina is predominantly located. The control system **180** processes the output signals from the quadrant detector **172** and generates control signals for the orientation imposer **120** which set an orientation which brings the beam spot on the retina to a reference point on the retina. The origin of the quadrant detector is placed so that the image of the retina reference point is centered there. This reference point is the point at which it is desired to have parallel-to-the-axis rays focus. The reference point is normally the fovea centralis.

A reference point other than the fovea centralis may be selected. However, it is preferred in most cases to select the fovea centralis as the reference point, since that ensures that the refractive correction determined will in fact result in focusing an image disposed on the optical axis at infinite distance at the point of maximum visual acuity. During measurements on a cooperative patient, this reference point is preferably established at the fovea centralis by asking the patient to fixate on the measurement light beam when it is on axis and its set impingement orientation is zero. The quadrant detector is then shifted so that the image of the beam spot on the retina is centered at its origin so that its output indicates that the beam is centered at the reference point.

FIG. **7** is a diagram illustrating an incident ray $\vec{A}$ disposed parallel to the optic axis which is refracted by the cornea at a measurement point **192** into the beam $\vec{B}$ which strikes the retina below the fovea centralis and an incident ray of light $\vec{C}$ disposed at an angle to the optic axis which is refracted by the cornea at measurement

point **192** into the beam $\vec{D}$ which strikes the retina at the fovea centralis. $\hat{M}$ is the normal to the tangent plane **96** at the measurement point **192**. How small a cross-section the measurement beam needs to have depends in part on the desired measurement accuracy, in part on the focusing limits of light and in part on how rapidly the refractive characteristics of the eye change with position. The size of the measurement region is determined by the size of the measurement beam. For a small enough measurement beam, the measurement region may be called a measurement point. The term "measurement point" is also used as the point at which the center of the measurement beam is directed, independent of its size. For refractions which vary slowly with the position, a larger beam cross-section can provide more accurate data because the diffractive nature of light allows a larger beam to be focused into a tighter spot on the retina. Thus, reducing the measurement beam's cross-section only improves measurement accuracy up to a point. As illustrated in FIG. **7**, the angle of the ray of light $\vec{C}$ is substantially displaced from the optical axis for drawing clarity. It is this deflection (in two dimensions) of the incident beam from parallel to optical axis which provides the data which enables the refraction of the eye to be determined.

Where the visual axis is treated as the Z-axis of an XYZ coordinate system, the XY plane can be located tangent to the cornea at its intersection with the visual axis. The orientation of the measurement beam may be uniquely specified by specifying its angle in the XZ plane relative to the normal $\hat{M}$ and in the YZ plane relative to the normal $\hat{M}$.

Conceptually, a parallel-to-the-axis measurement beam is directed at each measurement point on the cornea and the general direction of the resulting bright spot's displacement from the fovea centralis is determined from the output of the quadrant detector. In response to that output signal, the control system **180** sets the orientation imposer **120**'s A/O scanner **122** to deflect the orientation of the beam to cause the bright spot to move closer to the fovea centralis. When that bright spot is centered in the fovea centralis, it is centered in the quadrant detector whose output signal then indicates that all the quadrants are receiving substantially equal illumination at which point the deflection angles (vertical=YZ-plane and horizontal=XZ-plane) imposed by the A/O scanner **122** are recorded along with the location of the measurement point on the cornea as a data point for a corneal map of the eye's refractive characteristics.

Where a quadrant detector is used to detect the location of the bright spot on the retina, the parallel-to-the-axis beam produces no quantitative data, unless the bright spot for such a beam is centered in the fovea centralis. Consequently, in the interest of system simplicity, speed and elegance, an initial beam or ray oriented parallel to the refractometer's optical axis is used only with the first data point of a scan (as a default position). Thereafter, the measurement beam deflection angle is maintained at its deflected value as the measurement point is scanned across the eye and the quadrant detector's output is used as a feedback signal to adjust the A/O scanner angle to maintain the bright spot centered in the quadrant detector as the measurement point (beam) moves. Thus, this system operates on the null principle in which feedback control signals are used to maintain the bright spot centered in the quadrant detector with the control signals themselves providing the measurement data, rather than in an open loop manner in which the position of the bright spot must be continually measured, with the measured position of the bright spot being the data. Since measuring the position of the bright spot is a time consuming process, the null system of this invention can operate much more rapidly than an open loop system. Further, it provides substantially increased measurement accuracy over that provided by an open loop system. Consequently, this system can accurately measure the refractive characteristics of the eye in almost unbelievably short times.

The scanning pattern across the eye with use of the scanning disk **132** is illustrated in FIG. **8**. In this pattern, each scan line is scanned in the same direction as successive apertures in the disk come into alignment with the laser beam. Successive scans are all in the same direction and the size of a measurement point **192** is determined by the size of the apertures **134**. Each aperture **134** in the scanning disk controls scanning across a strip of the cornea which, although actually an arc, is essentially straight because of the small portion of the scanning disk subtended by the light beam from the lens system **124**. The individual scan lines are illustrated as being spaced apart vertically for drawing clarity. It will be understood that in an actual system, they may be spaced apart, just contiguous or overlapping, depending on the positioning of the apertures **134** in the scanning disk **132**.

With a constantly rotating scanning disk **132**, the locations of measurement points along the scan line for a given hole in the disk is determined by the point in time at which the data is taken. Acoustic/optic scanners, quadrant detectors and electronic systems, are available which are fast enough to institute a change in the impingement orientation of the measurement beam and determine the effect of that change in less than 10 microseconds in this null system. This makes it possible to take measurements at a rate of one every 30 microseconds if no more than three orientation adjustments are needed per measurement point on the average. One measurement point every 30 microseconds corresponds to 100 measurement points in 0.003 second. Once a given aperture **134** in the scanning disk has scanned past the active area of a cornea, the next lower aperture in the scanning disk comes into the beam from the telescope and starts the next higher scan across the cornea. With the scanning disk rotating at 18,000 rpm, a complete revolution of the scanning disk takes 0.0033 second. Consequently, the entire scanning of the eye can be done in 0.0033 second. This total scanning time is fast enough that the eye does not accommodate (that is, refocus) in response to the stimulation provided by the measurement light beam. At a nominal disk speed of 1,800 rpm the entire scan pattern would be completed in 0.033 second. Preferably, a map having from about 25 to 100 data points is generated in order to provide detailed information on the existing refractive characteristics of the eye. More or fewer data points may be used as may be preferred. A scanning disk **132** may be used in the FIG. **1** system **8** for measurement point control, provided that the light source **12** is pulse or flashed in synchronism with the rotation of the scanning disk so that the light source is only on when the aperture **134** is positioned at the measurement point at which data is presently being taken.

For scan line sweeps of the type illustrated in FIG. **8**, the orientation which results in the bright spot being centered in the fovea centralis is expected to vary rela-

tively smoothly with position along the scan line for typical corneal configurations. Abrupt changes are expected only with a relatively rough surfaced (injured or diseased) corneas. Thus, the setting of the A/O scanner **122** deflection angle will normally vary in a smooth manner which requires only minor variations in the deflection setting to keep the bright spot centered in the fovea centralis as the measurement point moves across to the eye.

A major advantage of this null scanning technique is that the control system **180** operates essentially as a negative feedback loop which continuously adjusts the A/O scanner **122** to keep the bright spot centered in the quadrant detector (at a null). The use of the scanning disk which scans across one "strip" of the cornea at a time provides the ability to take data points as close together along that strip as may be considered desirable. It is only at the transition between different apertures in the scanning disk (which control the scanning across different strips of the cornea), where a significant abrupt change in orientation required from the orientation imposer **120** should occur. However, the orientation imposer setting for the beginning of one scan line can be expected to be similar to the orientation for the beginning of the previous scan line. Consequently, if desired, during the "dead" time between scan lines, the scanner can be switched from its end-of-the-first-scan-line value back to its beginning-of-the-first-scan-line value in anticipation of the beginning of the second scan line in order to minimize feedback loop settling time.

At the beginning of each scan line in FIG. **8**, the measurement beam is preferably positioned on the cornea in a location where it strikes the iris rather than passing through the pupil. The iris scatters this incident light in a manner quite similar to that in which the retina scatters the incident light. Consequently, even with the use of a polarized system, substantial light will reach the quadrant detector while the beam is impinging on the iris. The intensity of the light striking the quadrant detector will be substantially greater while the beam is striking the iris than it is when the beam is striking the retina. This is (1) because of the small portion of light which is scattered by the retina rather than being absorbed and (2) because of the relatively small solid angle of the light scattered by the retina which can reach the quadrant detector as compared to the solid angle for which light scattered by the iris can reach the photodetector.

While this relatively high intensity light striking the quadrant detector when the beam is on the iris might initially seem to be a problem, it is actually a benefit in that it enables automatic alignment of the system and automatic tracking of the alignment of the system. In particular, the topmost aperture in the scanning disk should result in the beam striking the iris for the full scan. The first aperture for which the measurement beam passes through the pupil will have a brief period of low intensity light impinging on the photodetector **172**. During that time, useful data will be taken. As successive apertures scan the eye, the period of low intensity light on the quadrant detector will increase until the scan which crosses the center of the eye. Thereafter, the period of low intensity light on the quadrant detector will decrease with successive scans until there is no period of low intensity. For proper alignment, the "circle" of beam position for which low intensity illumination strikes the quadrant detector should be centered in the scan pattern. We say "circle" because although the pupil is often thought of as being circular, many pupils are not perfect circles. Consequently, proper alignment of the system can be checked after the data is taken. Further, while the data is being taken, any unexpected substantial offset in the point at which the low intensity portion of the scan begins or ends is an indication that the eye has moved relative to the measurement system. Thus, proper alignment is automatically determined and checked.

Proper alignment can be checked in the initial stages of the scanning process if, instead of the aperture pattern illustrated in FIG. **4** in which successive apertures are disposed on a single inwardly curving spiral, the apertures are alternated between the outermost aperture and the innermost aperture working successively toward the middle aperture. In that way, the first aperture scans the bottom of the cornea, the second aperture scans the top of the cornea, the third aperture scans the next strip toward the center of the eye at the bottom of the cornea, the fourth aperture scans the next strip toward the center of the eye at the top of the eye and so forth. In this manner, for a properly aligned system with a circular pupil, the system is properly aligned when after the first scan in which the beam passes through the pupil, every following scan of the beam passes through the pupil. If that does not occur, then the eye is misaligned with respect to the measurement system and realignment is desirable prior to taking the measurements.

During the time the quadrant detector output is large because the measurement beam is striking the iris, the beam impingement orientation does not need to be adjusted, since the beam cannot strike the fovea centralis and thus its image cannot be centered in the quadrant detector. Pinning of the orientation adjustment portion of the electronics at a maximum deflection angle in an attempt to center this "image" is preferably avoided by including a threshold detector in the orientation adjustment portion of the control system to freeze the orientation for quadrant detector outputs in excess of the threshold value.

Control system **180** serves many functions in this system. It provides appropriate control signals to the orientation imposer and the position shifter, it receives the signals from the position sensor, establishes the locations of the measurement points, determines the impingement orientation for each measurement point, stores the measurement values for subsequent use or output and so forth. This storage is preferably in electronic form, but may also be provided in paper or other forms. The control system can also perform the data reduction which is discussed hereinafter in connection with determining appropriate corrections for the measured eye and so forth.

One disadvantage of the system **108** of FIG. **4** is the fact that it is rather inefficient in the use of laser power. In particular, the laser beam which emerges from the hole in the scanning disk is a small fraction of the overall area of the beam striking the disk. The resulting waste of laser power is of concern from an efficiency point of view. Also of possible concern is the fact that if the scanning disk were, for some reason, removed from the apparatus and the apparatus were turned on with a patient's eye in the measurement position, the full laser power would be incident on the eye. That could cause damage to the eye.

These potential disadvantages of the FIGS. **4–6** embodiment of the invention are avoided in accordance

with an alternative embodiment **208** illustrated in FIGS. **9–11**. In the system **208**, reference numerals which are higher by **100** than corresponding reference numerals in the system **108** identify portions of the system which perform substantially the same function as their corresponding system **108** components. In system **208**, the sensing portion of the system, the control system and the internal components of the eye are omitted for drawing clarity. It will be understood that in FIGS. **9–11**, they would be similar to those shown in FIGS. **4–6**. In FIG. **9**, the cornea **242** of the eye is positioned at twice the focal length f of the collimating lens **214** from the collimating lens. The beam splitter **268** serves the same purpose as the beam splitter **168** in system **108**. To the left of the collimating lens **214**, an orientation imposer **220** is positioned at twice the focal length of the collimating lens from the collimating lens and thus is conjugate to the cornea. Also on the left-hand side of the collimating lens is a position shifter **230** which is positioned at the focal plane of the collimating lens and preferably centered at the focal point of the collimating lens. The laser **212** provides the measurement light beam.

Suitable devices for use as the orientation imposer **220** are acoustic/optic scanners, galvanometer mounted mirrors or other devices. Suitable devices for use as the position shifter **230** are galvanometer mounted mirrors or other devices. Acoustic/optic scanners are not suitable at this time because of their requirement that the incident beam be disposed strictly on and parallel to their axis. It will be recognized that where galvanometer mounted mirrors are used to control the deflections which select the orientation or position, the optical axis will not be a straight line, but will be reflected at each of the mirrors. However, the effect will be similar. The orientation imposer **220** and the measurement surface (cornea) may be positioned at any conjugate locations for which the distance from the collimating lens is greater than f, so long as the angled beam emerging from orientation imposer **220** passes through the two-dimensional position shifter **230** in its active region.

FIG. **9** illustrates the system with the orientation imposer **220** set to introduce a deflection angle while the position shifter **230** is set to an on-axis setting (no deflection). It will be noted that the light beam in the deflected position still strikes the cornea at the same point as it would without the orientation imposing deflection because of the conjugate locations of the orientation imposer **220** and the cornea **242**.

In FIG. **10**, the system is illustrated with the orientation imposer **220** set to a parallel-to-the-axis setting (no deflection) and the position shifter **230** set to position the beam at a desired, off-axis, measurement point on the cornea. It will be noted that the position at which the beam strikes the cornea is displaced from the optical axis by a distance in the Y-direction of $f\tan\nu$, where ν is the angle of deflection in the YZ plane introduced by the position shifter **230**. This is simply the focal length f length of the collimating lens times the tangent of the angle of deflection set by the position shifter. This geometric formula is well known. This position offset is a result of the deflection introduced by the position shifter **230** placing its emergent beam at an orientation which causes that ray to be coincident with the direction of an undeflected ray from a point in the left-hand 2f plane which is that distance ($f\tan\nu$) below the optical axis (a point which the collimating lens conjugates to the corresponding conjugate point at the opposite 2f plane (i.e. at the cornea)). This is true for all angles ν which do not deflect the beam outside the collimating lens. While in FIG. **10** the illustration is for the YZ plane, it will be understood that for a position which is not in the YZ plane, this same diagram applies for that position's component in the YZ plane since that component is established by the Y deflection imposed by the position shifter **230**. In that situation, there would a be a similar diagram which would apply in the XZ plane for the component of the beam's position in the XZ plane which is controlled by the X-direction deflection established by the position shifter **230**.

In FIG. **11**, the system **208** is illustrated with both the orientation imposer **220** and the position shifter **230** set to provide deflections. In particular, the orientation imposer **220** is set to produce the same deflection as in FIG. **9** and the position shifter **230** is set to provide the same deflection as in FIG. **10**. It will be noted that the position at which the measurement beam strikes the cornea is unchanged by the addition of the orientation deflection and the orientation at which the measurement beam strikes the cornea relative to the optical axis of the projection portion **210** of the system (the beam's relative orientation) is unaffected by the position displacement. Consequently, the position of the measurement point and the orientation of the incident beam are independently controlled.

System **208** has the advantage that the entire laser beam is used in the measurement process. Consequently, system **208** is much more efficient in its use of laser energy than system **108** is and reduces or eliminates the risk of exposure of the eye to an unintended high intensity of light. Further unlike the system **108** which uses a scanning disk, the position setting for the system **208** may be randomly controlled in any desired manner since the position is controlled by the position shifter **230** which can be a random access device.

It will be noted that where a galvanometer mounted mirror is used to produce the deflections which establish the position of the beam, then the position deflection may be slightly displaced from the focal plane of the collimating lens for some angle deflection settings. Such variations can be compensated for by a correction table which once measured and determined, remains invariant for the corresponding orientation and position deflection settings. It will be further recognized that the significance of any offset from the focal plane depends in part on the focal length f of the collimating lens. Where the focal length of the collimating lens is relatively long, such deviations from the focal plane will have a smaller effect than where the focal length of the collimating lens is quite short. It will be recognized that other small aberrations may be present in either mirror or acoustic/optic scanner systems, but that in the detailed engineering design of such systems, those aberrations can be measured and compensated for if they have an undesired effect on the measurement accuracy.

While the system **208** is preferably operated in the same manner as has been described for the system **108**, that is by selecting a measurement point and adjusting the impingement orientation of the measurement beam to cause that beam to be refracted to the fovea centralis, it is also conceivable (in either system) to instead set an impingement orientation and then map the locus of positions for which that deflection angle results in the beam being centered in the fovea centralis. However, such a procedure is not at this time preferred, unless it is being used to check measurements of refraction errors

which have already been performed such that the expected locus of such points is already known and thus may be swept in an efficient manner. Alternatively, in a fixed orientation scan mode, the quadrant in which the bright spot is located can be determined and recorded for each measurement point as a means of expediting the process of finding the optimum orientation for each measurement point by selecting orientations for subsequent scans which should approach optimum for selected measurement points at which optimum values have not been determined.

While it is preferred to place the beam splitter between the collimating lens **114** or **214** and the eye, it should be recognized that the beam splitter can be placed in other locations (such as between the positioner and the collimating lens) as long as it still achieves its purpose of deflecting light emerging from the eye toward the position sensing photodetector.

Both subjective and objective embodiments of a refractometer in accordance with the present invention have been illustrated and described with corresponding orientation imposition and control systems and techniques. It will be recognized that these various techniques are not limited to use with the particular type of system (subjective or objective) in which they have been disclosed, but may be used in the other type as well.

While separate objective and subjective embodiments have been illustrated and described, both embodiments may be incorporated in the same refractometer by providing for substitution of a reference generator for a sensor system or vice versa. Alternative or combined projection portions may also be employed.

In order to determine how to correct the refractive errors determined during the measurement process, the existing contour of the cornea or lenticule is measured separately using an instrument such as the CMS Keratometer produced by Computed Anatomy, Inc. The angle of a normal to the corneal surface at each measurement point (perpendicular to a plane tangent to the cornea surface at that measurement point) or equivalent contour data is determined and stored in association with its measurement point. For each measurement point, the desired change in refraction obtained from the current invention and the orientation of the existing normal to the surface-to-be-shaped obtained from the keratometer may be used to determine the change in the surface configuration required to cause a light ray disposed parallel to the optical axis and striking the cornea at the measurement point to impinge on the retina in the fovea centralis.

The determination of the required surface angle change is made using Snell's law, the index of refraction (n_1) of the material on the side of the measurement surface away from the eye (typically 1.0003 for air) and the index of refraction (n_2) of the material on the side of the measurement surface toward the retina (typically 1.34 for the cornea) in combination with the measured beam impingement angle for a measurement light beam striking the fovea centralis and the angle of the normal to the existing surface at the measurement point. The relationships used in determining the angle of a normal to the surface of the cornea which provides proper refraction at a measurement point are illustrated in FIGS. **12A** and **12B**.

During the initial portions of the following discussion, the angles indicated in FIGS. **12A** and **12B** should be ignored. In FIGS. **12A** and **12B**, the surface of the cornea is omitted from the figure for drawing clarity. A plane **96** tangent to the corneal surface at a measurement point **192** has a normal $\hat{M}$. An initial trial beam arrives at the measurement point **192** along the unit vector $\hat{A}$. The unit vector $\hat{A}$ is parallel to the reference incident beam direction which will generally be parallel to the optical axis of the eye and the measurement system. In passing from the air into the cornea, the incident beam is refracted and continues on a path coincident with the unit vector $\hat{B}$, passes through the eye's lens and strikes the retina (neither shown) outside the fovea centralis. With a refractometer in accordance with this invention, an incident vector direction $\hat{C}$ is found which results in refraction of that beam along the vector $\hat{D}$ within the cornea which results in the beam striking the retina in the center of the fovea centralis. Thus, the measurement data recorded for this measurement point is the vector direction $\hat{C}$.

In order to provide corrected refraction, the angle of the corneal surface should be changed to have a tangent plane **96'** in FIG. **12B**. The new tangent plane **96'** has a normal $\hat{N}$ which is displaced from the normal $\hat{M}$ to the existing tangent plane **96**. The new tangent plane **96'** must be chosen so that a beam incident at the measurement point along the unit vector $\hat{A}$ will be refracted by the cornea along the unit vector $\hat{D}$. For derivation of the relationship between the normals $\hat{N}$ and $\hat{M}$, an additional unit vector $\hat{F}$ is shown in FIG. **12B** which represents the direction of refraction of the beam $\hat{A}$ for the general case of a changed normal. The normal $\hat{N}$ which produces proper refraction is found by setting the vector $\hat{F}$ equal to the vector $\hat{D}$.

During the analysis of the changes to be made in the corneal surface, the assumption will be made that the angle of the corneal surface is changed without changing its position. In actual practice, the position change is likely to be small enough that it can be ignored. However, those skilled in geometry will recognize that it is straightforward to include this surface position shift in the relationships developed here by adding a translation to the coordinate system transformation used hereinafter during this explanation. However, such translation is omitted here for simplicity and clarity of the discussion. For simplicity and clarity in the discussion, the relationship between the normals of the uncorrected and a corrected corneal surface will be calculated for the simplified case wherein the surface normals and all the vectors defined above lie in a single plane. This simple case is illustrated in FIGS. **12A** and **12B** when it is assumed that all vectors lie in the plane of the paper. It is also directly applicable to any cornea or portion of a cornea whose anterior surface is essentially cylindrically symmetric about the visual axis through the region of interest and the only refraction changes required preserve that symmetry. This is also a good approximation to the rigorous solution for cases involving moderately asymmetric corneas.

Those readers for whom the derivation of equation (21) below is not of interest can skip to the paragraph containing Equation (21).

Turning now to the derivation of the relationship between the normals in which all vectors and normals are in a single plane, the angle α is the angle of the unit vector $\hat{A}$ from the unit normal vector $\hat{M}$ and β is the angle of the unit vector $\hat{B}$ from the unit normal vector $-\hat{M}$. In this explanation, counterclockwise rotation is taken as positive. Thus, in the illustration both α and β are positive. The air in front of the eye has a refractive

index n_1 and the cornea itself has a refractive index n_2. The relationship between the vectors $\hat{A}$ and $\hat{B}$ are given by Snell's Law as:

$$\sin \alpha = n \sin \beta \quad (1)$$

where

$$n = n_2/n_1 \quad (2)$$

We can solve equation (1) for β in terms of α which yields:

$$\beta = \arcsin[n^{-1} \sin \alpha] \quad (3)$$

During the process of measuring the refraction at measurement point **192**, it is found that a beam in the direction of the unit vector $\hat{C}$ when incident at the point **192** is refracted to strike the retina in the fovea centralis. In passing into the cornea, the beam $\hat{C}$ is refracted into the beam $\hat{D}$. Beam $\hat{C}$ is at an angle χ to the normal $\hat{M}$ and is displaced from the beam $\hat{A}$ by a rotation through an angle ϵ. The angle χ is related to the angles α and ϵ by the following equation:

$$\alpha + \epsilon = \chi \quad (4)$$

The diffracted beam $\hat{D}$ is disposed at an angle δ relative to the normal $-\hat{M}$. In a manner similar to Equation (3), the angle δ may be expressed as:

$$\delta = \arcsin[n^{-1} \sin(\alpha + \epsilon)] \quad (5)$$

Turning now to FIG. **12B**, the angle of the initial trial beam $\hat{A}$ relative to the new surface normal $\hat{N}$ is α' where the new normal $\hat{N}$ is obtained from the old normal $\hat{M}$ by rotation through the angle θ as shown, α' may be expressed as follows:

$$\alpha' = \alpha - \theta \quad (6)$$

it being noted that θ is a rotation in the negative sense in this illustration. The light beam along the unit vector $\hat{A}$ is diffracted by its passage into the cornea along the unit vector $\hat{F}$ which is disposed at an angle ϕ' with respect to the new surface normal $-\hat{N}$. By equation (1):

$$\sin \alpha' = n \sin \phi' \quad (7)$$

substituting for α', yields:

$$\sin(\alpha - \theta) = n \sin(\phi') \quad (8)$$

which may be solved for ϕ' to obtain:

$$\phi' = \arcsin[n^{-1} \sin(\alpha - \theta)] \quad (9)$$

The angle between the desired diffracted beam direction $\hat{D}$ and the normal $-\hat{N}$ is δ' which may be expressed as:

$$\delta' = \delta - \theta \quad (10)$$

The surface normal $\hat{N}$ required to provide proper refraction for this region of the cornea is obtained when the unit vectors $\hat{D}$ and $\hat{F}$ are coincident. Thus, the desired new normal vector $\hat{N}$ is obtained by setting $\phi' = \delta'$ and solving the equations. More particularly,

$$\phi' = \delta' = \delta - \theta \quad (11)$$

or

$$\phi' = \delta - \theta \quad (12)$$

Substituting the value of ϕ' obtained in equation (9) and the value of δ obtained in equation (5) yields

$$\arcsin[n^{-1} \sin(\alpha - \theta)] = \arcsin[n^{-1} \sin(\alpha + \epsilon)] - \theta \quad (13)$$

which simplifies successively to:

$$n^{-1} \sin(\alpha - \theta) = \sin\{\arcsin[n^{-1} \sin(\alpha + \epsilon)] - \theta\} \quad (14)$$

$$\sin(\alpha - \theta) = n \sin\{\arcsin[n^{-1} \sin(\alpha + \epsilon)] - \theta\} \quad (15)$$

For any given measurement point, the values of α, ϵ and n will be known. Consequently, equation (15) can be easily solved for θ which is the desired change in surface angle by methods of graphing, computer analysis or approximation. In an actual measurement system, because of the number of data points in the measurement of a single eye, this analysis will be done by computer in a manner which is straightforward. This equation can be solved explicitly when the arguments of the sin functions are sufficiently small that the approximation:

$$\sin x = x \quad (16)$$

which also implies:

$$\arcsin x = x \quad (17)$$

is valid. It is normally considered that this approximation is valid for arguments of less than 6 degrees. Using equations (16) and (17) to simplify equation (15) leads successively to:

$$\alpha - \theta = n \arcsin[n^{-1}(\alpha + \epsilon)] - n\theta \quad (18)$$

$$(n-1)\theta = n[n^{-1}(\alpha + \epsilon)] - \alpha \quad (19)$$

$$\theta = \epsilon/(n-1) \quad (20)$$

The index of refraction for the cornea is approximately 1.33, thus, the denominator is equation (2) is equal to 0.33 and:

$$\theta = 3\epsilon \quad (21)$$

Thus, the deviation of the new $\hat{M}$ normal-to-the-surface from the old-normal-to-the surface $\hat{N}$ is three times the deviation between the vectors $\hat{A}$ and $\hat{C}$.

While the value $\theta = 3\epsilon$ is only valid for small angles, most refractive errors fall in this range. For those situations in which the refractive errors are larger, equation (15) may be easily solved by computer so long as all of the vectors are disposed in a common plane.

For those situations in which the simplifying assumption that all of the vectors are in a common plane does not hold, a derivation similar to that given above may be done for the general situation where the position of each vector must be specified by its components in two different planes. Where the Z axis of a rectangular coordinate system S is disposed coincident with the normal $\hat{M}$, the vectors are specified by their angles of deviation from the Z axis in the ZX and ZY planes. The new normal $\hat{N}$ is then coincident with the Z' axis of a transformed coordinate system S'. Such a transformation is

straightforward for one of ordinary skill in the arts of geometry including transformations of coordinate systems.

While the method for determining the new desired normal $\hat{N}$ has been derived using simplifying assumptions in order to be tractable in this patent, it will be understood that in a refractometry system employing this invention, all of the data reduction is expected to be done by computer and presumably in software. As such, the required transformations and calculations can be done very rapidly with almost any desired degree of accuracy in order to produce a map of the cornea specifying the desired new normal at each of the measurement points. Alternatively, these calculations may be done once for common values and stored as a look-up table, with resort to detached calculation being reserved for anomalous cases whose values are not in the table.

For clarity and conciseness, the exposed surface of a lenticule which is attached to the eye or the cornea of an eye which has no lenticule attached thereto is referred to as the anterior surface of the eye. It will be understood that by anterior surface of the eye, we mean the exposed surface of the cornea or the lenticule. That anterior surface may or may not have the epithelium present thereover in accordance with the condition being discussed. During measurement of the refractive characteristics of the eye, it is preferred to have the epithelium and tear film present. During shaping of the anterior surface of the eye by laser ablation, it is customary to remove the epithelium before performing the shaping.

Once the desired new normal $\hat{N}$ to the surface has been determined for each measurement point, a new surface contour which will provide those desired normals $\hat{N}$ at each data point may be determined. This may preferably be done beginning at the optical axis of the eye and working outward from there to beyond the visually active portion of the lenticule or cornea.

In determining the new surface contour, experience with the effect of minor deviations from perfect refraction should be taken in to account in determining the optimum surface in terms of vision correction versus the quantity of corneal or lenticule material which needs to be removed. Similarly, where the corneal surface has an indentation in it which is relatively small in area and which would call for removing substantial corneal material over the rest of the cornea to correct the refraction in that small depression, it may be considered desirable to leave that small depression uncorrected. It will be understood that many considerations will go into the ophthalmologist's decision as to how to correct the measured refractive errors and that it is desirable to have the measurement system provide the ophthalmologist with alternative suggestions extending from the limit of safe material removal (if the refractive errors call for such a large correction) to lesser corrections which optimize other criteria such as material removal and so forth.

It will also be recognized that the ideal or optimum correction surface may have substantial local variations with the result that the correction is much more detailed than that provided by merely prism, cylindrical and spherical corrections. Such detailed correction may preferably be provided by the mask controlled laser shaping technique disclosed in related, incorporated by reference, U.S. patent application Ser. No. 07/402,946, entitled, "Laser Shaping With an Area Patterning Mask". Other techniques may also be used. Where it is considered desirable to do so, such as in situations where the correction will be done with eyeglasses or contact lenses, the prism, cylindrical and spherical portions of this correction may be extracted from this data and a new surface contour determined which will provide that correction. Further, for eyeglasses, the measured refractive error can be directly converted to diopters of correction required without knowledge of the existing contour of the cornea. Even in those situations where the correction will be done by shaping of the cornea or a lenticule, it may be desirable to derive prism, cylindrical and spherical corrections and compare them with the more detailed corrective surfaces as part of the process of selecting the actual corrective surface to be used.

Control system **180** may include these data reduction and contour determination functions or they may be separately performed on a different computer which is provided with both the refraction map of the eye and the contour of the cornea.

While the greatest benefit is obtained from the results of using this autorefractometer system by providing spatially resolved correction of the patient's vision or adjustment of the characteristics of other optical systems, it should be understood that prior art corrections which are limited to spherical, cylindrical and astigmatism can be derived from this data and applied in the prior art manner. Such use of this invention takes advantage of its short measurement time, but fails to make use of much of the information it can provide. Nevertheless, such use of the data is within the scope of the invention. Such low order correction information can be extracted from the spatially resolved refractive data by curve fitting procedures. Curve fitting procedures can be used in two dimensions with the fitting of a curve being done simultaneously with respect to the data along a number of different meridians of the eye. Alternatively, 3D or surface fitting techniques may be used as may any other appropriate techniques.

The term measurement surface has been loosely interchanged with the surface of the cornea. This introduces a slight error if the impingement orientation imposer or the position shifter (which ever is disposed conjugate to the cornea) is a plane, whereas, the cornea is curved. However, the distance between the collimating lens **114** or **214** and the cornea **142** or **242** on one hand and between the collimating lens **114** or **214** and the conjugate selector **130** or **220** on the other can be made large enough that any resulting measurement error is insignificant. Alternatively, the conjugate selector could be moved forward and back to maintain it at the same distance from collimating lens as the measurement point on the cornea.

While the preferred retina position detector in this embodiment is the quadrant detector **172**, other detection techniques may be used. These include the use of a two dimensional array of light sensitive devices to determine the actual spot at which the bright spot is located. Other detectors, and other measurement techniques may also be employed for measuring the eye's refraction as a function of position along the surface of the cornea.

While the description of the use of the apparatus **108** of FIG. **4** and apparatus **208** of FIG. **9** has been in terms of measuring the refraction of the eye referenced to the surface of the cornea, it should be understood that the refraction measurement may be referenced to any de-

sired location. In particular, if the measurements being taken are for the design of a contact lens, then it is preferred to place the measurement surface at the location where the surface of the contact lens will be by adjusting the position of the eye to place the expected position of the contact lens' surface at the conjugate location to the orientation or position selector. In this way, the refraction required at that surface in order to refract all rays extending parallel to the optical axis to the fovea centralis is determined directly and an appropriately shaped contact lens may be fabricated to provide that change in refraction. The measurement technique is similar where rather than a contact lens, a lenticule for essentially permanent attachment to the cornea is being fabricated. The measurement surface may also be made the location in which eyeglass lenses will be positioned in order to determine the correction which is appropriate for eyeglass lenses. Thus, the term "measurement surface" is used to refer to the surface (whether a physical interface between two different materials or an "imaginary" surface located at a specific location within one material such as air) at which the refractive characteristics are determined.

The non-subjective determination of the eye's refraction provided by this invention is desirable because it enables the refraction of an eye to be measured independent of the age, present mental capacity or state of consciousness of the patient and makes such measurement feasible from the time of birth on. It also makes measurement and correction of animal vision possible.

The discussion of the measurement process has been general. Normally, these measurements will be made on an uncorrected eye. However, they can also be made on an already corrected eye on which prior art correction has already been done, whether by corneal sculpturing (reshaping), attachment of a lenticule or by the presence of a contact lens. In these situations, the low order corrections (prism, cylindrical and spherical) have already been made (unless subsequent changes have taken place) and the system will be measuring data which relates to higher order terms only or to changes in those low order corrections. Once a correction based on such measurements has been determined, it can be applied to the cornea or lenticule, and if based on measurements with a contact lens in place, should have the contact lens correction included in it unless the patient desires to continue to wear the contact lens and have only the higher order corrections sculpted on the anterior surface of the eye. One reason for using a combination of a contact lens and sculptured correction would be where the low order corrections are large enough to raise concerns with respect to excessive thinning of the cornea if provided by corneal sculpturing. The higher order terms by themselves should not run that risk. Thus, a combination of corneal sculpturing and contact lens is appropriate for some patients.

While the discussion of the illustrated embodiments has concentrated on the measurement of the refractive characteristics of an eye because this system provides so many benefits over the prior art when used to measure an eye, it should be recognized that this measurement system can be used to measure any optical system with appropriate adaptation.

In optical systems where the image surface is a separate element of the system, the system for focusing an image of the image surface on a photodetector, such as the quadrant detector **172**, may be omitted and the image detector itself may replace the image surface of the optical system during the measurement process. That is, the image surface does not have to be part of the optical system under test, but will be where the system under test is an eye. In other optical systems, the reference point from which displacement of a beam is determined or to which it is desired to deflect a beam will depend on the particular characteristics of the optical system. Thus, in some optical systems, there will be no equivalent to the fovea centralis or more than one equivalent.

While this measurement system may be used for any optical system, without restriction, it is more ideally suited to the measurement of an eye than to the measurement of a camera lens system. This is because the eye only accurately focuses the portion of the image which is within a few degrees of the optical axis and provides less accurate focus, or at least a less detailed mental image for portions of the image outside that small solid angle. Thus, the eye's refractive characteristics can be measured with sufficient accuracy by measuring them only for that small solid angle around the optic axis. In contrast, in a camera lens system, the entire image field of view is expected to be clearly focused on the film in order to provide a sharp picture of the entire field of view. Consequently, in order for this measurement system to determine the entire refractive characteristics of a camera lens system, measurements must be taken from many different positions of the measurement light source relative to the camera's lens system. While such measurements can be made to characterize such a lens system, such a lens system, unlike the eye, might be more efficiently tested by other test techniques.

The laser scanning systems of FIGS. **1**, **4** and **9** are of general utility for other uses than testing optical systems. Their ability to independently control beam position and beam orientation at a surface has utility in many areas. For example, these systems can be used for optically addressing different devices, with the beam position selecting one group of devices out of a plurality of groups and the beam orientation selecting an individual member of the selected group, where the devices are positioned relative to a conjugate surface in a manner which causes them to be illuminated one at a time as a function of the angle of incidence. For example, positioning them a distance from the conjugate plane or having fiber optic cables disposed at different orientations and other techniques may be used.

Information about the eye's refractive characteristics can also be obtained, in an objective system, by using a measurement beam which is always parallel to the optical axis in combination with a photodetector which provides output signals which facilitate determination of the location of the bright spot on the retina. The photodetector may be an X-Y array of photosensitive cells such as a charge coupled device imager. While such a technique enables the present refractive errors of the eye to be determined, at the present time it requires much more time to determine the location of the image of the beam than is required in the preferred embodiments to move the beam to the reference point. It is for this reason that such a system is not preferred. Such a system may be provided by substituting an array detector for the quadrant detector either in system **108** or system **208** and either omitting the orientation imposer or by controlling the orientation imposer in the system to retain the measurement beam parallel to the optical axis.

While determination of proper refraction for an image position at infinite distance is most easily performed, the system may also be employed to perform a refraction for an image which is substantially closer to the eye. In so doing, the fixation point is moved to the desired image distance and the refraction is performed in the same manner as has been described.

In general, the data obtained can be preserved in any of a variety of ways. These including storing it in a computer or other control system, printing it out in a permanent hardcopy form, displaying it for an operator to write down, further processing it into control data for use in generating a corrective lens or lenticule or for use in modifying the existing surface of the cornea to provide improved vision or any of a wide variety of other techniques. All such techniques fall in the general class of storing, recording or preserving the data for a sufficient period of time to enable the measured refraction data to be put to therapeutic or diagnostic use. We use the word "storing" as a general term which encompasses such preservation of the data thus obtained, no matter how that storage is performed.

While the invention has been described in detail herein in accord with certain embodiments thereof, many modifications and changes therein may be effected by those skilled in the art. Accordingly, it is intended by the appended claims to cover all such modifications and changes as fall within the true spirit and scope of the invention.

What is claimed is:

1. A refractometer comprising:

means for providing a reference pattern to be viewed by an eye whose refraction is to be measured wherein said reference pattern comprises an annulus;

means for providing a measurement pattern to the eye wherein said measurement pattern comprises a disk-like pattern, said means for providing a measurement pattern being positioned adjacent to said means for providing a reference pattern;

means, connected to said means for providing a measurement pattern, for adjusting said means for providing a measurement pattern to change a position and/or orientation of said measurement pattern in order to enable a patient to use the eye to perceive said measurement pattern in a desired relationship to said reference pattern; and

means for storing data representative of the position and/or orientation of said measurement pattern when said measurement pattern is in said desired relationship to said reference pattern, said data being indicative of refraction characteristics of the eye.

2. A method for determining the characteristics of an eye comprising:

(a) providing a reference pattern to said eye;

(b) directing a measuring beam of light into said eye, said beam passing through a measurement point on an anterior surface of said eye and being narrower in cross-section than the entrance aperture of said eye;

(c) sensing an offset between a reference point on the retina and a location at which said beam impinges on the retina;

(d) changing the orientation at which said beam impinges on said anterior surface at said measurement point to an orientation for which said beam impinges on said retina at said reference point;

(e) storing, for each measuring point, the orientation in step (d) for which said beam impinges on said retina at said reference point;

(f) storing the location of each measurement point in association with said orientation;

(g) repeating said method for at least three measurement points on said anterior surface of said eye;

(h) determining the refractive characteristics of said eye from the measured orientations for which said beam impinges on the retina at the reference point; and

(i) determining a spatially resolved refraction from said refractive characteristics.

3. The method recited in claim 2 wherein step (d) comprises:

feeding back a signal representative of the sensed direction from said reference point to the location where said beam impinges on said retina, said feedback being to a control system which controls the orientation of said beam and, said feedback signal having a polarity to drive said impingement-on-the-retina point to said reference point in a self-centering manner.

4. The method recited in claim 3 further comprising the step of:

determining the refractive characteristics of said eye at said measurement point from the measured orientation for which said beam, when disposed at said measurement point, impinges on the retina at said reference point.

5. The method recited in claim 2 wherein said step of changing said orientation comprises:

the patient whose eye is being examined controlling the orientation of said measurement beam at said measurement point to bring the image of the measurement beam into a predetermined relationship with respect to a reference pattern.

6. A method for determining vision correction parameters for an eye comprising:

(a) directing a beam of light into said eye, said beam passing through a measurement point on the anterior surface of said eye, said beam being narrower in cross-section than the entrance aperture of said eye;

(b) sensing an offset between a reference point on the retina of said eye and a location where said beam impinges on said retina;

(c) while keeping said beam directed at said measurement point, changing the orientation of said beam relative to the optical axis of said eye to an orientation which shifts the location of said beam's impingement point on said retina toward said reference point wherein said beam impinges on said retina at said reference point;

(d) storing, for each measurement point on said anterior surface, the relative orientation for which said beam impinges on said retina at said reference point, said stored relative orientation being dependent on the refractive characteristics of the eye;

(e) determining from said orientation data, a first point on said anterior surface where minimal correction is required; and

(f) determining for all other points on said anterior surface the degree of correction required relative to said first point.

7. The method recited in claim 6 further comprising the step of:

determining a detailed pattern for shaping an optical surface located substantially at said anterior surface to provide correction for said eye, said optical surface being selected from the group comprising: a surface of a cornea of said eye, a surface of a contact lens, and a surface of a lenticule.

8. The method recited in claim **6** further comprising:
extracting a spherical correction from said refractive characteristics.

9. The method recited in claim **8** further comprising:
extracting a cylindrical correction from said refractive characteristics.

10. The method recited in claim **9** further comprising:
extracting from said refractive characteristics a correction which is more detailed than cylindrical and spherical corrections.

11. The method recited in claim **6** further comprising:
extracting from said refractive characteristics a correction which is more detailed than cylindrical and spherical corrections.

12. The refractometer for measuring the deviation of the refractive characteristics of an eye having a retina and a cornea from a desired optical performance of said eye comprising:
means for providing a reference beam of light which forms a first image of a reference pattern on said retina after passing through a first point on said cornea;
means for directing a second beam of light into said eye with a separately controllable position and angular orientation at said cornea, said second beam forming a second image on said retina, said reference beam and said second beam having diameters at said cornea which are substantially smaller than a predetermined size of an entrance aperture of said eye;
means for sensing an alignment of said second image with respect to said first image;
means for altering said angular orientation of said second beam in order to produce an alignment of said second image with respect to said first image that is substantially indicative of said desired optical performance of said eye;
means for storing said indicative orientation of said second image with respect to said first image; and
means for providing a spatially resolved map of said refractive characteristics of said eye by operating said means for directing said second beam over a plurality of predetermined measurement regions on an anterior surface of said eye.

13. The refractometer, recited in claim **12**, wherein:
said means for altering said angular orientation comprises:
a control system to which said means for directing is responsive.

14. The refractometer as recited in claim **12**, wherein said sensing means is further comprised of:
an electronic image sensing means viewing said first and second images on said retina through said eye; and an image processing system which determines said alignment of said first and second images.

15. The refractometer recited in claim **12** wherein:
said means for providing a reference beam comprises;
a source of the projected second light beam;
a collimating lens disposed in the path of said second beam;
means for imposing an impingement orientation on said second beam, said means for imposing being disposed in the path of said second beam between said light source and said collimating lens;
means for positioning said second beam at selected measurement points, said means for positioning being disposed in the path of said second beam between said light source and said collimating lens; and
said sensing portion which is comprised of:
a transducer for converting sensed light to an electrical signal, and
means for imaging said retina onto said transducer.

16. The refractometer recited in claim **15** wherein:
said means for positioning is disposed between said means for imposing and said collimating lens.

17. The refractometer recited in claim **15** wherein:
said means for positioning and said collimating lens are positioned such that said means for positioning is at a conjugate position with respect to an intended position of said anterior surface of said eye during said measurement.

18. The refractometer recited in claim **15** wherein:
said means for positioning comprises:
means for scanning.

19. The refractometer recited in claim **17** wherein:
said means for positioning comprises means:
for scanning said second beam along said anterior surface of said eye in a random access manner.

20. The refractometer recited in claim **19** wherein:
said means for positioning comprises:
a scanning mirror.

21. The refractometer recited in claim **18** wherein said means for scanning comprises:
a movable opaque member having a transmissive portion.

22. The refractometer recited in claim **21** wherein said transmissive portion of said movable opaque member comprises:
an aperture in said member.

23. The refractometer recited in claim **15** wherein:
said means for imposing comprises:
a two-dimensional acoustic/optical scanner.

24. The refractometer recited in claim **15** wherein:
said means for positioning is disposed substantially at the focal plane of said collimating lens.

25. The refractometer recited in claim **24** wherein:
said means for positioning comprises:
a scanning mirror.

26. The refractometer recited in claim **25** wherein:
said means for imposing is disposed at a conjugate location to said eye with respect to said collimating lens.

27. The refractometer recited in claim **26** wherein:
said means for imposing comprises:
a two-dimensional acoustic/optical scanner.

28. The refractometer recited in claim **26** wherein said sensing portion comprises:
means for deflecting light emerging from said eye away from the optical axis of said projecting portion; and
means for focusing light, which is deflected by said means for deflecting, onto said transducer as an image of said retina.

29. The refractometer recited in claim **28** wherein:
said means for deflecting comprises:
a beam splitter which is disposed in the path of said second light beam between said source and an intended position of said eye during measurement.

30. The refractometer recited in claim **29** wherein:

said means for deflecting is disposed between said collimating lens and the position of the eye during said measurement.

31. The refractometer recited in claim **29** wherein:

said beam splitter is a polarizing beam splitter and said second beam is polarized in a pass orientation of said beam splitter.

32. The refractometer recited in claim **28** wherein:

said transducer comprises:

a quadrant detector.

33. The refractometer recited in claim **32** further comprising a control means connected to receive an output of said quadrant detector and to control said means for imposing an impingement orientation and to keep said second beam centered in said quadrant detector as the measurement point is scanned along the anterior surface of said eye.

34. The refractometer recited in claim **33** wherein:

said control means is configured to, in response to a sensed second beam location on the retina which is away from said reference point, to cause said means for imposing to impose a new impingement orientation which is changed in a direction to move the sensed location of said second beam on the retina toward the reference point.

35. The refractometer recited in claim **33** further comprising:

means for relating the impingement angles which placed the sensed position of said second beam at the reference point on the retina to change in the shape of said anterior surface which will cause the eye to exhibit more desirable refraction.

36. A refractometer comprising:

means for providing a reference pattern to be viewed by an eye whose refraction is to be measured wherein said reference pattern comprises an annulus;

means for providing a measurement pattern to the eye wherein said measurement pattern comprises a disk-like pattern, said means for providing a measurement pattern being positioned adjacent to said means for providing a reference pattern;

means, connected to said means for providing a measurement pattern, for adjusting said means for providing a measurement pattern to change a position and/or orientation of said measurement pattern in order to enable a patient to use the eye to perceive said measurement pattern in a desired relationship to said reference pattern; and

means for providing data indicative of refraction characteristics of the eye and based upon adjustments made to the means for providing a measurement pattern in order to bring said measurement pattern into said desired relationship to said reference pattern.

[57] **ABSTRACT**

An air spaced reverse telephoto objective lens for use in a laser chemical vapor deposition system or the like having a quartz plate window. The objective lens includes a negative component having a first air-spaced doublet wherein each doublet element is made of crown glass and a negative meniscus crown glass element spaced from said first air-spaced doublet. The objective lens further includes an aperture stop, a positive component including second and third doublet components for effecting color correction, and a pair of bi-convex elements for effecting spherical aberration correction. The objective lens provides a common focal plane for both illuminating light and laser light passing through the objective lens and the quartz plate window.

REVERSE TELEPHOTO AGRON OBJECTIVE LENS

FIELD OF THE INVENTION

This invention relates to the field of optical lenses and, more particularly, reverse telephoto objective lens with a long working distance for projecting and focusing a finely focused spot of light at a significant distance from the exit lens element.

BACKGROUND OF THE INVENTION

In manufacturing processes which use a vapor deposition technique, a vapor of a metal such as gold is created within a vacuum chamber which contains the workpiece. The workpiece is held on a movable stage such that it may be moved relative to a window which is typically a quartz plate in the wall of the vacuum chamber. In order to deposit the gold onto the substrate, a laser beam is used to locally heat a very, very small region of the silicon substrate. The heating of the substrate creates a condition and environment which permits the gold molecules to deposit out of the vapor form onto the surface of the silicon substrate.

The gold molecules, when deposited on the silicon substrate, may create electrical conductors on the insulations. In order to create extremely fine electrically conductive paths on the insulation surface of the silicon, it is necessary to very, very finely focus the laser beam while at the same time passing the focused laser beam through the quartz plate which serves as the window into the working vacuum chamber.

Since the lens elements must all remain outside the vacuum chamber, it is necessary for the lens assembly to have a sufficiently long back working distance between the exit or last element and the focal point such that the focused beam may be passed through the quartz plat and sufficiently inside the vacuum chamber to focus on the surface of the silicon slab where the gold molecules of the gold vapor are to be deposited. The reverse telephoto nature of a lens displaces the principle point outside the lens assembly providing a longer back working distance between the lens assembly and the focal point, while maintaining a relatively short focal length.

In order to project the maximum amount of illumination from the laser and the laser beam onto the focus point within the vacuum chamber of the vapor deposition device, it is necessary to expand the laser beam as received from the laser from a 1.6 millimeter diameter to approximately a 10.8 millimeter diameter where the beam enters the reverse telephoto objective lens of this invention. By expanding the beam to that diameter, the maximum beam diameter may be then introduced into the reverse telephoto lens thus causing the maximum controllable focus into an extremely fine point of approximately 3.14 microns airy disk diameter. Lenses for such expansion are known in the art.

OBJECTS OF THE INVENTION

It is an object of the invention to accurately focus a beam of coherent laser light to an extremely fine focal point, and to cause the focal point to be positioned at a substantial distance from the exit element of the lens.

It is another object of the invention to focus an expanded entering beam of coherent radiation from a laser into a finely controlled focused point of light on the opposite side of a quartz plate.

It is a further object of the invention to focus the light of an expanded coherent radiation beam within a vapor deposition vacuum chamber.

SUMMARY OF THE INVENTION

The focusing of the entering beam of coherent laser radiation into the extremely fine focus point within the vacuum chamber of a vapor deposition apparatus is accomplished by a lens having a negative component and a positive component. The negative component is comprised of a doublet component and a negative miniscus element. The positive component is comprised of two doublets and two bi-convex elements.

The entire lens apparatus is color corrected for selected light frequencies by the selection of appropriate glasses for the elements of the lens. However, each element of the lens is not an individually color corrected element.

The elements are air spaced from each other to avoid the effects caused by cementing lenses thereby avoiding the absorption of the energy by the cement of cemented lens assemblies. By avoiding the absorption of the light and energy, the cracking of the cement or lens elements due to heat build up is avoided.

Due to the color correction of the overall lens assembly, the same lens may be used not only for focusing of the laser beam at the desire point and to the desired diameter, but also may be used for visual of inspection of the work.

The objects of the invention are accomplished and the shortcomings and deficiencies of the prior art such as cemented element lenses are overcome by the selection of materials, the accurate formation of each individual lens element together with the accurate placement and spacing of the lens elements from the adjacent lens elements as will be better understood from reference to the drawing and the detailed description of the invention to follow.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** illustrates the lens elements and their spacing relative to each other and to the quartz plate which forms the window of the vapor deposition gas chamber.

FIG. **2** is formed of three color transverse ray aberration plots for the lens of FIG. **1** on axis and the tangential and sagittal plots for the off axis points at one degree and two degrees field angles, as labeled.

FIG. **3** is formed of three color diffraction MTF plots for the lens of FIG. **1** on axis and the tangential (T) and sagittal (S) plots for the off axis points at one degree and two degrees field angles, as labeled.

DETAILED DESCRIPTION OF THE INVENTION

With reference to the drawing, the nine lens elements of the reverse telephoto argon objective lens are illustrated together with other pertinent elements of the optical system.

The mounting hardware uses conventional materials and fabrication techniques to insure that the lens elements remain in their proper relative positions. Preferred materials are stainless steel to avoid thermal expansion over the long barrel length of the lens assembly.

The reverse telephoto lens **10** shown in FIG. **1** is comprised of a negative component **12** which is further comprised of lens elements **1**, **2** and **3**. Negative component **12** acts to spread the light beam that enters surface **S1** of lens element **1** so that the light beam diameter may

be controlled by aperture stop **18**. The two separate glass lens elements **1** and **2** are selected from the available glass types to help color correct the lens. Additionally, the negative component acts to move the principle point of the lens assembly and positions the principle surface outside the lens assembly and toward the focal point. This displacement of the principle surface increases the back working distance to permit the projecting of the beam of laser light well within the chamber of the vapor deposition equipment. The shifting of the principle surface also shortens the focal length of the lens assembly.

The positive component **14** of the lens assembly **10** is illustrated to the right of the aperture stop **18** and is comprised of two doublet lens elements **4** and **5** and lens elements **6** and **7** together with bi-convex elements **8** and **9**.

Again, doublets **4**, **5** and **6**, **7** further act to color correct the lens by the judicious selection of glass types. Color correction is not normally necessary for laser lenses since the laser is monochromatic. However, the color correction of the lens over a band of orange light is desirable since the lens is used in a dual purpose role with the other purpose being an objective lens of a viewing system such as a television type inspection camera. The camera provides signals to a monitor to display the work area. The orange illumination light may be focused by the lens on the work area. The reflected orange illumination provides the image for the inspection camera.

Positive components **14** take the diverged beam passing through aperture stop **18** and focuses the rays of the beam to a focal point **22**. In route from lens element **9** to focal point **22**, the focused beam passes through quartz plate **16** which is a window in the wall of the vapor deposition gas chamber with which this lens assembly is used.

Reference is made to the table which follows below which sets forth the significant parameters of the individual lens elements, together with the respective spacing between lens elements.

All dimensions are expressed in terms of millimeters. The lens element numbers correspond to the reference numerals associated with a lens element in the drawing while the surfaces are designated by an S with a numeral, the numeral corresponding to the numerical sequence of the surface starting with the entering surface and terminating with the exit surface of the lens assembly. The radius of the spherical surface of each lens element is expressed as a positive number where the center of the radius is to the right of the surface as shown in the drawing and a negative number where the center of the radius is located to the left of the surface referred to, as illustrated in the drawing.

The thickness of the lens is expressed in a linear thickness of millimeters measured at the axis of the lens.

The air spacing is designated in the form of $D_{x\text{-}y}$. The x and the y are the lens numbers immediately adjacent the air space distance. Thus, for example, the air space between lenses **4** and **5** would be $D_{4\text{-}5}$.

The column headed "Glass" utilizes the glass designations found on a Schott Glass Map published by Schott Glass Technologies. The use of a designation on the Schott glass map are as a matter of convenience. The alternative technique for disclosing the characteristics of the glass is by expressing the index of refraction and the Abbe' V number.

The columns designated Index @ λ and a number followed by the symbol for microns is the refraction index for that particular wavelength of light. Three separate wavelengths of light are illustrated for purposes of defining the refractive index of the glass. The Abbe' V number is likewise shown for each glass selection.

	S16 = −54.94		0.08						
9	S17 = 31.61	4.94		26.0	LAKN 7	1.656713	1.650638	1.651598	58.52
	S18 = −129.80								

Individual lens elements fabricated to the dimensions indicated in the above table with a thickness tolerance of plus or minus 25.0 microns, diameter tolerances of plus 0 minus 25.0 microns and the radiuses of the surfaces to less than one fringe sphericity and to less than one fringe of power. The lens elements are then positioned relative to each other and held relative to the aperture stop **18** such that an air gap to the left of the aperture stop has a 28.25 millimeter length and the air gap to the right of the aperture stop has a 29.70 millimeter length. This assembly results in an air gapped reverse telephoto lens which will focus an entering laser beam having an entrance diameter of approximately 10.8 millimeters to an extremely fine 3.14 micron Airy Disk diameter at the focal point **22** where the back working distance of this lens assembly is about 42.0 millimeters.

Since the diameter of the Airy Disk is a function of the focal length of the lens, according to the formula:

$$\phi = \frac{2.44 \lambda F}{D} \text{ where}$$

ϕ=Diameter of the Airy Disk,
λ=Wavelength of light,
F=Focal length, and
D=Diameter of entering laser beam,

it is highly desirable to have a small focal length to allow the use of a smaller diameter entering laser beam. By using a reverse telephoto lens arrangement, the focal length may be smaller than a non-reverse telephoto lens, while maintaining a larger back working distance. The need for unduly large entering laser beams complicates the design of equipment, particularly the beam spreading lens necessary to precede the reverse telephoto lens. The long back working distance affords adequate room to insert the quartz plate **16** between the exit lens element **9** and the focal point **22**.

It is preferred that all nine element **1–9** of the lens assembly **10** be coated with a broad band anti-reflection coating which is formulated to be peaked at 0.5145 micron wavelength.

Referring to FIGS. **2** and **3**, it is readily seen that a lens assembly made according to this description is not aberration limited, but is limited only by diffraction. The transverse ray aberration plots of FIG. **2** shows very little degradation due to aberrations and vary from perfect by only approximately 1.5 microns while the lens has an Airy Disk diameter of about 3.14 microns for the lens F stop of 2.5. The diffraction MTF plots, FIG. **3**, illustrates that the lens will have limitations due to diffraction.

The lens assembly is corrected for use with a 16 millimeter quartz plate **16**. The foregoing lens further has an effective focal length of 27.0 millimeters, a working numerical aperture of 0.2, lens thickness, glass only, of 137.25 millimeters and a workable field of view plus or minus 2.0 millimeters (plus or minus 4.2 degrees) with color correction corrected for a band of wavelengths between 0.5876 and 0.6328 microns in the visible spectrum and highly corrected for wavelengths of 0.5145 microns, and 0.5876 microns and 0.6050 microns.

The foregoing is a description of the invention we desire to protect by Letters Patent is defined by the claims that follow.

We claim:

1. An air spaced reverse telephoto type/objective lens for use in a laser chemical vapor deposition system having a quartz window, said objective lens comprising, from the object side to the image side:

a negative component including a first air-spaced doublet wherein each doublet element is made of crown glass having an Abbe' V number greater than 50 and a negative meniscus crown glass element spaced from said first air-spaced doublet;

an aperture stop; and

a positive component including second and third air-spaced doublet components for effecting color correction and a pair of bi-convex elements for effecting spherical aberration correction;

said objective lens providing a common focal plane for both illuminating light and laser light passing through said objective lens and said quartz plate window.

2. The lens of claim **1** wherein said lens elements conform to the radius and the materials set forth in the table following:

Lens #	Surface Radius	Material
1	S1 = 43.64	LAK 28
	S2 = −186.85	
2	S3 = −186.85	BK 10
	S4 = 17.09	
3	S5 = 99.80	LAK 9
	S6 = 48.42	
4	AS7 = 998.80	F 5
	S8 = 112.75	
5	S9 = 62.74	LAKN 7
	S10 = −35.14	
6	S11 = −25.00	SF 12
	S12 = 20.93	
7	S13 = 20.93	LAK 10
	S14 = 31.82	
8	S15 = 58.85	LAKN 7
	S6 = −54.94	
9	S17 = 31.61	LAKN 7
	S18 = −129.80	

wherein surfaces are designated from the surface laser light enters first and progresses to the surface said laser light exits with each lens element having an odd and even numbered surface in ascending order respectively.

3. The lens of claim **2** wherein the inter lens air spacing at the axis of the lens, $D_{x\text{-}y}$, with the x and y being surface numbers bounding said inner lens air spacing, in millimeters are $D_{2\text{-}3}$=0.025; $D_{4\text{-}5}$=10.00; $D_{6\text{-}7}$=57.95; $D_{8\text{-}9}$=0.84; $D_{10\text{-}11}$=9.00; $D_{12\text{-}13}$=0.025; $D_{14\text{-}15}$=2.50; and $D_{16\text{-}17}$=0.08.

4. The lens of claim **3** wherein each said lens element comprises an anti-reflective coating.

5. The lens of claim **3** wherein said aperture stop is disposed between lens surfaces **6** and **7**.

6. An air spaced reverse telephoto lens comprising a plurality of lens elements designated by lens numbers, **1–9**;

said lens elements having center lens element distances separating them designated $D_{x\text{-}y}$, where x and y are lens numbers for lenses defining said center lens distances;

said lens elements each having an entry surface and an exit surface, each said surface having a radius;

each of said lens elements further having a thickness T_L;

each of said lens elements being fabricated from a designated material;

and said lens numbers, surface numbers, radius, thickness, center lens element distance and material conforming to specifications set out in a table below:

LENS #	RADIUS OF SURFACE	THICKNESS TL	AIR-SPACE $D_{x\text{-}y}$	CLEAR APERTURE	LENS MATERIAL	INDEX@λ = 0.5146μ	INDEX@λ = 0.6050μ	INDEX@λ = 0.5876μ

[57] **ABSTRACT**

This specification discloses an objective lens disposed forwardly of a prism block for dividing light into a plurality of color components, the objective lens having an optical filter differing in spectral transmission factor between the central area thereof and the marginal areas thereof, this filter being given the characteristic that one of the marginal areas transmits much of magenta light therethrough and the other marginal area transmits much of green light therethrough, thereby suppressing the coloring of a blurred image based on the light incidence angle dependency of the color dividing surface of the prism block.

OBJECTIVE LENS HAVING A FILTER

This application is a continuation of application Ser. No. 07/691,422 filed Apr. 25, 1991 now abandoned.

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to an objective lens, and particularly to an objective lens suitable for use in a color video camera having a prism block having dichroic film on the image side of the objective lens and dividing a light beam into a plurality of color components.

2. Related Background Art

In a three-tube type TV camera, a three-color resolving optical system comprising a plurality of prisms, color filters or the like is provided as means for color-resolving an incident light beam into a plurality of predetermined color lights between a photo-taking lens and an image pickup plate (or an image pickup tube or a solid state image pickup element).

This three-color resolving optical system is composed chiefly of a prism block comprising three to four prisms of a predetermined shape each having multilayer film, for color resolution provided on one surface thereof and combined as a unit while having a predetermined relation therebetween. The optical system is designed to resolve a light beam incident from the photo-taking lens into color lights of plural wavelength bands through the reflecting surfaces for color resolution of the prisms and direct the color lights to respective image pickup plates.

FIG. **9** of the accompanying drawings is a schematic view of a prior-art three-color resolving optical system comprising three prisms. In FIG. **9**, the reference numeral **91** designates a photo-taking lens, the reference numeral **92** denotes a blue resolving prism, and the reference numeral **93** designates a red resolving prism having its entrance surface **93***b* disposed with a minute gap with respect to the blue resolving prism **92**. The reference numeral **94** denotes a green resolving prism having its entrance surface **94***a* adhesively secured to the reflecting surface **93***a* of the red resolving prism **93**.

In FIG. **9**, of a light beam passed through the photo-taking lens **91**, blue light B is separated by the light dividing surface **92***a* of the blue resolving prism **92**, which is coated with dichroic film, and is totally reflected by the entrance surface **92***b* of the blue resolving prism **92**, whereafter it emerges from the exit surface **92***c* of the blue resolving prism. Red color R is separated by the light dividing surface **93***a* of the red resolving prism **93**, which is coated with dichroic film, and is totally reflected by the entrance surface **93***b* of the red resolving prism, whereafter it emerges from the exit surface **93***c* of the red resolving prism. The remaining green light G, than the blue and red components passes through the green resolving prism **94** and emerges from the exit surface **94***c* of this prism. The blue light B, the red light R and the green light G, thus, total three light beams, and are directed to image pickup plates, not shown.

In the prior-art three-color resolving optical system shown in FIG. **9**, when light beams U (dot-and-dash line), C (solid line) and L (dotted line) passes through the central portion and marginal portion of the photo-taking lens as shown enter the blue dichroic film provided on the light dividing surface **92***a* of the blue resolving prism **92** and the red dichroic film provided on the light dividing surface **93***a* of the red resolving prism **93**, which prisms are positioned in the course of the arrival of the light beams at the respective image pickup plates, not shown, there are created differences among the angles of incidence of the light beams U, C and L. Therefore, the spectral transmission characteristics for the light beams U, C and L become different from one another as shown, for example, in FIG. **10** of the accompanying drawings. Respective lines in FIG. **10** correspond to respective lines in FIG. **9**. In FIG. **10**, the abscissa represents wavelength.

Therefore, when the color reproduction of a color image is effected in an in-focus state (a position Y indicated in FIG. **9**), no color misregistration occurs to the object image, but when the color reproduction of a color image is effected, for example, in a state in which the object is deep and is out of focus (positions x and z indicated in FIG. **9**), a blurred image gradually becomes colored in the vertical direction thereof.

Assuming that the image pickup surface lies at the position Y, when the coloring of the blurred image at this time is watched on a color monitor, the blurred image on the image pickup surface Y, when the position x is the image point, will appear as magenta in the upper portion thereof and as green in the lower portion thereof, as shown in FIG. **11** of the accompanying drawings. Also, the blurred image on the image pickup surface Y when the position Z is the image point will conversely appear as green in the upper portion thereof and as magenta in the lower portion thereof, as shown in FIG. **12** of the accompanying drawings. Thus, there has been problems in that the quality of the image, when a color image which is out of focus is represented, becomes greatly deteriorated.

SUMMARY OF THE INVENTION

It is a first object of the present invention to provide an optical device which can suppress the coloring of a blurred image and obtain a good quality image.

It is a second object of the present invention to provide a photo-taking lens having an optical unit of suitable spectral transmission characteristic for a TV camera, a video camera or the like.

BRIEF DESCRIPTION OF THE DRAWINGS

FIGS. **1** and **4** are schematic views showing the essential portions of photo-taking lenses according to first and second embodiments, respectively, of the present invention.

FIG. **2** is a view of the color filter in FIG. **1** taken along arrow A in FIG. **1**.

FIG. **3** is a graph illustrating the spectral transmission characteristic of the color filter shown in FIG. **1**.

FIG. **5** is a view of the color filter in FIG. **4** taken along arrow B in FIG. **4**.

FIGS. **6** and **7** are graphs illustrating the spectral transmission characteristic of the color filter shown in FIG. **4**.

FIG. **8** is a view of a color filter according to a third embodiment of the present invention.

FIG. **9** is a schematic view showing the essential portions of a color resolving optical system according to the prior art.

FIG. **10** illustrates the spectral transmission characteristics of light beams which cause the coloring of a blurred image in the prior art.

FIGS. **11** and **12** illustrate blurred images on a color monitor according to the prior art.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

FIG. 1 is a schematic view showing the essential portions of an optical device having a filter having a predetermined spectral transmission factor according to a first embodiment of the present invention.

In FIG. 1, the reference numeral 1 designates an objective lens having a plurality of lenses and endowed with the zooming function. The objective lens 1 has a stop 2 at a predetermined position therein. The reference character 0 denotes the optic axis of the objective lens.

The reference numeral 3 designates a color filter according to the present invention. The color filter 3 is disposed near the position of the stop 2 (the pupil position), and partially has a spectral transmission factor to correct the coloring of a blurred image based on the incidence angle dependency of a light beam entering a prism block which will be described later.

The reference numeral 4 denotes a blue resolving prism, and the reference character 4*b* designates the light dividing surface (the reflecting or transmitting surface) thereof. The light dividing surface 4*b* is coated with blue dichroic film to effect color resolution, and separates and reflects a light beam of blue component.

The reference numeral 5 denotes a red resolving prism disposed with a slight air space with respect to the blue resolving prism. The reference character 5*b* designates the light dividing surface (the reflecting or transmitting surface) of the red resolving prism 5. The light dividing surface 5*b* is coated with red dichroic film to effect color resolution, and separates and reflects a light beam of red component.

The reference numeral 6 denotes a prism adhesively secured to the light dividing surface 5*b* of the red resolving prism 5.

FIG. 2 is a front view of the color filter 3 according to the present invention as it is seen in the direction of arrow A in FIG. 1.

The color filter 3 of the present embodiment has the characteristic that the spectral transmission factor of the AO side marginal portion (the upper hatched portion as viewed in FIG. 2) is set as indicated by a solid line in FIG. 3 to compensate for the incidence angle dependency of a light beam entering the prism block at various angles so as to transmit much of magenta light and the spectral transmission factor of the Al side marginal portion (the lower hatched portion as viewed in FIG. 2) is set as indicated by a dotted line in FIG. 3 so as to transmit much of green light.

In the present embodiment, by such a construction, the light beams from an object, not shown, are caused to enter the entrance surface 4*a* of the blue resolving prism 4 in such a manner that the A0 side of the marginal portion which is on the same side as the direction in which red light is imaged transmits much magenta light by the color filter disposed near the position of the stop 2 in the objective lens 1 and the A1 side of the marginal portion which is opposite to said direction transmits much of green light.

Of the incident light beams, the light beam of a blue wavelength band is reflected by the light dividing surface 4*b* coated with the blue dichroic film, whereafter it is totally reflected by a reflecting surface 4*a*′ on the same plane as the entrance surface 4*a* of the blue resolving prism 4 so as to emerge from the exit surface 4*c* of the prism 4, and is directed to an image pickup plate for blue, not shown.

Also, the light beams other than the light beam of blue component transmitted through the light dividing surface 4*b* of the blue resolving prism 4 enter the entrance surface 5*a* of the red resolving prism 5, and of the incident light beams, the light beam of red wavelength band is reflected by the light dividing surface 5*b* coated with the red dichroic film, whereafter it is totally reflected by a reflecting surface 5*a*′ on the same plane as the entrance surface 5*a* of the red resolving prism 5 so as to emerge from the exit surface 5*c* of the prism 5, and is directed to an image pickup plate for red, not shown.

On the other hand, the light beam of green component transmitted through the light dividing surface 5*b* of the red resolving prism 5 passes through the prism 6, emerges from the exit surface 6*c* of the prism 6 and is directed to an image pickup plate for green, not shown. The object images are formed on the surfaces of the predetermined image pickup plates so as to obtain image information, thereby representing a good color image.

Also, even in a state in which the object is deep and is out of focus at this time (the positions X and Z indicated in FIG. 9), the color filter having the spectral transmission factor shown in FIG. 3 is disposed near the position f the stop in the objective lens, whereby a good color image can be obtained without any color misregistration being created in a blurred image when the color image is color-reproduced.

If filters in the form of very thin sheets are stuck to the upper and lower portions of the vicinity of the stop, the color filter can be easily realized.

Also, the present invention is equally applicable even if a dye is thinly applied to the surface of a glass plate as another filter.

FIG. 4 is a schematic view showing the essential portions of a photo-taking lens having a filter having a predetermined spectral transmission factor according to a second embodiment of the present invention.

In FIG. 4, elements identical to those shown in FIG. 1 are given identical reference numerals. The reference numeral 40 designates a color filter. The optical density, i.e., the transmission factor, of this color filter 40 is controlled so as to be stepwisely higher, that is, higher in the transmission factor for the subject color light, from the central portion of the color filter 40 toward the marginal portion (the B0 and B1 sides) thereof.

FIG. 5 is a front view of the color filter 40 as it is seen in the direction of arrow B in FIG. 4.

The spectral transmission factors of the portions U3, U2, U1 and U0 of the color filter 40 of FIG. 5 from the central portion thereof toward the B0 side of the marginal portion are shown in FIG. 6. Also the spectral transmission factors of the portions L3, L2, L1 and L0 of the color filter 40 from the central portion thereof toward the B1 side of the marginal portion are shown in FIG. 7.

In the present embodiment, the color filter 40 thus constructed is disposed near the position of the stop 2 in the objective lens 1 as previously described, whereby the light beam from an object, not shown, has much of its magenta light stepwisely transmitted through the color filter 40 from the central portion thereof toward the B0 side of the marginal portion thereof and has much of its green light stepwisely transmitted through the color filter 40 from the central portion thereof toward the B1 side of the marginal portion thereof.

Thereby, even in an out-of-focus state, the color misregistration of a blurred image when a color image is color-reproduced can be prevented better than in the first embodiment shown in FIG. **1**, whereby a good color image is obtained.

FIG. **8** is a front view of a color filter according to a third embodiment of the present invention as it is seen in the direction B when it is disposed at the position of the stop shown in FIG. **4**.

The color filter **80** in this embodiment is of the so-called gradient type in which the spectral characteristic of the color filter **80** continuously differs among the various portions thereof.

The density of this color filter **80** is controlled so as to be continuously higher that is, higher in the transmission factor for the subject color light, from the central portion thereof toward the marginal portion thereof (the C0 and C1 sides).

The color filter **80** thus constructed is disposed near the position of the stop in the objective lens **1** as in the aforedescribed embodiments, whereby the light beam from the object is controlled so that much of magenta light may be continuously transmitted through the color filter **80** from the central portion thereof toward the C0 side of the marginal portion thereof and much of green light may be continuously transmitted through the color filter **80** from the central portion thereof toward the C1 side of the marginal portion thereof.

Thereby, when even in an out-of-focus state, a color image is color-reproduced, there can be obtained the effect that the color misregistration of a blurred image can hardly be recognized.

As a method of making the color filter of the present embodiment, for example, a glass plate, a magenta filter and a green filter are stuck to one another in a wedge-like fashion and polished and shaped into a parallel flat plate.

As described above, according to the present invention, when the light beam from the objective lens is to be resolved into a plurality of color lights of different wavelength bands through a plurality of prisms and object images are to be formed on image pickup plates for respective color resolving systems, spectral characteristic control means whose spectral transmission factor is partly controlled, for example, a color filter or the like, is disposed near the position of the stop in the objective lens, whereby there can be achieved a photo-taking lens having spectral characteristic control means suitable, for example, for a TV camera, a video camera or the like which can improve the quality of the image without creating any color misregistration when a color image is color-reproduced even in an out-of-focus state.

What is claimed is:

1. An objective lens unit disposed forwardly of a prism block for dividing light into a plurality of light components, said objective lens unit comprising:

optical conveying means for conveying light beams from an object along an optical light path; and

an optical unit disposed in the optical light path and differing in the transmission factor for a wavelength depending on the areas of said optical unit.

2. An objective lens unit according to claim **1**, further having a stop and wherein said optical unit is positioned near said stop.

3. An objective lens unit according to claim **1**, wherein said optical unit is more deeply colored in the peripheral area thereof than in the central area thereof.

4. An objective lens unit according to claim **3**, wherein said transmission factor varies by small amounts.

5. An objective lens unit according to claim **3**, wherein said optical unit has a predetermined transmission factor characteristic in an area thereof located in a predetermined direction away from the optic axis of said objective lens unit, and has another transmission factor characteristic in an area there located in the direction opposite to said predetermined direction and away from the optic axis of said objective lens unit.

6. An objective lens according to claim **5**, wherein the area located in said predetermined direction away from the optic axis of said objective lens unit has a magenta-like color, and the area far in the opposite direction has a green-like color.

7. A photographing system including:

an objective lens unit comprising both:

optical conveying means for conveying light beams from an object along an optical light path; and

an optical filter differing in the transmission factor for wavelength depending on the areas thereof and disposed in the optical light path; and

a prism block positioned adjacent to the image plane side of said objective lens unit and having dichroic film and dividing light emerging from said objective lens unit into a plurality of color components.

8. A photographing system according to claim **7**, further having a stop and wherein said optical filter is positioned near said stop.

9. A photographing system according to claim **7**, wherein said optical filter is more deeply colored in the peripheral area thereof than in the central area thereof.

10. A photographing system according to claim **9**, wherein said transmission factor varies by small amounts.

11. A photographing system according to claim **9**, wherein said optical filter has a predetermined transmission factor characteristic in an area thereof located in a predetermined direction away from the optic axis of said object lens unit, and has another transmission factor characteristic in an area thereof located in the direction opposite to said predetermined direction and away from the optic axis of said objective lens unit.

12. A photographing system according to claim **11**, wherein the area located in said predetermined direction away from the optic axis of said objective lens unit has a magenta-like color, and the area far in the opposite direction has a green-like color.

[57] **ABSTRACT**

An auto-focusing system includes a focus condition detector which detects focus condition based on the infrared light. A data producer is provided for producing a deflection signal indicating a difference between an image forming distance for the infrared light and that for the visible light, due to aberration. In accordance with the detected focus condition and deflection signal, an objective lens is shifted to a position for properly focusing an image of visible light on an image forming plane.

AUTO-FOCUSING SYSTEM FOR CAMERAS WITH IN INTERCHANGEABLE OBJECTIVE LENS

This application is a divisional application of application Ser. No. 154,540, filed Feb. 5, 1988, now U.S. Pat. No. 5,130,734 which is a continuation application of application Ser. No. 828,653, filed Feb. 12, 1986, and now abandoned, which is a continuation application of application Ser. No. 561,972, filed Dec. 16, 1983 and is now U.S. Pat. No. 4,602,861.

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to an auto-focusing device and method of a camera of an interchangeable objective lens type and, more particularly, to an auto-focusing system wherein the reflected light from an object to be photographed passes through the objective lens of the interchangeable lens and forms an image on or near a predetermined image forming plane, which image is detected for detecting the degree of out of focus, thereby controlling the lens shift by the detected degree of out of focus. The present invention also relates to an interchangeable lens itself for use in the above described type of camera.

2. Description of the Prior Art

There have been conventionally proposed various types of the above described auto-focusing method, but most of them use visible light Therefore, when the intensity of the visible light is very weak, such as when the scenery is dark, it is very difficult to detect the focusing condition of the target object, resulting in an error control of the objective lens. Also, for detecting the image, a charge accumulating device, such as CCD, can be employed, but would result in a disadvantage that the charging period becomes long as the visible light becomes weak, resulting in long time of focus detection.

It is known in the art that the photoelectric conversion device, such as CCD or photodiode, for use in focus detection is generally more sensitive to infrared rays than the visible rays. Also, it is known in the art that the infrared rays reflect at a high rate even on a black object and also on an organic object.

From this view point, it is possible to detect, if the infrared rays are used for focus detection, the focusing condition of an object even if the object is located in a dark place, and consequently improving the focus detection ability.

But, on the other hand, if the infrared rays are used for focus detection, it takes a disadvantage that there will be a difference in focusing distance between the the infrared rays and the visible rays, due to color aberration, and such a difference varies as the type of an interchangeable lens mounted on a camera body changes. Therefore, unless a suitable correction is effected, a picture taken by an auto-focusing system using the infrared rays always results more or less in out of focus.

To remove the above disadvantage, an improved auto-focusing system is proposed in Japanese Patent Laid-open Publication (Tokkaisho) No. 57-154224, wherein a signal pin having a length corresponding to the focusing distance difference is provided to each interchangeable lens, and a focus detecting device having a means to correct the focusing distance difference by the signal pin are provided. According to the proposed device as described above, the signal pin extending from the lens must have a required strength to avoid undesirable break or bent, and also the signal pin should be positioned with a high accuracy to enable the precise correction. Also, the focus detecting device provided in the camera body will have a complicated structure, resulting in high manufacturing cost, and because of the complicated structure, it may not be able to correct the difference to the required degree due to the inaccuracy of size and positioning of each constructing part.

Furthermore, according to the auto-focusing device disclosed in Tokkaisho No. 57-154224, it is very difficult to detect the focusing when a target object is under a weak visible light and yet containing almost no infrared rays, such as under fluorescent lamp, not only when detecting the focus condition by way of visible light, but also by way of infrared rays. Moreover, if the target object has no or hardly any contrast, such as in the case of plain wall, it is very difficult to detect the focus condition even when using the infrared rays.

Another improved auto-focusing system is proposed in Japanese Patent Laid-open Publication (Tokkaisho) No. 57-150808, which is so designed that the focus condition can be detected either by the visible rays or infrared rays. The auto-focusing system according to Tokkaisho No. 57-150808 comprises two photoelectric conversion means, one for visible rays and the other for infrared rays, and a beam splitter for dividing the rays from the object in terms of amount into rays to be directed to the visible light photoelectric conversion means and to the infrared light photoelectric conversion means. An infrared cut filter is disposed between the visible light photoelectric conversion means and beam splitter for cutting the infrared rays to be directed to the visible light photoelectric conversion means. Each photoelectric conversion means is connected, through a discrimination circuit, to a selection circuit and further to a focus condition detecting circuit.

According to the auto-focusing system of Tokkaisho No. 57-150808, it is stated that when no infrared light pass filter is used to carry out photographing using visible rays, almost the same amount of light impinges on both photoelectric conversion means and, therefore, the outputs from both photoelectric conversion means have approximately the same level. Thus, the discrimination circuit discriminates that the ratio of outputs from both photoelectric conversion means is approximately equal to one, thereby actuating the selection circuit to select output from the visible light photoelectric conversion means.

It further states that when the infrared light pass filter is used to carry out photographing using infrared rays, the amount of light impinging on the infrared light photoelectric conversion means is greater than that on the visible light photoelectric conversion means. Thus, the discrimination circuit discriminates that the ratio of outputs from both photoelectric conversion means is not equal to one, thereby actuating the selection circuit to select output from the infrared light photoelectric conversion means.

The focus condition detecting circuit operates in response to the output signal selected by the selection circuit.

From a practical point of view, however, there are a variety of objects differing from one another in reflection properties. Thus, it is not always true that the ratio between outputs from the visible light photoelectric conversion means and from the infrared light photoelectric conversion means is constant with use of no

infrared light pass filter. Thus, it is practically very difficult to set a level or borderline for causing selection of an output from visible light photoelectric conversion means whenever photographs are taken using the visible light. Therefore, even when the output from the visible light photoelectric conversion means is selected, there may be a case wherein the focus detection is carried out using the infrared rays, resulting in out of focus, because there is a difference in an image forming distance of the objective lens between the visible rays and infrared rays. Moreover, when taking a photograph under the A-light source (tungsten type lamp) or under the natural light, there may be a case in which the infrared rays are stronger than the visible rays. In such a case, the photographing is carried out using the visible rays, but the focus detection is carried out using infrared rays, resulting in an error in focus adjustment.

Also, according to the prior art, it is well know to emit an auxiliary light to the object, when the object is too dark to carry out the focus detection. In this case, if the object is people, and when the auxiliary light is visible light, such an auxiliary light makes people unpleasant. In order to overcome this, an improved focus detecting device is disclosed in Japanese Patent Laid-open Publication (Tokkaisho) 55-111929, which device emits, instead of visible lights, infrared rays as the auxiliary light when the target object is very dark and has less contrast. However, Japanese Patent Laid-open Publication (Tokkaisho) 55-111929 does not take any consideration to the difference in focusing distance between the the infrared rays and the visible rays, due to color aberration of the objective lens.

SUMMARY OF THE INVENTION

The present invention has been developed with a view to substantially solving the above described disadvantages and has for its essential object to provide an improved auto-focusing system which can carry out an auto-focusing operation for the visible light using infrared rays with high accuracy, without employing any mechanical or optical correcting means.

It is also an essential object of the present invention to provide an auto-focusing system of the above described type which can carry out an auto-focusing operation quickly and accurately, with an aid of emission of infrared rays, even when the target object is dark or has a low contrast.

It is a further object of the present invention to provide an interchangeable lens suited for use with a camera employing an auto-focusing system of the above described type.

According to the auto-focusing system of the present invention, a focus condition is detected based on the infrared light. A data producer is provided for producing a deflection signal indicating a difference between an image forming distance for the infrared light and that for the visible light, due to aberration. In accordance with the detected focus condition and deflection signal, an objective lens is shifted to a position for properly focusing an image of visible light on a predetermined image forming plane.

Furthermore, according to the present invention, an auxiliary light source for emitting infrared light is provided for lighting an object, thus facilitating the focus condition detection. According to one embodiment, a dark object is brightened by the emitted infrared light to increase the detecting level, and according to another embodiment, a plain object, such as a wall, is spot-lighted by the emitted infrared light to provide a contrast.

Moreover, according to the present invention, the objective lens can be shifted in one step or in two steps to bring it to the properly focused position for the visible light. In the case of one step, an amount of lens shift is calculated using the detected focus condition based on the infrared light and deflection signal, and then, the lens is shifted in accordance with the calculated result. In the case of two steps, the lens is first shifted based on the focus detection under the infrared light, and is shifted again based on the deflection signal.

BRIEF DESCRIPTION OF THE DRAWINGS

These and other objects and features of the present invention will become apparent from the following description taken in conjunction with preferred embodiments thereof with reference to the accompanying drawings, throughout which like parts are designated by like reference numerals, and in which:

FIG. **1***a* is a block diagram of an auto-focusing system according to the present invention;

FIG. **1***b* is a diagrammatic view showing an optical arrangement of the auto-focusing system of the present invention employed in a camera;

FIG. **2***a* is a graph showing a spectral sensitivity of a visible light photoelectric conversion means and a normalized reflectance of a first reflecting face of a beam splitter;

FIG. **2***b* is a graph similar to FIG. **2***a*, but particularly showing a spectral sensitivity of an infrared light photoelectric conversion means;

FIG. **3** is a diagrammatic view showing one example of a beam splitter employed in the auto-focusing system of FIG. **1***a*;

FIG. **4** is a graph showing a normalized reflectance of a junction face of glass blocks of defining the beam splitter of FIG. **3**;

FIG. **5** is a diagrammatic view showing another example of a beam splitter;

FIG. **6** is a graph showing a normalized reflectance of the beam splitter of FIG. **5**, particularly when the incident angle of the beam is 45°;

FIG. **7** is a diagrammatic view showing a major portion of optical arrangement employing the beam splitter of FIG. **5**;

FIGS. **8***a* and **8***b* taken together show a circuit diagram of an auto-focusing system according to one embodiment the present invention, wherein characters A–E in FIG. **8***a* are connected to corresponding characters in FIG. **8***b*;

FIG. **9***a* and **9***b* taken together show a detailed circuit diagram of interface circuit and data output circuit shown in FIG. **8***b*, wherein characters **J1–J4** in FIG. **9***a* are terminals connectable to terminals in FIG. **9***b* with corresponding characters;

FIGS. **10** and **11** are circuit diagrams showing modifications of the circuit shown in FIG. **9***b*;

FIGS. **12***a* and **12***b* taken together show a flow chart of the auto-focus detection carried out by the circuit of FIGS. **8***a* and **8***b*, wherein characters F–I in FIG. **12***a* are connected to corresponding characters in FIG. **12***b*;

FIG. **13** is a circuit diagram showing a major portion of an auto-focusing system according to another embodiment the present invention;

FIG. **14** is a circuit diagram showing a major portion of an auto-focusing system according to yet another embodiment the present invention;

FIG. 15 is a flow chart of the auto-focus detection carried out by the circuit of FIG. 14;

FIG. 16 is a flow chart similar to FIG. 15, but showing only a modified portion;

FIG. 17 is a flow chart showing a detail of a step #51 of FIG. 15 or 16 for the detection of contrast;

FIG. 18 is a diagrammatic view of a camera installed with a device for emitting infrared rays to an object to be photographed;

FIG. 19 is a diagrammatic view of an interchangeable lens installed with a device for emitting infrared rays to an object to be photographed;

FIG. 20 is a diagrammatic exploded view of a filter employed in the interchangeable lens of FIG. 19, particularly showing an arrangement for emitting infrared rays; and

FIG. 21 is a circuit diagram of an auto-focusing system according to a further embodiment the present invention.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

Referring to FIG. 1*a*, a block diagram of an auto-focusing system of the present invention is shown. A reference number 2 designates an objective lens included in an interchangeable lens; 7 designates a beam splitter defining a major portion of an optical arrangement of focus detector; and 9*a* and 9*b* designate photoelectric conversion devices for visible light and infrared light, respectively. The beam splitter 7 is provided for splitting the light from a target object and passed through the lens 2 into visible light and infrared light, and for this purpose, it has a first and second reflecting faces 7*a* and 7*b*. The first reflecting face 7*a* has a normalized reflectance (normalized in percentage of reflected light when the incident light is rendered as "1") as shown by a real line in FIG. 2*a* , and a normalized transmittance (normalized in percentage of transmitted light when the incident light is rendered as "1") as shown by a real line in FIG. 2*b*. As apparent from the graphs of FIGS. 2*a* and 2*b*, lights having wavelength of about 700 nanometers or longer, i.e., lights in infrared and/or near-infrared region, are reflected on the first reflecting face 7*a*, and lights having wavelength of less than about 700 nanometers, i.e., visible lights, are transmitted through the first reflecting face 7*a*.

A term infrared used herein includes a range in which photoelectric conversion device 9*b* for the infrared light is sensitive, such as lights having wavelength of 650–900 nanometers. Thus, a term infrared used herein includes near-infrared and partly visible lights of long wavelength.

The photoelectric conversion device 9*a* is so located as to receive the lights transmitted through the first reflecting face 7*a*. Thus it mainly receives visible lights. The photoelectric conversion device 9*b* is so located as to receive the lights reflected from the second reflecting face 7*b* which has a high reflectance at least in the infrared region. Thus, the photoelectric conversion device 9*b* mainly receives infrared lights.

Instead of the beam splitter 7 described above, a normal beam splitter which merely splits the lights in terms of amount can be employed. In this case, a filter for cutting infrared rays should be provided in front of the visible light photoelectric conversion device 9*a*, and a filter of cutting visible light should be provided in front of the infrared light photoelectric conversion device 9*b*.

Referring to FIG. 1*b*, an optical arrangement of a single-reflex interchangeable lens type camera employing the auto-focusing system of the present invention is shown. A reference number 1 designates a main mirror defined by a half-mirror plate; 6 designates a submirror supported by the main mirror 1; 8*a* and 8*b* designate relay lenses; 3 is a pentaprism; 4 is an eyepiece lens; 5 is a focus plate; and 10 is a predetermined image forming plane (film plane) for which objective lens 2 is to be adjusted to focus visual light thereon. Both main mirror 1 and submirror 6 have a uniform reflectance characteristic to all colors including visible light and infrared light. The photoelectric conversion devices 9*a* and 9*b* have a normalized spectral sensitivity (normalized in percentage when the maximum sensitivity is rendered as "1"), as shown by a dotted line in FIGS. 2*a* and 2*b*.

Because of the color aberration of the objective lens, an image forming distance for the infrared light is longer than that for the visible light by an amount dL, and such an amount dL is referred to as deflection dL. The deflection dL varies with respect to the type of interchangeable lens depending on the various factors, such as number and arrangement of lenses defining one interchangeable lens, focal length, etc. Therefore, each interchangeable lens has its own deflection dL which is different from the deflection dL of another interchangeable lens. Furthermore, the deflection dL varies relatively to the change of focus distance, or to the change of focal length if the interchangeable lens is a zoom lens.

If the lens is shifted to an in-focus position in accordance with a focus detection carried out by the infrared lights, and thereafter, if a picture is taken with visible light, the picture will result in out of focus. To obtain a properly focused picture, in this case, it is necessary to correct the deflection dL, which is intrinsic to each type of interchangeable lens.

According to the optical arrangement shown in FIG. 1*a* or 1*b*, an optical distance between the lens 2 and relay lens 8*b*, or infrared light photoelectric conversion device 9*b*, is longer than an optical distance between the lens 2 and relay lens 8*a*, or visible light photoelectric conversion device 9*a*, by an optical distance d/n, wherein d is an actual distance between the first and second reflecting faces 7*a* and 7*b*, and n is a refractive index of the beam splitter 7, provided that the photoelectric conversion devices 9*a* and 9*b* are both positioned at the same distance from the beam splitter 7. If the optical distance d/n is selected to be equal to the deflection dL for one standard lens, an image of visible light can be properly focused on the visible light conversion device 9*a* as well as on predetermined image forming plane 10 and, at the same time, an image of infrared light can be properly focused on the infrared light conversion device 9*b*, provided that said one standard lens is mounted on the camera. Thus, in this case, the lens can be properly focused for the visible light with the focus detection carried out by the infrared light.

If the lens is changed to another interchangeable lens having a deflection dL' which is greater than the deflection dL, such a deflection dL' can not be properly corrected by the optical distance d/n. To properly correct the deflection dL', the camera must be provided with a following correction data S:

$$S = dL' - d/n$$

In the foregoing description, the infrared lights having a predetermined wavelength should be used for

determining the data S, and in the case of using the beam splitter 7, such a wavelength should preferably be 830 nanometers, at which the production of normalized reflectance of the reflecting face 7*a* and normalized spectral sensitivity of the photoelectric conversion device 9*b* takes the maximum value.

Referring again to FIG. 1*a*, both outputs from the visible light photoelectric conversion device 9*a* and from the infrared light photoelectric conversion device 9*b* are applied to a discrimination circuit 11 and also to selection circuit 12. The discrimination circuit 11 discriminates which one of the two outputs from the devices 9*a* and 9*b* is greater, and produces a discrimination signal indicating the one which is greater. The discrimination signal is applied to the selection circuit 12, and also to other circuits, such as a gate circuit 13-1 provided in a focus detection calculation circuit 13. A reference number 16 designates a data output circuit installed in each interchangeable lens for producing a correction data S intrinsic to each interchangeable lens The data output circuit 16 is connectable, when the lens is mounted on the camera, to a read-out circuit 17 for supplying the correction data S to the gate circuit 13-1.

When the gate circuit 13-1 is receiving a discrimination signal indicating that the output from the infrared light photoelectric conversion device 9*b* is greater than that from the visible light photoelectric conversion device 9*a*, the gate circuit 13-1 permits to pass the correction data S from the read-out circuit 17 to a subtractor 13-3.

On the contrary, when the gate circuit 13-1 is receiving a discrimination signal indicating that the output from the visible light photoelectric conversion device 9*a* is greater than that from the infrared light photoelectric conversion device 9*b*, the gate circuit 13-1 cuts the correction data S, and instead, provides a data representing zero to the subtractor 13-3.

The selection circuit 12 operates in such a manner that it produces the output from the infrared light photoelectric conversion device 9*b* when the discrimination signal indicating that the output from the infrared light photoelectric conversion device 9*b* is greater than that from the visible light photoelectric conversion device 9*a*. Contrary, the selection circuit 12 produces the output from the visible light photoelectric conversion device 9*a* when the discrimination signal indicating that the output from the visible light photoelectric conversion device 9*a* is greater than that from the infrared light photoelectric conversion device 9*b*. The output produced from the selection circuit 12 is applied to a calculation circuit 13-2 which calculates an amount of defocus (out of focus) of the image formed by visual light on image forming plane 10 as well as on the device 9*a*, and also a direction of defocus whether it is defocused forwardly or rearwardly. After calculating, the calculation circuit 13-2 produces a defocus signal dF representing the calculated amount and direction of defocus. The defocus signal dF is applied to a subtractor 13-3 which subtracts the data S from the defocus signal dF and produces an absolute value of the subtracted result, i.e., $|dF-S|$. When the data S is equal to zero, the subtracted result is $|dF|$. The subtractor 13-3 also produces a signal representing + or − for the direction of defocus.

The outputs of the subtractor 13-3 are applied to a display device DP for displaying the amount and direction of defocus as obtained from the subtractor 13-3, and also to a lens driver LCO for driving the lens 2 based on the direction of defocus signal from the subtractor 13-3.

In the foregoing description, the amount and direction of defocus can be calculated in a manner disclosed in U.S. Pat. Nos. 4,333,007 patented Jun. 1, 1982 to Langlais et al., 4,341,953 patented Jul. 27, 1982 to Sakai et al., or in Japanese Patent Laid-open Publication (Tokkaisho) No. 57-45510.

Furthermore, when the visible light photoelectric conversion device 9*a* is selected for carrying out the focus detection with visible light, the display device DP displays information based on the signal $|dF|$, but when the infrared light photoelectric conversion device 9*b* is selected for carrying out the focus detection with infrared light, the display device DP displays information based on the signal $|dF-S|$. Therefore, in either cases, the objective lens can be so adjusted as to properly focus the image for the visible light.

According to the block diagram shown in FIG 1*a*, each interchangeable lens produces a data S (=dL-d/n) which is determined by the deflection dL and distance d/n with an assumption that the distance d/n is constant. If the distance d/n of one camera body is difference from the other camera body, and if the interchangeable lens is applicable to both camera bodies, it is necessary to change the data S with respect to the change of the distance d/n. This can be accomplished by two different ways. The first way is to store a data dL to each interchangeable lens, and store a data d/n to each camera body, and by the use of data dL from the lens and d/n from the camera body, the required data S is calculated. The second way is to store a data S to each interchangeable lens, in which S is equal to dL-d/n, wherein d/n is an optical distance for the standard camera body. The camera body other than the standard is stored with a difference dP between the optical distance d/n for the standard camera and its optical distance d/n. When the interchangeable lens is mounted on the standard camera body, the data S from the lens is used in the camera body without any change. But, when the interchangeable lens is mounted on a non-standard camera body, the data S from the lens is corrected using the difference dP.

Referring to FIG. 3, there is shown a first modification of the beam splitter 7 described above. A beam splitter 7′ shown therein includes a parallelepiped glass block 56, a triangle glass block 57, and a multi-film layer 58 sandwiched between blocks 56 and 57. The multi-film layer 58 is defined by twenty-three films deposited one over the other by a suitable depositing method. The twenty-three films have refractive index and optical thickness as given in Table 1 below.

TABLE 1

Layer No.	1	2	3	4

23					
1.38					

TABLE 1-continued

$0.32\lambda_0$

*Note: λ_0 = 1100 nanometers

It is to be noted that the glass blocks **56** and **57** have a refractive index of 1.5168. Of the twenty-three films in the multi-film layer **58**, the films having a refractive index of 1.38 as shown in Table 1 are made of MgF_2, and the films having a refractive index of 2.30 are made of TiO_2 or CeO_2. When light rays hit on the junction face between the glass blocks **56** and **57** with an incident angle of 45°, as illustrated in FIG. **3**, rays in infrared region reflect with a high percentages, but rays in visible light region reflect with a low percentages, as shown in a graph of FIG. **4**, wherein abscissa and ordinate represent, respectively, wavelength in nanometers and normalized reflectance Rf in percentages. More specifically, the reflectance is less than 10% within a visible light range, such as 460–660 nanometers, and is greater than 90% within an infrared light range, such as 800–870 nanometers. Since twenty-three films of the multi-film layer **58** are made of dielectric material, such as MgF_2, and TiO_2, or CeO_2, no light is absorbed in these films. Thus, the transmittance Tf of the rays through the junction can be given as:

$$Tf \div 100 - Rf\ (\%).$$

Therefore, it can be said that the transmittance is greater than 90% in a visible light range, 460–660 nanometers, and is less than 10% in an infrared light range, 800–870 nanometers. Thus, when the beam splitter 7' is used, it is possible to divide the incident light into visible light and infrared light with almost no loss of light.

Referring to FIG. **5**, there is shown a second modification of the beam splitter **7** described above. A beam splitter 7'' shown therein is a so-called half-mirror type defined by a base glass plate **60** and a multi-film layer **61** deposited on the base glass plate **60**. The multi-film layer **61** has thirteen films deposited one over the other through a suitable depositing method. The thirteen films have refractive index and optical thickness as given in Table 2 below.

TABLE 2

Layer No.	1	2	3	4	5	6	7	8	9	10
Refractive Index n	1.38	2.30	1.38	2.30	1.38	2.30	1.38	2.30	1.38	2.30
Optical Thickness nd	$0.125\lambda_0$	$0.25\lambda_0$	$0.25\lambda_0$	$0.25\lambda_0$	$0.25\lambda_0$	$0.25\lambda_0$	$0.25\lambda_0$	$0.25\lambda_0$	$0.25\lambda_0$	$0.25\lambda_0$

11	12	13
1.38	2.30	1.38
$0.25\lambda_0$	$0.25\lambda_0$	$0.32\lambda_0$

*Note: λ_0 = 1000 nanometers

It is to be noted that the base glass plate **60** has a refractive index of 1.5168. Of the thirteen films in the multi-film layer **61**, the films having a refractive index of 1.38 as shown in Table 2 are made of MgF_2, and the films having a refractive index of 2.30 are made of TiO_2 or CeO_2. When light rays hit on the beam splitter 7'' with an incident angle of 45°, as illustrated in FIG. **5**, rays in infrared region reflect with a high percentages, but rays in visible light region reflect with a low percentages, as shown in a graph of FIG. **6**, wherein abscissa and ordinate represent, respectively, wavelength in nanometers and normalized reflectance Rf in percentages. More specifically, the reflectance is very low (thus, transmittance is very high) in a visible light range, such as 400–700 nanometers, and is very high (thus, transmittance is very low) in an infrared light range, such as 800–1000 nanometers.

Referring to FIG. **7**, a major portion of the optical arrangement of the focus detecting device employing the beam splitter 7'' is shown. In FIG. **7**, **62** is a reflection mirror, **8'** is an optical element having relay lenses **8'***a* and **8'***b*.

It is to be noted that the auto-focusing system according to the present invention can be arranged in different manner than the above described arrangement.

For example, in the beam splitter **7** shown in FIGS. **1***a* and **1***b*, the second reflecting face **7***b* can be so arranged as to have reflectance and transmittance characteristic varied with respect to wavelength in a similar manner to the first reflecting face **7***a*. More specifically, the second reflecting face **7***b* can be so arranged as to have a normalized reflectance as shown by a dot-dash line in FIG. **2***a*. When this is done, the range in which the infrared light photoelectric conversion device **9***b* receives light is narrowed. Accordingly, the wavelength of light that can be detected by the infrared light photoelectric conversion device **9***b* is limited to a certain narrow range, resulting in preciseness of the deflection dL. Thus, the correction using the deflection dL (or data S) can be done with a high accuracy. Also, in a case where an auxiliary light is emitted, an infrared LED or infrared laser having intense beam with a high reflectance to the first and second reflecting faces **7***a* and **7***b* should be used, thereby improving the accuracy of the correction using deflection dL (or data S). In this case, it is preferable to provide a light absorber at left end surface, when viewed in FIG. **1***b*, of the beam splitter **7**, so that the lights which have passed through the second reflecting face **7***b* will not reflect back on such an end surface.

Also, in the above description, a beam splitter having a high transmittance of visible light and a high reflectance of infrared light is used. But instead, a beam splitter having a high reflectance of visible light and a high transmittance of infrared light can be used.

Furthermore, a beam splitter having three reflecting faces can be used. In this case, the first reflecting face reflects infrared lights and transmits visible lights. The second reflecting face receives the infrared lights reflected from the first reflecting face and reflects infrared lights having a wavelength of a first particular range, and transmits infrared lights having a wavelength of a second particular range. The third reflecting face receives and reflects the infrared lights having a wavelength of the second particular range. In this case, two infrared light photoelectric conversion devices should be provided: one for receiving the infrared lights from the second reflecting face; and the other for receiving the infrared lights from the third reflecting face.

Referring to FIGS. **8***a* and **8***b*, a circuit diagram of the auto-focusing system according to one embodiment of the present invention is shown, in which characters A–E in circle in FIG. **8***a* are connected to corresponding characters in circuit in FIG. **8***b*.

A reference character IRD at upper left corner of FIG. **8***a* is a photoelectric conversion element for monitoring infrared lights, and VSD is a photoelectric conversion element for monitoring visible lights. The photoelectric conversion element IRD is provided in the infrared light photoelectric conversion device **9***b*,

shown in FIG. 1*a* or 1*b*, and the photoelectric conversion element VSD is provided in the visible light photoelectric conversion device 9*a*. These photoelectric conversion elements IRD and VSD are coupled with operational amplifiers OA1 and OA2 and logarithmic compression diodes D1 and D2, thereby defining light measuring circuits. The outputs of the operational amplifiers OA1 and OA2 are compared with each other in a comparator AC1. When the output from the amplifier OA1 is greater than that from the amplifier OA2, i.e., when the infrared lights are stronger than the visible lights, the comparator AC1 produces HIGH, and when the output from the amplifier OA2 is greater than that from the amplifier OA1, i.e., when the visible lights are stronger than the infrared lights, the comparator AC1 produces LOW.

The output of the operational amplifier OA1 is also compared with a reference voltage from a constant voltage source CE2 by a comparator AC3. When the output from the operational amplifier OA1 representing the infrared light level is smaller than the reference voltage from the voltage source CE2, the comparator AC3 produces HIGH. But, when the output from the amplifier OA1 is greater than the reference voltage from the voltage source CE2, the comparator AC3 produces LOW.

Likewise, the output of the operational amplifier OA2 is also compared a reference voltage from a constant voltage source CE1 by a comparator AC2. When the output from the operational amplifier OA2 representing the visible light level is greater than the reference voltage from the voltage source CE1, the comparator AC2 produces HIGH. But, when the output from the amplifier OA2 is smaller than the reference voltage from the voltage source CE1, the comparator AC2 produces LOW.

A logic circuit defined by inverter IN1, AND gates AN1 and AN2 and OR gates OR1 and OR2 receives the outputs from three comparators AC1, AC2 and AC3 and selects which one of the two outputs from photoelectric conversion devices 9*a* and 9*b* should be used, and determines whether or not an infrared LED for the auxiliary light should be actuated to emit infrared light for the focus detection. A detail of operation of the logic circuit is shown below in Table 3.

TABLE 3

	Output levels of Photoelectric Conversion Elements IRD & VSD	AC1	AC2	AC3	IN1	AN1	AN2	OR1	OR2	Selected Element IRD or VSD	Infrared LED IRL ON or OFF
1	IRD > VSD + IRD > CE2	H	ϕ	L	L	L	L	L	H	IRD	OFF
2	IRD > VSD + IRD < CE2	H	ϕ	H	L	L	H	H	H	IRD	ON
3	VSD > IRD + VSD > CE1	L	L	ϕ	H	L	L	L	L	VSD	OFF
4	VSD > IRD + VSD < CE1	L	H	ϕ	H	H	L	H	H	IRD	ON

NOTE:
(1) + means "at the same time".
(2) ϕ means "either H or L".

As understood from Table 3, row 1, when the output level of photoelectric conversion element IRD is greater than that from the element VSD and, at the same time, greater than the reference voltage from the voltage source CE2, comparators AC1 and AC3 produces HIGH and LOW, respectively. Thus, the AND gate AN2 produces LOW, and the inverter IN1 produces LOW, thereby producing LOW from the AND gate AN1. Furthermore, OR gate OR1 produces LOW and OR gate OR2 produces HIGH. Thus, when a data flip-flop DF1 receives a clock pulse, its Q output produces LOW. Thus, an AND gate AN3 produces LOW to turn off transistor BT1. As a result, the infrared LED IRL is maintained OFF. Moreover, when a data flip-flop DF2 receives a clock pulse, its Q output produces HIGH, and its $\overline{Q}$ output produces LOW, thus turning an analog switches AS1 and AS4 on, permitting the transmission of signal from a CCD (charge coupled device) IRC provided in the infrared light photoelectric conversion device 9*b*, and turning an analog switches AS2 and AS3 off, cutting signal from a CCD VSC provided in the visible light photoelectric conversion device 9*a*.

The operation shown in Table 3 under other rows is similar to that described above.

As apparent from Table 3, rows 1 and 2, when ever the output level of infrared light photoelectric conversion element IRD is greater than that from the visible light photoelectric conversion element VSD, infrared light photoelectric conversion device 9*b* is selected. In this case, if the output level of infrared light photoelectric conversion element IRD is lower than a predetermined level (row 2), the infrared LED IRL is actuated to emit auxiliary light of infrared rays.

Contrary, the visible light photoelectric conversion device 9*a* is selected only when the output level of visible light photographic conversion element VSD is greater than that from the infrared light photoelectric conversion element IRD and, at the same time, greater than a predetermined level (row 3). When the output level of visible light photographic conversion element VSD is greater than that from the infrared light photoelectric conversion element IRD, but less than the predetermined level (row 4), the infrared light photoelectric conversion device 9*b* is selected and, at the same time, the infrared LED IRL is actuated to emit auxiliary light of infrared rays.

A further detail of the circuit shown in FIG. 8*a* will become apparent from the following description.

The output of the OR gate OR1 is connected to D input of data flip-flop DF1, and the output of the OR gate OR2 is connected to D input of data flip-flop DF2. Each of the data flip-flops DF1 and DF2 has a clock terminal CL which is connected to an output 03 of a microcomputer MCO (FIG. 8*b*). When the microcomputer MCO produces from its output 03 a start measuring signal for effecting the start of light measuring for the focus detection, data flip-flops DF1 and DF2 latches the data at their D input.

Still referring to FIG. 8*a*, a reference character COT designates a controller for controlling the light measuring operation for the focus detection, IRC is a CCD provided in the infrared light photoelectric conversion device 9*b*, and VSC is a CCD provided in the visible light photoelectric conversion device 9*a*. These CCDs IRC and VSC are provided for the focus detection. A

sample-and-hold circuit SH is provided for holding analog signal from either CCD IRC or VSC, and an analog-to-digital converter AD is provided for converting an output of sample-and-hold circuit SH from analog to digital form.

When the start measuring signal, which is a pulse, is applied from output **03** of microcomputer MCO to input ST of controller COT, the controller COT produces from its output ϕR a reset pulse which is applied to each of analog switches **AS5** and **AS6**, thereby turning the analog switches **AS5** and **AS6** on. By the turn on of the analog switches **AS5** and **AS6**, each of the CCDs IRC and VSC are charged through terminals IAD and VAD up to a level equal to a constant voltage source **CE5**. The output ϕR is also connected to a set terminal S of a flip-flop **FF1**. Thus, by a reset pulse produced from the output ϕR, the flip-flop **FF1** is turned to set condition, thereby producing HIGH from Q output of the flip-flop **FF1**. This HIGH is applied to AND gate **AN3**, and if the data flip-flop **DF1** is producing HIGH at this moment, the AND gate **AN3** produces HIGH, thereby conducting transistor **BT1**. Thus, the LED IRL emits infrared beams.

The CCDs IRC and VSC receive signals from their own light receiving elements, charge the signals, and produce gradually-increasing voltage signals representing the charged amount in each CCD from their outputs IAD and VAD. In this case, when the data flip-flop **DF2** is producing HIGH from its Q output (meaning that CCD IRC of infrared should be used), analog switch **AS4** conducts to transmit voltage signal from output IAD of CCD IRC to comparator **AC4**. On the other hand, when the $\overline{Q}$ output of flip-flop **DF2** is producing HIGH, analog switch **AS3** conducts to transmit voltage signal from output VAD of CCD VSC to comparator **AC4**.

The comparator **AC4** compares the gradually increasing voltage signal from output IAD or VAD with a reference voltage from a constant voltage source **CE3**, and when the voltage signal reaches the reference voltage from the voltage source **CE3**, it produces HIGH which is applied to controller COT. Thereupon, the controller COT produces a transmission pulse from its output ϕT, thereby shifting the charge stored in each CCD IRC or VSC to transmission gate. The transmission pulse is also applied to reset terminal R of flip-flop **FF1**, thereby resetting the flip-flop **FF1**. Thus, the LED IRL for the auxiliary light stops the infrared light emission. Thereafter, output terminal IRS or VSS of CCD IRC or VSC continuously produce stored charge in accordance with transmission clocks from outputs ϕ**1**, ϕ**2** and ϕ**3**. In this case, when the data flip-flop **DF2** is producing HIGH from its Q output, analog switch **AS1** conducts to transmit the signal representing the received infrared light from output IRS to sample-and-hold circuit SH. But, when the data flip-flop **DF2** is producing HIGH from its $\overline{Q}$ output, analog switch **AS2** conducts to transmit the signal representing the received visible light from output VSS to sample-and-hold circuit SH.

The controller COT produces from its terminal ϕS a pulse for effecting the sample-and-hold operation in the circuit SH and, thereafter, produces a pulse from its terminal ϕC to AD converter AD for effecting analog-to-digital conversion. Then, controller COT produces from its output TR a pulse to an input **i4** of microcomputer MCO for the indication that the data transmission will be carried out. Thereupon, the AD converted data by the AD converter AD is transmitted from controller COT to microcomputer MCO through its input port **IP1**. Thereafter, the above described series operation of producing stored charge, sample-and-hold, AD conversion; and data transmission is repeated for a number of times equal to the number of light receiving element in CCD IRC or VSC. When repeated for the required number of times, the controller COT produces from its output EN a pulse indicating the completion of transmission to an input **i6** of microcomputer MCO, thereby stopping the repetition.

According to the above description, the determination of which one of the two CCDs should be selected and the determination of whether or not to turn on the LED IRL are carried out by the use of photoelectric conversion elements IRD and VSD. But, both determinations can be done without such elements IRD and VSD. For example, before carrying out the light measuring for the focus detection, the CCDs IRC and VSC are actuated to store charges corresponding to the infrared and visible lights, respectively, and the voltage signals representing the charged amounts, as produced from the outputs IAD and VAD, can be used as output signals from the elements IRD and VSD, or from the amplifiers **OA1** and **OA2** if such voltage signals have enough high amplitude.

Referring particularly to FIG. **8***b*, the auto-focusing system further includes a battery BA for supplying D.C. power and a manually operable switch MS, such as one provided in association with a shutter release button (not shown) and closes upon depression to a half-way down. The switch MS is connected to an inverter **IN2** which, when the switch MS is turned on, produces HIGH, thereby starting the microcomputer MCO to carry out the focus condition detection and focus adjustment and, at the same time, starting a light measuring, calculation and display circuit LM. Also, in response to the closure of the switch MS, the microcomputer MCO produces HIGH from its output **01**, thereby producing LOW from an inverter **IN3** to turn a transistor **BT2** to a conductive state. Thus, D.C. power is supplied to line Vcc.

Another manually operable switch RS is provided, for example in association with a shutter release button, and closes upon depression to its full way. When the switch RS closes, an inverter **IN4** produces HIGH. In this case, if an exposure control circuit EC is in a preparatory condition and an inverter **IN0** is producing HIGH, AND gate **AN0** produces HIGH, thereby stopping the microcomputer to further carry out the focus condition detection and focus adjustment. Then, it is waited until the exposure control stops. Also, when the switch RS closes, the exposure control circuit EC carries out an exposure control operation based on exposure control values from the light-measuring, calculation and display circuit LM. When the exposure control operation completes, the exposure control circuit EC produces HIGH indicating the completion of operation, and applies it to input **i1** of the microcomputer MCO. The exposure control circuit EC produces LOW when an exposure control arrangement has completed its charge and when the preparation for the exposure control operation is completed.

A display device DP receives data from an output port **OP1** of the microcomputer MCO and displays either one of in-focus, near-focus and far-focus. A motor drive circuit MDR receives data from an output port **OP2** and drives a motor MO either in forward or

backward direction, thereby operating a lens drive mechanism LDR to shift the lens to an in-focus position. An encoder EN is coupled to lens drive mechanism LDR for producing a pulse each time the lens is shifted for a predetermined unit distance. An interface circuit IF is provided, which takes data necessary for driving the lens from a data producing circuit LDO in response to a pulse from output 02 of microcomputer MCO. The data producing circuit LDO, provided in the interchangeable lens mounted on a camera body, supplies the data S (or data dL) and data K representing the rate of lens shift with respect to a predetermined number of pulses produced from the encoder EN.

Next, a detail of the interface circuit IF and data producing circuit LDO is described with reference to FIGS. 9*a* and 9*b*, wherein terminals J1 to J4 provided in a camera body are connectable to corresponding terminals J1' to J4' provided in an interchangeable lens.

Referring particularly to FIG. 9*a*, when microcomputer MCO produces HIGH from its output 02, a flip-flop FF5 is set, thereby producing HIGH from Q output of flip-flop FF5. Then, when a clock terminal CL of data flip-flop DF5 receives a clock pulse from oscillator OSC, the data flip-flop DF5 produces HIGH from its Q output. Accordingly, an AND gate AN10 is enabled to transmit a train of clock pulses from oscillator OSC to clock terminal CL of a ring counter CO1. In response to each clock pulse, the ring counter CO1 counts up. More specifically, when the ring counter CO1 has counted one clock pulse, it produces HIGH from its output b0 and produces LOW from the rest of its outputs; when it has counted two clock pulses, it produces HIGH from its output b1 and produces LOW from the rest of its outputs; when it has counted ten clock pulses, it produces HIGH from its output b9 and produces LOW from the rest of its outputs; when it has counted eleven clock pulses, it produces HIGH from its output b0 and produces LOW from the rest of its outputs; and so on.

Referring also to FIG. 9*b*, the Q output of data flip-flop DF5 is also connected through terminals J1 and J1' to the circuit provided in the mounted interchangeable lens. More specifically, the terminal J1' is connected to a latch circuit LA3 which upon receipt of HIGH from the Q output of data flip-flop DF5, latches 5-bit data representing a distance between the object to be photographed and the camera from a focus distance reading device DD through analog switches AS15–AS19. The focus distance reading device DD reads the distance between the object to be photographed and the camera by detecting the shifted position of be objective lens. The terminal J1' is also connected to a delay circuit DL which after a predetermined period from the receipt of HIGH from the Q output of data flip-flop DF5, produces HIGH which is inverted to LOW by an inverter IN10. The HIGH from the delay circuit DL is applied to analog switches AS10–AS15 to turn on the same, and LOW from the inverter IN10 is applied to analog switches AS15–AS19 to turn off the same. Thus, when a HIGH is produced from the delay circuit DL, a decoder DE receives 10-bit signal (5-bit distance data from the latch LA3 and 5-bit focal length data from a focal length setting circuit FD) which is converted to 6-bit signal and applied to a ROM RO at its least significant six bits.

In FIG. 9*b*, the focus distance reading device DD and focal length setting device FD are each formed by a coded plate (not shown) and a portion enclosed by a dot-dash line can be formed in a single IC chip. According to the arrangement shown in FIG. 9*b*, it is possible to transmit 10-bit signal from the devices DD and DF to the IC chip through only six lines: five lines extending from the latch LA3; and one line extending from the delay circuit DL, resulting in fewer connections between the IC chip and its associated circuit. Furthermore, the circuit shown in FIG. 9*b* is particularly designed for the employment in an interchangeable lens having data S (or data dL) and data K which vary with respect to the change of focusing distance and focal length. Therefore, signals representing these two variants as produced from the devices DD and FD are converted by the decoder DE into 6-bit signal to be applied to the ROM RO at its least significant six bits.

Moreover, the Q output of data flip-flop DF5 is connected through terminals J1 and J1' to AND gate AN14. Thus, the AND gate AN14 is enabled upon receipt of HIGH from the data flip-flop DF5, thereby permitting the supply of clock pulses from the oscillator (FIG. 9*a*) through the terminal J2 and J2' to a ring counter CO2, which operates in the same manner as the above-described ring counter CO1.

When the ring counter CO1 receives second clock pulse to its clock terminal CL, it produces HIGH from its output b1 for the first time. Accordingly, a counter C03 (FIG. 9*b*) connected to the output b1 of the counter CO1 through terminals J3 and J3' counts up to one, thereby producing a 2-bit signal "01" from its outputs Q1 and Q2. These outputs Q1 and Q2 of the counter C03 are connected to two most significant bit terminals of ROM RO. Thus, in this case, the ROM RO receives an 8-bit signal "01XXXXXX" (XXXXXX is a 6-bit output from decoder DE.) which is an address for designating a location in ROM RO where data S (or dL) corresponding to the detected focus distance and set focal length is stored. Then, when output L2 of ring counter CO2 produces HIGH, the designated data S (or dL) defined by a plurality of bits, such as 8 bits, in ROM RO is transferred parallelly to a shift register SR2. Thereafter, in a synchronized relation with the clock pulses from the terminal J2', the data S (or dL) is sent out bit-by-bit in response to the positive edge of each clock pulse from a terminal OUT of the shift register SR2, and is transferred though the terminals J4' and J4 to a shift register SR1 provided in interface circuit IF in a camera body. The shift register SR1 stores the data S (or dL) bit-by-bit in response to the negative edge of each clock pulse from the oscillator OSC. Therefore, the storing of the data S (or dL) in the shift register SR1 starts in synchronized relation to the negative edge of a pulse produced from terminal b2 of the ring counter CO1 and ends in synchronized relation to the negative edge of a pulse produced from terminal b9 of the ring counter CO1.

Thereafter, when terminal b0 of the ring counter CO1 produces HIGH for the second time, a data flip-flop DF7 produces HIGH from its Q output. At this moment, a data flip-flop DF8 is producing HIGH from its $\overline{Q}$ output, an AND gate AN11 is enabled to produce HIGH from terminal b0 of ring counter CO1. And, in response to the positive edge of HIGH produced from AND gate AN11, a latch LA1 stores data S (or dL) from shift register SR1.

Then, while terminal b1 of the ring counter CO1 is producing HIGH for the second time, this HIGH is applied through terminals J3 and J3' to counter C03 which then produces "10" from its outputs Q1 and Q2. Thus, in this case, the ROM RO receives an 8-bit signal

"10XXXXXX" which is an address for designating a location in ROM RO where data K corresponding to the read focus distance and set focal length is stored. Then, in response to the positive edge of a pulse produced from output L2 of ring counter CO2, the designated data K is transferred to shift register SR2. Thereafter, in a synchronized relation with the clock pulses from the terminal J2', the data K is sent out bit-by-bit in response to the positive edge of each clock pulse from a terminal OUT of the shift register SR2, and is transferred though the terminals J4' and J4 to a shift register SR1 provided in interface circuit IF in a camera body. The shift register SR1 stores the data K bit-by-bit in response to the negative edge of each clock pulse from the oscillator OSC. Therefore, the storing of the 8-bit data K in the shift register SR1 starts in synchronized relation to the negative edge of a pulse produced from terminal b2 of the ring counter CO1 and ends in synchronized relation to the negative edge of a pulse produced from terminal b9 of the ring counter CO1.

Thereafter, when terminal b0 of the ring counter CO1 produces HIGH, a data flip-flop DF8 produces HIGH from its Q output. Therefore, an AND gate AN12 is enabled to produce HIGH from terminal b0 of ring counter CO1. And, in response to the positive edge of HIGH produced from AND gate AN12, a latch LA2 stores data K from shift register SR1. The HIGH from AND gate AN12 is also applied through an OR gate OR10 to reset terminal of each of flip-flop FF5, data flip-flops DF5, DF6, DF7 and DF8 and ring counter CO1, thereby resetting these circuits. When the data flip-flop DF5 is reset, its Q output produces LOW which is applied through terminals J1 and J1' and OR gate OR11 to reset terminal of each of counters CO2 and CO3, thereby resetting these counters.

The above described operation is carried out to provide necessary data S (or dL) and data K to the interface circuit IF of the camera body, and through input ports IP2 and IP3 to microcomputer MCO. And, whenever the condition of focus distance or focal length changes, the above described operation is repeated to renew the necessary data S (or dL) and data K.

In FIGS. 9*a* and 9*b*, reference characters PO1 and PO2 designate power-on-reset circuit, and each produces a reset signal when a power is supplied from a power supply line Vcc in response to the conduction of transistor BT2. The reset signal produced from the power-on-reset circuit PO1 is applied to OR gate OR10, and in response to the negative edge of the reset signal, each of flip-flop FF5, data flip-flop DF5, DF6, DF7 and DF8 and ring counter CO1 is reset. And, the reset signal produced from the power-on-reset circuit PO2 is applied to OR gate OR11, and in response to the negative edge of the reset signal, each of counters CO2 and CO3 is reset.

Referring to FIG. 10, a circuit which is a modification of the circuit of FIG. 9*b* is shown, and is arranged such that the data S (or dL) and data K vary with respect to the change of either one of focus distance or focal length. According to the circuit shown in FIG. 10, the ROM RO has its two most significant bits of 8-bit inputs connected to counter CO3, the least significant bit connected to ground, and the remaining five bits connected to focus distance measuring device DD or focal length setting device FD, which ever is provided in the circuit. The remaining parts and the operation of the circuit of FIG. 10 is similar to that described above in connection FIG. 9*b*.

Referring to FIG. 11, a circuit which is a further modification of the circuit of FIG. 9*b* is shown. According to this modification, a circuit DIA defined by diode arrays is provided in place of ROM RO. When output Q2 of counter CO3 produces HIGH, a diode array provided in circuit DIA and connected to the output Q2 is so actuated as to produce a signal represented data S (or dL). And, when output Q1 of counter CO3 produces HIGH, another diode array provided in circuit DIA and connected to the output Q1 is so actuated as to produce a signal representing data K. The remaining circuit of FIG. 11 is the same as that shown in FIG. 9*b*.

Next, the operation of the circuit of FIGS. 8*a* and 8*b* will be described with reference to a flow chart of FIGS. 12*a* and 12*b*. While the manual switch MS is turned off, microcomputer MCO is in a "HALT" condition consuming a very low electric power. When the switch MS is turned on, a HIGH produced from inverter IN2 is applied to an interruption terminal i0, whereby the microcomputer MCO starts to operate from step #0. At step #0, a HIGH is produced from output terminal 01, thereby producing a LOW from inverter IN3. Thus, transistor BT2 conducts to supply electric power to power supply line Vcc. Then, at step #1, it is discriminated whether or not switch RS is turned on, by the discrimination of signal at the input i3. When the switch RS is turned off, input i3 receives LOW from inverter IN4 through AND gate AN0. But if switch RS is turned on, input i3 receives HIGH from inverter IN4. When input i3 is receiving HIGH, i.e., when switch RS is on, the program advances to step #41 for the exposure control as will be described later. Contrary, when input i3 is receiving LOW, i.e., when switch RS is off, output 03 produces HIGH, at step #2 for starting the light measuring operation for the focus detection. Then, at step #3, output 02 produces HIGH to fetch data S (or dL) and data K from the mounted interchangeable lens.

Then, at step #4, it is waited until input i4 receives HIGH. When input i4 receives HIGH, data (of A-D converted value of charge in CCD VSC or IRC by one light receiving element) from controller COT is read into microcomputer MCO through input port IP1, at step #5. At step #6, it is discriminated whether input i6 is receiving HIGH. If input i6 is receiving LOW, the program returns back to step #4 for reading next data (of A-D converted value of charge in CCD VSC or IRC by another light receiving element). Contrary, if input i6 is receiving HIGH, as occurred when data of A-D converted value of charge in CCD VSC or IRC by all the light receiving elements is read in, the program advances to step #7. At step #7, it is discriminated whether or not input i3 is receiving HIGH, in the same manner as step #1. If input i3 is receiving HIGH, the program jumps to step #41. If not, then the program proceeds to step #8. At step #8, data S (or dL) is read in through input port IP2, and at step #9, data K is read in through input port IP3. Then, at step #10, an amount of defocus (out of focus) of the image formed on a CCD, and also a direction of defocus are calculated using data received through input port IP1. A manner for carrying out this calculation is disclosed, for example, in U.S. Pat. No. 4,333,007 patented Jun. 1, 1982 to Langlais et al., or in Japanese Patent Laid-open Publication (Tokkaisho) No. 57-45510.

Then, at step #11, it is discriminated whether input i5 is receiving HIGH or not. If input i5 is receiving HIGH, it is understood that the defocus signal dF (representing

the amount and direction of defocus) is calculated using output from CCD IRC provided in the infrared light photoelectric conversion device **9***b*. Therefore, microcomputer MCO carries out a calculation:

$$K\cdot(dF-dL)=N$$

using deflection data dL for correcting defocus signal dF and rate K which are obtained from ROM RO.

If input i5 is not receiving HIGH, it is understood that the defocus signal dF is calculated using output from CCD VSC provided in the visible light photoelectric conversion device **9***a*. In this case, microcomputer MCO carries out a calculation:

$$K\cdot dF=N$$

using defocus signal dF without correction and rate K.

It is to be noted that the calculated result N in the above two equations indicates a number of pulses to be produced from encoder EN to shift the mounted lens to the properly infocused position.

Then, at step **#14**, the focus condition is indicated through display device DP. And, at step **#15**, it is discriminated whether or not input i3 is receiving HIGH for discriminating whether the switch RS is turned on or not, in the same manner described above. At step **#16**, it is discriminated whether the number N is equal to zero or not. If it is zero, the program jumps to step **#38**, which will be described later. If not, the program advances to step **#17** for setting the number N in register M in microcomputer MCO. Then, at step **#18**, motor drive circuit MDR is actuated to start motor MO in forward or backward direction determined by dF, and then a data P0 is set up in a register P in microcomputer MCO, at step **#19**. Then, it is discriminated at step **#20** whether or not input i2 receives HIGH pulse from encoder EN. If input has received HIGH, the program advances to step **#21**, and if not, advances to step **#27**.

At step **#27**, it is discriminated whether or not input i3 is receiving HIGH to discriminate whether switch RS is closed or not. If input i3 is receiving HIGH, it is understood that an exposure control operation will be carried out. In this case, motor MO is stopped at step **#31**, and a flag JF in microcomputer MCO is reset, and then, the program advances to step **#41**. Contrary, if input i3 is receiving LOW, "1" is subtracted from the content of register P (step **#28**) and, thereafter, it is discriminated whether the content of register P is zero (step **#29**). If not equal to zero, the program advances to step **#30** at which it is discriminated whether flag JF is carrying zero or not. If flag JF is carrying zero, the program returns to step **#20** to repeat the discrimination whether input i2 receives HIGH pulse from encoder EN. But, if the flag JF is not carrying zero, the program advances to step **#25** at which it is discriminated whether or not input i2 is receiving LOW. If input i2 is receiving LOW, the program again goes to step **#27**. The above operation is repeatedly carried out until input i2 receives HIGH. If input i2 fails to receive HIGH before the content of the register P becomes zero, i.e., before a predetermined period of time, it is understood that the lens is unable to move any further because it is already shifted to one extreme end. In this case, motor MO is stopped at step **#33**, and a warning is displayed (step **#34**). Then, flag JF is reset at step **#35** and then program advances to step **#38**.

Returning back to step **#20**, if input i2 receives a HIGH pulse from encoder EN, the content of the register M, which is now N, is subtracted by "1" (step **#21**). Then, it is discriminated whether the content of the register is equal to zero or not (step **#22**). If not, "1" is set in flag JF (step **#23**) and a data P0 is set up in register P (step **#24**). Then, it is discriminated whether input i2 receives LOW, i.e., whether the HIGH pulse ends or not (step **#25**). If it is discriminated that the HIGH pulse has ended, the program advances to step **#26** to reset flag JF and, thereafter, it returns back to step **#19**.

In the foregoing description, the content of register M is subtracted by "1" only when it is discriminated that input i2 receives HIGH, i.e., in response to the positive edge of a pulse from encoder EN. Instead, according to one modification, the number N may be doubled and the content of register M is subtracted by "1" also when it is discriminated that input i2 receives LOW, i.e., in response not only to the positive edge, but also to the negative edge of a pulse from encoder EN. In this case, a discrimination step same as the step **#22** should be added between steps **#25** and **#26** for the discrimination whether the content of the register M is equal to zero or not. If it is equal to zero, the program advances to step **#36**, as in the case of step **#22** to end the lens adjustment, as will be described below. When this modification is employed, the lens position can be adjusted more precisely to the infocus position.

At step **#22**, if it is discriminated that the content of register M is equal to zero, it is understood that the lens is shifted to the infocus position. Therefore, at step **#36**, motor MO is stopped and, at step **#37**, it is indicated through display device DP that the lens is shifted to the infocus position.

At step **#38**, it is discriminated whether manual switch MS is on or not, by the discrimination of whether input i7 is receiving HIGH or not. If input i7 receives HIGH as occurs when manual switch MS turns on, the program returns back to step **#1** to repeat the above described operation. Contrary, if input i7 receives LOW, display device DP is turned off at step **#39** and LOW is produced from output **01** to turn transistor BT2 off, thereby cutting the supply of electric power to power supply line Vcc, and returning microcomputer MCO again to "HALT" condition. Also, if it is discriminated at step **#1** that switch RS is turned off, it is waited at step **#41** until input i1 receives HIGH. Then, after completing the exposure control operation and when input i1 receives HIGH pulse from exposure control circuit EC, the program advances to step **#38**.

Next, the description is directed to modifications of the above described embodiment.

As mentioned before, the photoelectric conversion element for the focus detection can be formed by diode arrays which respond immediately to the light, instead of an integration type which respond gradually to the light, such as ROM RO.

Also, according to the above description, the data dF is calculated using digital value, which is an A/D converted value of output signal from photoelectric conversion element. Instead, it is possible to calculate the data dF using analog value from the photoelectric conversion element, and the calculated result may be converted to digital form for the motor control and display.

Referring to FIG. **13**, another embodiment of the present invention is shown. According to this embodiment, the photoelectric conversion elements IRD and VSD are eliminated, and CCDs IRC and VSC are used for obtaining signals which determine whether to use

the auxiliary light, or not, and which determine which one of the two signals from CCDs IRC and VSC is to be used.

A counter CO10 is reset by a reset pulse ϕR, counts up by clock pulse ϕ1, and produces a pulse from its carry terminal after, e g., 40 msec. When this pulse is produced, the signals produced from outputs IAD and VAD from CCDs IRC and VSC are compared with each other in comparator AC10 and are each compared with a reference voltage from constant voltage source CE10 in comparators AC11 and AC12, and the compared signals are applied to logic circuit defined by AND gates AN21 and AN32 and inverter IN20. Furthermore, the outputs from AND gates AN21 and AN32 are stored in data flip-flops DF20 and DF21.

If the compared results are such that IAD is smaller than VAD (meaning that the infrared light is stronger than visible light) and IAD is smaller than a predetermined level CE10 (meaning that the infrared light is stronger than a predetermined level), or that IAD is equal to or greater than VAD (meaning that the infrared is not stronger than visible light) and VAD is weaker than the predetermined level CE10 (meaning that visible light is stronger than the predetermined level), both AND gates AN21 and AN22 produce LOW, thereby storing LOW in both data flip-flops DF20 and DF21. In this case, OR gate OR21 continues to produce LOW, thereby preventing LED IRL from emitting infrared light. In the above given situation, since both outputs from CCDs IRC and VSC reach the predetermined level CE10 before counter CO10 counts the time, e.g., 40 msec, the charge to CCDs can be completed within a predetermined period of time, such as 80 msec.

Contrary, if the compared results are such that IAD is smaller than VAD (meaning that the infrared light is stronger than visible light) and IAD is equal to or greater than a predetermined level CE10 (meaning that the infrared light is not stronger than a predetermined level), or that IAD is equal to or greater than VAD (meaning that the infrared is not stronger than visible light) and VAD is equal to or greater than the predetermined level CE10 (meaning that visible light is not stronger than the predetermined level), both AND gates AN21 and AN22 produce HIGH, thereby storing LOW in both data flip-flops DF20 and DF21. In this case, OR gate OR21 produces HIGH, thereby emitting infrared light from LED IRL. In the above given situation, an infrared light is emitted because, if CCD continues to charge without an auxiliary infrared light, the charging may not complete within a predetermined period of time, such as 80 msec., resulting in a long period of time for the focus detection.

When a signal level from outputs IAD or VAD reaches the reference voltage level of constant voltage source CE11, comparator AC13 or AC14 producers HIGH, thereby producing a HIGH pulse from one-shot circuit OS10 or OS11. Before producing a HIGH pulse from one-shot circuit OS10 or OS11, flip-flops FF10 and FF11 are both in reset condition. Therefore, a $\overline{Q}$ terminal of each flip-flop FF10 or FF11 is producing HIGH, thereby enabling AND gates AN24 and AN23.

When a HIGH pulse is produced from one-shot circuit OS10, it is transmitted through OR gate OR22 and AND gate AN23 to flip-flop FF10, thereby changing the flip-flop FF10 to set condition. Accordingly, flip-flop FF10 produces HIGH from its Q output which is applied to controller COT through OR gate OR23 and also to analog switch AS1, and LOW from its $\overline{Q}$ output which is applied to AND gate AN24, thereby disabling AND gate AN24 to cut any HIGH pulse from one-shot circuit OS11. Thus, flip-flop FF11 continues to produce LOW from its Q output and HIGH from its $\overline{Q}$ output. This condition is maintained until a reset pulse is produced from output 03 of microcomputer MCO.

Contrary, when a HIGH pulse is produced from one-shot circuit OS11, flip-flop FF11 is turned to set condition and flip-flop FF10 is maintained in reset condition, thereby providing HIGH to controller COT and analog switch AS2.

In the above described operation, when controller COT receives HIGH from OR gate OR23, controller COT produces a transmission pulse ϕT which is applied to CCDs VSC and IRC. Furthermore, in the above operation, when HIGH is applied to analog switch AS1, CCD IRC is selected for use in focus detection, and when HIGH is applied to analog switch AS2, CCD VSC is selected for use in focus detection. In this way, a CCD which is charged to a predetermined level first is selected to be used in focus detection.

An output of OR gate OR23 is also connected to a one-shot circuit OS12 which produces a HIGH pulse when OR gate OR23 produces HIGH. The HIGH pulse from one-shot circuit OS12 is transmitted through OR gate OR24 to a reset terminal of data flip-flops DF20 and DF21. Accordingly, if LED has been emitting infrared light, the light emission stops when data flip-flops DF20 and DF21 resets.

A counter CO11 is reset by a reset pulse ϕR from controller COT, and counts a predetermined period of time, such as 80 msec., by the count of clock pulses ϕ1 and produces a pulse from its carry terminal when counting has completed. If both comparators AC13 and AC14 are producing LOW at a moment when a pulse is produced from the counter CO11, the pulse from the counter CO11 is applied through OR gate OR22 and AND gate AN23 to set terminal of flip-flop FF10. Thus, flip-flop FF10 produces HIGH from its Q output, thereby actuating the controller COT to produce a transmission pulse ϕT and, at the same time, selecting CCD IRC provided in the infrared light photoelectric conversion device 9*b*. The above described operation is carried out when the object is relatively dark such that a CCD fails to charge up to a predetermined level within 80 msec. In this case, the charging is forcibly ended at the end of counting 80 msec. Furthermore, since LED IRL emits infrared light under this operation, it is more likely that CCD IRC for the infrared light produces a higher output level than that from CCD VSC for the visible light. Therefore, under this operation, it is so arranged that CCD IRC is selected.

Referring to FIG. 14, yet another embodiment of the present invention is shown. When compared with the first embodiment shown in FIGS. 8*a* and 8*b*, this embodiment has no photoelectric conversion elements IRD and VSD, and has only one CCD IRC, which is sensitive to infrared light. Furthermore, LED emits infrared light only when it is so determined that the data dF, calculated by the use of output from CCD IRC, is unreliable due to low contrast.

An operation of the auto-focusing system of FIG. 14 is described hereinbelow.

Referring also to FIG. 15 showing a flow chart of operation by the circuit of FIG. 14, the steps up to step #10 is the same as those shown in FIG. 12*a* and, therefore, data dF is calculated using output signal from

CCD IRC for the infrared light. Thus, the data dF is equal to amount and direction of defocus based on the infrared light. Then, at step #51, it is discriminated whether or not a data of contrast as obtained through a calculation carried out in step #10 is above a predetermined level. If the contrast data is below a predetermined level, the program advances to step #52 for producing a warning signal because the obtained data dF is unreliable. Then, at step #53, it is discriminated whether output 04 of microcomputer MCO is producing HIGH, or not. If output 04 is producing HIGH, it is understood that the data dF has been calculated with the aid of auxiliary infrared light. Therefore, in this case, there is no need to calculate the data dF again with the aid of auxiliary infrared light, because there will be hardly any difference in the newly calculated result. In this case, the program advances to step #12.

Contrary, if output 04 is not producing HIGH, HIGH is produced from output 04 and, thereafter, the program returns back to step #1 to repeat the light measurement by the CCD IRC under the auxiliary infrared light and the calculation of data dF.

While output 04 is producing HIGH to enable AND gate AN30 (FIG. 14), a reset pulse produced from output ϕR is applied to set terminal of flip-flop FF20. Thus, flip-flop FF20 produces HIGH from its Q output effecting an emission of infrared light. Thereafter, when a transmission pulse is produced from output ϕT, this pulse is applied through AND gate AN31 and OR gate OR30 to reset terminal of flip-flop FF20. Thus, flip-flop FF20 produces LOW from its Q output stopping the emission of infrared light.

Next, at step #12, amount and direction of rotation of motor MO is calculated using data dF, data S (or dL) and data K, as described earlier. Then, after carrying out steps #14–#16, which are the same as those shown in FIG. 12*a*, the program advances to step #55. A program including steps #55–#58 indicates the same operation of steps #17 and #18 shown in FIG. 12*a*, but in more details. At step #55, data |N| representing an amount of rotation of motor MO is stored in register M. At step #56, it is discriminated whether N is smaller than zero or not. If it is smaller than zero, motor MO is driven forward direction. If it is greater than zero, motor MO is driving backwardly. Thereafter, the program advances to step #19.

When the focus adjustment operation through steps #16, #35 and #37 completes, the program advances to step #59 at which it is discriminated whether switch RS is turned on or not. If switch RS is not turned on, it is further discriminated whether switch MS is turned off by the discrimination whether input i7 is receiving LOW. If input i7 is not receiving LOW, the above described operation is repeated, and when input i7 receives LOW, display device DP is disabled, and LOW is produced from each of outputs 01 and 04, thereby returning microcomputer MCO to HALT condition. Therefore, according to the flow chart shown in FIG. 15, when one cycle of focus adjustment operation completes, it is necessary to open the switch MS to start a new cycle of focus adjustment operation.

Furthermore, when it is discriminated that output i3 is producing HIGH as a result of closure of switch RS, output 04 produces LOW at step #63, and it is waited, after the completion of exposure control operation, until input i1 receives HIGH. When i1 receives HIGH, it is discriminated whether or not input i7 is receiving HIGH as a result of closure of switch MS. If input i7 is receiving HIGH, the program returns back to step #1, thereby repeating the focus adjustment operation. If input i7 is receiving LOW, the program advances to step #61 to end the operation.

It is to be noted that in FIG. 14, if switch RS closes to produce HIGH from AND gate AN0, a one-shot circuit OS20 produces a HIGH pulse which is applied through OR gate OR30 to a reset terminal of flip-flop FF20. Accordingly, a LOW is produced from Q output of flip-flop FF20 to stop the emission of infrared light.

Referring to FIG. 16, there is shown a flow chart which is a modification of the flow chart shown in FIG. 15. If it is discriminated at step #51 that the image lacks contrast, and when it is discriminated that data dF is calculated with an aid of auxiliary light at step #53, it is understood that the situation in this case is such that the object to be photographed is located very far from the camera. In this case, data Nm is set for the amount and direction of rotation of motor MO to shift the lens to the infinite focusing position. Thereafter, the program advances to step #14.

According to the modification of FIG. 14, only a CCD IRC, which is sensitive to infrared light, is necessary for the optical arrangement of focus detection. From this view point, the circuit of FIG. 1*a* can be simplified such that photoelectric conversion device 9*a* may be deleted, or beam splitter 7 can be replaced with a filter which cuts lights other than infrared light, and the transmitted infrared light is relayed through a suitable relay lens to CCD IRC.

According to the modification described above in connection with FIG. 14, infrared beam is emitted when an object has a low contrast, such as when aiming at a plain wall with a single color. In this case, the purpose for emitting infrared beam is to present a contrast around the spot receiving infrared beam. To this end, the spot on which the infrared beam impinges, or at least a border line of the lit spot should be included in an area for the focus detection. Therefore, the diameter of the infrared beam for the above described modification should be made smaller than that for the embodiments shown in FIGS. 8*a* and 8*b* and FIG. 13.

Referring to FIG. 17, a detailed flow chart of step #51 shown in FIGS. 15 and 16 for determining whether the contrast is low or not is shown. At step #80, a register C in microcomputer MCO is reset to "0", and at step #81, a register i is stored with "1". Then, at step #82, an absolute value of a difference between output ai from ith light receiving element and output ai+1 from (i+1)th light receiving element, which is substantially equal to the contrast difference between the two neighboring light receiving elements, is added with the content of register C and the sum is stored in the same register C. Thus, register C is now storing:

$$|ai-ai+1|.$$

At step #83, "1" is added to the content of register i, and at step #84, the content of the register i is compared with a number n (n is equal to the number of the total light receiving elements). If, the content of register i is smaller than n-1, the program returns back to step #82, thereby repeating the steps #82 and #82. Thus, the contrast differences between the two neighboring light receiving elements are added for n-1 times. When the content of the register i becomes equal to n-1, the program advances to step #85. At this step, the content of the register C is storing:

$$|a1-a2|+|a2-a3|+\ldots$$
$$+|an-2-an-1|+|an-1-an|,$$

which represents the contrast of the image.

At step #85, it is discriminated whether the content of the register C carrying a sum of the above formula is greater than a predetermined value CD or not. If the content of the register C is greater than the value CD, this means that the image has an enough contrast. In this case, the program advances to step #12. Contrary, if the content of the register C is not greater than the value CD, this means that the contrast is relatively low and, therefore, the program goes to step #52.

Referring to FIG. 18, an example of an optical arrangement for installing infrared LED IRL is shown. Submirror 6 has two reflection faces 6*a* and 6*b* which are slightly slanted with each other. Light ray L1 reflected from an object to be photographed and passing though the picture taking lens reflects on reflection face 6*a* and impinges on beam splitter 7. Infrared LED IRL is mounted on a base plate on which the beam splitter 7 is provided. Infrared light ray L2 emitted from LED IRL reflects on reflection face 6*b*, passes through main mirror 1 and picture taking lens, and directs to an object to be photographed.

It is to be noted that the light rays L1 and L2, when extended through submirror 6, intersect with each other at a point 10*a* on film surface 10. Accordingly, infrared LED IRL is installed as if light beam L2 is emitted from point 10*a*. Furthermore, emitted light beam L2 hits on a spot which is the same as the spot for the focus detection.

It is also to be noted that, from a practical point of view, reflection faces 6*a* and 6*b* may not be so precisely arranged as to intersect light rays L1 and L2 exactly on the point 10*a*, but should be so arranged as if light ray L2 emits not from the point 10*a* but from a point within a spot for the focus detection.

Furthermore, according to the arrangement shown in FIG. 18, a plate 20 is provided for holding beam splitter 7 and for intercepting infrared light beam from LED IRL, thereby preventing the infrared light from LED IRL from being directly impinged on the photoelectric conversion devices 9*a* and 9*b*. Reference numerals 21, 22 and 23 designate a gear arrangement for reducing the speed and transmitting the driving force of motor MO, and 24 is an actuator integrally provided to gear 23. When an interchangeable lens is mounted on a camera, actuator 24 engages a shaft 34 (FIG. 19). Thus, when actuator 24 rotates shaft 34, the focusing position of the lens is changed, thereby carrying out the focus adjustment. Furthermore, 25 designates a rotating plate defining encoder EN, and 26 designates a separation plate for separating the camera into a dark space and a lower space for intalling gears and motor MO. Separation plate 26 has an opening for the path of light beam from LED IRL and light beam into the beam splitter.

Moreover, according to the arrangement shown in FIG. 18, relay lens 8*a* and 8*b* are both integrally formed by a transparent plastic and are held by plate 20 together with beam splitter 7.

Referring to FIGS. 19 and 20, another example of an optical arrangement for installing infrared LED IRL is shown. Instead of the camera body, LED IRL is provided in a filter F, which can be detachably mounted on an interchangeable lens at its end remote from the camera-body receiving end. Filter F comprises a frame 30 having a threaded cylinder portion for engagement with the lens and a pair of filter plates 31 and 32 which are mold-formed by acrylic resin and each having a configuration of a half-circle. Filter plates 31 and 32 have, respectively, recessed face 31*a* and projecting face 32*a* which are slanted 45° to the flat face of the filter plates. Filter plates 31 and 32 are accommodated in frame 30 with faces 31*a* and 32*a* parallelly facing each other with a small air gap therebetween. Filter plate 31 has a lens 31*b* formed thereon on opposite side of recessed face 31*a*. Filter F also has an aperture plate 33 and infrared LED IRL. The infrared beam emitted from the LED IRL passes through aperture plate 33, serving as F-stop, and lens 31*b* reflects totally at face 31*a*, thereby emitting infrared beam from the center of the filter F and in alignment with the axis of the lens.

According to the arrangement shown in FIGS. 19 and 20, since there is no or very little angular difference between the projecting beam from the camera to the object and reflected beam from the object to the camera, there will be no parallax observed between the projecting and receiving beams. Furthermore, since the recess 31*a*, as well as the projection 32*a*, can be formed very small, it has little or no affect on the focus detection or on the exposure operation.

Referring now to FIG. 21, an auto-focusing system according a further embodiment of the present invention is shown. The auto-focusing, according to the auto-focusing system of FIG. 21 is done by the contrast detection, and this method is disclosed, e.g., in U.S. Pat. No. 4,341,953 patented Jul. 27, 1983 to Sakai et al, in Japanese Patent Laid-open Publication (Tokkaisho) No. 57-72110 or in Tokkaisho No. 57-88418. A focus detection calculation circuit 13' shown in FIG. 21 is provided to produce only the direction of defocus. When an image is blur because of front-focus, a terminal Ta produces HIGH, and when it is so because of rear-focus, a terminal Tc produces HIGH. And, when an image is properly focused, a terminal Tb produces HIGH. Based on these HIGH signals, a display DP' viewable through the viewfinder indicates a focused condition whether it is in front-focus, rear-focus or infocus condition. Terminals Ta and Tc are also connected to AND gates AN40 and AN41, respectively, and terminal Tb is connected to an inverting input of both AND gates AN40 and AN41. Motor drive circuit MDR is connected to an output of AND gate AN40 and also to an output of AND gate AN41 through OR gate OR40. When AND gate 40 produces HIGH from its output, motor drive circuit MDR is so actuated as to drive the motor MO in, e.g., forward direction, thereby shifting the lens to infinite focus position. Contrary, when OR gate OR40 produces HIGH from its output, motor drive circuit MDR is so actuated as to drive the motor MO in, e.g., reverse direction, thereby shifting the lens to near focus position. Furthermore, when AND gate AN40 or OR gate OR40 stops producing HIGH to supply LOW from both AND gate AN40 and OR gate OR40, motor drive circuit MDR immediately stops the motor MO, thereby stopping the lens shift.

A one-shot circuit OS40 produces a HIGH pulse in response to HIGH from terminal Tb, thereby setting flip-flop FF40. Thus, flip-flop FF40 produces HIGH from its Q output. Furthermore, the HIGH pulse from one-shot circuit OS40 is applied to counter CO40, thereby resetting the counter CO40, which is provided for counting the number of pulses from encoder EN, to zero. A digital comparator DC compared the output of

counter CO40 with data S (or dL) stored in a data reading circuit DR as obtained from data output circuit LDO provided in an interchangeable lens. When two signals match with each other, comparator DC produces LOW which is applied to AND gate AN42. An output of AND gate AN42 is connected to OR gate OR 40. Furthermore, the output of comparator DC is connected to one-shot OS41. Thus, in response to the change of output from comparator DC from HIGH to LOW, one-shot circuit OS41 produces HIGH to reset flip-flop FF40.

The auto-focusing system according to the embodiment shown in FIG. 21 operates as follows. When focus detection is started by infrared light, and when circuit 13' produces HIGH from its output terminal Ta, AND gate AN40 produces HIGH, thereby turning the motor MO forwardly to effect the lens shift toward infinite focus position. Then, when the lens is shifted to a position at which the image formed by infrared light properly focuses on a predetermined image forming plane, terminal Ta produces LOW and, at the same time, terminal Tb produces HIGH. Thus, one-shot circuit OS40 produces a HIGH pulse, thereby setting flip-flop FF40. Thus, flip-flop FF40 produces HIGH from its output Q. Thus, the motor MO is turned in the reverse direction to effect the lens shift toward near-focus position. This lens shift is detected by encoder EN and counter CO40 and, when the lens shift is effected for a required amount determined by the data S (or dL) stored in data reading circuit DR, comparator DC produces LOW, thereby producing LOW from AND gate AN42 and OR gate OR40. Since, at this moment, AND gate AN41 is producing LOW, motor drive circuit MDR receives LOW from OR gate OR40, thereby immediately stopping the motor MO.

It is to be noted that when comparator DC changes its output from HIGH to LOW, one-shot circuit OS41 produces HIGH, thereby resetting flip-flop FF40. Thus, flip-flop FF40 produces LOW from its Q output, thereby disabling AND gate AN42.

In contradistinction to the above, when focus detection is started by infrared light, and when circuit 13' produces HIGH from its output terminal Tc, both AND gate AN41 and OR gate OR40 produce HIGH, thereby turning the motor MO reversely to effect the lens shift toward near focus position. Then, when the lens is shifted to a position at which the image formed by infrared light properly focuses on the predetermined image forming plane, terminal Tc produces LOW and, at the same time, terminal Tb produces HIGH. Accordingly, AND gate AN41 produces LOW, but AND gate AN42 produces HIGH, because flip-flop FF40 produces HIGH from its Q output due to the HIGH pulse produced from one-shot circuit OS40. Thus, OR gate OR40 continues to produce HIGH. Accordingly, motor drive circuit MDR continues to drive the motor MO in the reverse direction. Thus, the lens shifts past the position for properly focusing an image by infrared light. The amount of lens shift past said position is detected by encoder EN and counter CO40 and, when the lens is shifted for a required amount determined by the data S (or dL) stored in data reading circuit DR, comparator DC produces LOW, thereby immediately stopping the lens in the same manner described above.

By the above described operation, the picture taking lens is shifted to a position at which the image formed by visible light focuses properly on the predetermined image forming plane, thereby completing the correction of the deflection dL.

In contrast to the embodiments described above in connection with FIGS. 8*a*, 8*b*, 13 and 14 offering a one-step control system, the lens, according to the embodiment described above in connection with FIG. 21, is controlled in two steps. First, the lens is shifted to a quasi-infocus position based on the focus detection carried out by the infrared light. Secondly, by the use of a signal representing the data S (or dL) as obtained from data output circuit IDO provided in the mounted interchangeable lens, the lens is further shifted to a true-infocus position for the visible light. This two-step control system can be applied to the previous embodiments of FIGS. 8*a*, 8*b*, 13 and 14, as described below.

In the embodiments described above in connection with FIGS. 8*a*, 8*b*, 13 and 14, focus detection is carried out by a so-called phase difference detecting system. When the two-step control system is employed, the lens is first shifted to a quasi-infocus position based on the defocus signal dF as obtained from focus detection calculation circuit 13 and, thereafter, the lens is further shifted in accordance to the signal S (or dL) to the true-infocus position for the visible light. More specifically, the lens is first shifted until encoder EN produces $N1=K\cdot dF$ pulses. Thereafter, the lens is further shifted until encoder EN produces $N2=K\cdot dL$ pulses. Accordingly, in total, the lens is shifted by a distance $N=N1-N2=K(dF-S)$, which is substantially equal to the distance of lens shift carried out in one-step control system.

In any one of the above described embodiments, various changes and modifications can be adapted. For example, beam splitter 7 can be eliminated when the focus condition detection is carried out based on only infrares light. In this case, an infrared light pass filter should be provided between submirror 6 and photoelectric conversion device 9*b* for transmitting only the infrared light to device 9*b*. When this arrangement is employed, it is not necessary to take the optical length d/n for the infrared light between first and second reflecting faces 7*a* and 7*b* into consideration. Therefore, data output circuit 16 needs to produce only the deflection signal dL.

Although the present invention has been fully described with reference to several preferred embodiments, many modifications and variations thereof will now be apparent to those skilled in the art, and the scope of the present invention is therefore to be limited not by the details of the preferred embodiments described above, but only by the terms of appended claims.

What is claimed is:

1. In an automatic focusing system for a camera with an interchangeable objective lens and a camera body for mounting the interchangeable lens, the improvement, comprising:

means for receiving light from the object through the objective lens to produce a signal representative of the received light;

means for processing the signal from said light receiving means to produce defocus data representative of the amount and direction of defocus of an image formed by the objective lens with respect to a predetermined focal plane;

means for providing first data and second data different from said first data, both said first and second

data being intrinsic to the interchangeable objective lens actually mounted on the camera body;

first means for determining the amount of focusing movement necessary for the objective lens to focus the object in accordance with said amount of defocus in accordance with said first and said second data;

second means for determining the direction of focusing movement necessary for the objective lens to focus the object in accordance with said direction of defocus; and

means for carrying out the focusing movement of the objective lens with the amount and direction thereof determined by said first and said second determining means.

2. The improvement according to claim 1, wherein said first data represents converting information necessary for converting said amount of defocus into said amount of focusing movement.

3. The improvement according to claim 2, wherein said providing means alters the contents of said first data in accordance with the change in the photographing distance of the interchangeable lens.

4. The improvement according to claim 1, wherein said providing means alters the contents of said first data in accordance with the change in focal length of the interchangeable objective lens.

5. The improvement according to claim 2, wherein said second data represents correcting information for correcting the influence of the aberration of the objective lens on said amount of focusing movement.

6. The improvement according to claim 1, wherein said second data represents correcting information for correcting the influence of the aberration of the objective lens on said amount of focusing movement.

7. The improvement according to claim 1, wherein said providing means further provides third data different from said first and second data, said third data being intrinsic to the interchangeable objective lens actually mounted on the camera body, and wherein said second determining means determines the direction of focusing movement in accordance with said direction of defocus and said third data.

8. The improvement according to claim 7, wherein said third data represents information to determine whether or not to reverse the relationship between said direction of focusing movement and said direction of defocus.

9. The improvement according to claim 1, wherein said providing means is located within the interchangeable objective lens, and said first data and said second data are sequentially transmitted to the camera body in which said receiving means, said processing means and said first and second determining means are located.

10. In an automatic focusing system for a camera with an interchangeable objective lens and a camera body for mounting the interchangeable lens, the improvement, comprising:

means for receiving light from the object through the objective lens to produce a signal representative of the received light;

means for processing the signal from said light receiving means to produce defocus data representative of the amount and direction of defocus of an image formed by the objective lens with respect to a predetermined focal plane;

means for providing data representative of converting information for converting said amount of defocus into the amount of focusing movement necessary for the objective lens to focus the object, the data being intrinsic to the interchangeable objective lens actually mounted on the camera body, wherein said providing means includes means for altering the contents of said data in accordance with the change in photographing distance of the interchangeable objective lens;

first means for determining said amount of focusing movement necessary for the objective lens to focus the object in accordance with said amount of defocus and said data from said providing means;

second means for determining the direction of focusing movement necessary for the objective lens to focus the object in accordance with said direction of defocus; and

means for carrying out the focusing movement of the objective lens with the amount and direction determined by said first and second determining means.

11. The improvement according to claim 10, wherein said providing means is located within the interchangeable objective lens, and data is transmitted to the camera body in which said receiving means, said processing means and said first and second determining means are located.

12. In an automatic focusing system for a camera including an interchangeable objective lens to be mounted on a camera body having means for receiving light from the object through the objective lens to produce a signal representative of the received light, means for processing the signal to produce defocus data representative of the amount and direction of defocus of an image formed by the objective lens with respect to a predetermined focal plane, and means for determining the amount and direction of focusing movement necessary for the objective lens to focus the object in accordance with the amount and direction of defocus and data intrinsic to the interchangeable objective lens actually mounted on the camera body, said interchangeable objective lens comprising:

means for providing data intrinsic to the interchangeable objective lens, said data including data representative of converting information for converting said amount of defocus into the amount of defocusing movement necessary for the objective lens to focus the object, wherein said providing means includes means for altering the contents of said data in accordance with the change in photographing distance of the interchangeable objective lens; and

means for transmitting the data to the camera body.

13. The interchangeable objective lens according to claim 12, further comprising means for generating information of photographing distance, wherein said altering means is responsive to said generating means.

14. The interchangeable objective lens according to claim 12, further comprising means for generating information representative of the current focusing position of the objective interchangeable lens, wherein said altering means is responsive to said generating means.

15. In an automatic focusing system for a camera including an interchangeable objective lens to be mounted on a camera body having means for receiving light from the object through the objective lens to produce a signal representative of the received light, means for processing the signal to produce defocus data representative of the amount and direction of defocus of an image formed by the objective lens with respect to a predetermined focal plane, and means for determining

the amount and direction of focusing movement necessary for the objective lens to focus the object in accordance with the amount and direction of defocus and data intrinsic to the interchangeable objective lens actually mounted on the camera body, said interchangeable objective lens comprising:

means for providing data intrinsic to the interchangeable objective lens, said data including first data and second data different from said first data, both of said first and second data being utilized for determining the amount of focusing movement necessary for the objective lens to focus the object; and

means for sequentially transmitting said first and second data to the camera body.

16. The interchangeable objective lens according to claim **15**, wherein said first data represents converting information necessary for converting said amount of defocus into said amount of focusing movement.

17. The interchangeable objective lens according to claim **16**, wherein said second data represents correcting information for correcting the influence of the aberration of the objective lens on said amount of focusing movement.

18. The interchangeable objective lens according to claim **15**, wherein said second data represents correcting information for correcting the influence of the aberration of the objective lens on said amount of focusing movement.

19. In an automatic focusing system for a camera with an interchangeable objective lens having means for providing data intrinsic to the objective lens and a camera body for mounting the interchangeable lens, the camera body comprising:

means for receiving light from the object through the objective lens to produce a signal representative of the received light;

means for processing the signal from said light receiving means to produce defocus data representative of the amount and direction of defocus of an image formed by the objective lens with respect to a predetermined focal plane;

means for sequentially receiving, from the interchangeable objective lens, data intrinsic to the objective lens, the data including first data and second data different from said first data;

first means for determining the amount of focusing movement necessary for the objective lens to focus the object in accordance with said amount of defocus in accordance with said first and said second data;

second means for determining the direction of focusing movement necessary for the objective lens to focus the object in accordance with said direction of defocus.

20. The camera body according to claim **19**, wherein said first data represents converting information necessary for converting said amount of defocus into said amount of focusing movement.

21. The camera body according to claim **20**, wherein said second data represents correcting information for correcting the influence of the aberration of the objective lens on said amount of focus movement.

22. The camera body according to claim **19**, wherein said second data represents correcting information for correcting the influence of the aberration of the objective lens on said amount of focusing movement.

23. An interchangeable zoom lens including an optical system adjustable for both focusing and zooming, and adapted to be detachably mounted on a camera body which is provided with focus detection means for detecting an amount of defocus of an object image formed by said optical system, and means for determining the focus adjustment of said optical system in accordance with the detected amount of defocus, said interchangeable zoom lens comprising:

a code plate for producing a plurality of digital focal length signals representing given discrete focal lengths of said optical system in accordance with the zooming adjustment of said optical system;

circuit means for outputting a predetermined one of a plurality of outputs in response to a predetermined one of a plurality of inputs, said plurality of outputs including a plurality of conversion coefficients needed for converting the detected amount of defocus into the amount of focus adjustment determined by said determining means, said conversion coefficients being intrinsic to said interchangeable lens and having values depending upon the given discrete focal lengths of said optical system represented by said digital focal length signals, respectively;

means for applying one of said digital focal length signals, being produced, to said circuit means as said predetermined input to cause said circuit means to output one of said conversion coefficients as said predetermined output, the value of which depends upon the focal length of said optical system represented by said one digital focal length signal being produced; and

transmission means for transmitting the output conversion coefficient to said camera body.

24. An interchangeable zoom lens including an optical system adjustable for focusing and adapted to be detachably mounted on a camera body which is provided with focus detection means for detecting an amount of defocus of an object image formed by said optical system, and means for determining the focus adjustment of said optical system in accordance with the detected amount of defocus, said interchangeable zoom lens comprising:

a code plate for producing a plurality of digital photographic distance signals representing given discrete photographic distances of said optical system in accordance with the adjustment of said optical system for focusing;

circuit means for storing a predetermined one of a plurality of outputs in response to a predetermined one of a plurality of inputs, said plurality of outputs including a plurality of conversion coefficients needed for converting the detected amount of defocus into the amount of focus adjustment determined by said determining means, said conversion coefficients being intrinsic to said interchangeable lens and having values depending upon the discrete photographic distances of said optical system represented by said digital photographic distance signals, respectively;

means for applying one of said digital photographic distance signals, being produced, to said circuit means as said predetermined input to cause said circuit means to output one of said conversion coefficients as said predetermined output, the value of which depends upon the photographic distance of said optical system represented by said one digital photographic distance signal being produced; and

transmission means for transmitting the output conversion coefficient to said camera body.

25. An interchangeable zoom lens including an optical system adjustable for both focusing and zooming, and adapted to be detachable mounted on a camera body which is provided with focus detection means for detecting an amount of defocus of an object image formed by said optical system, and means for determining the focus adjustment of said optical system in accordance with the detected amount of defocus, said interchangeable zoom lens comprising:

a first code plate for producing a plurality of digital focal length signals representing given discrete focal lengths of said optical system in accordance with the zooming adjustment of said optical system;

a second code plate for producing a plurality of digital photographic distance signals representing given discrete photographic distances of said optical system in accordance with the focus adjustment of said optical system;

circuit means for outputting a predetermined one of a plurality of outputs in response to a predetermined one of a plurality of inputs, said plurality of outputs including a plurality of conversion coefficients needed for converting the detected amount of defocus into the amount of focus adjustment determined by said determining means, said conversion coefficients being intrinsic to said interchangeable lens and having values depending upon the given discrete focal lengths of said optical system represented by said digital focal length signals and also upon said given photographic distances of said optical system represented by said digital photographic distance signals, respectively;

means for applying a combination of one of said digital focal length signals, being produced, to said circuit means as said predetermined input to cause said circuit means to output one of said conversion coefficients as said predetermined output, the value of which depends upon the focal length and the photographic distance of said optical system represented by said one digital focal length signal and said one digital photographic distance signal being produced; and

transmission means for transmitting the output conversion coefficient to said camera body.

WIDE ANGLE OBJECTIVE LENS

BACKGROUND OF THE INVENTION

1.Field of the Invention

This invention relates to a wide angle objective lens, and particularly to a wide angle objective lens suitable for use with a 35 mm format lens shutter camera, a 35 mm format camera with a range finder or the like.

2. Related Background Art

An optical system of four-unit construction of the so-called telephoto type in which a posterior unit having negative refractive power is disposed rearwardly of an anterior unit of positive-negative-positive lens unit construction having positive refractive power to shorten the full length of a standard lens for a compact camera to the focal plane thereof is known as is disclosed, for example, in Japanese Patent Publication No. 44-10831.

As a wide angle objective lens of such telephoto type and having an angle of view wider than that of a standard lens, there are known an example in which as disclosed in U.S. Pat. No. 4,394,073, an anterior unit disposed forwardly of a negative posterior unit is made into a four-unit construction of positive-negative-positive-positive to thereby improve coma and the eclipse of the marginal light flux, an example in which as disclosed in U.S. Pat. No. 4,235,521, a negative posterior unit is comprised of two negative and positive meniscus lenses to thereby achieve an angle of view of 60° or greater and brightness of F-number 2.8, an example in which as disclosed in Japanese Laid-Open Patent Application No. 1-209413, a negative lens component in an anterior unit is a cemented lens comprising a negative biconcave lens and a positive meniscus lens, etc..

In these optical systems of the telephoto type, however, in order to achieve the compactness thereof, the refractive powers of the anterior unit having positive refractive power and the posterior unit having negative refractive power have been made great and moreover, the air gap between the anterior unit and the posterior unit has been made great. Therefore, the marginal light flux has been eclipsed, and this has led to the disadvantages that not only the quantity of marginal light becomes deficient, but also distortion shifts greatly to the positive and chromatic difference of magnification also is greatly fluctuated by the angle of view. Further, the refractive power of each lens component is great, and this has led to the disadvantage that curvature of image field increases.

Also, in the aforementioned U.S. Pat. No. 4,235,521, a positive lens is disposed most adjacent to the image side and this has led to the disadvantage that the effecitve diameter of this positive lens most adjacent to the image side becomes great and further, from the mutual ecccentricity or inclination or the like of the negative lens and the positive lens in the posterior unit, it has been difficult to provide a predetermined optical performance in manufacture. Also in the wide angle lens described in the aforementioned U.S. Pat. No. 4,394,073, from the mutual eccentricity or inclination or the like of a negative second lens component and a positive third lens component, it has been difficult to obtain a predetermined optical performance in manufacture.

Further, in the wide angle lens described in the aforementioned Japanese Laid-Open Patent Application No. 1-209413, the cemented surface in a negative second lens component has negative refractive power and therefore, positive spherical aberration of high order has occurred and the correction of spherical aberration could not be sufficiently accomplished.

SUMMARY OF THE INVENTION

Accordingly, it is an object of the present invention to solve the above-noted problems peculiar to the wide angle lenses according to the prior art and to provide a compact wide angle objective lens of high performance in which the fluctuation of aberrations when focusing is effected is suppressed and an improvement in the performance in a short distance in-focus state is achieved and also the deterioration of the performance by the eccentricity of each lens unit is little.

To achieve the above object, the wide angle objective lens according to the present invention includes, in succession from the object side, a positive first lens component comprising a positive meniscus lens having its convex surface facing the object side, a positive second lens component comprising a cemented meniscus lens comprising a negative lens and a positive lens cemented together and having its concave surface facing the object side, a positive third lens component comprising a cemented meniscus lens comprising a negative lens and a positive lens cemented together and having its concave surface facing the object side, and a negative fourth lens component comprising a negative meniscus lens having its concave surface facing the object side, and is constructed into a refractive power arrangement of the telephoto type as a whole. It also has a stop between the second lens component and the third lens component.

As described above, in the present invention, the three lens components in the anterior unit are comprised of only lens units having positive refractive power and therefore, if the combined refractive power of this anterior unit is the same, the refractive power of each lens component can be made smaller than in the prior-art wide angle lenses of positive-negative-positive lens unit construction and accordingly, it is possible to suppess the deterioration of the performance caused by the eccentricity of each lens component. Also, the refractive index of the positive lens in the second lens component is made higher than that of the negative lens in the same lens component to thereby suppress astigmatism and curvature of image field and further, the cemented surface thereof is endowed with positive refractive power to thereby correct spherical aberration better. Also, in order to well suppress negative astigmatism occurring when short distance focusing is effected, that surface of the second lens component which is most adjacent to the image side is designed to have its convex surface fact the image side.

Further, when the refractive index of the negative lens in the second lens component for d-line ($\lambda=597.6$ nm) is n_{21} and the refractive index of the positive lens in the same lens component for d-line ($\lambda=597.6$ nm) is n_{22} and the radius of curvature of that surface of the second lens component which is most adjacent to the image side is r_{22} and the radius of curvature of the cemented surface in the second lens component is r_{2M} and the focal length of the third lens component is f_3 and the radius of curvature of that surface of the third lens component which is most adjacent to the object side is r_{31} and the mean value of the absolute values of the refractive powers of the first to fourth lens components

is ψ_{1-4} and the refractive power of the entire optical system is ψ and the refractive power ψ_{2M} of the cemented surface in the second lens component is expressed as $\psi_{2M}=(n_{22}-n_{21})/r_{2M}$, the first to fourth lens components may preferably be designed to satisfy the following conditions:

$$-0.9 \leqq \psi_{2M} \cdot r_{22} \leqq -0.1 : r_{22} < 0$$

$$-0.6 \leqq r_{31}/f_3 \leqq -0.1 : r_{31} < 0$$

$$\psi_{104}/\psi < 0.9$$

Other objects, features and effects of the present invention will become fully apparent from the following detailed description taken in conjunction with the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 shows the lens construction of first to fourth embodiments of the present invention.

FIG. 2 shows the lens construction of a fifth embodiment of the present invention.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

Some embodiments of the present invention will hereinafter be described in detail with reference to the accompanying drawings.

FIG. 1 shows the lens construction of first to fourth embodiments of the present invention, and FIG. 2 shows the lens construction of a fifth embodiment in which the spacing between a third lens component and a fourth lens component is very short.

Any of the wide angle lenses of the present invention, as shown in FIGS. 1 and 2, includes, in succession from the object side, a first lens component L1 which is a positive meniscus lens having its convex surface facing the object side, a second lens component L2 comprising a cemented meniscus lens comprising a negative lens L21 and a positive lens L22 cemented together and having its concave surface facing the object side, and having positive refractive power, a third lens component L3 comprising a cemented meniscus lens comprising a negative lens L31 and a positive lens L32 cemented together and having its concave surface facing the object side, and having positive refractive power, and a fourth lens component L4 which is a positive meniscus lens having its convex surface facing the object side, and further has a stop S between the second lens unit L2 and the third lens unit L3.

The wide angle lens of the present invention is of a construction of so-called telephoto type refractive power arrangement as a whole, from the fact that as described above, the first lens component L1, the second lens component L2 and the third lens component L3 each have positive refractive power and the fourth lens component L4 has negative refractive power.

The prior-art wide angle lens of the telephoto type has an anterior unit having positive refractive power and comprised of three positive, negative and positive lens components or four positive, negative, positive and positive lens components, and the refractive power of each lens component is very strong and therefore, due to the eccentricity, inclination or the like of the lenses, it has been difficult to provide a predetermined optical performance in manufacture. It has also suffered from the disadvantage that chromatic difference of magnification is greatly fluctuated by the angle of view.

So, according to the present invention, the anterior unit is comprised of only three lens components each having positive refractive power, and even if the combined refractive power of the anterior unit is the same as the combined refractive power of the anterior unit of the prior-art positive-negative-positive lens construction, the refractive power of each lens component can be made small and it is possible to suppress the deterioration of performance caused by the eccentricity of each unit.

Also, by the stop S being disposed between the positive second lens component L2 and the positive third lens component L3, it is made possible to increase the quantity of marginal light and make the refractive power distributions before and behind the stop substantially approximate to a symmetrical type, thereby correcting distortion better.

Also, that surface of the second lens component L2 which is most adjacent to the image side has its convex surface face the image side to well suppress negative astigmatism occurring when the short distance focusing by the totally axially moving system is effected.

In the lens system of the conventional telephoto type, the correction of spherical aberration has heretofore been effected chiefly by that surface of the negative second lens unit which is most adjacent to the object side, while in the present invention, the refractive index of the positive lens in the second lens component L2 is made higher than that of the negative lens in the same lens component to decrease Petzval sum and suppress astigmatism and curvature of image field and further, the cemented surface thereof is endowed with positive refractive power to thereby cause negative spherical aberration of high order to occur, and correct spherical aberration better.

Further, the third lens component L3 is designed such that the surface thereof which is most adjacent to the object side has its concave surface face the stop S, and this surface shares the correction of spherical aberration with the cemented surface in the second lens component L2. Also, since said surface which is most adjacent to the object side has its concave surface face the stop S, aberrations to off-axis rays are not liable to occur and it becomes possible to obtain a good image plane performance.

The fourth lens component L4 is a negative meniscus lens having its concave surface facing the stop S in order to correct curvature of image field and astigmatism sufficiently.

The wide angle lens of the present invention is constructed as described above, and it is desirable that the wide angle lens of the present invention be further designed to satisfy the following conditions:

$$-0.9 \leqq \psi_{2M} \cdot r_{22} \leqq -0.1 : r_{22} < 0 \quad (1)$$

$$-0.6 \leqq r_{31}/f_3 \leqq -0.1 : r_{31} < 0 \quad (2)$$

$$\psi_{104}/\psi < 0.9 \quad (3)$$

where

ψ_{2M}: the refractive power of the cemented surface in the second lens component L2 expressed by the following equation:

$$\psi_{2M}=(n_{22}-n_{21})/r_{2M}$$

r_{22}: the radius of curvature of that surface of the second lens component L2 which is most adjacent to the image side;

n_{21}: the refractive index of the negative lens L21 in the second lens component L2 for d-line (λ=587.6 nm);

n_{22}: the refractive index of the positive lens L22 in the second lens component L2 for d-line (λ=587.6 nm);

r_{2M}: the radius of curvature of the cemented surface in the second lens component L2;

r_{31}: the radius of curvature of that surface of the third lens component L3 which is most adjacent to the object side;

f_3: the focal length of the third lens component L3;

ψ_{1-4}: the mean value of the absolute values of the refractive powers of the first to fourth lens components L1 to L4;

ψ: the refractive power of the entire optical system.

Further, with regard to the third lens component L3 and the fourth lens component L4, it is desirable that the wide angle lens of the present invention be designed to satisfy the following conditions:

$$0<\psi_{3M}/\psi<0.5:\ r_{3M}>0 \quad (4)$$

$$0.2\leqq t_3/t_2\leqq 1.0, \quad (5)$$

where

ψ_{3M}: the refractive power of the cemented surface in the third lens component L3 expressed by the following equation:

$$\psi_{3M}=(n_{32}-n_{31})/r_{3M}$$

ψ: the refractive power of the entire optical system;

r_{3M}: the radius of curvature of the cemented surface in the third lens component L3;

n_{31}: the refractive index of the negative lens L31 in the third lens component L3 for d-line (λ=587.6 nm);

n_{32}: the refractive index of the positive lens L32 in the third lens component L3 for d-line (λ=587.6 nm);

t_2: the air gap on the optical axis from that surface of the second lens component L2 which is most adjacent to the image side to that surface of the third lens component L3 which is most adjacent to the object side;

t_3: the air gap on the optical axis from that surface of the third lens component L3 which is most adjacent to the image side to that surface of the fourth lens component L4 which is most adjacent to the object side.

Furthermore, when the mean value of the refractive indices of the positive lenses L1, L22 and L32 in the entire optical system for d-line (587.6 nm) is Np and the mean value of the refractive indices of the negative lenses L21, L31 and L4 for d-line (λ=587.6 nm) is Nn, it is desirable that the wide angle lens of the present invention be designed to satisfy the following conditions:

$$Np>1.70 \quad (6)$$

$$Nn>1.70 \quad (7)$$

The above-mentioned conditional expressions in the present invention will hereinafter be described in detail.

Conditional expression (1) is a condition for contriving the balance with spherical aberration and curvature of image field and further, the amount of fluctuation of astigmatism during the short distance focusing by the totally axially moving system.

When the lower limit of conditional expression (1) is exceeded, the following cases ① and ② are conceivable:

① A case where the refractive power ψ_{2M} of the cemented surface in the second lens component L2 is great; and

② A case where the radius of curvature r_{22} of that surface of the second lens component L2 which is most adjacent to the image side is negative and great.

In case ①, curvature of image field decreases, but positive distortion increases and negative spherical aberration become uncorrectable. In case ②, astigmatic difference becomes small and spherical aberration can be corrected well, but curvature of image field increases. Also, during short distance focusing, negative astigmatism occurs greatly, and this is not preferable.

When the upper limit of conditional expression (1) is exceeded, the following cases ③ and ④ are conceivable:

③ A case where the refractive power ψ_{2M} of the cemented surface in the second lens component L2 is small; and

④ A case where the radius of curvature r_{22} of that surface of the second lens component L2 which is most adjacent to the image side is negative and small.

In case ③, spherical aberration can be corrected well, but curvatrue of image field increases, and this is not preferable. In case ④, curvatrue of image field decreases and negative astigmatism occurring during short distance focusing can be suppressed to a small level, but astigmatic difference becomes great and negative spherical aberration become uncorrectable.

Conditional expression (2) is a condition for contriving the balance between on-axis aberrations and off-axis aberrations.

When the lower limit of conditional expression (2) is exceeded, the following cases ⑤ and ⑥ are conceivable:

⑤ A case where the radius of curvature r_{31} of that surface of the third lens component L3 which is most adjacent to the object side is negative and great; and

⑥ A case where the focal length f_2 of the second lens component L2 is small.

In case ⑤, curvature of image field decreases and astigmatic difference also becomes small, but positive distortion increases and spherical aberration becomes uncorrectable. In case ⑥, spherical aberration can be corrected well, but Petzval sum increases greatly to the positive and curvature of image field increases and thus, a good image plane performance becomes unobtainable.

When the upper limit of conditional expression (2) is exceeded, the following cases ⑦ and ⑧ are conceivable:

⑦ A case where the radius of curvature r_{31} of that surface of the third lens component L3 which is most adjacent to the object side is small; and

⑧ A case where the focal length f_2 of the second lens component L2 is great.

In case ⑦, spherical aberration can be corrected well, but curvature of image field increases and astigmatic difference becomes great. In case ⑧, curvature of

image field decreases and a good image plane performance is obtained, but spherical aberration becomes uncorrectable.

Conditional expression (3) is a condition for prescribing the deterioration of performance caused by the mutual eccentricity, inclination, etc. of the lens components.

If the upper limit of this conditional expression is exceeded, the refractive power of each lens component will become strong and therefore, the deterioration of performance by the mutual eccentricity of the lens components will become great, and this is not preferable. Also, curvature of image field will increase and the quantity of marginal light will be remarkably reduced, and this is not preferable.

Conditional expressions (4) and (5) will now be described in detail.

Conditional expression (4) is a condition for prescribing the refractive power of the cemented surface in the third lens component L3.

If the upper limit of conditional expression (4) is exceeded, negative spherical aberration of high order will occur and the correction of spherical aberration will become possible, but astigmatic difference will increase in a portion having a great angle of view and therefore, a good image plane performance will become unobtainable. If conversely, the lower limit of conditional expression (4) is exceeded, positive distortion will occur greatly and the correction of spherical aberration will be deficient.

Conditional expression (5) is a condition for contriving the balance between on-axis aberrations and off-axis aberrations.

When the lower limit of this conditional expression (5) is exceeded, the following cases (9) and (10) are conceivable:

(9) A case where t_3 is small; and

(10) A case where t_2 is great.

In case (9), the difference between the heights of the on-axis ray and the off-axis ray becomes small in the fourth lens component L4 and therefore, the degree of freedom of aberration correction is deficient and on-axis aberrations and off-axis aberrations cannot be corrected independently of each other. Also, to render the focal length of the optical system into a predetermined value, the refractive power of the fourth lens component L4 becomes great and therefore, curvature of image field increases, and this is not desirable. In case (10), on-axis aberrations and off-axis aberrations can be corrected independently of each other, but if an increase in the quantity of marginal light is contrived, the effective diameter of the lens will become large, and this is not preferable.

Also, when the upper limit of conditional expression (5) is exceeded, the following cases (11) and (12) are conceivable:

A case where t_3 is great; and

A case where t_2 is small.

In case (11), conversely to the aforedescribed case (9), on-axis aberrations and off-axis aberrations can be corrected independently of each other and a better image plane performance can be obtained. However, the effective diameter of the lens becomes large, and this is not preferable. In case (12), the difference between the heights of the on-axis ray and the off-axis ray becomes small in the lenses far from the stop S and therefore, the degree of freedom of aberration correction is deficient and on-axis aberrations and off-axis aberrations cannot be corrected independently of each other. It also becomes impossible to dispose the stop and a shutter mechanism, and this is not preferable.

Conditional expressions (6) and (7) are conditions regarding the distribution of the refractive index in the optical system.

If the lower limit of conditional expression (6) is exceeded or if the upper limit of conditional expression (7) is exceeded, Petzval sum will exhibit a great positive value and thus, curvature of image field and negative astigmatism will become uncorrectable, and this is not preferable.

The constructions of the embodiments of the present invention will now be described in greater detail.

In any of the first to fourth embodiments, as shown in FIG. 1, the first lens component L1 comprises a positive meniscus lens having its convex surface facing the object side, and the second lens component L2 is comprised of a positive cemented meniscus lens comprising a biconcave lens L21 and a biconvex lens L22 having a refractive index higher than that of the biconcave lens L21, the lenses L21 and L22 being cemented together, the positive cemented meniscus lens having its concave surface facing the object side. The third lens component L3, like the second lens component L2, comprises a positive cemented meniscus lens comprising a biconcave lens L31 and a bicovex lens L32 having a refractive index higher than that of the biconcave Lens L31, the lenses L31 and L32 being cemented together, the positive cemented meniscus lens having its concave surface facing the object side, and the fourth lens component L4 comprises a negative meniscus lens having its concave surface facing the object side, and the entire lens system is comprised of four units six lenses. The stop S is provided between the second lens component L2 and the third lens component L3.

The fifth embodiment assumes a construction substantially similar to the constructions of the first to fourth embodiments, with the exception that as shown in FIG. 2, the lens thickness of the biconvex lens L32 in the third lens component L3 is relatively great and the on-axis air gap between this biconvex lens L32 and the fourth lens component L4 is very short.

In any of the above-described embodiments, focusing is effected from infinity to a close distance by the totally axially moving system.

The numerical data of the respective embodiments of the present invention will be shown in Tables 1 to 5 below. In these tables, the numbers at the left end represent the order from the object side, r represents the radius of curvature of each lens surface, d represents the spacing between adjacent lens surfaces, and the refractive index n and Abbe number ν are values for d-line (λ=587.6 nm). FN represents F-number, and 2ω indicates the angle of view.

10	−58.521	69.40		

The condition-corresponding values of the fifth embodiment are as follows:

(1)	$\psi_{2M} \cdot r_{22}$	= −0.651
(2)	r_{31}/f_3	= −0.537
(3)	ψ_{1-4}/ψ	= 0.891
(4)	ψ_{3M}/ψ	= 0.214
(5)	t_3/t_2	= 0.325
(6)	Np	= 1.761
(7)	Nn	= 1.604

In any of the above-described embodiments of the present invention, various aberrations are corrected well and the fluctuations of the various aberrations are suppressed particularly from during infinity focusing to during short distance focusing, and there is maintained

a good optical performance even during short distance focusing.

By introducing an aspherical surface into the first lens component L1 or the fourth lens component L4 of the present invention, it is possible to correct astigmatism and curvature of image field better and achieve a wide angle. Also, it is a matter of course from the way of using popular aspherical lenses that by introducing an aspherical surface into the second lens component L2 or the third lens component L3, it is possible to correct spherical aberration better and achieve a great aperture.

According to the present invention, a wide angle lens which is as bright as the order of F2.8 and has little distortion can be realized by a relatively simple lens construction. The present invention can be used as a lens not only for 35 mm format cameras, but also for large format cameras.

What is claimed is:

1. A wide angle objective lens including in succession from the object side:

a first lens component comprising a positive meniscus lens having its convex surface facing the object side;

a second lens component comprising a cemented meniscus lens comprising a negative lens and a positive lens cemented together and having its concave surface facing the object side and having positive refractive power;

a third lens component comprising a cemented meniscus lens comprising a negative lens and a positive lens cemented together and having its concave surface facing the object side and having positive refractive power; and

a fourth lens component comprising a negative meniscus lens having its concave surface facing the object side; and

further having a stop between said second lens component and said third lens component;

said wide angle objective lens being designed to satisfy the following conditions when the refractive power ψ_{2M} of the cemented surface in said second lens component is expressed as $\psi_{2M}=(n_{22}-n_{21})/r_{2M}$ and the mean value of the absolute values of the refractive powers of said first to fourth lens components is ψ_{1-4} and the refractive power of the entire optical system is ψ:

$$-0.9 \leqq \psi_{2M} \cdot r_{22} \leqq -0.1;\ r_{22}<0$$

$$-0.6 \leqq r_{31} \cdot f_3 \leqq -0.1;\ r_{31}<0$$

$$\psi_{1-4}/\psi<0.9,$$

n_{21}: the refractive index of the negative lens in the second lens component for d-line ($\lambda=587.6$ nm);

n_{22}: the refractive index of the positive lens in the second lens component for d-line ($\lambda=587.6$ nm);

r_{2M}: the radius of curvature of the cemented surface in the second lens compartment;

r_{22}: the radius of curvature of that surface of the second lens component which is most adjacent to the image side;

r_{31}: the radius of curvature of that surface of the third lens component which is most adjacent to the object side;

f_3: the focal length of the third lens component.

2. A wide angle objective lens according to claim 1, wherein when the refractive power ψ_{3M} of the cemented surface in said third lens component is expressed as $\psi_{3M}=(n_{32}-n_{31})/r_{3M}$, said third lens component is designed to satisfy the following condition:

$$0<\psi_{3M}/\psi<0.5;\ r_{3M}>0,$$

where

n_{31}: the refractive index of the negative lens in the third lens component for d-line ($\lambda=587.6$ nm);

n_{32}: the refractive index of the positive lens in the third lens component for d-line ($\lambda=587.6$ nm);

r_{3M}: the radius of curvature of the cemented surface in the third lens component;

ψ: the refractive power of the entire optical system.

3. A wide angle objective lens according to claim 1, wherein when the air gap on the optical axis from that surface of said second lens component which is most adjacent to the image side to that surface of said third lens component which is most adjacent to the object side is t_2 and the air gap on the optical axis from that surface of said third lens component which is most adjacent to the image side to that surface of said fourth lens component which is most adjacent to the object side is t_3, said second to fourth lens components are disposed so as to satisfy the following condition:

$$0.2 \leqq t_3/t_2 \leqq 1.0$$

4. A wide angle objective lens according to claim 1, wherein when the mean value of the refractive indices of the positive meniscus lens in said first lens component, the positive lens in said second lens component and the positive lens in said third lens component for d-line ($\lambda=587.6$ nm) is Np and the mean value of the refractive indices of the negative lens in said second lens component, the negative lens in said third lens component and said third lens component for d-line ($\lambda=587.6$ nm) is Nn, said wide angle objective lens is designed to further satisfy the following conditions:

$$Np>1.70,\ Nn<1.70$$

5. A wide angle objective lens according to claim 1, deisgned in accordance with the following data:

f = 100.0
FN = 2.88
2ω = 63.6

	r	d	ν	n
1	39.671	9.14	41.0	1.80500

3	−130.700	2.86	27.8	1.69911
4	57.143	10.00	43.3	1.84042
5	−133.667	12.00		
6	−39.290	2.86	35.5	1.59507
7	114.917	10.14	44.7	1.80218
8	−42.384	8.57		
9	−25.630	4.57	64.1	1.51680
10	−39.674	57.48		

(1)	$\psi_{2M} \cdot r_{22}$	= −0.331
(2)	r_{31}/f_3	= −0.295
(3)	ψ_{1-4}/ψ	= 0.628
(4)	ψ_{3M}/ψ	= 0.180
(5)	t_3/t_2	= 0.714
(6)	Np	= 1.816
(7)	Nn	= 1.604

where the numbers at the left end represent the order from the object side, r represents the radius of curvature of each lens surface, d represents the spacing between

adjacent lens surfaces, the refractive index n and Abbe number ν indicate values for d-line (λ=587.6 nm), FN indicates F-number, and 2ω indicates the angle of view;

t_2: the air gap on the optical axis from that surface of the second lens component which is most adjacent to the image side to that surface of the third lens component which is most adjacent to the object side;

t_3: the air gap on the optical axis from that surface of the third lens component which is most adjacent to the image side to that surface of the fourth lens component which is most adjacent to the object side;

Np: the mean value of the refractive indices of the positive meniscus lens of the first lens component, the positive lens in the second lens component and the positive lens in the third lens component for d-line (λ=587.6 nm);

Nn: the mean value of the refractive indices of the negative lens in the second lens component, the negative lens in the third lens component and the third lens component for d-line (λ=587.6 nm);

ψ_{3M}: the refractive power of the cemented surface in the third lens component expressed by the following equation: $\psi_{3M}=(n_{32}-n_{31})/r_{3M}$ (n_{31}: the refractive index of the negative lens in the third lens component for d-line (λ=587.6 nm), n_{32}: the refractive index of the positive lens in the third lens component for d-line (λ=587.6 nm), r_{3M}: the radius of curvature of the cemented surface in the third lens component).

6. A wide angle objective lens according to claim 1, designed in accordance with the following data:

f = 100.0
FN = 2.88
2ω = 63.4

	r	d	ν	n
1	40.936	9.14	44.7	1.80218

where the numbers at the left end represent the order from the object side, r represents the radius of curvature of each lens surface, d represents the spacing between adjacent lens surfaces, the refractive index n and Abbe number ν indicate values for d-line ($\lambda=587.6$ nm), FN indicates F-number, and 2ω indicates the angle of view;

t_2: the air gap on the optical axis from that surface of the second lens component which is most adjacent to the image side to that surface of the third lens component which is most adjacent to the object side;

t_3: the air gap on the optical axis from that surface of the third lens component which is most adjacent to the image side to that surface of the fourth lens component which is most adjacent to the object side;

Np: the mean value of the refractive indices of the positive meniscus lens of the first lens component, the positive lens in the second lens component and the positive lens in the third lens component for d-line ($\lambda=587.6$ nm);

Nn: the mean value of the refractive indices of the negative lens in the second lens component, the negative lens in the third lens component and the third lens component for d-line ($\lambda=587.6$ nm);

ψ_{3M}: the refractive power of the cemented surface in the third lens component expressed by the following equation: $\psi_{3M}=(n_{32}-n_{31})/r_{3M}$ (n_{31}: the refractive index of the negative lens in the third lens component for d-line ($\lambda=587.6$ nm), n_{32}: the refractive index of the positive lens in the third lens component for d-line ($\lambda=587.6$ nm), r_{3M}: the radius of curvature of the cemented surface in the third lens component).

10. A wide angle objective lens including in succession from the object side:

a first lens component comprising a positive meniscus lens having its convex surface facing the object side;

a second lens component comprising a cemented meniscus lens comprising a negative biconcave lens and a positive biconvex lens cemented together and having its concave surface facing the object side and having positive refractive power;

a third lens component comprising a cemented meniscus lens comprising a negative biconcave lens and a positive biconvex lens cemented together and

having its concave surface facing the object side and having positive refractive power; and

a fourth lens component comprising a negative meniscus lens having its concave surface facing the object side; and

further having a stop between said second lens component and said third lens component.

11. A wide angle objective lens according to claim **10**, wherein when the refractive index of said biconcave lens in said second lens component for d-line ($\lambda=587.6$ nm) is n_{21} and the refractive index of said biconvex lens for d-line ($\lambda=587.6$ nm) is n_{22} and the radius of curvature of the cemented surface of said biconcave lens and said biconvex lens is r_{2M} and the radius of curvature of that surface of said second lens component which is most adjacent to the image side is r_{22} and the refractive power ψ_{2M} of the cemented surface of said biconcave lens and said biconvex lens is expressed as $\psi_{2M}=(n_{22}-n_{21})/r_{2M}$, said second lens component is designed to satisfy the following condition:

$$-0.9 \leqq \psi_{2M} \cdot r_{22} \leqq -0.1;\ r_{22}<0$$

12. A wide angle objective lens according to claim **10**, wherein when the radius of curvature of that surface of said third lens component which is most adjacent to the object side is r_{31} and the focal length of said third lens component is f_3 and the refractive index of said concave lens in said third lens component for d-line ($\lambda=587.6$ nm) is n_{31} and the refractive index of said biconvex lens for d-line ($\lambda=587.6$ nm) is n_{32} and the radius of curvature of the cemented surface of said biconcave lens and said biconvex lens is r_{3M} and the refractive power of the entire optical system is ψ and the refractive power ψ_{3M} of the cemented surface of said bocincave lens and said biconvex lens is expressed as $\psi_{3M}=(n_{32}-n_{31})/r_{3M}$, said third lens component is designed to satisfy the following conditions:

$$-0.6 \leqq r_{31} \cdot f_3 \leqq -0.1;\ r_{31}<0$$

$$0<\psi_{3M}/\psi<0.5;\ r_{3M}>0$$

13. A wide angle objective lens according to claim **10**, wherein when the mean value of the absolute values of the refractive powers of said first to fourth lens components is $\psi_{1\text{-}4}$ and the refractive power of the entire optical system is ψ, said lens components are designed to further satisfy the following condition:

$$\psi_{1\text{-}4}/\psi<0.9$$

14. A wide angle objective lens according to claim **10**, wherein when the air gap on the optical axis from that surface of said second lens component which is most adjacent to the image side to that surface of said third lens component which is most adjacent to the object side is t_2 and the air gap on the optical axis from that surface of said third lens component which is most adjacent to the image side to that surface of said fourth lens component which is most adjacent to the object side is t_3, said second to fourth lens components are designed to satisfy the following condition:

$$0.2 \leqq t_3/t_2 \leqq 1.0$$

15. A wide angle objective lens according to claim **10**, wherein when the mean value of the refractive indices of the positive meniscus lens in said first lens component, the positive biconvex lens in said second lens component and the positive biconvex lens in said third lens component for d-line ($\lambda=587.6$ nm) is Np and the mean value of the refractive indices of the negative biconcave lens in said second lens component, the negative biconcave lens in said third lens component and the negative meniscus lens of said fourth lens component for d-line ($\lambda=587.6$ nm) is Nn, said wide angle objective lens is designed to further satisfy the following conditions:

$$Np>1.70,\ Nn<1.70.$$

[57] **ABSTRACT**

A system for focusing a zoom lens objective of a color television camera. A luminance or green video signal derived from a portion of the picture is full-wave rectified and then averaged. The sharpest focus corresponds to the highest value of that average. The signal is converted to digital form and processed by a microcomputer for automatic focusing control by finding the signal maximum with shifting of the lens focus setting. The video signal is stripped of its d.c. component before rectification, but is used with its full bandwidth.

SYSTEM FOR FOCUSING A TELEVISION CAMERA OBJECTIVE LENS

This invention concerns the focusing of a television camera objective, which is typically a zoom lens equipped with lens shifting means for focus, by a system in which a focus signal derived from a video signal is generated by rectification or absolute value formation followed by averaging of a video signal relating to a region of a television picture. The focus signal so derived is digitalized and processed in a microcomputer programmed for shifting the lens, comparing focus status values and deriving control signals for optimizing the focus status.

Such an automatic focusing circuit for a television camera is disclosed in U.S. Pat. No. 4,638,364. In this case the luminance component of the video signal is passed through a high-pass filter for deriving the focus signal, so that only the high-frequeny components of the luminance signal contribute to the generation of the focus signal.

A similar provision for carrying out focus correction is known from the adjustment system of a television camera disclosed in European Patent 0 084 908 B1. Here also only the higher frequency components of the video signal are measured and are set at a maximum value for seeking the best focus.

If only the higher frequency components of this video signal are used for measuring the sharpness of the picture, however, the objective positioning may indeed lie close to the actual focus position, but this point of actual focus cannot be readily found by the automatic means described in the above references. There is a further disadvantage in those systems that the objective cannot be focused with reference to horizontal lines, because these vertical transitions have no high frequency components of the video signal in the neighborhood of the actually focussed condition.

SUMMARY OF THE INVENTION

It is an object of the present invention to provide automatic focusing of a television camera in which, for practically every possible setting, of, a zoom lens objective an optimal focusing can be obtained in the shortest time.

Briefly, the video signal from which the focus signal is derived is the d.c.-free luminance or green signal of the camera and it is utilized with full bandwidth. The system of the invention has the advantage that even video signals generated far from the actual focussed point can be used to derive information signals for automatic focussing of the objective. There is a further advantage that the objective can also be focussed with reference to horizontal lines, i.e. vertical transitions.

The portion of the picture in which the video signal used for focusing is derived can be made manually selectable and for this purpose the selection of the picture portion for generating the focus signal can utilize a gate that is open during the time the video signal relates to that picture portion.

The above-mentioned gate can be located in circuit just before or just after the rectifying circuit of the video signal processing.

BRIEF DESCRIPTION OF THE DRAWINGS

The invention is further described by way of illustrative example with reference to the annexed drawings, in which:

FIG. **1** is a circuit block diagram of a system of the invention;

FIG. **2A** is a somewhat more detailed circuit block diagram of the mid-portion of the diagram of FIG. **1**.

FIG. **2B** is a graphical representation of a signal at poing B of FIG. **2A**;

FIG. **2C** is a graphical representation of a signal at point C of FIG. **2A**;

FIG. **3A** is a time-amplitude diagram of output signals of the full wave rectifier of FIG. **2** before the focusing adjustment has been found;

FIG. **3B** is a time-amplitude diagram of the output signal of the full wave rectifier of FIG. **2** after the focus adjustment has been found;

FIG. **4** are two typical sharpness curves of a zoom lens television camera objective, with axial position of the objective as the horizontal variable; and

FIG. **5** is a diagram showing another embodiment of the invention differing from the embodiment of FIG. **1**.

DESCRIPTION OF THE ILLUSTRATED EMBODIMENT

In the circuit block diagram of FIG. **1** the luminance signal Y or the green signal G of a video signal is obtained from the television camera **1** having a zoom-lens **2**, and is supplied to a region selecting circuit **3** through a filter **12**, **13**, which converts the Y or G video signal into a d.c.-free video signal without appreciably limiting its bandwidth.

A so-called cursor pulse signal is supplied at the terminal **4** of the selection circuit **3**. The cursor pulse signal defines a manually selected portion of the picture in which the picture sharpness is to be measured. It operates a switch **14** as shown in FIG. **2A** for time-wise limiting of the signal passing through the switch so that only that part of the signal relating to the selected picture region will be passed on. The size and position of this picture region can be selected, for example, by the camera operator, by a manual control **17** and a time gate signal generator **18**. Manually controlled cursor signals for selecting picture areas are well known and do not need to be further described here.

The video signal of the selected picture portion is then supplied to a full wave rectifier circuit **6** at the output of which the rectified video signal is made available during the intervals in which the selected picture portion is being scanned by the camera. This signal is then supplied to a measurement circuit **7** in which the amplitude of the average value of the rectified video signal is produced and converted into a digital signal, for example a 12-bit signal.

The measurement result is then utilized to determine the picture sharpness for the focus adjustment. For that purpose the digital signal is supplied to a microcomputer **8**. The microcomputer **8** is programmed to provide a focus adjustment signal for the zoom lens **2** over the line or cable **9** for setting the optimal picture sharpness by control of the lens shifting device **10** with which the zoom lens **2** is equipped. The lens shifting device **10** is only symbolically shown in FIG. **1** because electronically controlled lens shifting devices for suitable for various kinds of automatic focus are well known. A common way of axially shifting an objective lens is by a

screw or micrometer drive. The connection **9** may include a conductor for reporting the position of the objective lens to the microcomputer **8**.

The processing of the digital measurement signal for generating the focus signal in the microcomputer **8** is of the kind disclosed in the above-mentioned European patent document Ep 0 084 908 B1 or of the kind disclosed in the article "The Computer as a Camera-Operation and Image-Quality Manager" by F. J. van Roessel and E. Tienkamp in SMPTE Journal, November, 1987, page 1079ff. These publications describe such programming in so great detail that it is not necessary to describe that subject matter further here.

In FIG. **2A** a portion of the system of FIG. **1** according to the invention is shown in somewhat more detail, and the same parts that appear in FIGS. **1** and **2A** are designated with the same reference numerals. In FIG. **2A** the video signal Y or G is present at the terminal **11** and is supplied through a resistance-capacitance network **12**, **13** to a switch **14**. The numeral **3** in FIG. **2A** identifies a switch **14** and the resistor **15** as the picture region selection circuit **3** of FIG. **1**. The capacitor **13** eliminates the d.c. component of the video signal The cursor pulse signal supplied to the switch **14** from the terminal **4** closes the switch **14**, when it has positive amplitude and thereby allows the further conduction of the video signal, now stripped of its d.c. component, past the circuit point B to the full wave rectifier **6**. In the absence of the positive cursor pulse the switch **14** is open and a d.c. voltage of 0 volt is present at the input of the full wave rectifier, as assured by the input resistance **15** connected to ground. The cursor pulse is symbolized by the wave shape **4A** below the terminal **4** in FIG. **2A**. It operates a switch **14** and thus defines a time-wise limiting of the Y or G video signal supplied to the circuit point B and shown in FIG. **2B**. By so doing it likewise provides a time-wise limiting of the signal produced by the full wave rectifier **6**, as shown in FIG. **2C** which is supplied to the averaging and digitizing unit **7**. FIG. **2B** shows a voltage-time graph of a typical signal at point B of FIG. **2A**. In FIG. **2B** a horizontal line during the open period of the switch **14** is labelled 0V to designate the 0 voltage level. The signal at C at the output of the full wave rectifier **6** can be used to highlight the selected picture portion on a local monitor or in the camera's electronic finder. This is indicated by the branching connection **16** in FIG. **2C**.

After full-wave rectification of this signal present at point B there is produced at the circuit point C at the output of the full wave rectifier **6** a video signal having the signal course illustrated in FIG. **2C**. The average value of this signal at circuit point C is a measure for the picture sharpness set by the position of the shifting device of the lens **2**. The video signal at point C, as mentioned above, is converted from analog to digital form for a very large dynamic range in the measurement circuit **7**. The resulting **12** bit measurement output signal is then supplied to the microcomputer **8** and there further processed. Details of this video signal processing can, as mentioned above, be found in the above-mentioned article by van Roessel and Tienkamp.

It will now be explained, by reference to FIGS. **3A** and **3B**, how the signal average value produced in the measurement circuit **7** before analog to digital conversion provides a measure for the picture sharpness. Both FIGS. **3A** and **3B** show the course of a full-wave rectified video signal at point C that is produced by scanning an alternating succession of black and white areas. The signal of FIG. **3A** has rounded edges and oblique flanks, because the lens was not focussed on the test pattern. In contrast thereto the signal of FIG. **3B** resulting from optimal focusing on the test picture has steep flanks and unrounded corners. It is thus easily visible that the average value of the signal of FIG. **3B** is greater than that of the signal of FIG. **3A**. The principle of this measurement system, however, is not limited to the use of any particular kind of test picture. It can also be used, advantageously, for focusing on a picture of normal picture content.

FIG. **4** shows two typical curves of the degree of sharpness as a function of the focus position of the objective lens. Curve A illustrates camera exposure to a scene with a telephoto setting (small picture angle) of a zoom lens and the curve B is generated with a wide angle setting of the zoom lens **2**. In both cases the focus point F of the zoom lens **2** is readily recognizable.

FIG. **5** is a diagram of a modification of FIG. **1** that has been mentioned already at the end of the Summary of the Invention. In FIG. **5** the gate **3** for time-wise allowing passage only of a video signal relating to the portion of the field of view that has been selected for focusing is located after the full wave rectifier **6** instead of before it, as shown in FIG. **1**. It still precedes the averaging means **7**.

The system of the invention can be used with particular advantage for high definition television (HDTV) cameras. With such cameras it is often difficult for the camera operator to focus a zoom lens objective optimally, because the picture reproduction on the picture screen of the electronic finder is not sharp enough. With use of the invention this disadvantage can be avoided if the rectified video signal at point C is supplied either to a monitor or to the electronic finder of the television camera **1** for manual focusing or, by pressing a button, supplied instead through the measurement circuit **7** to the microcomputer **8** for automatic focusing. Of course the system of the invention can also be used in conventional television cameras, whether in automatized studio operation or by retrofit into existing equipment to simplify the operation for the cameramen.

Although the invention has been described with reference to a particular illustrative example, it will be understood that variations and modifications are possible within the inventive concept.

I claim:

1. Apparatus for focusing a zoom-lens objective of a television camera having means for axially shifting said objective over a focusing position range, said shifting means having a control input for an electrical control signal, comprising:

electrical filter means, connected to a source of a luminance or green component of a video signal produced by said camera, for eliminating a d.c. component of said luminance or green component of said video signal and providing, at an output of said electrical filter means, the remainder of said luminance or green component of said video signal at its full bandwidth;

means, connected to said output of said d.c. component eliminating means, for full wave rectification of said full-bandwidth remainder of said luminance or green component of said video signal and for providing a rectified video signal at an output of aid rectification means;

means for averaging said rectified video signal component and means for converting successive aver-

age values thereof to digital signal values provided at an output of said averaging and converting means;

means for time-wise limiting the input to said means for averaging said rectified video signal to the rectification product of time-segments of said component remainder of said video signal which relate to a portion of a total field of view of said camera, said time-wise limiting means being interposed between said source of a luminance or green component of a video signal and said means for averaging said rectified video signal. and

signal processing means connected to said output of said averaging and converting means and to said control input of said zoom-lens objective sifting means for producing said electrical control signal in response to said digital signal values so as to position said shifting means at a position at which said digital signal values show a maximum for said focusing position range.

2. The apparatus of claim 1, wherein said means for time-wise limiting the input to said averaging and converting means includes means for manually selecting a portion of a total field of view of said camera.

3. The apparatus of claim 2, wherein sad means for selecting said portion of a total field of view of said camera comprises means for generating cursor pulses defining the time intervals during which said portion of a total field of view of said camera is being scanned by said camera and wherein said means (14) for time-wise limiting the input to said averaging means is responsive to said cursor pulses for allowing passage through said time-wise limiting means of a video signal relating only to said portion of a total field of view of said camera.

4. The apparatus of claim 3, wherein said time-wise limiting means is interposed between an output of said means for eliminating any d.c. component of said luminance or green component of said video signal and an input of said means for full-wave rectification of said component of said video signal.

5. The apparatus of claim 3, wherein said time-wise limiting means is interposed between said output of said rectification means and an input of said averaging and converting means.

[57] ABSTRACT

Eye alignment is determined by producing a combined iris/retinal image by use of an imaging system. The relative position of the centroid of the pupil and various structures on the retina is indicative of the eye alignment. The eye alignment may be determined by comparing a combined iris/retinal image at the present time with a stored iris/retinal image at a past time. The imaging system may be a laser scanning ophthalmoscope.

OBJECTIVE EYE ALIGNMENT MEASUREMENT METHOD AND SYSTEM

CROSS REFERENCE TO RELATED APPLICATION

This application relates to copending application Ser. No. 557,263, filed Jul. 24, 1990, assigned to the same assignee as the present invention.

BACKGROUND OF THE INVENTION

This invention relates to a system and method for aligning the eyes of a subject.

There are a number of situations where the alignment of a subject's eyes are important. The subject may be human or may be a research animal.

When taking certain types of eye measurements, one may need to know that the eye alignment is in a particular reference position. For example, if one measures the cornea of a person's eye before some type of treatment and one wishes to repeat those measurements after the treatment to determine how much, if any, the treatment has affected the measurements, one must ensure that the eye alignment is in the same position each time the particular measurements are made. Otherwise, the difference in data from before and after the treatment might be due to a change in eye alignment rather than the treatment.

In addition to those situations where one needs to ensure that eye alignment is in the same position for two or more different measurements, there are situations where eye alignment is desirable for diagnostic measurements of eye performance. There are situations when a human subject can simply be requested to fixate on a particular object. Thus, the human may state that he is currently looking at a light source, thereby providing "subjective" eye alignment information. However, there are situations where a doctor or researcher would like "objective" eye alignment information indicating the orientation of the eye and, to the extent possible, indicating what the eye is viewing. For example, very young children cannot be relied upon to fixate on such an object for measurements, such as refraction measurements which are very desirable to ensure that "in focus" images are being received when the child's brain is learning to interpret images. Likewise, adults subjected to extended eye examinations may become tired or subject to other duress and fail to maintain reliable fixation. A patient who is subjected to a therapeutic process such as laser ablation eye surgery may not be able to maintain desired eye orientation over an extended treatment time because of applied anesthesia, fatigue, or distraction by the procedure. Further, a research animal usually cannot be trained to fixate during eye measurements.

In each of the above cases, the failure or inability of the subject to maintain eye fixation upon an object can produce eye measurements or treatments that are seriously in error.

Therefore, there are situations where absolute eye alignment data is needed (i.e., the eye is aligned in a certain manner) and situations where comparative eye alignment data (i.e., the eye is in the same alignment as when earlier measurements were taken) are needed and one cannot rely upon a subject maintaining the alignment.

The use of various optical/electronic systems for making eye measurements has become more common in recent years. One example of such a system is shown in U.S. Pat. No. 4,213,678 to Pomerantzeff and Webb issued on Jul. 22, 1980. That patent discloses a scanning laser ophthalmoscope (SLO) for scanning a portion of the eye fundus. That patent, coinvented by one of the present inventors, is hereby incorporated by reference.

OBJECTS AND SUMMARY OF THE INVENTION

Accordingly, a primary object of the present invention is to provide a new and improved method and system for determining objective eye alignment.

A more specific object of the present invention is to provide objective eye alignment information which may provide the eye alignment relative to some external point or line, such as an instrument axis, or to provide eye alignment information by indicating when the present eye alignment is the same as an earlier eye alignment.

A further object of the present invention is to provide eye alignment data which can be used in combination with other diagnostic and therapeutic instruments. In other words, an object is to allow eye alignment data to be provided without requiring instrumentation which would block or prevent use of diagnostic and/or therapeutic devices which may advantageously use eye alignment information for improving their diagnostic and/or therapeutic operations.

Yet another object of the present invention is to allow one to bring the eye of a subject to a particular desired alignment, while the subject is under general anesthesia or is otherwise unable to cooperate in bringing his eye to a particular alignment.

A still further object of the present invention is to provide eye alignment information in a reliable and convenient fashion.

A more specific object of the present invention is to provide an imaging system and a method of use of an imaging system for determining objective eye alignment.

The above and other objects of the present invention, which will become more apparent as the following detailed description is considered, are realized by a method of determining objective eye alignment. A subject's eye is positioned relative to an imaging system to allow imaging of the eye. The imaging system provides an iris image of an iris portion of the subject's eye and a retinal image of a retinal portion of the subject's eye. The iris image and the retinal image are used to determine objective eye alignment. Preferably, the imaging system obtains the iris image and the retinal image within a time no greater than 50 milliseconds. To minimize intervening eye movements the time of obtaining the images would preferably be substantially less than that. The iris image and the retinal image are simultaneously displayed on a first monitor of the imaging system. (As used herein, "simultaneous display" means that the images appear simultaneous to a human eye.)

The eye alignment may be determined in two different manners. A first way of determining the eye alignment includes the step of comparing the iris image and the retinal image with a stored image of the iris portion and the retinal portion, the stored image corresponding to eye alignment at a previous time. More specifically, this first manner involves finding an eye position at which the iris image and the retinal image are substantially identical to the stored image. A second manner of

determining eye alignment involves finding a relationship between an instrument axis of the imaging system and an axis of the subject's eye. More specifically, the axis of the subject's eye may be the pupillary axis.

The iris image and the retinal image are provided by the imaging system scanning a beam across the eye and detecting scatter from the application of the beam to the eye. The beam is preferably a beam of electromagnetic radiation in the infra-red, visible or ultraviolet portions of the spectrum..

The method of the present invention may alternately be described as a method of determining objective eye alignment including a step of scanning a light beam from an imaging system across a subject's eyes such that the light beam strikes an iris portion adjacent a pupil and strikes a retinal portion. Scattered light from the application of the light beam to the iris portion and the retinal portion is then detected by operation of the imaging system. Nearly simultaneous (meaning simultaneous or within 50 milliseconds thereof) views of the iris portion and the retinal portion are generated by operation of the imaging system. The nearly simultaneous views are then used to determine objective eye alignment. The light beam is scanned between extremes of scan which cross in front of the object's eye. More specifically, the extremes of scan preferably cross at least three centimeters in front of the subject's eye (i.e., the closest point on the subject's eye to the scan crossing point is 3 centimeters or greater). The light beam applied to the subject's eye has a diameter of no more than 1 millimeter at the iris.

The system of the present invention is a system for measuring objective eye alignment including a scanner for scanning a beam across a subject's eye such that the beam strikes an iris portion adjacent a pupil and strikes a retinal portion. A detector for detecting scatter from the application of the beam to the iris portion and the retinal portion is operatively connected to a first monitor for showing simultaneous views (i.e., they appear simultaneous to a human eye) of the iris portion and the retinal portion based upon the scatter detected by the detector. The simultaneous views provide objective eye alignment information. More specifically, the scanner scans a light beam. The system may further include a second monitor and storage means to supply the second monitor with a stored image of the iris portion and the retinal portion at a previous time.

BRIEF DESCRIPTION OF THE DRAWINGS

The above and other features of the present invention will be more readily understood when the following detailed description is considered in conjunction with the accompanying drawings wherein like characters represent like parts throughout the several views and in which:

FIG. 1 shows a general schematic diagram illustrating how the present eye alignment system may be used in conjunction with another eye diagnostic instrument;

FIG. 2 shows a simplified view illustrating how the present alignment system may apply beams to the eye of a subject;

FIG. 3A, 3B, and 3C show separate images which the present system may provide for purposes of determining eye alignment information;

FIG. 4 shows an arrangement wherein the present eye alignment system is operating in conjunction with a known instrument which provides measurements of a cornea of the subject's eye; and

FIG. 5 shows a detailed view of an arrangement which may be used to provide the scanning.

DETAILED DESCRIPTION

With reference now to FIG. 1, there is shown a simplified view of part of a subject's eye 10 with an alignment imaging system 12 positioned to allow determination of the eye 10. The alignment imaging system or imager 12 according to the present invention is used to provide eye alignment information in a manner discussed in more detail below. For purposes of an initial general explanation, the arrangement of FIG. 1 shows how this alignment imaging system 12 may be used in combination with some other previously known eye diagnostic instrument 14. In particular, the instrument 14 might be some instrument which may diagnose conditions in the eye 10. The instrument 14 may alternately be some sort of therapeutic instrument (not separately indicated in the diagram) which may be used at the same time as the eye alignment imaging system 12. At any rate, the instrument 14 might be useful independently of any alignment information provided by the alignment system 12 or, more likely, the instrument 14 may use the alignment information from alignment system 12 for more accurately diagnosing and/or applying treatment to the eye 10.

As shown in FIG. 1, a light source 16 may supply light to a reflector 18 which in turn supplies the light to a beam splitter 20 by way of a lens 22. The light from source 16 is applied to the eye 10 and reflects back through the beam splitter 20 to the instrument 14. The eye diagnostic instrument 14 may produce data about the eye 10 depending upon the light reaching the diagnostic instrument 14.

At the same time as the instrument 14 is operating to provide the diagnostic information, the alignment imager 12 uses a reflector 24 and the beam splitter 20 to obtain alignment data about the eye. A manner in which the alignment imager 12 and eye diagnostic instrument 14 may be operated at the same time without one instrument blocking the other is shown in FIG. 1, it being readily appreciated that various other optical configurations could be used. A technique by which light from the alignment imager 12 and light from source 16 used with the instrument 14 can be used at the same time without interfering with each other will be discussed in more detail below, it simply being noted at present that these lights may be at different wavelengths (i.e., different colors) to avoid such interference. It should also be noted that, although the preferred embodiment of the present invention does use an alignment imaging system having a scanned light beam, other imaging systems might possibly be used. Further, the instrument 14 does not necessarily have to be an eye diagnostic instrument using a light source such as source 16. Finally, although FIG. 1 shows the alignment imaging system 12 being used in conjunction with the instrument 14, the alignment imaging system 12 may be used without regard to any other instrument such as instrument 14.

The manner in which the alignment imager 12 functions to determine the alignment of the eye will be explained by reference to the simplified concept drawing of FIG. 2. As shown in FIG. 2, a scanner 26 scans a beam of light 28 across the eye 10, the beam of light 28 passing through lens 30 prior to its application to the eye 10. As shown, the beam 28 has first and second scan extremes 32F and 32S respectively, which cross at point 34, which point is in front of the subject's eye 10. By

crossing in front of the subject's eye, the extremes of scan of beam **28** will allow it to fall upon the edges of iris **36** and, where the beam passes through the pupil **38** within the iris **36**, a retinal portion **40** at the back of eye **10**. By having the light beam **28** scan across the eye **10** and by using a detector (not shown in FIG. **2**, will be discussed in more detail below), the general principle of FIG. **2** may be used to provide a flying spot camera. In order to allow one to have a flying spot camera from the arrangement of FIG. **2** wherein one is able to provide an iris image corresponding to that portion of iris **36** upon which the beam **28** hits and a retinal image corresponding to retinal portion **40**, the point **34** at which the extremes of scan cross is typically about 3 centimeters in front of the subject's eye **10** (i.e., the point **34** is about 3 centimeters from the closest point on the eye **10**). Additionally, and in order to provide a relatively good focus on the iris portion, the beam **28** will have a beam diameter of no more than 1 millimeter and preferably 0.5 millimeters or slightly above that. In other words, the beam diameter will be at or between 1.0 millimeters and 0.5 millimeters. Note that use of too small a beam diameter would degrade the resolution at the retina **40**, whereas use of too large a beam diameter would interfere with the ability of the system to get a good focus on the portions of iris **36** which are around the pupil **38**.

In order to fully define the orientation of a generally spherical object such as an eye, certain information is required. If one is using alignment to simply mean the direction of a particular axis of the eye, simply identifying the location of two points along such an axis would indicate the alignment of the eye. However, as used herein, "alignment" will be interpreted as also including information about rotation of the eye about such an axis. Thus, if the particular axis within the eye corresponds to the look direction, rotating the eye about such a look direction axis may maintain the same object in view, even though the orientation of the eye relative to that object has changed. (In practice, the axis within the eye which is used for reference purposes may or may not correspond to the look direction, but this will be discussed in more detail below.) If one wants alignment information to include not only the direction and position of an eye axis but also the rotational position of the eye relative to that axis, this information can be determined by using at least three well-separated points lying in two nearly perpendicular planes. For such a measurement, two of these three points are used to determine the direction and position of the axis, whereas the third point is within a plane normal to the axis, which plane also includes one of the other two points.

The above discussion of eye alignment information will be more readily understood by reference to FIGS. **3A**, **3B**, and **3C** which show images corresponding to the operation of the present invention. In particular, FIG. **3A** shows an iris image **36I** having an edge **36E** which defines the outside boundaries of the pupil (not separately labeled in these figures). For ease of illustration, the image **36I** of the figures is simplified and does not include the large number of irregularities which would be disposed at the image of iris edge **36E**. Within the closed loop of edge **36E** is the image of the retinal portion corresponding to retinal portion **40** of FIG. **2**. In particular, and as shown in FIGS. **3A**, **3B**, and **3C**, this retinal image part of the combined iris portion/retinal portion image includes the fovea **42** and the optical disc **44**, both of which are disposed at the retina of the subject's eye.

Although various axes or lines might be used within a subject's eye for defining the alignment of the eye, the discussion which follows makes reference to the pupillary axis, which may be defined as a line between the centroid **46** of the pupil (area within edge **36E** in the image figures) and the fovea **42** (more specifically, the center of the foveola). In FIGS. **3A**, **3B** and **3C**, the centroid of the pupil is shown as an "X" **46**.

In the view of FIG. **3A**, the dextral eye shown therein with the centroid **46** of the pupil disposed at about the mid point between the fovea **42** and the center of optical disc **44**. Since the fovea and disc are separated by about 15° in the vision field, the pupillary axis between the centroid and the fovea **42** (more specifically, the center of the foveola, not separately shown) is directed about 7.5° to the right of the alignment instrument axis. The alignment instrument axis (not separately shown in these figures) has an axis normal to the plane of view of FIGS. **3A**, **3B**, and **3C**. This instrument axis will be considered to extend through the centroid **46** in order to clarify the discussion which follows. Relative positioning between the subject's eye and the eye alignment imaging system or other techniques may be used to provide that the alignment instrument axis extends through the centroid, although it is not essential that a uniquely defined alignment instrument axis extend through the centroid **46**. Instead, one might simply define an instrument point of view axis corresponding to the direction of "view" of the instrument and which passes through the centroid **46**.

Although the pupillary axis would be directed about 7.5° to the right of the alignment instrument axis (or alignment point of view axis) in the position of FIG. **3A**, one can say that the eye is looking about 7.5° to the right of the instrument axis only to the extent that one is certain that the subject's visual axis necessarily extends between the centroid **46** and the fovea **42** (more specifically, center of foveola). For certain purposes, it may be reasonable or necessary to assume that the visual axis of the subject's eye is the same as the pupillary axis. However, the use of the present method does not require that this assumption be made.

In the view of FIG. **3B**, the eye orientation has changed so that the pupillary axis is now only a few degrees to the right of the instrument axis. If the fovea **42** were moved slightly to the left in the view of FIG. **3B** such that it was centered beneath the centroid **46**, then the pupillary axis would be directly in line with the alignment instrument axis (or instrument point of view axis).

In the view of FIG. **3C**, the eye has rotated about an axis extending through centroid **46**, but the separation between centroid **46** and fovea **42** (i.e., the separation distance as viewed) has remained constant. As shown in the views of FIGS. **3A**, **3B**, and **3C**, the optical disc **44** may have a number of visible fine blood vessels **48** extending near it. The vessels may include crossing points **48C** (only one shown for simplicity). By noting that the crossing point **48C** has moved counter-clockwise about 30° between the positions of FIGS. **3B** and **3C**, this indicates that the eye has rotated about 30° counter-clockwise. The centroid **46** may be used as the origin for defining angles of rotation.

The alignment of the eye can thus be established by knowing the relationship between the centroid **46** and the fovea **42**. This relationship can establish the angle

between the pupillary axis and the instrument axis. However, if the fovea **42** and centroid **46** are both in line with the instrument axis, the position of an additional point must be used in order to determine uniquely or establish alignment of the eye provided that we use the term "alignment" to include rotation about the pupillary axis. Accordingly, use of the image of the optical disc **44** and, especially, the crossings of visible fine blood vessels such as crossing **44C** will allow us to uniquely establish the alignment of the eye.

The image of the retina portion as appearing within the iris edge **36E** would usually appear as a dark hole in a bright surrounding image because the reflectivity of the iris is much greater than that of the retina in most cases. The substantial detail within the darker retinal image, especially the visible fine blood vessels near the optical disc are quite suitable for computer vision processing. For example, processing can be used to locate and indicate the pupil centroid **46**. Various known pattern recognition techniques may be used to compare retinal detail to a reference image of the same eye.

The imaging system **12** used for eye alignment must meet relatively demanding performance requirements to accomplish its full purpose. The eye alignment information must be obtained and indicated in a time that is short compared to the time during which the eye normally changes its alignment significantly. A typical acceptable time is believed to be about 30 to 50 milliseconds. Within a fraction of this time, the imaging system **12** must form an image with sufficient resolution and depth of focus to provide accurate measurement of the pupil centroid and the retinal detail. Typically, the relatively low reflectivity of the retina means that it must be illuminated artificially to satisfy these requirements, but injurious light levels must be avoided. Further, it is best to avoid uncomfortable light levels because eye responses such as accommodation, aversion or blinking may result and may invalidate a diagnostic measurement. The imaging system should also provide frequent images in order to follow eye motion to guide the approach to proper alignment.

By using the general principles of operation of the scanning laser ophthalmoscope (SLO) co-invented by one of the present inventors and described in more detail in the incorporated by reference U.S. Pat. No. 4,213,678, one can provide an imaging system which will meet the criteria specified above. The SLO has two major advantages for providing alignment information based upon the showing of a dual iris image and retinal image. In particular, the SLO provides retinal images at TV rates with relatively low levels of retinal illumination. Further, the SLO, as modified for the present purposes, may provide high resolution with the large depth of focus required to image both the pupil and the retina.

FIG. **4** shows the eye alignment imaging system **12** in position for measuring a subject's eye **10**, while the eye **10** is, at the same time subject to measurement by a Computer Modeling System (CMS) keratograph having an illumination head **50** and a camera **42**. The illumination head **50** and the camera **52** are part of the CMS manufactured by Computed Anatomy, Inc. and designed to provide topographic measurements of a cornea. The CMS head **50** and camera **52** are simply shown in FIG. **4** to illustrate how the present invention may be used in combination with a particular known diagnostic instrument. Additionally, the head **50** and camera **52** are included in FIG. **4** to show a specific manner in which the present imaging system **12** may be used without interference between it and another eye diagnostic instrument. Specifically, the illumination head **50** may use red light and a filter **54** may only allow red light to pass through to the camera **52**. In that fashion, the camera **52** will avoid errors which might otherwise be caused by light from the imaging system **12** since the imaging system **12** may use green light from laser source **56**.

The green light from laser light source **56** is supplied to a scanner **26** which may scan the beam **28** in a pattern in order to image a retinal portion and an iris portion of the eye **10** as discussed in detail previously. Numerous scanning patterns could be used, but the preferred scanning pattern resembles a conventional interlaced television scanning pattern except that image scanning is continued during the backward sweep, this pattern being discussed in more detail in the incorporated by reference Pomerantzeff patent. The scanner **26** may include various optical elements as will be discussed in detail below. The light from the scanner **26** will pass through the beam splitter **58** on its way to the eye **10**. The beam splitter **58** is preferably a polarizing beam splitter. Since the scanner **26** may supply polarized light (by use of a polarized laser **56**) and the polarized light is about 98% transmitted through the polarizing beam splitter **58**, most of the beam energy from scanner **26** will pass through to the eye **10**. Additionally, the reflections from the cornea and lens of the eye **10**, which are interfering signals for present purposes, will generally still be polarized such that these reflections will pass through the polarizing beam splitter **58** and will not be directed towards a light detector **60**. However, unlike the reflections from the cornea and lens, the scatter returning from the iris and retina are substantially depolarized such that about 50% of the light returning from the surface of interest will be deflected towards the light detector **60**. Thus, use of a polarizing laser **56** and a polarized beam splitter **58** allows one to substantially increase the strength of light returning from the surfaces of interest relative to reflections from surfaces which are not of interest for alignment purposes. The reflected light supplied to light detector **60** goes through filter **62** which would be a green filter corresponding to the green light from laser **56**. The filter **62** will minimize the response of the light detector **60** to reflections from the red light used by the illumination head **50**.

In addition to having the scan crossing point **34** disposed in front of the eye as shown, note that the system does not include any optical elements between that crossing point **34** and the eye **10**. Among other modifications to the SLO disclosed by the Pomerantzeff incorporated by reference patent, the diameter of beam **28** would generally be significantly smaller than the diameter used for high resolution at the retina when the SLO is used as a fundus camera in accord with the Pomerantzeff patent. By use of a smaller beam than in the fundus camera application of the SLO, one can get a good focus on the pupil, while at the same time having a sufficient depth of focus that the retina features can be used for alignment purposes. It should briefly be noted that the SLO fundus camera as described in the incorporated by reference Pomerantzeff patent uses a stop **88** in FIG. **1** of that patent having an aperture therein which corresponds to the size of the pupil, thereby preventing the detector from detecting light reflected from the iris. Although the present system **12** may include a stop **64**, the stop will have an aperture which is sufficiently wide

to allow light from the iris to pass there through. In other words, the light detector **60** will be able to receive reflected light from the iris as well as the retina. The stop **64** may avoid reflections or stray light from outside the area upon which the light beam **28** is applied.

The light detector **60** is connected to an amplifier **68** which provides an output to a scan converter **70**. The scan converter **70** in turn supplies an output to a real-time monitor **72**. Additionally, the scan converter **70** might be connected to a print-out device (not shown). Generally, the operation of the amplifier **68**, scan converter **70**, and monitor **72** will be the same as the corresponding components in FIG. **2** of the Pomerantzeff patent. It should also be noted that, for ease of illustration, the timing and synchronization, scan amplitude and centering, X driver and Y driver blocks have not been shown in FIG. **4**, it being readily understood that these may operate in the same manner as shown and discussed relative to FIG. **2** of the Pomerantzeff patent.

As shown in FIG. **4**, the arrangement may also include a storage means **74** which may store the image of a particular eye alignment (i.e., a combined iris image and retinal image which reveals eye alignment information). The storage means **74** may be a digital memory or any of various known types. Alternately, one could use a videotape recorder (not shown) to store past alignment data, in which case the video tape recorder might be connected directly to the output of amplifier **68**.

Regardless of the type of storage means **74** which is used, it may supply a signal to a past image monitor **76**. The monitor **76** will show a previous eye alignment in accord with the digital memory, video tape, or other type of storage means **74**. Although FIG. **4** shows two separate monitors **72** and **76**, these monitors might simply be separate halves of a cathode ray tube (not separately shown) by use of known splitscreen techniques. In that case, one half of the screen would show the past combined iris/retinal image, whereas the other half of the screen would show the real-time combined iris/retinal image. The two separate monitors **72** and **76** may collectively be considered as a monitor means.

By use of the storage means **74**, one can use the system **12** to determine that the eye **10** is back into a previous orientation. For example, the eye **10** may be in a relatively arbitrary position when the CMS keratograph is first used. When the keratograph is used, one would also use the imaging system **12** to provide a combined iris/retinal image which would be stored within the storage means **74**. A doctor or other person may then perform some therapeutic procedure upon the eye **10**. In order to determine what effect, if any, the therapeutic procedure has had upon the topography of the cornea, one would like to remeasure the cornea. However, in order to have meaningful data, the eye **10** must be oriented the same way it was when the cornea measurements were first made.

Ensuring that the post-therapeutic cornea measurements are made with the eye in the same orientation as the pre-therapeutic measurements, one would first position the eye **10** relative to the imaging system **12** to allow it to image the eye. The imaging system **12** would then provide an iris image of the iris portion of the subject's eye and a retinal image of a retinal portion of the eye. This post-therapeutic combined image is then used to determine objective eye alignment. More specifically, the doctor or other medical professional could move the subject's head, or, more directly, his eye until the real-time monitor **72** shows a combined image which is substantially identical to the combined image of the pre-therapeutic combined image which may be on display in the past image monitor **76**. In order to return the eye **10** to its same alignment as in the past-therapeutic combined image, the person manipulating the eye would ensure that the relative positions of the pupil centroid **46**, fovea **42**, and optical disc **44** (refer back momentarily to FIGS. **3A**, **3B**, and **3C**) are the same as in the pre-therapeutic combined image. To that end, the positioning of the crossings of blood vessels **48C** (again referring to FIGS. **3A**, **3B**, and **3C**) and the blood vessels themselves may be especially helpful in establishing that eye alignment is the same for the post-therapeutic measurement as it was for the pre-therapeutic measurement. Indeed, one might use several features of the blood vessels around the optical disc to return to a previous alignment without necessarily specifically considering the position of the fovea.

In addition to using various known computer vision processing techniques to automatically supply the centroid **46** (FIGS. **3A**, **3B**, and **3C**), one could alternately simply insert the centroid in the image by the operator locating the centroid and inserting it using known technology to insert points or marks on an image.

Upon the past image monitor **76** and the real-time monitor **72** showing that the post-therapeutic eye alignment is the same as the pre-therapeutic eye alignment, one may then turn on the CMS keratograph to provide the cornea measurements. Since the alignment of the eye **10** is the same as it was when the original cornea measurements were made, differences between the cornea measurements before and after the therapeutic procedure can reasonably be said to result from the therapeutic procedure.

As an alternative to having the operator bring the eye **10** into the same alignment for the post-therapeutic measurement as the alignment in the pre-therapeutic measurement, the past combined iris/retinal image may be compared to the real-time combined image and the difference in orientation could be calculated. In that case, the cornea measurements may be made in a post-therapeutic alignment which is different than the pre-therapeutic alignment, but computer software could be used to provide a transformation to convert the post-therapeutic cornea values into corresponding pre-therapeutic values. To take a simple example, if the pre-therapeutic measurement was made with the pupillary axis in line with the instrument axis, and the eye alignment imaging system **12** shows that the post-therapeutic cornea measurements are being made with the pupillary axis still in line with the instrument axis, but with the eye rotated 30° counter-clockwise about the pupillary axis, the post-therapeutic cornea measurements would be transformed by, in effect, rotating the cornea measurements 30° counter-clockwise about the pupillary axis.

In addition to allowing one to determine eye alignment information by comparison of before and after combined iris/retinal images, a single combined iris/-retinal image might be used to determine objective eye alignment in the same fashion as discussed above during the initial explanation of FIG. **3A**. In other words, the relative positioning of the fovea **42**, optical disc **44** and centroid **46** in FIG. **3A** was indicative of the pupillary axis being directed about 7.5° to the left of the alignment instrument axis. Depending upon the degree of accuracy which is required in a particular application, one might assume that the pupillary axis corresponds to the

visual axis such that information about the direction of the pupillary axis could be used to infer what the subject (such as a test animal) was viewing. Since the visual axis does not pass through the centroid of the pupil for all subjects, this assumption that the pupillary axis and visual axis coincide would be an inappropriate assumption under other circumstances.

Upon determining the eye alignment by the relationship between the pupillary axis and the instrument axis (and preferably also including some indication about the rotation of the eye), one could continue to track this eye alignment data with the alignment imaging system **12** of the present invention during a therapeutic procedure upon the eye **10**. Alternately, one could obtain this alignment data and, in effect, transfer the alignment data to an eye tracker. The eye tracker is a known instrument which is simpler than the present invention, but normally yields incomplete or inaccurate alignment data. By using one of several known types of eye trackers to which the alignment data from system **12** has been transferred, the system **12** may be removed from its position whereas it images eye **10** such that the system **12** will be out of the way of any therapeutic instruments which might be used on the person's eye. The eye tracker will provide information based upon a starting point supplied by the system **12**.

The scanner **26** of FIG. **4** may be constructed in any of various generally known ways to provide the desired scan pattern as discussed above. However, with reference now to FIG. **5**, an especially advantageous manner of constructing the scanner **26** will be discussed. The laser light source **56** supplies light to a reflector **78** which reflects the light to a beam expander **80**. An acousto-optic deflector **82** may be used to provide TV rate deflection without moving parts or excessive sound. However, the acousto-optic deflector has a large aperture. As the deflector **82** is a diffraction limited device, the number of resolvable positions is proportional to the aperture in the direction of scan. In order to supply a sufficiently large number of resolvable positions, acousto-optic deflectors have large apertures only in the necessary direction. Accordingly, they require a light beam which is much wider than it is high. Although the necessary beam may be provided with cylindrical mirrors and off-axis parabaloids (not shown) or various other anamorphic schemes, the arrangement of FIG. **5** uses a Brewster telescope having prism chains **84** and **86** which are relatively easy to align and more compact than various other anamorphic schemes. The portion **84** of the Brewster telescope in front of the acousto-optic deflector **82** increases one dimension of the beam from expander **80** by four times, whereas the portion **86** of the Brewster telescope after the deflector **82** returns the beam to the same dimensions as it had when entering the first part of the Brewster telescope. Portion **86** of the Brewster telescope also multiplies the scan angle by four. A moving-mirror galvanometer **88** is used to provide vertical deflection, the mirror being shown just above its actual working position for ease of illustration. The light from the reflector **88** would go to a relay lens **90** and on to the polarizing beam splitter **58**. (Although the relay lens **90** was not shown in FIG. **4**, such a lens would preferably be used between the scanner **26** and polarizing beam splitter **58** of FIG. **4**.)

Although various specific constructions have been included herein, it is to be understood that these are for illustrative purposes only. Various modifications and adaptations will be apparent to those of skill in the art. Accordingly, the scope of the present invention should be determined by reference to the claims appended hereto.

What is claimed is:

1. A method of determining objective eye alignment comprising the steps of:

positioning a subject's eye relative to an imaging system to allow imaging of the subject's eye;

applying a beam to the subject's eye;

using the imaging system to detect a portion of the beam returned after striking the subject's eye and to generate, based on the detected portion of the beam, an iris image of an iris portion of the subject's eye and a retinal image of a retinal portion of the subject's eye; and

observing positions of said iris image and said retinal image to determine objective eye alignment.

2. The method of claim **1** wherein the imaging system obtains the iris image and the retinal image within a time no greater than 50 milliseconds.

3. The method of claim **2** further comprising simultaneously displaying the iris image and the retinal image on a first monitor of the imaging system.

4. The method of claim **1** wherein the eye alignment is determined by comparing the iris image and the retinal image with a stored image of an iris portion and a retinal portion corresponding to eye alignment at a previous time.

5. The method of claim **4** wherein the eye alignment is determined by finding an eye position at which the iris image and the retinal image are substantially identical to the stored image.

6. The method of claim **1** wherein the eye alignment is determined by finding a relationship between an instrument axis of the imaging system and an axis of the patient's eye.

7. The method of claim **6** wherein the axis of the subject's eye is a pupillary axis.

8. The method of claim **1** further comprising the step of simultaneously displaying the iris image and the retinal image, and wherein the imaging system develops the iris image and the retinal image by scanning the beam across the eye and detecting scatter from the application of the beam to the eye.

9. The method of claim **8** wherein the beam is a light beam.

10. A method of determining objective eye alignment comprising the steps of:

scanning a light beam from an imaging system across a subject's eye such that the light beam strikes an iris portion adjacent a pupil and strikes a retinal portion;

detecting, by operation of the imaging system, scattered light from the application of the light beam to the iris portion and the retinal portion;

generating nearly simultaneous views of the iris portion and the retinal portion by operation of the imaging system; and

using said nearly simultaneous views to determine objective eye alignment.

11. The method of claim **10** wherein the light beam is scanned between extremes of scan which cross in front of the subject's eye.

12. The method of claim **11** wherein said extremes of scan cross at least 3 centimeters in front of the subject's eye.

13. The method of claim **10** wherein the light beam has a diameter of no more than 1 millimeter.

14. The method of claim 10 wherein the eye alignment is determined by comparing a real-time image to a stored image representative of eye alignment at a previous time.

15. The method of claim 14 wherein the eye alignment is determined by finding an eye position at which the real-time image is substantially identical to the stored image.

16. The method of claim 10 wherein the eye alignment is determined by finding a relationship between an instrument axis of the imaging system and an axis of the subject's eye.

17. The method of claim 16 wherein the axis of the subject's eye is a pupillary axis.

18. A system for measuring objective eye alignment comprising:

a scanner for scanning a beam across a subject's eye such that the beam strikes an iris portion adjacent a pupil and strikes a retinal portion;

a detector for detecting scatter from the application of the beam to the iris portion and the retinal portion;

a stop having an aperture through which scatter from the application of the beam to the iris portion and the retinal portion passes on its way to said detector; and

a first monitor operatively connected to said detector for showing simultaneous views of the iris portion and the retinal portion based upon the scatter detected by the detector, the simultaneous views providing objective eye alignment information.

19. The system of claim 18 wherein said scanner scans a light beam.

20. The system of claim 18 wherein said scanner scans the beam between extremes of scan which cross in front of the subject's eye.

21. A system for measuring objective eye alignment comprising:

a scanner for scanning a beam across a subject's eye such that the beam strikes an iris portion adjacent a pupil and strikes a retinal portion;

a detector for detecting scatter from the application of the beam to the iris portion and the retinal portion;

a first monitor operatively connected to said detector for showing simultaneous views of the iris portion and the retinal portion based upon the scatter detected by the detector, the simultaneous views providing objective eye alignment information; and a second monitor and storage means to supply the second monitor with a stored image of the iris portion and the retinal portion at a previous time.

22. A system for measuring objective eye alignment comprising:

a scanner for scanning a beam across a subject's eye such that the beam strikes an iris portion adjacent a pupil and strikes a retinal portion;

a detector for detecting scatter from the application of the beam to the iris portion and the retinal portion;

monitor means operatively connected to said detector for showing simultaneous views of the iris portion and the retinal portion based upon the scatter detected by the detector, the simultaneous views providing objective eye alignment information; and

storage means connected to the monitor means for supplying the monitor means with a stored image of the iris portion and the retinal portion at a previous time.

[57] **ABSTRACT**

A stereoscopic objective lens system for video endoscopes and borescopes includes a full diameter collimator lens systems and a pair of half-diameter stereo lens systems. The lens systems can be formed of doublet lenses or a combination of singlet and doublet lenses, or of gradient index lenses, or of a mixture of such lenses. The full-diameter lens system collimates object points, imaging object points to infinity to present equal-angle pairs from symmetrically disposed object points to the small stereo pair. This equal-angle property enables accurate object/image mapping onto the final stereo image pair, such that all parts of each left/right image can be mapped to within a fraction of a video pixel to each other.

STEREO VIDEO ENDOSCOPE OBJECTIVE LENS SYSTEM

BACKGROUND OF THE INVENTION

This application is a Continuation-In-Part of U.S. patent application Ser. No. 687,330 filed Apr. 18, 1991, now U.S. Pat. No. 5,122,650.

This invention relates generally to optical lens systems, and, more particularly, relates to stereoscopic objective lens designs adapted for use in stereo video endoscopes.

Medical endoscopes are widely utilized to view internal regions of the human body during diagnostic, surgical, and other medical procedures. Endoscopes typically include a long, thin, rigid or semi-rigid optical cylinder affixed to a viewing mechanism. The cylinder is sufficiently narrow to be inserted through a small opening in the body, which may be natural or surgical. When the endoscope is inserted and positioned for use, an image of the object being viewed is formed at an inserted end of the endoscope by an objective lens. The image passes through a series of relay lenses down the cylinder to an eye lens or video camera at a viewing end of the endoscope.

In recent years, researchers have attempted to improve the imaging available through endoscopic devices by developing stereoscopic video endoscopes. These endoscopes present an apparently three-dimensional image on a video monitor. The stereoscopic effect is created by producing two optical images—a left image and a right image—through the endoscope. The left and right optical images are presented by the endoscope to left and right image sensors, which may be charge-coupled device (CCD) cameras or other image sensing devices. The sensing devices convert the left and right optical images into left and right video images which are then presented as alternating left-right images on a monitor, at a switching rate higher than the flicker-sensing limit of the human eye, so that observed images appear flicker-free.

The images are alternately switched from a left-hand polarization mode to a right-hand polarization mode, such that, for example, the left image has a left-hand polarization and the right image has a right-hand polarization. In accord with his example, the observer wears polarized glasses in which the left lens has the left-hand polarization and the right lens has the right-hand polarization. Thus, the left eye sees only images from the left channel of the endoscope system and the right eye sees only images from the right channel, resulting in stereoscopic viewing.

The following U.S. and foreign patents disclose examples of stereo endoscopes, some of which utilize video imaging and display elements:

U.S.	4,061,135
U.S.	4,615,332
U.S.	4,651,201
U.S.	4,862,873
U.S.	4,873,572
U.S.	4,895,431
EP	211,783

In particular, U.S. Pat. No. 4,061,135 discloses a binocular endoscope in which images are transmitted from the viewed object to the viewing station through an optical system utilizing a dove prism and mechanical linkage to compensate for rotation effects.

U.S. Pat. No. 4,615,332 discloses a binocular endoscope having flexible light guides and binocular eyepieces.

U.S. Pat. No. 4,651,201 discloses a stereoscopic video endoscope including two image guides and an illumination light guide. The image guides are optically coupled to a stereoscopic viewer for three dimensional viewing. The viewer includes couplings for attaching miniature video cameras that can be connected to a head-mounted stereoscopic video display.

U.S. Pat. No. 4,862,873 discloses a stereo endoscope having two light guides for carrying images of an object to an electro-optical imaging assembly. A lens system directs light from the object to the objective end of the light guides. Illuminating light is transmitted to the object from the opposite end of one light guide, thereby illuminating the object. Simultaneously, the image transmitted through the other optical guide is conducted to the imaging assembly.

U.S. Pat. No. 4,873,572 discloses a stereo endoscope having a CCD camera module and two image-forming lens systems that form two object images. The object images are integrated and directed to the CCD camera to provide a stereoscopic output. The lens systems include red, green, and blue color filters disposed at the camera imaging surface.

U.S. Pat. No. 4,895,431 discloses an endoscope apparatus that generates a three-dimensional image of an object from overlapping images recorded by a camera. The endoscope includes an insertion module and a movable end section capable of being deflected through an angle. A first image is recorded with the end section positioned at a first angle. A second image, partially overlapping the first image, is recorded after moving the end section to a second angle. The relative position of the movable end section is detected by an encoder that generates position signals for input to a microprocessor, which utilizes the position signals to generate a three-dimensional image of the object.

European Patent No. 211,783 discloses a stereo video endoscope in which two light pipes deliver two images of the same object. These images are presented by a binocular device to the user's eyes to show a three dimensional image of the target. The apparatus includes two television cameras and video recorders for recording the images. The recorded images can be displayed on separate screens and viewed by a binocular viewing system.

Most conventional stereo endoscopes, however, share a number of deficiencies associated with their objective lens systems. These problems include a bulky and unwieldy configuration; high cost and complexity of fabricating the objective lens system; and the mediocre optical performance afforded by conventional objective lens systems.

An additional problem associated with conventional stereo video endoscope objectives involves the requirement that all portions of each left/right image be mapped to within a fraction of a video pixel to each other. This pixel mapping condition is a significant optical design constraint, because the object-to-image ray paths through the lens system are quite different for the left and right image points associated with a common object point.

Accordingly, it is a general object of the present invention to provide improved stereo endoscope objec-

tive lens systems that overcome the problems associated with conventional designs.

A more specific object is to provide an improved stereo endoscope objective lens system having optical elements that facilitate assembly of the system.

It is another object of the invention to provide an improved stereo endoscope objective lens system having elements that are substantially less expensive to manufacture than the elements of conventional systems.

A further object is to provide an improved stereo endoscope objective lens system having optical performance characteristics that are substantially superior to the performance characteristics of conventional systems.

Another object of the invention is to provide a stereo objective lens system affording a pixel mapped image.

The above and other objects and advantages of this invention will become more readily apparent when the following description is read in conjunction with the accompanying drawings.

SUMMARY OF THE INVENTION

The foregoing objects are attained by the invention, which provides an improved stereo endoscope objective lens system for video imaging in medical endoscopes and industrial borescopes.

One aspect of the invention includes two full-diameter doublets and a double set of two half-diameter identical doublets. The full-diameter doublets substantially collimate object points, i.e., image them substantially to infinity.

In accord with this aspect of the invention, most of the optical power necessary to accomplish this collimation is provided by in the first or outer doublet, while the second collimator doublet is of low power.

In a further aspect of the invention, the smaller doublets are identical, so that they can be most economically fabricated in production quantities. This is advantageous because these small lenses are inherently difficult to manufacture.

In another aspect of the invention, the large collimator lens system presents equal-angle pairs from symmetrically disposed object points to the small stereo lens systems. This equal-angle solution provides accurate object/image mapping onto the final stereo image pair. In this design, the larger, and hence easier to fabricate, collimator lens system carries the corrective burden, so that the smaller, more difficult to manufacture lenses can be made as simple as possible.

In still another aspect of the invention the collimator lens system may be formed of a combination of singlet and doublet lenses.

In another embodiment gradient index (GRIN) lenses can be substituted for either the collimator doublets or the stereo doublet pairs or both. These lenses are more economical to fabricate and can be constructed to produce the same ray bending and hence the same optical output as the doublet lenses.

The invention will next be described in connection with certain illustrated embodiments; however, it should be clear to those skilled in the art that various modifications, additions and subtractions can be made without departing from the spirit or scope of the claims.

BRIEF DESCRIPTION OF THE DRAWINGS

For a fuller understanding of the nature and objects of the invention, reference should be made to the following detailed description and the accompanying drawings, in which:

FIG. **1** is a schematic diagram depicting a stereo video endoscope utilizing an objective lens system constructed in accordance with the invention;

FIG. **2** is an optical schematic diagram depicting an objective lens system constructed in accordance with the invention, showing light rays transmitted through the system;

FIG. **3** is an optical schematic diagram depicting the objective lens system of FIG. **2** in combination with relay lenses for transmitting the optical images;

FIG. **4** is an optical schematic diagram of the objective lens system of FIG. **2** illustrating the location of the surfaces specified in Table A; and

FIG. **5** is a optical diagram of the objective lens system of FIG. **2** incorporating gradient index lenses in place of the doublet lenses.

FIG. **6** and **7** are optical schematic diagrams depicting an objective lens system constructed in accordance with the invention wherein the collimating lens system is formed of a combination of singlet and doublet lenses.

DESCRIPTION OF ILLUSTRATED EMBODIMENTS

FIG. **1** depicts the invention, an endoscope objective system **100**, utilized in a stereo video endoscopy system **1** for generating stereoscopic images of an object **12**. The system **1** includes a stereoscopic endoscope **10** containing objective system **100**; sensing modules **152**, **154**; switching module **156**; and a monitor **158**. In addition to objective lens system **100**, the endoscope **10** includes conventional relay lenses or optical fibers **150** for transmitting light collected by the endoscope objective system **100** to light sensing modules **152**, **154**.

The endoscope objective system **100** generates left and right optical images of the object **12** that are processed by sensing elements **152**, **154** and video switching module **156** in a known manner to display an apparently three-dimensional image of the object **12** on video monitor **158**.

The stereoscopic effect is created by producing two optical images—a left image and a right image—through the endoscope objective system **100**. The left and right optical images generated by the objective system **100** are presented by the relay lens or optical fiber system **150** to left and right image sensors **152**, **154**, which can be conventional charge-coupled device (CCD) cameras or other image sensing devices. The CCD elements operate in a known manner to convert the light collected by the objective system **100**, and transmitted by the relay lenses or optical fibers **150**, into electrical signals representative of the left and right optical images of the object **12**.

Conventional video switching circuitry **156** transmits the electronic signals representative of left and right video images as alternating left-right images on the monitor **158**. In accord with known video practice, these alternating images are presented at a switching rate higher than the flicker-sensing limit of the human eye, so that observed images appear flicker-free.

Moreover, the images can be alternately switched from a left-hand polarization mode to a right-hand polarization mode, such that, for example, the left image has a left-hand polarization and the right image has a right-hand polarization. The observer wears polarized glasses in which the left lens has the left-hand polarization and the right lens has the right-hand polarization.

Thus, when the observer views the monitor **158**, the left eye sees only images from the left channel of the endoscope system and the right eye sees only images from the right channel, resulting in stereoscopic viewing. Video switching and display equipment of this type is commercially available from Stereographics, Inc. of San Rafael, Calif.; and from Tektronix Corp., of Beaverton, Oreg.

The accuracy and quality of the image displayed on monitor **158** is controlled by the performance of the endoscope objective system **100**, which is the subject of the present invention. FIGS. **2** and **3** depict an objective lens system **100** constructed in accordance with the invention, showing light rays transmitted through the system. FIGS. **2** and **3** depict the same system, with two elements being omitted from FIG. **3** for purposes of clarity.

As indicated in FIG. **2**, one embodiment of the objective system **100** includes two full-diameter doublets **110**, **112** and a double set of two half-diameter identical doublets **114**, **116**, **118**, **120**. The full-diameter doublets collimate object points, i.e., image them to infinity. In accordance with the invention, most of the optical power required to accomplish this collimation is provided by the first collimator doublet **110** closest to the object **12**, while the second collimator doublet **112** can have a very low optical power.

Those skilled in the art will appreciate that the lenses of the objective system **100** depicted in FIG. **2** define a sequence of sixteen optical surfaces. A working example of a set of lenses for objective system **100** is set forth below in Table A.

TABLE A

SURFACE	RADIUS	THICKNESS	APERTURE	GLASS
1	—	−4.002608	0.225000	AIR

4	53.596342	0.400000	3.000000	AIR
5	−11.075366	1.600000	2.500000	SK5
6	−3.318618	1.500000	3.000000	SF8
7	−31.896589	−1.200000	2.500000	AIR
8	—	1.900000	0.464074	AIR
9	2.747539	1.600000	1.500000	SSKN8
10	−3.153676	0.700000	1.500000	SF1
11	4.815753	0.250000	1.500000	AIR
12	2.747539	1.600000	1.500000	SF1
13	−3.153676	0.700000	1.500000	SSKN8
14	4.815753	0.400000	1.500000	AIR
15	—	0.001000	1.400000	BK7
16	—	—	1.400000	AIR

In Table A, the numerical value in the "RADIUS" and "THICKNESS" columns are set forth in millimeters. The "GLASS" descriptions are standard optical glass characterizations as found in the product catalog of the Schott Glass Company of the Federal Republic of Germany. The "THICKNESS" column refers to the distance to the next optical surface. For example, in connection with surface **3**, the number 1.5000 signifies 1.5 millimeters to surface **4**. The column "RADIUS" refers to the radii of curvature of the respective curved surfaces. In this working example, the lens diameters are 6 millimeters for the large doublets and 3 millimeters for the small doublets. The 14 overall object-to-image distance is 28.3 millimeters. The image diameter is 2.5 millimeters.

In Table A, the surfaces correspond to the labeled surfaces in FIG. **4**. The surfaces in the table identified as **1**, **8**, **15** and **16** do not correspond to actual surfaces, but are artifacts introduced by the specific program employed to generate this table. For clarity the numbered surfaces from table A are designated with an S following the numeral, for example, the surface designated 2S in FIG. **4** corresponds to the surface **2** in table A.

The system **100** is designed so that all parts of each left/right image are mapped to within a selected distance of each other such that stereoscopic image quality is maintained. For video applications, this selected distance is typically a fraction of a video pixel. This is a difficult condition to satisfy, because the object-to-image ray paths through the lens system are quite different for the left and right image points of a common object point. FIG. **2** clearly illustrates this path difference. The ray paths shown in FIG. **2** demonstrate how differently an object point is imaged through the lens elements for the left and right images.

The objective system **100** depicted in FIG. **2** is able to map all parts of each left/right image to within a fraction of a video pixel to each other, because the large collimator doublets present equal-angle pairs from symmetrically disposed object points to the small stereo doublet pairs.

This exact equal-angle solution results in an accurate object/image mapping onto the final stereo image pair. Accuracy is also enhanced by the combination of a first high power collimator doublet **110** and a second, lower power collimator doublet **112**. This second doublet **112** strongly influences the optical solution to the image-mapping problem.

A further advantage is provided in that the smaller doublets **114**, **116**, **118**, and **120** are identical, so that they can be most economically fabricated in production quantities. This characteristic tends to offset the inherent difficulty of manufacturing small lenses. The larger, and hence easier to fabricate, doublets carry the corrective burden, so that the smaller, more difficult to manufacture lenses can be as simple as possible.

FIG. **5** illustrates an objective system **100** where the lens systems are formed of gradient index lenses (GRINS) in place of the doublet lenses. These lenses can be manufactured to duplicate the optical performance of the doublet lenses. In FIG. **5** a full diameter GRIN collimator lens **210** performs the collimator function and a matched pair of GRIN one half diameter stereo lenses **214** an **216** complete the objective lens assembly. The pair of stereo lenses produce left and right images **226** and **228** on the image plane. (A pair of aperture stops **220** and **222** may be employed to define the pupils.)

Of course aperture stops may be placed at other locations in the objective lens system according to the purposes of the designer.

FIGS. **6** and **7** illustrate objective lens systems in which the collimator lens system is formed of a combination of singlet and doublet lenses. The embodiment of the objective system **100** illustrated in FIG. **6** includes in the collimator lens system **306** a singlet lens **310** coupled to a doublet lens **312**, coupled to another singlet lens **313**. The stereo lens pair system **308** is formed as in FIG. **2** by a pair of doublet lenses **314** ad **316** coupled to a second pair of doublet lenses **316** and **320**. The full diameter lens system collimates object points. The critical requirement is that the collimator system present equal angle pairs from symmetrically disposed object points to the small stereo lens pairs. This can be accomplished with a doublet lens system as illustrated in FIG. **2**, a GRIN lens system as illustrated in FIG. **5**, combina-

tions of singlets and doublets as illustrated in FIGS. **6** or **7**, triplet lenses or combinations of the above. Of course, the stereo lens system can be formed of GRIN lenses also, as well as combinations of singlets, doublets, and triplets as above.

A working example of a set of lenses for implementation of the objective lens system **100** illustrated in FIG. **6** is set forth in Table B. As in Table A, the numerical value in the radius and thickness columns are in millimeters. The "GLASS" descriptions are standard optical glass characterizations as found in the product catalog of the Schott Glass Company of the Federal Republic of Germany. The "THICKNESS" column refers to the distance to the next optical surface. For example, in connection with surface **3**, the number 1.5000 signifies 1.5 millimeters to surface **4**. The column "RADIUS" refers to the radii of curvature of the respective curved surfaces.

In Table B lens surfaces **1**, **2**, **9**, **16** and **17** do not correspond to actual lens surfaces.

FIG. **7** illustrates another collimator lens combination **306**, employing a sequence of two singlet lenses **320** and **322** followed by doublet lenses **323**. The physical characteristics for this sequence are set forth in Table C.

Table C is a working example of the objective lens system illustrated in FIG. **7**.

In Table C lens surfaces **1**, **2**, **9**, **16** and **17** do not correspond to physical lens surfaces.

As indicated in FIG. **1**, the endoscope objective system **100** can be utilized in connection with optical fiber elements or a set of relay lenses **150** to conduct light from the objective system to the sensing element **152**, **154**. An example of the relay lens system **150** that can be employed with the objective system **100** is depicted in FIG. **3**.

The relay lens system of FIG. **3** includes a plurality of rod relays **160**, **162**, **164** utilized in combination with objective system **100**. Those skilled in the art will recognize that a wide range of relay lens systems can be employed with an objective system constructed in accordance with the invention.

Alternatively, an endoscope constructed in accordance with the invention can employ a conventional CCD array mounted within the same housing as the objective system. As indicated in FIG. **2**, the CCD array can include left and right sensing elements **152**, **154**, disposed to receive the optical images generated at the output of doublets **118** and **120**. The design and construction of CCD elements having more than one photosensitive region in a monolithic package is well known in the art. The electrical signals generated by the CCD array can be conducted from the housing by a conventional conduit. This configuration eliminates the requirement for a relay lens system or optical fibers.

The system **100** depicted in FIGS. **2** and **3** offers advantages for use in medical endoscopes and industrial borescopes. The configuration offers the advantage of being adaptable to fit into a small tube diameter, as small as 3 millimeters. The design also affords high resolution and low distortion for diagnostic and surgical use, and for high-accuracy industrial measurement applications.

It will thus be seen that the invention efficiently attains the objects set forth above, among those made apparent from the preceding description.

It will be understood that changes may be made in the above construction and in the foregoing sequences of operation without departing from the scope of the invention. It is accordingly intended that all matter contained in the above description or shown in the accompanying drawings be interpreted as illustrative rather than in a limiting sense.

It is also to be understood that the following claims are intended to cover all of the generic and specific features of the invention as described herein, and all statements of the scope of the invention which, as a matter of language, might be said to fall therebetween.

Having described the invention, what is claimed as new and secured by Letters Patent is:

1. A stereoscopic objective lens system for a stereo video endoscope, the objective lens system converting optical images of an object generated at an objective end of the objective system to pixel-mapped left and right optical images at an image plane end of the objective system, the objective lens system comprising,

A. a gradient index collimator lens element proximate the objective end for collecting light from points on the object,

said gradient index lens having a first optical axis, a selected diameter and a selected optical power,

wherein said gradient index lens images the object points substantially to infinity so that light transmitted by the gradient index lens from the object points is substantially collimated,

B. a right/left pair of stereo gradient index lenses situated adjacent said gradient index collimator

lens for collecting light from said gradient index collimator lens,

said first right/left pair of stereo gradient index lenses including,

a right gradient lens and

a left gradient lens,

the optical axis of said right stereo lens and the optical axis of said left stereo lens being substantially parallel to the optical axis of collimator lens,

wherein said collimator lens and said right/left pair of stereo lenses cooperate so that the collimator lens presents equal-angle light ray pairs from symmetrically disposed object points to the right/left pair of stereo lenses, and

said right stereo lens collects light from said collimator lens to generate a right image at the image plane,

said left stereo lens collects light from said collimator lens to generate a left image at the image plane, such that corresponding portions of each left/right image are mapped to within a selected distance of each other.

2. A lens system according to claim 1, wherein said right stereo lens and said left stereo lens, are substantially identical.

3. A lens system according to claim 1 wherein the diameter of said right stereo lens and said left stereo lens, are approximately one-half the diameter of said collimator lens.

4. Stereoscopic endoscope apparatus for displaying stereoscopic images of an object, the apparatus comprising

A. a stereoscopic objective lens system,

the objective lens system converting optical images of the object generated at an objective end of the objective system to pixel-mapped left and right optical images at an image plane end of the objective system,

the objective lens system including,

(i) a collimator lens system proximate the objective end for collecting light from points on the object,

said collimator lens system having a defined optical axis, a selected diameter and a selected optical power, such that said collimator lens system images the object points substantially to infinity so that light transmitted by said collimator lens system from the object points is substantially collimated,

(ii) a right/left pair of stereo lens systems situated adjacent said collimator lens system for collecting light from said collimator lens system, said right-/left pair of stereo lens systems including,

a right stereo lens system having a defined optical axis and a selected diameter,

a left stereo lens system having a defined optical axis and a selected diameter equal to the diameter of said right stereo lens system,

the optical axis of said right lens system and the optical axis of said left lens system being substantially parallel to the defined optical axis of said collimator lens system,

wherein said collimator lens system and said right-/left pair of stereo lens systems cooperate so that the collimator lens system presents equal-angle light ray pairs from symmetrically disposed object points to said right/left pair of stereo lens systems.

5. An apparatus in accordance with claim 4 wherein at least one of said collimator lens systems or said right-/left pair of stereo lens systems are formed of gradient index lenses and corresponding portions of each left/-right image are mapped to within a selected distance of each other, and wherein at least one of said collimator lens systems or said right/left pair of stereo lens systems are formed of gradient index lenses.

6. An apparatus in accordance with either of claims 4 or 5 wherein the diameter of each of said left and right stereo lens systems is substantially one half the diameter of said collimator lens system.

7. An apparatus in accordance with claim 4 and further including right and left optical sensing means, situated at right and left regions of the image plane, respectively, for converting said right and left optical images to electrical signals representative of right and left video signals in response to said right and left optical images, respectively.

8. An apparatus in accordance with claim 5 and further including right and left optical sensing means, situated at right and left regions of the image plane, respectively, for converting said right and left optical images to electrical signals representative of right and left video signals in response to said right and left optical images, respectively.

9. Apparatus in accordance with either of claims 4 or 5 having aperture stops between said collimator and said right/left pair of stereo lens systems.

10. Apparatus according to either of claims 7 or 8, further comprising video monitor means, in electrical communication with said first and second optical sensing means, for displaying right and left video images in response to said electrical signals generated by the first and second optical sensing means.

11. Apparatus according to claim 7 wherein said right and left optical sensing means include at least one CCD element.

12. Apparatus according to claim 8 wherein said right and left optical sensing means include at least one CCD element.

13. Apparatus according to claim 11 wherein said objective lens system is contained within a housing, and said at least one CCD element is disposed within said housing in proximity to said objective lens system so that optical images generated by said objective lens system are transmitted to said at least one CCD element.

14. A stereoscopic endoscope apparatus in accordance with claim 4 wherein said collimator lens system comprises

A. a first collimator doublet lens element proximate the objective end for collecting light from points on the object,

said first doublet lens having a first optical axis, a selected diameter and a selected optical power,

B. A second collimator doublet lens for collecting light from said first collimator doublet lens,

said second collimator doublet lens being situated adjacent said first collimator doublet lens, so that the optical axis of said second collimator doublet lens is substantially collinear with the optical axis of the first collimator double lens,

said second collimator doublet lens having a selected diameter and a selected optical power,

wherein said first and second collimator doublet lenses cooperate to image the object points substantially to infinity so that light transmitted by the second collimator doublet lens from the object points is substantially collimated.

15. A stereoscopic apparatus in accordance with claim 4, wherein said collimator lens system comprises a gradient index lens providing substantially the same optical output as a doublet lens in imaging the object points substantially to infinity.

16. A stereoscopic apparatus in accordance with claim 4 wherein said collimator lens system comprises,

a first collimator singlet lens proximate the objective end for collecting light from points on the object,

a first collimator doublet lens for collecting light from said first collimator singlet lens, and

a second collimator singlet lens proximate to said first collimator doublet lens for collecting light from said first collimator doublet lens,

said collimator singlet lenses and said collimator doublet lens all having colinear optical axes and wherein said first and second collimator singlet lenses and said first collimator doublet lens cooperate to image the object points substantially to infinity.

17. A stereoscopic apparatus in accordance with claim 4 wherein said collimator lens system comprises,

a first collimator singlet lens proximate the objective end for collecting light from points on the objective,

a second collimator singlet lens for collecting light from said first collimator singlet lens, and

a first collimator doublet lens proximate said second collimator singlet lens for collecting light from said second collimator singlet lens, wherein said first and second collimator singlet lenses and said first collimator doublet lens cooperate to image the object points substantially to infinity.

[57] **ABSTRACT**

An objective optical system for endoscopes comprising, in the order from the object side, a front negative lens unit, an aperture stop, a positive lens unit comprising at least one positive lens component, and an infrared cut filter arranged immediately before said aperture stop, said objective optical system being adapted so as to allow rays to be incident on said filter at heights lower than the outside circumference of said filter.

OBJECTIVE LENS SYSTEM FOR ENDOSCOPES

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to an objective lens system for endoscopes.

2. Description of the Prior Art

As an objective lens system for endoscopes, there is known the lens system disclosed by Japanese Patent Kokai Publication No. Sho 62-173415. This objective lens system has defects that the lens system has a long total length, that the outside diameter of the lens system is large as compared with the diameter of an image formed thereby, and so on.

Further, as another conventional example of objective lens systems, there is also known the lens system disclosed by Japanese Patent Kokai Publication No. Sho 63-26123. This objective lens system has defects that the lens system has a narrow field angle and that the lens system produces remarkable distortion which deforms the marginal portion of an image formed thereby.

Furthermore, used as endoscopes are fiber scopes which use image guides and, in addition, video scopes which use solid-state image pickup devices such as CCD's in the distal ends thereof.

In the recent years where video scopes have smaller outside diameters owing to compacter designs of image pickup devices, there are developed video scopes for observing interiors of bronchial tubes and urinary organs.

Video scopes do not permit reproducing colors or images formed on the monitors therefor since the solid-state image pickup devices have sensitivity not only to visible rays but also to infrared rays. It is therefore necessary to arrange filters for shielding the infrared rays in the optical systems of video scopes. Further, when a laser ranging from near infared to far infrared regions is used for medical treatment through video scopes, the laser saturates the CCD's, thereby hindering observation of locations to be treated due to smear and blooming. It is therefore necessary to arrange filters for cutting off wavelengths of the laser in the objective optical systems.

Thickness of the infrared cut filters, CCD cover glass, laser shielding filters, etc. remains unchanged even after the image pickup devices have compacter designs and the optical systems have shorter focal lengths. Accordingly, the optical path lengths as measured in the direction of the thickness of the filters are long relative to the focal lengths.

As an objective lens system for endoscopes comprising filters in the optical system thereof, there is known the lens system which has the composition illustrated in FIG. 1. This optical system is usually of the retrofocus type and satisfies the following relationship.

$$I=f\sin\theta$$

wherein the reference symbol I represents the image height, the reference symbol f designates the focal length of the optical system and the reference symbol θ denotes the half field angle of the optical system.

In order to arrange filters, F_1, F_2 and a cover glass C which have long optical path lengths as compared with the focal length f in this type of lens system, it is necessary to select a high retro ratio (a value obtained by dividing the distance as measured from the final surface to the image surface of a lens system by the focal length thereof). When a high retro ratio is selected, without prolonging total length, for a lens system which has a short total length, each of the lens components has strengthened power, thereby making it difficult to correct aberrations. Since focal length of the lens system is further shortened especially by widening field angle thereof, it is impossible to widen the field angle of the lens system.

When an attempt is made to correct aberrations favorably in this type of lens system, the lens system comprises a larger number of lens components, a longer total length accordingly and becomes unsuited for use with endoscopes for observing interiors of thin tubes.

The absorption type of infrared cut filters are usually made of phosphate glass materials. Since the phosphate glass materials have low resistance to humidity, these materials must always be coated so as to prevent contact with ambient air. The coated filters may be injured on the circumferences thereof or the coating may peel off and, in such a condition, the injured portion is exposed to ambient air and may allow the filters to become whitely turbid from the marginal portions thereof. It is necessary to design the filters in such a manner that rays are incident on the filters at the portions rather lower than the outside diameters of the filters. However, in the above-described type of lens system wherein the two filters F_1 and F_2 are arranged before the CCD cover glass C, rays are incident on the filters at heights which are nearly the same as the image height or higher than the image height, and since the filters are arranged at locations where rays are highest in the lens system, it is impossible to set the heights of rays at levels sufficiently lower than the diameters of the filters.

SUMMARY OF THE INVENTION

A primary object of the present invention is to provide an objective optical system for endoscopes which has a short total length, a small outside diameter, a wide field angle and favorably corrected distortion.

Another object of the present invention is to provide an objective optical system for endoscopes having a short total length and comprising filters on which rays are incident at low portions thereof.

A further object of the present invention is to provide a video endoscope equipped with the objective optical system described above in the distal end thereof.

The objective optical system for endoscopes according to the present invention consists of a front lens unit comprising a lens component having negative refractive power and a rear lens unit comprising a positive lens element which are arranged with an aperture stop interposed therebetween, each of said front lens unit and said rear lens unit comprising at least one aspherical surface, said front lens unit satisfying either of the following conditions (A) and (B), said rear lens unit satisfying either of the following conditions (C) and (D), and said objective optical system satisfying the following condition (E):

(A) The aspherical surface which has a shape including portions having curvature progressively enhanced as the portions are farther from the optical axis is arranged as an object side surface in said front lens unit.

(B) The aspherical surface which has a shape including portions having curvature is progressively lowered

as the portions are farther from the optical axis is arranged as an image side surface in said front lens unit.

(C) The aspherical surface which has a shape having curvature is progressively lowered as the portions are farther from the optical axis is arranged as an object side surface in said rear lens unit.

(D) The aspherical surface which has a shape including portions having curvature progressively enhanced as the portions are farther from the optical axis is arranged as an image side surface in said rear lens unit.

(E) $0.2f<D_A<8f$ wherein the reference symbol D_A represents the optical path length as measured from the aperture stop to the aspherical surface arranged in the rear lens unit.

Description will be made below on the reason why both distortion and curvature of field are corrected sufficiently favorably in the objective optical system for endoscopes using the aspherical surfaces as explained above.

The conventional objective optical system, for endoscopes having the composition illustrated in FIG. **1** produces strongly negative distortion because the principal ray is refracted, as image height increases, by the front lens unit and the rear lens unit in the direction to widen the field angle when the principal ray is traced inversely from the image side. It is therefore possible to correct the strongly negative distortion by arranging an aspherical surface which weakens refractive power for the principal ray as the surface portions are farther from the optical axis.

For this purpose, it is sufficient to design an object side surface on a lens component arranged in the front lens unit so as to include portions whose curvature is enhanced as the portions are farther from the optical axis, to design an image side surface of a lens component arranged in the front lens unit so as to include portions whose curvature is lowered as the portions are farther from the optical axis, to design an object side surface of a lens component arranged in the rear lens unit so as to include portions whose curvature is lowered as the portions are farther from the optical axis or to design an image side surface of a lens component arranged in the rear lens unit so as to include portions whose curvature is enhanced as the portions are farther from the optical axis.

The surfaces illustrated in FIG. **2** and FIG. **3** are also included among the surfaces whose curvature is progressively enhanced as the surface portions are farther from the optical axes. Sign of curvature is considered as positive when the center of the spherical surface in contact with the aspherical surface of interest at a certain point is located on the object side of the aspherical surface or as negative when the center of the spherical surface in contact with the aspherical surface at a certain point is located on the image side of the aspherical surface. Therefore, FIG. **2** shows an example of aspherical surface whose curvature is progressively enhanced as the surface portions are farther from the optical axis (when the signs of curvature are taken into consideration, the negative curvature of a surface concave on the object side is enhanced to the positive curvature of a surface convex on the object side). In the example shown in FIG. **3**, curvature is once enhanced and then is lowered. The aspherical surface shown in FIG. **3** is usable for correcting distortion since undulation of a distortion curve as shown in FIG. **4** is practially allowable, and the marginal portion of the aspherical surface through which the lower ray passes but the principal ray does not pass has no relation to the correction of distortion.

FIG. **5** and FIG. **6** exemplify surfaces whose curvature is progressively lowered as the surface portions are farther from the optical axis.

As is understood from the foregoing description, the aspherical surface to be arranged in the front lens unit of the objective optical system for endoscopes according to the present invention is a surface, which may be such an aspherical surface as that shown in FIG. **2** or FIG. **3**, including at least portions whose curvature is progressively enhanced as the portions are farther from the optical axis when the aspherical surface is designed as an object side surface of a lens element, or a surface, which may be such a surface as that shown in FIG. **5** or FIG. **6**, including at least portions whose curvature is progressively lowered as the portions are farther from the optical axis when it is designed as an image side surface of a lens element. The objective lens system comprising at least one aspherical surface such as that described above is capable of favorably correcting distortion.

Shape of an aspherical surface can generally be expressed by the following formula (i):

$$x = \frac{Cy^2}{1+\sqrt{1-pC^2y^2}} + By^2 + Ey^4 + Fy^6 + Gy^8 + \ldots$$

wherein the reference symbols x and y represent coordinates values when the optical axis is taken as the abscissa, the direction toward the image is taken as positive, the intersection between the optical axis and the aspherical surface is taken as the origin, and the direction perpendicular to the abscissa is taken as the ordinate as shown in FIG. **7**, the reference symbol C designates the inverse number of the radius of curvature of the circle in contact with the aspherical surface in the vicinity of the optical axis, the reference symbol p denotes the conical constant, and the reference symbols B, E, F, G, . . . represent the aspherical surface coefficients of the second order, fourth order, sixth order and eighth order respectively.

In the objective optical system for endoscopes according to the present invention, it is desirable that departure between the plane surface and the aspherical surface used as the extremely object side surface of the front lens unit, i.e., values of the aspherical surface coefficient of the fourth order E and the aspherical surface coefficient of the sixth order F satisfy at least either of the following conditions (5) and (6):

$$0.0006/f^3<E<0.6/f^3 \quad (5)$$

$$0.0001/f^5<F<0.1/f^5 \quad (6)$$

In order to correct distortion sufficiently favorably by the aspherical surface used in the front lens unit, $0.0006/f^3$ must be smaller than the value of E. That is to say, distortion cannot be corrected sufficiently favorably when the lower limit of the condition (5) is exceeded. If the upper limit of the condition (5) is exceeded, in contrast, it will be impossible to correct astigmatism and the lens element can be difficultly manufactured.

Further, it is possible to correct distortion by selecting a value of F so as to satisfy the condition (6). If the lower limit of the condition (6) is exceeded, distortion

will be corrected insufficiently. If the upper limit of the condition (6) is exceeded, in contrast, it will be impossible to correct astigmatism sufficiently and the lens element can hardly be manufactured.

When only distortion is to be corrected in a lens system such as the objective optical system for endoscopes according to the present invention, it is sufficient to arrange the above-described aspherical surface only on either side of the aperture stop. In such a case, however, the meridional curvature of field will be largely swollen at the intermediate image height and image quality will be remarkably degraded. When an aspherical surface is arranged in each of the front lens unit and the rear lens unit, the meridional curvature of field due to the aspherical surface arranged in the front lens unit and the meridional curvature of field due to the aspherical surface arranged in the rear lens unit are swollen in the direction reverse to each other and cancelled with each other, thereby effacing the swelling in the optical system as a whole.

In the objective optical system for endoscopes according to the present invention, it is desirable that the aspherical surface arranged in the rear lens unit satisfies the following condition (7):

$$0.2f < D_A < 8f \tag{7}$$

wherein the reference symbol D_A represents the optical path length as measured from the aperture stop to the aspherical surface, said optical path length including, when a lens is interposed in the section, a value obtained by dividing thickness on the optical axis by the refractive index thereof.

By arranging the aspherical surface in the rear lens unit at a location rather close to the aperture stop, it is possible to reserve a large difference between the heights of the upper ray and the lower ray passing through the aspherical surface and accordingly to obtain an advantage for correction of coma. If the aspherical surface is too close to the aperture stop, however, correction of astigmatism will undesirably become difficult.

Let us now define Seidel's aberrations as expressed by the formulae (ii) and (iii) to be described later. These definitions are the same as those adopted for the universal lens design program ACCOS-V. When the object distance is represented by OB, the numerical aperture of the marginal ray is designated by NA and the refractive index of the medium located on the object side of the first lens surface is denoted by n_0, ACCOS-V determines the height of ray on the first surface by the following formula:

$$H_0 = OB \times \tan\{\sin^{-1}(NA/n_0)\}$$

In contrast, the present invention determines the height of ray H: by the following formula:

$$H_0 = OB \times (NA/n_0)$$

Accordingly, each of the aberration coefficients is determined in the present invention by performing the paraxial tracing on the basis of H_0 calculated as $H_0 = OB \times (NA/n_0)$. NA is taken as $\frac{1}{2}$FNO.

Speaking more concretely, the aberration coefficient for the meridional ray ($\overline{X}=0$) is calculated by the formula (ii), whereas the aberration coefficient for the sagital ray ($\overline{Y}=0$) is calculated by the formula (iii):

$$\Delta Y = (SA3)\overline{Y}^3 + (CMA3)\overline{Y}^2\overline{H} + \{3(AST3) + (PTZ3)\}\overline{Y}\overline{H}^2 + (DIS3)\overline{H}^3 + (SA5)\overline{Y}^5 + (CMA5)\overline{Y}^4\overline{H} + (TOBSA)\overline{Y}^3\overline{H}^2 + (ELCMA)\overline{Y}^2\overline{H}^3 + \{5(AST5) + (PTZ5)\}\overline{Y}\overline{H}^4 + (DIS5)\overline{H}^5 + (SA7)\overline{Y}^7 \tag{ii}$$

$$\Delta X = (SA3)\overline{X}^3 + \{(AST3) + (PTZ3)\}\overline{X}\overline{H}^2 + (SA5)\overline{X}^5 + (SOBSA)\overline{X}^3\overline{H}^2 + \{(AST5) + (PTZ5)\}\overline{X}\overline{H}^4 + (SA7)\overline{X}^7 \tag{iii}$$

In the above-mentioned formula (ii), the reference symbol ΔY represents deviation between the paraxial image point (the image point in the aplanatic condition) and the actual image point, the reference symbol $\overline{Y}$ designates the position of incidence of the paraxial principal ray on the image surface normalized to the maximum image height and the reference symbol F denotes the position of incidence of the marginal ray on the pupil surface normalized to the pupil diameter. Further, the reference symbols SA3, SA5 and SA7 represent spherical aberrations of the third order, fifth order and seventh order respectively, the reference symbols CMA3 and CMA5 designate the tangential comas of the third order and fifth order respectively, the reference symbols AST3 and AST5 denote astigmatisms of the third order and fifth order respectively the reference symbols PTZ3 and PTZ5 represent Petzval's sums of the third order and fifth order respectively, the reference symbols DIS3 and DIS5 designate distortion of the third order and fifth order respectively, the reference symbol TOBSA denotes tangential oblique spherical aberration of the fifth order, the reference symbol ELCMA represents elliptic coma of the fifth order, and the reference symbol SOBSA designates sagital oblique spherical aberration of the fifth order.

When the i'th surface in the rear lens unit is designed as an aspherical surface, it can be considered that the i'th surface is obtained by deviating the spherical surface (the reference sphere) for a predetermined distance. Let us represent the coma of the third order produced by the reference sphere by Si, designate the coma of the third order produced by the deviation from the reference sphere by Ai, and denote the values obtained by normalizing Si and Ai to F number by ARi and SRi respectively.

When a plural number of aspherical surfaces are arranged in the rear lens unit, the coma coefficients are expressed as follows:

$$A_R = \Sigma ARi$$

$$S_R = \Sigma SRi$$

When a total of the coefficients of coma of the third order produced by surfaces having negative refractive power in the front lens unit is represented by A_2, it is desirable that the front lens unit satisfies the following conditions (8) and (9):

$$-13 < A_2/(A_R + S_R) < -0.03 \tag{8}$$

$$-0.2 < A_R < 0.2 \tag{9}$$

Since an objective lens system for endoscopes generally comprises surfaces having strongly negative refractive powers in the front lens unit for obtaining a wide field angle, remarkable coma is produced by these sur-

faces. It is therefore necessary to cancel this coma with the aberration produced in the rear lens unit so that coma is corrected favorably in the objective lens system as a whole. In addition, when the first lens component consists of a plural number of lens elements as illustrated in FIG. **8** through FIG. **10**, the air-contact surface located on the image side has strongly negative refractive power in the case shown in FIG. **8** or FIG. **10** wherein the lens component consists of lens elements cemented to each other, whereas the image side surface of the lens element arranged on the object side has the strongly negative refractive power in the case shown in FIG. **9** wherein the elements of the first lens component are separated from each other. It is necessary to cancel the negative coma produced by these surfaces with the aberration produced in the rear lens unit. It is therefore desirable that A_2 and (A_R+S_R) are equal to each other in the absolute values thereof and have signs which are reverse to each other. From the viewpoint of practical use, however, it is sufficient that $A_2/(A_R+S_R)$ is within the range defined by the condition (8).

Further, if A_R has too large a value, the other aberrations will be aggravated and can hardly be corrected. If A_R has too small a value, in contrast, it will be impossible to correct the coma produced by the front lens unit. It is therefore desirable that A_R has a value within the range defined by the condition (9).

Now description will be made on an objective optical system according to the present invention which is characterized in location of a filter. Speaking concretely, the optical system consists, in the order from the object side, of a front lens unit having negative refractive power, an aperture stop and a rear lens unit which has positive refractive power and comprises at least one positive lens component, and comprises either an infrared cut filter or a filter for shielding laser arranged immediately before the aperture stop.

By composing the objective optical system as described above, the present invention has succeeded in shortening total length of the optical system and lowering height of the ray incident on said filter, thereby obtaining high resolution.

In order to reserve a space for arranging the filter immediately before the aperture stop, it is necessary to design the front lens unit so as to satisfy the following condition (10):

$$0.3<|f_1/f|<4.0 \quad (10)$$

wherein the reference symbol f_1 represents the focal length of the front lens unit and the reference symbol f designates the focal length of the objective optical system as a whole.

If the lower limit of the condition (10) is exceeded, the airspace reserved between the rear lens unit and the front lens unit will be narrowed, thereby making it difficult to arrange the filter immediately before the aperture stop. If the upper limit of the condition (10) is exceeded, the airspace reserved between the rear lens unit and the front lens unit will be too wide, thereby undesirably prolonging the total length of the objective optical system.

Further, it is desirable that the rear lens unit satisfies the following condition (11):

$$I/f_2<0.64 \quad (11)$$

wherein the reference symbol f_2 represents the focal length of the rear lens unit and the reference symbol I designates the maximum image height.

The condition (11) is required for limiting the angle of incidence of the offaxial ray on the filter arranged immediately before the filter.

When the angle of incidence exceeds 40°, transmittance of an interference filter, which is to be used as said infrared cut filter, is abruptly enhanced for the rays in the infrared region and the filter cannot cut off these rays. Further, when an absorption filter is to be used as the infrared cut filter, optical path length in terms of glass thereof is largely different dependently on image heights, thereby producing color ununiformity on the image. Therefore, it is necessary to select a small angle of incidence on the infrared cut filter which may be either an interference filter or an absorption filter.

If the upper limit of the condition (11) is exceeded, the principal ray will have an undesirably large angle of incidence on the filter.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** shows a sectional view illustrating the conventional objective optical system for endoscopes;

FIG. **2** and FIG. **3** show sectional views illustrating examples of aspherical lens elements having aspherical surfaces on the object side;

FIG. **4** shows a curve illustrating an example of distortion;

FIG. **5** and FIG. **6** show sectional views illustrating examples of aspherical lens elements having aspherical surfaces on the image side;

FIG. **7** shows a diagram illustrating the coordinates system for the formula of aspherical surface;

FIG. **8** through FIG. **10** show sectional views illustrating examples of the front lens unit of the objective optical system according to the present invention;

FIG. **11** through FIG. **26** show sectional views illustrating Embodiments 1 through 16 of the objective optical system for endoscopes according to the present invention;

FIG. **27** through FIG. **42** show curves illustrating aberration characteristics of the Embodiments 1 through 16 of the present invention;

FIG. **43** shows a sectional view illustrating refracted condition of a ray in the objective optical system for endoscopes according to the present invention;

FIG. **44** shows curves illustrating relationship between inclination angle of the principal ray and amounts of aberrations;

FIG. **45** shows a sectional view illustrating an example of wide-angle camera lens system; and

FIG. **46** shows a sectional view illustrating refracted condition of the principal ray in the optical systems preferred as the Embodiments 5 through 10 of the present invention.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

Now, the present invention will be described more detailedly below with reference to the preferred embodiments shown in the accompanying drawings and given in the form of the following numerical data:

wherein the reference symbol r_1, r_2, . . . represent radii of curvature on the surfaces of the respective lens elements, the reference symbols d_1, d_2, . . . designate thicknesses of the respective lens elements and the airspaces reserved therebetween, the reference symbols n_1, n_2, . . . denote refractive indices of the respective lens elements, and the reference symbols ν_1, ν_2, . . . represent Abbe's numbers of the respective lens elements.

The Embodiments 1 through 6 have the compositions illustrated in FIG. **11** through FIG. **16** respectively.

Out of these embodiments, each of the Embodiments 1 through 5 comprises a positive lens component which is arranged in the front lens unit before the aperture stop and designed as a cemented doublet satisfying the condition (3).

The Embodiments 7 and 8 have the compositions illustrated in FIG. **17** and FIG. **18** respectively wherein an absorption filter for cutting off the infrared rays is arranged immediately before the aperture stop and an interference filter for cutting off laser is arranged after the cemented doublet. The Embodiment 7 and 8 satisfy the following condition (12) in addition to the conditions (10) and (11):

$$1.0 < D/f < 5.0 \quad (12)$$

wherein the reference symbol D represents the optical path length as measured from the image side surface of the cemented doublet to a solid-state image pickup device.

The condition (12) defines the airspace required for arranging the filter arranged after the cemented doublet. If the lower limit of the condition (12) is exceeded while maintaining a short total length of the objective optical system, it will be impossible to reserve the airspace for arranging the filter and each lens surface will have strengthened power, thereby making it difficult to correct aberrations. If the upper limit of the condition (12) is exceeded, the airspace reserved between the optical system and the solid-state image pickup device will be too wide and the total length of the optical system will be prolonged.

The Embodiments 7 and 8 satisfy the conditions (10) through (12). Further, in the Embodiment 7, the offaxial principal ray has an angle of incidence of 25.3° on the front filter and an angle of incidence of 5.6° on the rear filter. Furthermore, when image height on the solid-state image pickup device is taken as 1, height of the offaxial principal ray on the absorption filter used as the infrared cut filter is approximately 0.35. In the Embodiment 8, the offaxial principal ray has an angle of incidence of 28.4° on the front filter and an angle of incidence of 2.5° on the rear filter, and height of the offaxial principal ray on the infrared cut filter is approximately 0.4 when the image height on the solid-state image pickup device is taken as 1.

The Embodiments 7 and 8 are designed so as to satisfy the conditions (10) through (12), and have short

total lengths, small angles of incidence on the filters or low heights of rays, and favorably corrected aberrations.

The Embodiments 9 and 10 have the compositions illustrated in FIG. **19** and FIG. **20** respectively, in each of which an interference filter for cutting off laser is arranged immediately before the aperture stop, and an absorption filter for cutting off the infrared rays is arranged between the positive lens component and the cemented doublet.

The Embodiments 9 and 10 satisfy the following conditions (13) and (14) in addition to the conditions (10) and (11):

$$0.5<f_{21}/f_2<3.0 \quad (13)$$

$$0.5<f_{22}/f_2<5.0 \quad (14)$$

wherein the reference symbol f_{21} represents the focal length of the positive lens component arranged immediately after the aperture stop and the reference symbol f_{22} designates the focal length of the cemented doublet.

The condition (13) is required for lowering the heights of the rays incident on the filter arranged after the aperture stop and the cemented doublet. The airspace reserved between the positive lens component arranged immediately after the aperture stop and the cemented doublet is defined by satisfying the conditions (13) and (14).

If the upper limit of the condition (13) is exceeded, the rays incident on the filter arranged after the aperture stop and the cemented doublet are enhanced, thereby making it necessary to enlarge the diameter of the lens system and making the lens system unsuited for use as an objective lens system for endoscopes. Further, ray incident on the cemented doublet is enhanced, thereby making it difficult to correct coma.

If the lower limit of the condition (14) is exceeded, the positive lens component arranged immediately after the aperture stop will have too strong power and produce spherical aberration.

In order to lower the height of the rays incident on the filter arranged after the aperture stop and the cemented doublet, and to make the optical system compact, it is desirable to design the objective optical system so as to satisfy the conditions (13) and (14).

In the Embodiment 9, the offaxial principal ray has an angle of incidence of 21.7° on the filter arranged before the aperture stop and an angle of incidence of 13.7° on the filter arranged after the aperture stop, and the image height on the infrared cut filter is approximately 0.55 when the image height on the solid-state image pickup device is taken as 1.

In the Embodiment 10, the offaxial principal ray has an angle of incidence of 22.3° on the front filter and an angle of incidence of 14.9° on the rear filter, and height of the offaxial principal ray on the infrared cut filter is approximately 0.6 when the height of the offaxial ray on the solid-state image pickup device is taken as 1.

As is understood from the foregoing description, the Embodiments 9 and 10 which are designed so as to satisfy the conditions (10), (11), (13) and (14) are optical systems having short total lengths, small angles of incidence on the filters or low heights of rays, and favorably corrected aberrations.

The Embodiments 11, 12 and 13 have the compositions illustrated in FIG. **21** through FIG. **23**, are of the type similar to the Embodiments 9 and 10, and use two aspherical surfaces respectively.

The Embodiments 7 through 10 are of the type consisting only of spherical lens elements. In the objective optical system of this type or the optical system shown in FIG. **43**, comparison between inclination angle θ relative to the optical axis of the principal ray P which is incident on the lens component L_1 arranged on the object side of the aperture stop and inclination angle θ' relative to the optical axis of the principal ray P which emerges from the lens component L_1 and is incident on the lens unit L_2 (comprising at least one positive lens component) located on the image side of the aperture stop, will clarify that θ' is prettily smaller than θ. This is apparent also from the fact that the lens component L_1 has a negative function for widening the field angle.

In the optical system having the above-described characteristic, it is known that there establishes between θ' and aberrations the relationship described below. When θ' is small, curvature of field, astigmatism and distortion are produced in small amounts, whereas spherical aberration is produced in a relatively large amount. FIG. **44** illustrates this relationship. Accordingly, it is sufficient that spherical aberration and coma are corrected when the pupil located between the lens unit L_2 having positive refractive power and the lens component L_1 having positive refractive power is considered as an object, and that the sine condition is satisfied.

The sine condition is described as follows:

When image height is represented by I, the focal length of the lens unit L_2 is designated by f_2 and the inclination angle of the principal ray P incident on the lens unit L_2 relative to the optical axis is denoted by θ', the following formula establishes in a telecentric optical system wherein the principal ray P is incident perpendicularly on the image surface I:

$$I=f_2\sin\theta'$$

When the lens component L_1 consists only of spherical lens elements as shown in FIG. **43**, departure from the sine condition is little even before the aperture stop S. Accordingly, the following formula of the sine condition establishes:

$$I=f\sin\theta$$

wherein the reference symbol f represents the focal length of the objective optical system as a whole and the reference symbol θ designates the inclination angle of the principal ray P incident on the lens component L_1 relative to the optical axis.

Under the restrictions imposed on outside diameters of lens systems and numbers of lens elements, the sine condition is nearly satisfied by almost all of the objective optical systems for endoscopes which are used currently.

In the optical systems satisfying the sine condition, distortion increases abruptly as θ is widened as illustrated in FIG. **44**. Relationship between distortion and θ can be expressed by the following formula:

$$DT(\theta)=\cos\theta-1$$

wherein the reference symbol DT represents a value given by the following formula:

$DT=(y-y_0)/y_0\times 100\ (\%)$

wherein the reference symbol y represents size of an image deformed due to distortion and the reference symbol y_0 designates size of an ideal image calculated by the paraxial theory.

In an ordinary objective optical system for endoscopes to which the formula of the sine condition and formula of distortion DT(θ) apply, negative distortion (barrel-type distortion) increases abruptly as θ is enlarged.

Values of DT(θ) corresponding to various field angles 2θ in an objective optical system satisfying $I=f\sin\theta$ are tabulated below:

Field angle 2θ	80°	100°	120°	140°
Distortion DT(θ)	−23	−36	−50	−66 (%)

As is understood from the foregoing description, the conventional objective optical systems produce remarkable negative distortion though the optical systems satisfy the sine condition for meeting the essential requirements for objective optical systems for endoscopes, or the optical systems have wide field angles, telecentric compositions, favorably corrected aberrations and compact designs.

When an object is observed through the objective optical systems for endoscopes which produce distortion as described above, the marginal portions of images are distorted and smaller than the central portions. Accordingly, such optical systems do not permit accurate measurements or analyses of forms of industrial products when the optical systems are applied to industrial inspections. Further such objective optical system may be causes of erroneous diagnoses when applied in the medical field.

Furthermore, the following formula establishes for the optical systems which produce little distortion, for example, the wide-angle photographic camera lens system illustrated in FIG. **45**:

$$I=f\tan\theta$$

In an optical system for which the above-mentioned formula establishes, light amount on the image surface is reduced at a rate of $\cos^4\theta$ as value of θ increases. In case of the conventional objective optical system for endoscopes which produces the negative distortion, however, image size is reduced from the central portion toward the marginal portion, thereby cancelling the reduction of light amount at the rate of $\cos^4\theta$. Accordingly, brightness is kept constant regardless of enlargement of θ in the optical system satisfying $I=f\sin\theta$.

The objective optical system for endoscopes satisfying the sine condition has a characteristic that brightness is constant over the entire range of an image from the center to the marginal portion thereof. However, this optical system is undesirable in that it has distortion. In the optical system satisfying $I=f\sin\theta$, it is therefore necessary to correct the distortion to the level similar to that produced in an optical system satisfying the relationship of $I=f\theta$.

Distortion DT(θ) corresponding to various values of 2θ of the optical system satisfying $I=f\theta$ are tabulated below:

Field angle 2θ	80°	100°	120°	140°
Distortion DT(θ)	−17	−27	−39.5	−55.5 (%)

The Embodiments 11 through 16 are objective optical systems for endoscopes which are designed so as to have distortion corrected to levels sufficient for practical use regardless of large field angles, in addition to the merits of the Embodiments 7 through 10, and obtain image brightness substantially constant from the center to the marginal portion of images. The Embodiments 11 through 16 use aspherical surfaces for obtaining the above-described merits. Speaking concretely, the Embodiments 11 through 16 use the aspherical surfaces in the optical system shown in FIG. **46** so as to satisfy the following formulae (iv) and (v):

$$I=f_2\sin\theta_2 \tag{iv}$$

$$I=f\theta_2 \tag{v}$$

The formula (iv) is a condition required for correcting spherical aberration, coma, etc., and applies to the rear lens unit arranged after the aperture stop.

Accordingly, distortion is produced in the rear lens units of the Embodiments 11 through 16 as θ_2 is enlarged, but the distortion is not produced so remarkably since θ_2 has small values. Further, the optical system satisfying the formula (iv) provides brightness which is constant from the center of an image to the marginal portion thereof regardless of enlargement of θ_2.

The formula (v) applies to an optical system which satisfies $I=f\theta$ and produces little distortion.

The objective optical systems preferred as the Embodiments 11 through 16 are adapted so as to correct distortion to a level sufficient for practical use and provide images having constant brightness from the center to the marginal portion thereof by designing an optical system having a front negative lens unit which is arranged after the pupil position S and satisfies $I=f\sin\theta_1$ so as to satisfy $I=f\theta$ through use of aspherical surfaces without departing from the sine condition $I=f_2\sin\theta_2$.

In addition, the aspherical surfaces have shapes which are expressed by the above-mentioned formula (i).

The Embodiments 11 through 16 satisfy the following conditions (15) in addition to the conditions (10) and (11):

$$f_2/f>\theta(rad)/0.64 \tag{15}$$

wherein the reference symbol θ represents the half field angles of the objective optical systems for endoscopes.

The condition (15) defines the angle of the ray incident on the filter arranged immediately before the aperture stop when the aspherical surfaces are arranged in the objective optical systems for correction of distortion.

If f_2/f is smaller than θ(rad)/0.64 in the condition (15), the ray incident on said filter will undesirably have a large angle of incidence.

The Embodiments 11 through 13 satisfy the conditions (10), (11), (12) and (15), whereas the Embodiments 14 through 16 satisfy the conditions (10), (11), (13) and (14). All of these embodiments have short total lengths, small angles of incidence on the filters, distortion corrected to levels sufficient for practical use and provide

brightness constant from the centers to the marginal portions of images.

The present invention has succeeded in providing an objective optical system for endoscopes which has a compact size, a wide field angle and favorably corrected distortion by adequately arranging aspherical surfaces. Further, the present invention makes it possible to lower height of the ray incident on the filter relative to the outside diameter of the filter, thereby providing an objective optical system for endoscopes having high resolution.

The objective optical system according to the present invention is designed for use in distal ends of endoscopes, and owing to the characteristics described above, contributes to more compact designs of distal ends of endoscopes and improvement of qualities of images formed by optical systems for endoscopes.

We claim:

1. An imaging optical system for endoscopes comprising:

an objective lens system comprising a front lens unit consisting of a lens component having negative refractive power and a cemented lens component having positive refractive power, an aperture stop and a rear lens unit including only one lens component, said one lens component being a cemented lens component having a positive refractive power,

an electronic image pickup means for receiving images formed by said objective lens system, and

a filter for eliminating infrared light and a properly limiting spectral sensitivity of said electronic image pickup means,

wherein each of said front unit and said rear lens unit including at least one aspherical surface, said front lens unit satisfying one of the following conditions (A) and (B), said rear lens unit satisfying one of the following conditions (C) and (D), and said objective lens system satisfying the following condition (E):

(A) the front lens unit includes, as an object side surface, an aspherical surface which has a shape including portions having curvature that is progressively enhanced as the portions are farther from the optical axis of said objective lens system;

(B) the front lens unit includes, as an image side surface, an aspherical surface which has a shape including portions having curvature that is progressively lowered as the portions are farther from the optical axis of said objective lens system;

(C) the rear lens unit includes, as an object side surface, an aspherical surface which has a shape including portions having curvature that is progressively lowered as the portions are farther from the optical axis of said objective lens system;

(D) the rear lens unit includes, as an image side surface, an aspherical surface which has a shape including portions having curvature that is progressively enhanced as the portions are farther away from the optical axis of the objective lens system; and

(E) $0.2f < D_A < 8f$

wherein the reference symbol D_A represents an optical path length as measured from the aperture stop to the aspherical surface disposed in said rear lens unit.

2. An objective optical system for endoscopes according to claim **1** which said aspherical surface is expressed by the formula given below and satisfies the following conditions:

$$x = \frac{C_1^2}{1 + \sqrt{1 - pC^2y^2}} + By^2 + Ey^4 + Fy^6 + Gy^8 + \ldots$$

$$0.0006/f^3 < E < 0.6/f^3$$
$$0.0001/f^5 < F < 0.1/f^5$$

wherein the reference symbols x and y represent coordinates values when the optical axis is taken as the abscissa, the direction toward the image is taken as positive, the intersection between the optical axis and the aspherical surface is taken as the origin, and the direction perpendicular to the abscissa is taken as the ordinate, the reference symbol C designates the inverse number of the radius of curvature of the circle in contact with the aspherical surface in the vicinity of the optical axis, the reference symbol p denotes the conical constant, and the reference symbols B, E, F, G, . . . represent the aspherical surface coefficients of the second order, fourth order, sixth order and eighth order respectively.

3. An objective optical system for endoscopes according to claim **1** wherein said aspherical surfaces arranged in the front lens unit satisfies the following conditions:

$$-13 < A_2/(A_R + S_R) < -0.03$$

$$-0.2 < A_R < 0.2$$

wherein the reference symbol S_R represents the total sum of the coefficients of coma of the third order to be produced by the reference spheres for the aspherical surfaces, the reference symbol A_R designates the total sum of the coefficients of coma to be produced due to the departure of the aspherical surfaces from the reference spheres therefor and the reference symbol A_2 denotes the total sum of the coefficients of coma of the third order to be produced by the surfaces having negative refractive powers in the front lens unit.

4. An endoscope equipped with an objective optical system in the distal end thereof, said objective optical system consisting of, in the order from the object side,

a negative lens component,

an infrared light cut filter,

an aperture stop, and

a positive lens unit comprising at least one positive lens component.

5. An endoscope according to claim **4** satisfying the following condition (10):

$$0.3 < |f_1/f| < 4.0 \quad (10)$$

wherein the reference symbol f_1 represents the focal length of said negative lens unit and the reference symbol f designates the focal length of said optical system as a whole.

6. An endoscope according to claim **4** or **5** wherein another filter is arranged on the image side of the lens component arranged in said positive lens unit at a location nearest said aperture stop.

7. An endoscope according to claim **6** satisfying the following condition (11):

$I/f_2 < 0.64$ (11)

wherein the reference symbol f_2 represents the focal length of the rear lens unit and the reference symbol I designates the maximum image height.

8. An endoscope according to claim 7 comprising a solid-state image pickup device on the exit side of said objective optical system and satisfying the following condition (12):

$$1.0 < D/f < 5.0 \quad (12)$$

wherein the reference symbol D represents the optical path length as measured from the extremely image side surface of the objective optical system to the solid-state image pickup device.

9. An endoscope according to claim 7 wherein said objective optical system satisfies the following conditions (13) and (14):

$$0.5 < f_{21}/f_2 < 3.0 \quad (13)$$

$$0.5 < f_{22}/f_2 < 5.0 \quad (14)$$

wherein the reference symbol f_{21} represents the focal length of the lens element arranged on the extremely object side in said positive lens unit and the reference symbol f_{22} designates the total focal length of the lens components arranged on the image side of said another filter.

10. An endoscope according to claim 7 comprising at least one aspherical surface in said objective optical system satisfying the following condition (15):

$$f_2/f < \theta/0.64 \quad (15)$$

wherein reference symbol f represents the focal length of the objective optical system as a whole, reference symbol f_2 designates the focal length of the rear lens unit and reference symbol θ denotes the half field angle of the objective optical system.

11. An endoscope according to claim 8 comprising at least one aspherical surface in said objective optical system satisfying the following condition (15):

$$f_2/f < \theta/0.64 \quad (15)$$

wherein reference symbol f represents the focal length of the objective optical system as a whole, reference symbol f_2 designates the focal length of the rear lens unit and reference symbol θ denotes the half field angle of the objective optical system.

12. An endoscope according to claim 9 comprising at least one aspherical surface in said objective optical system satisfying the following condition (15):

$$f_2/f < \theta/0.64 \quad (15)$$

wherein reference symbol f represents the focal length of the objective optical system as a whole, reference symbol f_2 designates the focal length of the rear lens unit and reference symbol θ denotes the half field angle of the objective optical system.

13. An imaging optical system for endoscopes comprising:

an objective lens system comprising a front lens unit consisting of a lens component having negative refractive power and a lens component having positive refractive power, an aperture stop and a rear lens unit consisting of a lens component having positive refractive power and a cemented lens component having a positive refractive power,

an electronic image pickup means for receiving images formed by said objective lens system, and

a filter for eliminating infrared light and properly limiting spectral sensitivity of said electronic image pickup means,

wherein each of said front lens unit and said rear lens unit includes at least one aspherical surface, said front lens unit satisfying one of the following conditions (A) and (B), said rear lens unit satisfying one of the following conditions (C) and (D), and said objective lens system satisfying the following condition (E):

(A) the front lens unit includes, as an object side surface, an aspherical surface which has a shape including portions having curvature that is progressively enhanced as the portions are farther from the optical axis of said objective lens system;

(B) the front lens unit includes, as an image side surface, an aspherical surface which has a shape including portions having curvature that is progressively lowered as the portions are farther from the optical axis of said objective lens system;

(C) the rear lens unit includes, as an object side surface, an aspherical surface which has a shape including portions having curvature that is progressively lowered as the portions are farther from the optical axis of said objective lens system;

(D) the rear lens unit includes, as an image side surface, an aspherical surface which has a shape including portions having curvature that is progressively enhanced as the portions are farther away from the optical axis of the objective lens system; and

(E) $0.2f < D_A < 8f$

wherein the reference symbol D_A represents an optical path length as measured from the aperture stop to the aspherical surface disposed in said rear lens unit.

[57] **ABSTRACT**

An objective refractor having no moving parts is disclosed. The refractor, which can be either a hand held or table mounted instrument, includes a reference array and an interrogating array projected onto the eye fundus. The reference array is projected from light sources and the interrogating array is projected to light detectors. Both the reference array and the interrogating array are projected onto the fundus of the eye through preselected spaced apart regions of the eye lens. The movement of the reference array with respect to the interrogating array is observed. By the expedient of making at least two sequential observations utilizing at least three separate regions of the eye lens, the amount of relative pattern displacements can be reduced to a requisite optical prescription for the eye.

OBJECTIVE REFRACTOR

BACKGROUND OF THE INVENTION

This invention relates to refractors and specifically to an objective refractor having reduced sensitivity to ambient light and improved reliability coupled with lower cost of production.

SUMMARY OF THE PRIOR ART

The cornea of the eye refracts light observed onto a photosensitive image surface, the fundus of the eye. Objective refraction has heretofore consisted of observing from the outside of the eye, image patterns projected to the inside of the eye on the fundus. When these image patterns are optimally recognized, the objective refraction prescription is generated.

Because the fundus of eye is a photosensitive surface, the intensity of light used to interrogate the eye must be at a level where impairment of its photosensitive function does not occur. Consequently it is desired to maintain this interrogating light to a low level or to a spectral band having little photosensitive effect.

Objective refractors have heretofore required relatively moving parts such as lenses placed in the front of the eye for the generation of a corrective eye prescription. These lenses are changed or moved to optimize the view of an image on the fundus of the eye. These lens in front of the eye complicate the objective refraction by adding relatively expensive moving parts and adding refractive interfaces. Very little light incident on the retinal image ever leaves the eye and the addition of refractive interfaces and moving lens members makes the low level light image harder to observe.

In some cases, it is desirable to produce an objective refraction in the presence of intense light sources associated with surgical illumination or diagnostic instruments such as slit lamp systems. These severe ambient light conditions generally render such objective refraction nonoperational.

Accordingly, there is a need for an objective refractor operable with low levels of interrogating light useful in objective refraction of the eye even in the presence of strong ambient light. Further, there is a need to limit relatively moving parts to improve reliability and reduce cost.

SUMMARY OF THE INVENTION

An objective refractor having no relatively moving parts such as lenses for generating corrective prescriptions and a minimum of refractive optical interfaces is disclosed. The refractor, which can be either a hand held or table mounted instrument includes a reference array and an interrogating array projected onto the fundus of the eye. The reference array is the real image at the eye projected from light detectors; the interrogating array is the real image at the eye projected from light sources. Both the reference array and the interrogating array are projected from disclosed patterns where the arrays are interchangeable one with another. Both the reference array and the interrogating array are projected onto the fundus of the eye through spaced apart regions of the eye lens. The movement of the reference array relative to the interrogating array for each region of the eye lens is observed. By the expedient of utilizing at least three separate regions of the eye lens, the amounts of relative pattern displacement can be reduced to a requisite optical prescription of sphere, cylinder and axis for the eye. Preferred patterns of interrogation together with a microprocessor driven embodiment are disclosed.

The preferred interrogating arrays are generated through a "basket weave" or "brick" pattern in which rectangles having a ratio of being twice as long as they are wide are utilized. The rectangles alternate in axial alignment with the major axis and minor axes of adjacent rectangles being alternately disposed at 90° angles. These rectangles with their alternating alignments are separated one from another by a spatial separation of at least one half the minor width of the rectangles. This separation disposes the rectangles in a "basket weave" pattern. This basket weave pattern delimits the boundaries of LED illumination projected through the pattern of rectangles onto the fundus. The interrogating pattern is pupiled at points on the eye lens and expanded to present the interrogating pattern on the fundus.

The LEDs, disposed in an eye lens sampling array are preferably sequentially illuminated. These point sources of light are projected through the basket weave pattern, and have real images of the point sources of light projected to the lens of the eye. The projection of the real images of the LEDs to the eye in effect pupils the light sources at the eye lens on precisely controlled locations. Deflection of the interrogating pattern for each eye lens sample location relative to a reference pattern can be measured to determine prescription. Preferably, the LEDs are duty cycled on the basis of a predicted prescription. Hence each LED effects a sample of the eye lens at precise eye lens locations for each predicted prescription.

The reference array is projected centrally of the eye and overlies the interrogating arrays as the interrogating arrays are projected by each of the LEDs. The reference array is preferably formed out of five discrete aperture types. These five discrete aperture types have their real image projected centrally through the eye in a repeating pattern of the five detectors. The pattern is selected such that the displacement of the interrogating array relative to the reference array can be identified either by the direction of a vector produced from vector addition or alternately the phase of a temporal scan when the interrogating arrays and the reference array are duty cycled, one with respect to the other.

The displacement measurement between interrogating and reference arrays is insensitive to background illumination and consequently provides for rejection of ambient light. Once the deflection of the interrogating arrays relative to the reference array is measured utilizing at least three separate regions of the eye lens, an optical prescription for the eye can be generated in sphere, cylinder and axis.

A microprocessor driven embodiment of the invention is disclosed. The microprocessor accesses in look up table memory values of interrogating LED duty cycles for refractive power in the x meridian, refractive power in the Y direction, and two values of cross cylinder (one for the X direction and one for the Y direction). The eye is electronically interrogated for a peak signal as LED duty cycle entries from each table are sequentially swept through the possible range of prescriptions. Values of power in the X meridian and values of power in the Y meridian are preferably swept first. Maximum signal from both sphere values enable one component of cross cylinder to be computed. Assuming the determined values of sphere, the eye is then

swept in the remaining component of cylinder to determine objective prescription. A sequence of rapidly determining patient prescription in a automated mode is disclosed.

Other Objects, Features and Advantages

Because of the relative theoretical complexity of this instrument, the invention will be discretely analyzed. First, the configuration of the optical instrument will be discussed. Secondly, the configuration of the interrogating and referencing patterns will be set forth. The relative movement of these patterns will be disclosed as enabling optical prescription. Finally, and taking the case of one interrogating light emitting diode (LED), the duty cycle of the LED relative to the separate duty cycle of the detectors will be set forth.

Thereafter, I disclose the preferred method relating to the operation of the objective refractor. This method includes supplying a cluster of light emitting diodes, and adjusting the phase of the diodes to emulate the prescription of a patient. Methods for estimating the prescription of the patient, and generating the final prescription of the patient are discussed. A microprocessor driven embodiment is disclosed.

As part of the above disclosure, methods are discussed for eliminating ripple that may be generated by the disclosed phasing of the light sources and detectors. Reference is also made to an accompanying use of light sources in conjunction with a CCD camera to generate prescription, this latter system not now being preferred.

Configuration of the Instrument

An object of this invention is to set forth the configuration of an objective refractor for examining the human eye. The instrument includes an objective lens for producing a conjugate image plane of the fundus of the eye being examined. Interrogating and reference arrays are first projected to the fundus conjugate plane and thereafter relayed to and from the fundus of the eye by the objective lens to determine optical prescription.

The interrogating array comprises an array of light emitting diodes projected through a pattern. Each light emitting diode is focused or pupiled to precise points on an eye lens and thus interrogates different regions of the eye lens being examined. Likewise, the reference array is focused to or pupiled at the central portion of the eye lens being examined. Both the interrogating array and the reference array are relayed between the conjugate image plane of the eye and the fundus of the eye. At this point it should be made clear that although the interrogating array and reference array may be conjugate to the fundus plane for an emmetropic eye, this is not strictly the condition for eyes having other refractive states.

Each LED projects its own separate array of interrogating rectangles. Moreover, the LEDs are each given discrete cycle timing with respect to their position on the eye and the predicted prescription for the eye. These LEDs together produce cumulatively a maximum signal when the selected eye prescription duty cycle timing is appropriate to the actual eye prescription.

The reference array is typically an array of preferably five types of optical elements, each directing light to a corresponding detector element. This reference array is similarly projected to a plane near the conjugate plane of the fundus. Preferably a single reference array is relayed from the fundus conjugate through an aperture which localizes the light rays to a small central region of the eye lens. In this manner, the reference array is relayed to a position of overlap on the various interrogating arrays at the fundus.

The reference array reads the displacement of the interrogating arrays. The detector elements of the reference array are actuated to receive light with each detector element having its own sequential duty cycle with respect to the other detector elements to provide a sequence of interrogation. By establishing proper timing and duty cycle of the LEDs of the interrogating array with respect to the duty cycle of the detectors of the reference array, the prescription of the eye can be determined.

An advantage of the disclosed instrument is that it is capable of being configured in a small package. Consequently, the disclosed instrument can be conveniently "tree" mounted to the instrument pole in an eye examination office or alternatively hand held, or incorporated in a table mounted instrument.

A further advantage of the light emitting diode array is that the size of the pupil can be measured by the device. This pupil size measurement is a useful aside of the instrument herein disclosed.

A further object of the disclosed instrument is that the optical train can be readily altered to that of a keratometer. Accordingly, when the disclosed instrument operates as a keratometer, the objective lens is configured so as to relay the keratometer target images to a common image plane after reflection from the cornea.

A further advantage of the disclosed invention is that the examination of the eye at a matrix of sample points is possible. By the using of a multiplicity of such sample points, the entirety of a fully open pupil can be refracted. While it will be normal to refract the center of the eye lens and ignore the periphery, it should be understood that it is possible to determine the full optical effect of the eye lens, including the periphery, to monitor disease, such as keratoconus of the cornea or to establish the size of regional departures from the nominal refractive state of the eye.

Yet another advantage of this instrument is that the LEDs are duty cycled in their interrogation. Pulsing of the LEDs to short high intensity pulses is possible. Consequently, the LEDs can produce on the fundus light differentials that can be easily detected and seen over ambient light.

Yet another advantage of this invention is that the LEDs can be both cycled in their relative phase with respect to one another and with respect to the detector elements to generate a prescription sensitive signal having significant magnitude over background illumination. At the same time, the LEDs can be duty cycled for high common mode rejection of extraneous signals, especially so-called harmonics.

Configuration of Interrogating and Reference Patterns

A further object of this invention is to describe reference and interrogating patterns. These patterns, when projected to the fundus of the eye, deliver telltale displacement readings of the patterns one to another and enable accurate determination of eye refractive error.

Two distinct patterns are utilized, a reference pattern and an interrogating pattern. Either pattern may be configured to be a light source, and the other is used as a detector pattern for corresponding photosensitive elements. In a preferred embodiment the pattern comprises optical aperture patterns through which are pro-

jected light sources onto the eye lens. The reference pattern comprises a second optical aperture pattern which directs light returning from a region of the eye lens onto a set of light detectors. Since the first and second patterns are interchangeable, they will be discussed in this section without regard to the fact that they can be interrogating or detecting in character.

In the preferred embodiment, one pattern has elements in a matrix of two apertures. The pattern of the two apertures are essentially "stackable" or infinitely repeatable into a repeating array. These two apertures from which the large array of any desired size are constructed each comprise rectangles. The rectangle of one aperture has its major axis orthogonally aligned with respect to the rectangle of the other aperture. Half the area of the pattern is made up of these rectangular apertures in the preferred embodiment. The remaining area constitutes a boarder. Each aperture of each rectangle is preferably twice as long as it is wide and has an area that is 5/2nds of the area of elements of the remaining pattern. The rectangles are separated one from another by a boarder having one half the thickness of the minor axes of the rectangles.

Regarding the sensitivity of the so-called brick pattern, either each of the bricks may be provided with discrete sensitivity or the areas of the bricks can be given one sensitivity and the area of the boarders may be provided with a second and different sensitivity. Required sensitivity can be imparted by discrete optoelectric elements, color filters, or preferably by aperture elements capable of deflecting light rays such as arrays of refractive or reflective prisms.

The remaining pattern is composed of five discrete optical aperture types, each preferably with a square configuration. Each of the five aperture types is distinct from the remaining four. Such distinct qualities can be imparted by discrete optoelectric elements, color filters, or preferably by aperture elements capable at deflecting light rays such as an array of reflective or refractive prismatic components.

Each square area is preferably 2/5ths the area of a typical rectangle of the previous pattern. The discrete elements of the five element array are generated in a so-called "knights move" pattern; elements repeat in a "two forward, one to the side" pattern. In fact, the generated displacement pattern represents discrete square roots of a sum of squares equal to the total number of discrete elements used in the reference pattern.

The elements of the reference pattern are selected in such a way that each element of the five elements used has distinctly different neighbors bounding that element on each side. Furthermore, the array of the five apertures are essentially "stackable" or infinitely repeatable into a repeating array of any desired size.

Each element of the five element array when sequentially emphasized, as for example by being sequentially illuminated, causes advancing borders or "fronts" to move across the array. There is a first sequence of emphasis for X-axis sensitivity; there is a second sequence of emphasis for Y axis sensitivity. In the preferred five element array here shown, two sequences of illumination each produce substantially uniform fronts moving through the total array; one front for one sequence moving at right angles to the remaining front for the remaining sequence. It is the detection of these two discrete fronts by their varying degrees of overlap between the reference and interrogation patterns that enables the displacement between the two patterns to be detected.

Relative alignment of the arrays one to another is disclosed. The two element array has the major axis of the rectangle parallel or orthogonal to the progressively moving array fronts. Consequently, overlap of the two arrays results in temporally phased signals or vector directions which are highly sensitive to relatively small movements between the arrays. Consequently, relative motion between the arrays and hence prescription of the eye can be rapidly determined.

An object of this invention is to disclose a sequence of array activation of the preferred five element array. According to this aspect, the array is assigned five arbitrary letter designations, these designations constituting the letters A through E and being illustrated in FIG. 4. A pattern is activated or interrogated in the order AEDBC for sensitivity in one orthogonal direction and in the order ADCEB for sensitivity in the remaining orthogonal direction. (See FIG. 4)

Rules for the expansion of the squares of a matrix are set forth for determining arrays of varying numbers of apertures which are the sum of two squares, this sum not including any number less than five but including 5, 8, 9, 10, 13, 16, etc. A specific example of a matrix having 8 elements is illustrated, it being left to the reader to generate additional matrices in accordance with the teachings of this invention.

An advantage of the patterns is that they are readily interchangeable as either interrogating or reference patterns. For example, I prefer that the five element pattern be the light detecting, reference pattern. However, this pattern can also function as the illuminating or interrogating pattern, the only limitation being that one array illuminate or interrogate and the other detect or form the reference.

A further object of this invention is to disclose two modes of analyzing the relative overlap of the patterns. According to a first embodiment of this invention, one pattern is sequentially illuminated in a timed cycle. In such sequential illumination, the squares of the preferred embodiment are illuminated either singly or in adjacent sets. Responsive to this cyclical illumination, advancing fronts of light sweep across the array pattern in the disclosed orthogonal patterns. These advancing fronts of light having their orthogonal patterns are observed through apertures of the complementary array. Each displaced orthogonal pattern is discretely observed. The resultant phase angle only—and not the magnitude—of produced light modulation contain the requisite displacement information.

According to a second and preferred embodiment of analysis of overlap, the reference and interrogating arrays are duty cycled, one with respect to another, dependent upon the predicted prescription of the patient. The respective observation of overlap between the reference pattern and many interrogating patterns is simultaneously collected, as by prisms deflecting rays from the discrete areas to respective detectors. These respective detectors resolve the light received from the overlapping reference and interrogating patterns in a vector format. The resultant angle (and not the magnitude) of the resultant vector determines the relative pattern displacement.

An advantage of both embodiments of measuring relative pattern movement is that these techniques are not sensitive to amplitude and only sensitive to temporal phase or vector direction. Consequently, the pattern

displacement technique assists in rejection of ambient light.

An advantage of this interrogation is that phase or vector determination may be repeated more than once over the expected total deflections encountered for the refraction of the human eye. For example, over a 15 diopter range, three 360° rotations of phase or vector angle might be utilized. There results an expanding scale having greater accuracy.

A further advantage of this aspect is that by assuming spherical and cylindrical aberrations of the eye, it is possible to calculate expected phase angles corresponding to those observed for each interrogating pattern corresponding to various pupil positions. The sphere-cylinder combination which most closely simulates the observed vector phase angles for the various spared apart points in the pupil area represents the preferred refractive finding for the eye.

Yet another advantage of the disclosed technique of pattern overlap is that irregularities on the fundus are in effect averaged over a substantial area of the retina. For example, the structure of the macula lueta of the retina will not appreciably interfere with pattern displacement as its irregularity will be averaged over its surroundings.

A further object of this invention is to disclose a detector configuration that is relatively insensitive to high levels of ambient light. Accordingly, five photosensitive elements in the preferred configuration are each given distinct emphasis by corresponding subsets of directional prisms which make up the interrogating array. The photosensitive elements are synchronous rectifiers, these rectifiers being given polarity and sequence for optimum detection along displacement directions shown in orthogonal axes on the eye.

An advantage of the disclosed synchronous rectifier circuit is that by the expedient of varying the exciting LED duty cycle according to estimated prescription read out, cumulative detector sensitivity results. Assuming 24 interrogating LEDs, a correct prescription will generate 24 times the signal of a random and incorrect interrogation. Over conventional methods, the disclosed timing protocol achieves a sensitivity that utilizing a single interrogating LED would require an increase in sample time in the order of 500 times.

Yet another advantage of the disclosed strength of signal from the detectors is that background lighting is easily discriminated from the phase relation indicating the correct generation of prescription. Consequently, the instrument can be used in high levels of background illumination.

A further advantage of the preferred detector array is that filtering of the received signals to preselect precise frequencies is not required. The disclosed detector resolves vectors from the difference of received signals. The detector is not subject to variations of phase shift in the filters necessary for the resolution of phase in temporal detection formats.

Objective Refractor Operation

Regarding the cycle of the LEDs in their phase relative to one another, the eye is first grossly swept, preferably in sphere, to determine a gross eye prescription. A first sweep is made in meridional power in a first (say x) orthogonal direction; a second sweep in meridional power is made in the second and remaining orthogonal direction. Combining the results of these two sweeps, and resolving one component of cross-cylinder, a best predicted gross prescription is selected.

The LEDs are thereafter given cycle timing relative to the detector array dependent upon their point projection position on the pupil of the eye and the deflection to be expected at that portion of the eye for the gross predicted prescription. This cycle timing is imparted so as to give detectors coupled to the reference array a maximum signal when the prescription is correct. With these cycle timings, it is possible for many interrogating arrays to impact the reference array and its detector with a cumulative signal indicating the determination of the correct prescription. A highly sensitive protocol results which readily signals generation of the correct prescription and incorporates common mode rejection.

A further object of this invention is to disclose a sequence for determining from an estimated prescription the more exact and finally correct prescription. According to this aspect of the invention, the field of LEDs has its interrogating cycle timing shifted by 90° along a field dividing line. LEDs on a first side of the dividing line are shifted by a 90° phase in a first direction; LEDs on a second and opposite side of the dividing line are shifted by a 90° phase in a second direction. Comparison examination of the resulting signal after the phase shifts generates a so-called "discrimination function." This discrimination function indicates both the direction and approximate amount of correction required for determination of a final and correct prescription.

Yet another object of this invention is to disclose an interrogation sequence relative to the respective dividing lines utilized to generate the correct prescription. According to this aspect of the invention, detector array interrogation is made sensitive to displacement between the interrogating array and the detecting array along a first direction. Phase shifting for the determination of the successive merit functions is made as a function of LED position normal to and parallel to the chosen direction of detecting array sensitivity. Thereafter, detector array interrogation is made sensitive to displacement between the interrogating array and the detecting array along a second direction. Phase shifting for the determination of the successive merit functions is again made as a function of LED position normal to and parallel to the second chosen direction of sensitivity. Utilizing the disclosed interrogation sequence, final correct prescription of the eye can be objectively determined.

Regarding the duty cycling of the LEDs, a duty cycle scenario is set forth in which harmonics of significant and interfering proportion are eliminated. Specifically, a duty cycle is disclosed which rejects major contributing harmonics, these harmonics including for the major portion the third and fifth Fourier cosine components.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a side elevation schematic illustrating an examiner hand holding an instrument objectively refracting the eye of a patient, the instrument here being shown in outline form broken away so that the inner optical paths may be understood and described;

FIG. 2A is an optical schematic of the layout of FIG. 1 utilized for an explanation of FIG. 1;

FIG. 2B is an expanded perspective view of five element prism array used in the so-called reference capacity for causing the relay of images from each of

the detecting patterns to discrete detectors, this prism array producing the optical pattern that is illustrated in FIG. 4;

FIG. 2C is a perspective view of the two element interrogating array this two element array producing the optical pattern that is illustrated in FIG. 3;

FIG. 2D is perspective view of the cornea of a human eye with the projection of the point sources of the light emitting diodes imaged near the surface of the cornea, it being remembered that the respective patterns of FIGS. 4, 5A and 5B only become visible after the patterns are projected to the fundus of the eye;

FIG. 3 is a plan view of the interrogating pattern of the preferred embodiment of this invention, this pattern being projected from the pupil represented by each light source image on FIG. 2D to the fundus of the eye;

FIG. 4 is a plan view of the reference pattern of this invention, the illustrated plan view having superimposed thereon directions of displacement labeled "X" and "Y", this pattern being the pattern of detectors that are projected through the central portion of the eye shown in FIG. 2D to the fundus of the eye;

FIG. 5A is an overlay of the interrogating pattern on the reference pattern illustrating the predominance of the "B" elements for the particular displacement illustrated, this pattern being representative of one light emitting diode only;

FIG. 5B is an overlay of the interrogating pattern on the reference pattern illustrating the viewing by the patterns of a 180° phase shift from the element "B", this pattern being representative of an alternate light emitting diode but having a differing displacement because of a different point of incidence on the eye of FIG. 2D;

FIG. 5C is a phase timing diagram useful for understanding the sequence of interrogation of the interrogating array of FIG. 3 with the reference array of FIG. 4;

FIG. 6 is a set of temporal plots of the displacements illustrated in FIGS. 5A and 5B;

FIG. 7A is a set of vector plots of the displacements illustrated in FIGS. 5A and 5B;

FIG. 7B is an overlay in a manner similar to that illustrated in FIGS. 5A and 5B disclosing the use of an eight element reference array with an overlying interrogating array;

FIG. 8 is an electrical schematic of a detector system for determining the merit function or discriminator function, the detector here illustrated utilizing synchronous light sensitive detectors switched by computer driven analog switches for reading the reference array, the duty cycle of interrogation being taken from the phasing timing diagram of FIG. 5C;

FIG. 9A is a temporal plot illustrating the desired polarity of the light sensitive synchronous rectifiers for the signal to be read from a typical LED of a particular phase being illustrated below the temporal plot as a schematic temporal band of lights;

FIG. 9B is a vector plot of the phase of the typical LED as imparted through the synchronous rectifier network of FIG. 9A;

FIG. 10 is an optical schematic of an emmetropic eye with interrogating bands of light focusing at the retina, the figure showing in broken lines a so-called "far sighted" and "near sighted" configuration of the retina for explaining the need to produce phase shifts for interrogation of the eye;

FIG. 11A is a table figure identifying the so-called 5 omega Fourier component;

FIG. 11B is a graphical representation of the source of the so-called 3 omega Fourier component which constitutes a portion of the square wave, it being noted that both the component of FIG. 11A and 11B can be removed by appropriate phase or duty cycle shifting of the interrogating LEDs;

FIG. 12A is a schematic showing an LED field with a vertical dividing line normal to the horizontal direction of displacement sensitivity illustrating the shifting of the phase of the field on either side of the dividing line by opposite increments of 90° to obtain a so-called discriminator function for one component of meridional refractive correction;

FIG. 12B is a schematic showing the LED field of FIG. 12A with a horizontal dividing line parallel to the direction of displacement sensitivity illustrating the shifting of the phase of the field on either side of the dividing line by opposite increments of 90° to obtain a so-called discriminator function for the 45–135 so-called "oblique" component of eye correction;

FIG. 12C is a schematic showing the LED field of FIG. 12A with horizontal dividing line normal to the vertical direction of displacement sensitivity illustrating the shifting of the phase of the field on either side of the dividing line by opposite increments of 90° to obtain the second and final component of meridional power correction, it being noted that the scans illustrated in FIGS. 12A, 12B and 12C are sufficient in their total for the generation of a prescription;

FIG. 12D is a schematic similar to FIG. 12B showing the LED field of FIG. 11C with a vertical dividing line parallel to the direction of displacement sensitivity illustrating the shifting of the phase of the field on either side of the dividing line by opposite increments of 90° to obtain a so-called merit function for the 45°–135° so-called "oblique" component of eye correction, the information obtained being redundant to the information obtained in FIG. 12B; and,

FIG. 13 is a schematic of the objective refractor of this invention with attachments for keratometry attached so that the instrument has both objective refraction capabilities and keratometry capabilities.

FIG. 14A is a schematic diagram of the eye lens having a positive spherical correction;

FIG. 14B is a schematic diagram of the eye lens having negative spherical correction;

FIG. 14C is a schematic diagram of the eye lens having so-called 0°–90° cylinder;

FIG. 14D is a schematic diagram of an eye lens having so-called 45°–135° cylinder; and,

FIG. 14E is a schematic of an eye having unknown optical characteristics with the minimum of three points being illustrated on the eye for determination of the traditional measurements of sphere, cylinder and axis with one of the three illustrated points being delineated in X and Y values for determining applicable equations for the computation of sphere, cylinder and axis.

FIG. 15A is a diagram of meridian sphere power plotted against intensity, the diagram illustrating how peaking of the intensity of the received signal occurs when sweep of a value approximating that of the correct prescription along the X axis of eye interrogation occurs;

FIG. 15B is a diagram of meridional power plotted against intensity, the diagram illustrating how peaking of the intensity of the received signal occurs when sweep of a different value approximating that of the

correct prescription along the Y axis of eye interrogation occurs;

FIG. 15C is a diagram of the peaks illustrated in FIGS. 15A and 15B plotted on the same axis for meridional power with the difference in the peaks plotting as 0°-90° cross cylinder (presuming instrument alignment with the horizontal and vertical);

FIG. 16A is a microprocessor schematic illustrating microprocessor hardware for effecting the scanning sequence necessary to generate a prescription with the apparatus of this invention;

FIG. 16B is a memory schematic for use with the microprocessor of FIG. 16A illustrating of the necessary look-up tables for the determination of a prescription utilizing the apparatus and process herein disclosed; and,

FIG. 16C is a schematic of a circuit for effecting illumination of the interrogating LEDs utilized with this invention.

DESCRIPTION OF THE PREFERRED EMBODIMENT

With respect to FIG. 1, a doctor D is shown examining the eye E of a patient P with the hand held objective refractor R. Specifically, interrogating LEDs 14 (only one LED here being shown) project their light through a two element optical brick pattern 16 having the interrogating pattern illustrated in FIG. 3. Light from the LEDs proceeds and is deflected at mirror 18 onto an apertured beam splitter 20. Brick pattern 16 is imaged at a fundus plane conjugate 22 through the action of lens 21. Plane 22 is conjugate through objective lens 0 to the fundus F of eye E. Consequently, an image of optical brick 16 will appear on fundus F of the eye E of patient P. The reader will understand that more than one light source is utilized; consequently, there will be more than one image of the brick pattern on the eye fundus.

Light emitting diodes 14 are projected through lens 17. Lens 17, lens 21 and lens 0 relay an image of the diodes to the cornea C of the patient. Consequently, the image of brick pattern 16 is pupiled at cornea C. This pupil at cornea C enables the light to be incident upon the cornea C at precisely controlled points. Refraction of the light entering through different locations on the cornea causes the brick pattern 16 to appear at corresponding locations on the fundus, depending on the refractive error of the eye.

Having set forth the projection of the image, the receiving path for light returning from the fundus can now be set forth. Specifically, beam splitter 20 has central aperture and a lens 28 which is preferably chosen to relay to the fundus of a normal eye a prism array. As will hereinafter be more fully set forth, the prism array assigns to the discrete detectors the pattern illustrated in FIG. 4.

A detector plate 30 is mounted immediately behind beam splitter 20. Plate 30 includes an aperture 32 through which central rays pass. These central rays are incident at a prism array 34 backed by a mirror 35. (The reader will understand that either the prism array 34 or the mirror 35 may include refractive power.)

The prism array 34 and mirror 35 retroreflect and deflect portions of images from the conjugate plane 22 to the discrete detectors. This image is relayed from the fundus F of eye E of patient P.

The respective images are reflected and deflected to the discrete photodetector array at individual elements 41, 42, 43, 44, 45 on the back side of detector plate 30. It is the difference in signal received at respective photodetectors 41-45 which enables the displacement of the light pattern to be determined for each interrogating LED.

It will be noted that the apparatus is provided with a data display 50 for directly reading out to the eye examiner the observed prescription. This much will be set forth with respect to FIGS. 16A-16C illustrating the microprocessor circuitry utilized with this invention.

Having set forth the preferred instrument, the theory behind the operation of this invention can be further discussed with respect to the schematic illustrated in FIG. 2A-2D.

Referring to FIG. 2A, fundus F from eye E has objective 0 relay an image of the fundus to the conjugate image plane 22. As in FIG. 1, a lens 21 relays a conjugate image of the first array 16 to fundus conjugate 22. Further, a second lens 28 relays a conjugate image of prism array 34 to fundus plane 22. First array 16 is illustrated separately in an expanded view in FIG. 2C. Prism array 34 is likewise illustrated in an expanded view of FIG. 2B. A cornea is illustrated in FIG. 2D.

Prism array 34 is facetted to deflect light to the respective detectors 41, 42, 43, 44 and 45. This array will be more fully set forth with respect to FIG. 2*b* and FIG. 4.

It will be seen that LEDs include respective array 14. This array can be passed in the entirety through all of the apertures zones of FIG. 3. Array 14 can be passed through the rectangular zones (see I). Alternately, array 14 can be passed through the zones surrounding the rectangular zones. (See II)

The LEDs 14 are in turn relayed to the lens of the eye in pattern 64 by lens 17, 21 and 0. This relay images the LEDs as point sources of light near the plane of the cornea. Thus, the brick pattern 16 is pupiled to point sources of light on the surface of the eye E (see FIG. 2D).

The effect of this pupiling can be readily understood. Specifically, refraction by the eye lens and cornea C will cause light of the array to be deflected. This deflection will be a function of the pupil deflection occurring purely locally at the image points of the LEDs. Thus, the deflection of the rays forming the interrogation pattern will be a function of the local qualities of the lens of the eye at the image point for a particular LED element on the eye lens.

I have shown here the LEDs to be an array of six evenly spaced light emitting diodes, 14A, 14B, 14C, 14D, 14E and 14F. The reader will understand that a greater number of LEDs will be used; it is not possible with the limited space of the drawing of FIG. 2A and FIG. 2D to illustrate such an exemplary spacing. Representative spacings are shown in FIGS. 12A-12D.

Referring both the schematic of FIG. 2A and the expanded view of the eye shown in FIG. 2D, the reader will note that I have not shown an LED registered to the exact center of the cornea C. This reason is that at this exact center location, the reference array 15 is pupiled. This reference array measures the displacement of the various arrays 14A, 14B, 14C, 14D, 14E and 14F. Having a LED project an interrogating array from a light emitting diode through the same aperture as the reference array does not yield useful information as both deflections should theoretically be the same.

Arrays having numerous LEDs have an additional advantage. The total field of such arrays will be obscured at the edges by a partially dilated eye. By having

such obscured LED images, the diameter of the pupil, a useful piece of medical information, can be determined responsive to objective refraction in ambient light.

Having set forth the operative portions of the instrument, attention may now be directed to the preferred embodiments of the patterns of elements here utilized.

First, and referring to FIGS. 3 and 4, two interchangeable patterns of elements are disclosed. As will hereinafter become more fully apparent, in the preferred embodiment I utilize the pattern of elements shown in FIG. 3 as an interrogating pattern. This pattern of elements constitutes a grid through which the light emitting diodes are pupiled at the lens of the eye. This pattern appears on the retina, deflected from the pupiled position on the cornea responsive to the power of the eye lens.

Referring to FIG. 4, this pattern of elements is preferably used as the reference array. That is to say, it is a pattern of distinct light sensitive areas which serve to define a reference position at the retina of the eye. Each element of the array is made distinct by its own prism facet. Each prism facet—overlying a specific set of areas of the interrogating array at the fundus plane of the eye—causes the returning retinal reflex light to be directed into a set of discrete photodetectors.

The reader should understand that the composite instrument includes one reference array for reading many interrogating arrays corresponding to each interrogating LED.

Referring to FIG. 2B, a prism array has been illustrated. This prism array has discrete prism facets, labeled respectively A, B, C, D, and E. Prism facets A–E cooperate with the discrete light sensitive elements 41–45. Specifically, each discrete facet is aligned to produce a pattern on the fundus of the eye identical to the pattern illustrated at FIG. 4. That is to say, all of the prism elements A of the prism pattern project an image of detector 41 to the elements A shown in FIG. 4. Likewise, all of the prism elements B of the prism pattern project an image of detector 42 to the elements B shown in FIG. 4. Similarly, all of the prism elements C of the prism pattern project an image of detector 43 to the elements C shown in FIG. 4. Additionally, all of the prism elements D of the prism pattern project an image of detector 44 to the elements D shown in FIG. 4. Finally, all of the prism elements E of the prism pattern project an image of detector 45 to the elements E shown in FIG. 4.

The array of FIG. 4 will appear at two discrete places. First, the array will appear at the fundus conjugate at plane 22. Second, the array will be pupiled at the eye E and thereafter appear on the fundus F of the eye.

It will be understood that the projection of prism elements and the photosensitive elements through the fundus of the eye occurs at a conjugate of aperture 31 relayed to cornea C of eye E. (See FIG. 2D at 31') It is sufficient to say that in appearance at the eye E, the reference array also acts through a small pupiled area—see 31' in FIG. 2D. It is only when the light expands to the pattern of FIG. 4 at the fundus of the eye that the useful expanded pattern of FIG. 4 is ready to interrogate the eye.

Referring to FIG. 4, it will be seen that the areas of the reference array are lettered A, B, C, D, E. Each reference area comprises squares. The elements B, C, D and E are provided with arrows. These arrows here indicate the direction of prism displacement. Element A is without an arrow. This is because in this example, element A passes light through the prism array without appreciable deflection.

Returning to FIG. 3, the rectangles having their major axis disposed vertically or horizontally. In this example, the rectangular areas (I) pass light. The surrounding area is labeled II and does not pass light.

The reader will understand that the following example employs the easier to understand case of the rectangular areas I of FIG. 3 occluding the five element array of FIG. 4. It will be understood that the boarders II about the rectangles could as well be used for the desired occlusion. Further, both of these areas could be utilized, each area being separately utilized from the remaining area.

There is a preferred relationship between the areas of the elements of FIG. 3 and the square areas of the elements of FIG. 4. Specifically, the rectangles are 5/2nds the area of each of the squares. Conversely, each of the squares is 2/5ths the area of the respective rectangles. Further, it will be noticed that each rectangular area is separated from its adjacent rectangular area by an interval equal to one half the width (narrow dimension) of the minor axis of the rectangle.

These dimensions are important. They have been empirically determined with respect to the two element array of FIG. 3 and the five element array of FIG. 4. I have found that this is the combination of arrays having the least respective number of elements. While these particular relative dimensions are important for the array here illustrated, the reader will understand that using techniques similar to those illustrated in FIGS. 5A and 5B, the determination of these dimensions can relatively easily be made once the principles of the illustrated pattern displacement is understood.

Referring to FIG. 3, the elements of the pattern are rectangles and are separated one from another in what appears to be a "basket weave" pattern. Specifically, rectangles with their major axis vertically disposed are centered with respect to the rectangles having their major axis orthogonally and horizontally disposed. The separation between the ends of the vertically disposed rectangles and the sides of the horizontally disposed rectangle is half the width of the minor dimension of the rectangles. Similarly, the separation between the ends of the horizontally disposed rectangles and the sides of the minor dimension vertically disposed rectangle is again half the width of the vertically disposed rectangles. There appears to be a "basket weave" orientation although some prefer the label "brick orientation".

It will be understood that the illustrated dimensions will admit of minor variations. For example, the dimensions of the rectangles of FIG. 3 and the squares of FIG. 4 can be slightly varied. It will be understood however, such variations will detract from the sensitivity for the relative displacements which occur during determining the prescriptive correction for the eye E.

It has been found that the disclosed apertures are ideal for overlay on the apertures of FIG. 4.

Having set forth the simple pattern of FIG. 3, the more complex pattern of FIG. 4 may now be more completely analyzed.

It can be seen that FIG. 4 consists of an array of 5 elements. The elements horizontally are aligned in the order A, D, E, C, B. The elements are each square and hence can form an infinitely repeating pattern if allowed to infinitely extend.

The elements repeat in what might be referred to as a "knight's move" pattern after the well known game of

Chess. That is to say, by moving two forward and one to the side, elements repeat.

This repeating pattern is derived from the total number of elements used and a sum of squares which equals this total number of elements used. Here, the total number of different elements used is five: A, B, C, D, and E. The two steps forward constitute the square root of four (4) or a total of two (2). The one step to the side constitutes the square root of 1 or one. It can be seen that the sum of these two squares (i.e., 4+1) is the same as five, the total number of elements used.

FIG. 4 has all "B" elements shaded. These shaded B elements cause a linear front of the elements B to appear. One element front is labeled X, the other perpendicular element front is labeled Y. It is by alignment of the major axes of rectangles I in FIG. 3 to these respective "fronts" that interrogation occurs.

It is with the respective X and Y axes that movement of one array with respect to the other array is described. In the array here shown having five such squares, the lowest number of elements is illustrated which permits unambiguous detection of movement in both the X and Y directions.

Presuming that the X axis advances upwardly and to the right in the Y axis direction, the order of element interrogation can be determined. Starting with the element A, the order is A, C, D, B, E, A, etc. This order can be determined by the reader in observing those elements which an advancing X axis sequentially contacts.

Assuming that the Y axis advances downward and to the right in the X axis direction, the order of interrogation is A, D, E, C, B, A, etc. As will hereinafter be pointed out, by either observing the direction of vectors or alternatively the phase of temporally produced cycles, the relative translation of the elements in both the X and Y directions can be determined.

Observing the diagram of FIG. 4, it will be observed that each square has a four distinctly different element neighbors. Take for example a square B. Nowhere in the disclosed pattern is one square B bounded on any of its four sides by an adjacent square B, or more than one square of the same type.

Further, it can be seen that if the squares are illuminated in the orders specified, advancing wavefronts of light will sweep across the elemental array. Such an order is either A, C, D, B, E (X direction) or A, D, E, C, B (Y direction) or the reverse of either order.

Alignment of the reference array to the interrogating array occurs along the X and Y axis as it is disposed in FIG. 4. The results of such alignment can be best seen in FIG. 5A and FIG. 5B.

Before analysis of the overlap produced at FIGS. 5A and 5B, at least two important points must be called to the attention of the reader.

First, the functionality here provided is the result of the vector sum of all of the light received from all of the elemental arrays. Only the direction or phase of the sum is important; the disclosed patterns are relatively insensitive to the resultant amplitude.

Secondly, although the examples of FIGS. 5A and 5B illustrate in the case of FIG. 5A, maximum visibility of element B and in the case of FIG. 5B minimum visibility of element B, it is misleading to consider the viewed portion or occluded portion of any single element alone. The device requires for its operation the sum of all elements, the minimum total being 5.

To assist the reader in further understanding, the plots of FIGS. 6 and 7 are provided. These respective plots assume temporal phasing of the five discrete light sources A-E. The reader will remember that the arrays can be either light sources or detectors. Accordingly, this description will be generically directed to either in the section of this description immediately following.

At this point in the description for ease of understanding of the invention, a 50% duty cycle will be assumed for all light sources, even though this is not preferred Later, the preferred 40% duty cycle will be introduced, it being pointed out that this duty cycle reduces certain harmonic inputs into the resulting output. As the understanding of these harmonic outputs requires understanding of system operation, explanation begins with the 50% duty cycle.

It is previously been mentioned that fronts of light will sweep across the five element display. Such sweeping will occur in either the X and Y direction as indicated on FIG. 4. This will be ACDBE for the advancement of the X axis and ADECB for the advancement of the Y axis. The reader must therefore keep in mind for the following descriptions that sensitivity of the arrays must be discretely activated for the X direction and thereafter discretely activated for the Y direction. Examples of this discrete activation follow.

Turning to FIG. 6, it will be seen that each of the detectors or lights are actuated on a 50% duty cycle. Each cycle has a total of 10 clock counts. Therefore for each detector or light to be on a 50% duty cycle, the device must be on for 5 clock counts and off for the remaining 5 clock counts. This actuation occurs here in the sequence B, A, D, E, C for interrogation in the X direction. The reader will see that with five elements to be evenly timed with respect to one another, each element must be time spaced from other elements by increments of two time counts. (See FIG. 6)

Starting with detectors or lights B, actuation from time period 0 through time period 5 will occur. Detectors or lights A actuate from time period 2 through time period 7, D from time period 4 through time period 9, E from time period 6 through time period 1 and finally C from time period 8 through time period 3.

Referring to FIG. 6, and remembering the displacement directions illustrated in FIG. 4, detector signals for X displacement equal to that shown in FIG. 5A are set forth. Similarly, and with reference to FIG. 5B, detector signals for the same X displacement are set forth immediately below. It can be seen that the two displacements produce two distinctly different temporal images.

The case of Y displacement is also illustrated in FIG. 6. Again commencing with light or detector B and commencing at time period 0, and ending at time period 5, the illumination sequence can likewise be understood. E commences at time period 2 and ends at time period 7. A commences at time period 4 and ceases at time period 9. C commences at time period 6 and ends at time period 1. Finally, D commences at time period 8 and ends at time period 3.

For the displacement given in FIG. 4 in the "Y" direction, a detection pattern for each of the time periods through the pattern illustrated for FIG. 5A is given in FIG. 6. Likewise, the detection is illustrated for the displacement in the "Y" direction in the amount illustrated in FIG. 5B is shown.

It will be understood that reception to or from each of the elements A, B, C, D, E can be indicated in a polar

coordinate format. In this polar coordinate format, the respective elements A-E are arrayed circularly in the order of the respective "X" and "Y" displacements. Such a polar coordinate format is set forth with respect to FIG. 7A.

Referring to FIG. 7A and remembering the displacement illustrated in FIG. 5A with the detector signal detected for FIG. 5A in the X direction, a vector diagram has been constructed. In this vector diagram for displacement in the X direction, the vector aligns with B. Similarly, and for displacement in the Y direction, again the vector aligns with B.

As translations gradually occurs from the alignment illustrated in FIG. 5A to the alignment illustrated in FIG. 5B, the vector sum of the elements will rotate. Rotation will occur counterclockwise presuming relative displacement of the pattern in one direction; displacement in the opposite direction will include opposite vector clockwise rotation. In the lower left portion of FIG. 7A, translation has occurred until the vector sum of the discrete elements has been transferred to an intermediate point between the vectors D and E for translation in the "X" direction.

Similarly, in the lower right portion of FIG. 7A, translation has occurred until the vector sum of the discrete elements has been transferred to an intermediate point between the vectors A and C for translation in the "Y" direction. It is to be understood that the vector format for each of the two directions "X" and "Y" is distinct and in the order that each of the elements would be interrogated by translation such as that shown in FIGS. 5A and 5B.

In the 5 position rotational pattern illustrated in FIG. 7A, each of the discrete vectors, D, A, B, E, C, for translation in the X direction and B, E, A, C, D for translation in the Y direction have been illustrated. The vectors have been added to yield a resultant vector direction. It can be seen that the vector direction is produced as the outcome of the respective translation. It is only the vector direction which yields a useful result. Vector magnitude is ignored.

I have previously mentioned that other arrays can possibly be utilized other than the five element array that I preferred. I illustrate such an alternate array in FIG. 7B.

Referring to FIG. 7B, an eight element array is shown. It includes the eight reference elements A, B, C, D, E, F, G, and H. Interrogating elements I are illustrated. The interrogating elements are also squares. These interrogating squares are shown having the same individual areas as the reference squares.

In the embodiment here shown, I have empirically determined that the interrogating squares can be the same size as the squares on the pattern referenced. While other sizes of squares or rectangles can be used, the same size of square here gives a simple output which directly indicates displacement. The reader will likewise understand that the boarders around the interrogating squares could as well be used for interrogation. In this latter case, the interrogating squares themselves would be opaque.

Just as the pattern of squares repeats, so does the interrogating pattern of squares. For example, the interrogating squares I are shown straddling each intersection of the adjacent elements DHGC in the example set forth in FIG. 7B.

The interrogating squares I are shown here straddling the adjacent elements DHGC. This is an exemplary displacement. As further translation occurs, other displacements will be generated.

Referring to the elements ABCDEFGH, these elements repeat in a two forward, two to the side arrayed infinitely stackable pattern. Following the rules set forth with respect to the pattern of FIG. 4, this repeating pattern is derived from a sum of the total number of squares. Here, the total number of elements is eight. The two steps forward constitute the square root of four. The two steps to the side constitute the square root of four. It can be seen that the sum of these two squares is eight, the total number of individual elements used.

All of the elements B are shaded. It can be seen that this shading give two directions of investigation. These directions of investigation are labeled "X" and "Y".

It will be understood that this is the second lowest number of squares that can detect relative displacement between the patterns in both the X and Y directions.

Presuming that interrogation of the advancing wave front parallel to the Y axis in the direction of the X axis is to occur, actuation of detector elements or illuminating elements as the case may be can include sequentially activating elements pairs G—E, C—D, H—F, and A—B (or the reverse of this order).

Likewise, presuming that interrogation of an advancing wave front parallel to the X axis in the direction of the Y axis is to occur, actuation of detector elements or illuminating elements as the case may be can include sequentially activating element pairs E—F, A—C, G—H, and B—D (or the reverse of this order).

The reader will understand that vector and temporal plots can be discretely developed for the illustrated array. By observing the discrete phase of the vector or the phase of the temporal cycles, the relative displacements between the patterns can be precisely determined.

I will hereafter set forth apparatus for the automated observation of the relative displacements between the patterns illustrated in FIGS. 3 and 4. This apparatus will be useful for the five element reference pattern of FIG. 4 and the two element interrogating pattern of FIG. 3. The reader will understand that through simple modification of the disclosed apparatus as to the interrogating pattern projected through element 16 of FIG. 2C and element 34 of FIG. 2B, techniques similar to those disclose hereafter can be used for the generation of a useful result from the pattern of FIG. 7B.

As is similar to the array of FIG. 4, the array of FIG. 7B has been discrete elements with all adjoining elements being distinctly different neighbors. Take any square B for example. Nowhere in the disclosed pattern are the sides of one square B bounded by another square B, or more than one other square of the same type.

Further, it can be seen that if the squares are illuminated in the specified order, advancing wavefronts of light will pass across the elemental array. This order is specified in element pairs immediately above.

The same caveats apply to this array. Directionality and displacement is only supplied by the vector sum of the array. Further, maximum or minimum visibility of any given element is misleading; summation of all elements is required.

It can be seen that the pattern for description of the embodiment herein is precisely equivalent to that pattern used for the disclosure of the five element array. It will be understood that this array is not preferred; it must contain at least three more individual elements than the preferred array of FIGS. 3 and 4.

Regarding the total number of elements utilized in the so-called reference pattern, the reader will recall that I require that the total number of elements used follow a "sum of squares" rule. Utilizing the sum of the squares of one and two, I have developed my preferred five element array illustrated in FIGS. 3, 4, 5A and 5B. Utilizing the sum of the squares of two and two, I have developed the eight element array illustrated in FIGS. 7B. Utilizing the sum of the squares one and three, the reader can develop an array utilizing 10 elements. Other arrays with more numerous elements are all possible. As the arrays increase, so does the difficulty of precisely directing the light sources and detectors to realize the utility of the patterns here disclosed such as FIGS. 4 and 7B.

I therefore prefer to utilize the five element pattern illustrated in FIG. 7A as a detector array.

Referring to FIG. 8 the electronics of an appropriate detector scheme for the five element array of my invention is illustrated. In the embodiment of FIG. 8, discrete detectors are switched on and off in a temporal pattern indicated in FIG. 9A. The device utilizes synchronous switches for detecting signals from the various light detectors.

I will hereafter set forth a microprocessor circuit with respect to FIG. 16A. This circuit will disclose the use of two sequencers and a multiplexer to choose between the two for sequencing the synchronous switches for the various light detectors utilized. One sequencer will sequence the switches for sensitivity in the X direction. The other sequencer will sequence the switches for sensitivity in the Y direction. For the present, it will suffice that the reader understand that by using a microprocessor clock signal and paired sequencers, the respective synchronous switches can each be activated to observe the presence of light.

The construction of the circuitry of FIG. 8 is easy to understand. Referring to FIG. 8, a differential amplifier 200 has a negative leg 202 for observing the absence of light and a positive leg 204 for observing the presence of light. Each light detectors A, B, C, D, and E is connected to a respective switch 208. Each of the switches acts under microprocessor controls and switches in a temporal pattern between a positive state and a negative state. The temporal pattern can best be seen with respect to FIG. 9A.

It will be remembered that for purposes of simplicity, we here are utilizing a 50% duty cycle of each of the light detectors 41, 42, 43, 44 and 45. That is to say for half of the respective time period each light detector will look for the presence of light. Signals indicating the presence of light will be output on line 204 and pass through the positive leg of amplifier 200. For the remaining half of the respective time period each light detector will look for the absence of light. Signals indicating the absence of light will be output on line 202 and pass through the negative leg of amplifier 200. Amplifier 200 will emit a signal that is additive of all of the outputs of all of the detectors.

As will hereinafter be set forth, the output of amplifier 200 is important. By the expedient of examining the total intensity of the signal output from amplifier 200, it is possible to ascertain when the apparatus of this invention determines a possible prescription component for a patient being examined.

Referring to FIG. 9A a group of ten time periods is illustrated. It can be seen that the switching here illustrated occurs in the direction of "X" sensitivity. That is to say in the order B, A, D, C, E. Switching for sensitivity in the "Y" direction in the order B, E, A, C, D could likewise occur.

It is required that the respective detectors 41–45 each sample for the presence and the absence of light at evenly spaced intervals throughout the ten (10) period time cycle here illustrated. For the exemplary 50% duty cycle here used, this imparts to each light detector a time period of 5 clock counts where the detector looks for the presence of light and a time period of 5 clock counts where the detector looks for the absence of light. In order for this spreading of the duty cycle to occur over the ten (10) period time cycle here illustrated, it is required that the duty cycle of each detector be offset by two of the time periods from any adjacently cycled detector.

In the example of FIG. 9A, detector B is in the negative state from time period 2 through time period 6; it is in the positive state from time period 7 through time period 1. Detector A is in the negative state from time period 4 through time period 8; it is in the positive state from time period 9 through time period 3.

Detector D is in the negative state from time period 6 through time period 10; it is in the positive state from tim period 1 through time period 5. Detector C is in the negative state from time period 8 through time period 2; it is in the positive state during time period 3 through time period 7. Finally, detector E is in the negative state from time period 10 through time period 4; it is in the positive state from tim period 5 through time period 9.

Assume that a single light emitting diode is given an arbitrary timing. The diode as illustrated in the bottom portion of FIG. 9A switches on at time period 4.3 and switches off at time period 9.2 for an approximate 50% duty cycle. Such a light source timing would be appropriate to an X pattern displacement corresponding to rotation of the vector as illustrated in FIG. 9B.

For example, suppose the relative displacement of a particular LED pupiled to the eye at one location gives the displacement pattern of FIG. 5A. Suppose the relative displacement of a particular LED pupiled to the eye at an adjacent location gives the displacement pattern of FIG. 5B. If the two LEDs are given the same duty cycles, differing detected voltages will emanate from amplifier 200 of FIG. 8 because of the differing overlap between the interrogating patterns and the reference pattern.

Referring to FIGS. 1, 2A, 2B and 2C, it will be remembered that detector element 41 is optically communicated to all the elements A, detector element 42 to optical elements B, detector element 43 to optical element C, detector element 44 to optical elements D and detector element 45 to optical elements E. Such alignments occur by appropriately adjusting the discrete prism facets of the prism array 34 (see FIG. 2B).

I naturally desire to read the individual patterns of my invention with a high signal to noise ratio. I therefore shift the phase of each discrete light emitting diode 14 at each location on the eye E so that for the sensed prescription, each detector element 41–45 receives separately the cumulative light from all of the LEDs. The cumulative reception of light enables my objective refractor to be operable in relatively high levels of background illumination.

Shift of the duty cycles of the LEDs 14 will be set forth hereinafter. Specifically, I will hereafter disclose formulas that can be applied to the specific locations interrogated by the LEDs. These formulas allow any-

one having skill in the art to predict the relative displacement between the pattern of FIG. 3 and FIG. 4 for any given prescription of the eye. From these relative predicted duty cycles, the duty cycles of the LEDs 14 interrogating the eye are varied. These variations occur so as to "sweep" the eye for the various prescriptive components in sphere and cylinder. When the eye is swept through a component which is closest to the actual eye prescription, the sequenced detectors 41–45 all receive the strongest possible signal. This strong signal indicates the presence of a prescriptive component in sphere or cylinder that is close to the actual value required for correction of the objective refraction of the eye.

The reader will understand that the prescription of the human eye expressed in terms of sphere, cylinder and axis is complex. Specifically, it is well known that sphere, cylinder and axis are all related one to another utilizing certain well known relationships (formulas) well known in the prior art. I therefore will disclose in summary format a sequence of sweeping the eye—and varying the duty cycle—for the various components of optical prescription. When this sequence is followed, it will be seen that the apparatus and process of this invention is quite capable of making an objective refraction for any normally encountered optical prescription.

Brief reference can be made to the diagram of the emmetropic eye illustrated in FIG. 10. It will be remembered from the description of FIG. 2A that each LED is imaged so a point source of light upon cornea C. Assuming that respective images of LEDs are incident upon the retina of an emmetropic eye at locations 312' and 323', this person enjoying hypothetical "perfect" vision. Assume further that both diodes 312 and 323 are given the time period illustrated in FIG. 9A. Presuming illumination of the "basket weave" pattern of FIG. 3, the patterns of LED 312 and 323 will identically overlap. For example, each of these LEDs may overlap rectangles as shown in FIG. 5B. Since neither LED 312 or LED 323 is relatively deflected upon reaching the retina, both arrays of rectangles will overlap one another.

I have previously illustrated with respect to FIG. 7A the phenomena of the relative displacements of the patterns with respect to one another. Specifically, I have demonstrated that as displacement occurs between the respective patterns, a vector which is the sum of the displacement can be generated. Just as the vector was generated in the case of FIG. 7A for the displacements of FIGS. 5A and 5B, a vector can be generated here for the relative displacement of FIG. 9A. This vector is plotted in FIG. 9B.

It now remains for this pattern of overlap at the eye to be read. This reading must occur through the projection of the images of the detectors 41–45 onto the pattern of the elements A–E shown in FIG. 5B.

Projection of the detector images has been previously set forth. Specifically, detector elements 41–45 will each be projected through prism array 34, with each element being projected in the repetitive pattern illustrated for the elements A–E of FIG. 5A. Presuming that the timing of the illumination of each diode and the timing of the enabling of each detector is the same, the reading of the overlap will be the same for LED 312 and 323.

Now let us presume that the hypothetical eye illustrated in FIG. 10 is hyperopic or "farsighted". Such a condition has been illustrated on the eye of FIG. 10 by shortening the distance between the eye lens and the fundus 503. It can be seen that the central ray of light from LED 312 strikes the upper portion of fundus 503 at point 502'. The central ray of light from LED 323 strikes the lower portion of fundus 503 at point 502".

Remembering that light from each of the LEDs 312 and 323 is projected through the "basket weave" pattern of FIG. 3, it can be seen from the lack of convergence between the two central rays from the respective LEDs that relative displacement will exist between the two patterns. I will suppose for the purpose of the present discussion that the projected "basket weave" pattern of FIG. 5A results from LED 312; similarly I will suppose for the purpose of the present discussion that the projected "basket weave" pattern of FIG. 5B results from LED 323. These differing displacements will result from the refractive power of the eye deflecting the pupiled image of each LED at the eye lens 500 to differing locations 502' and 502" on the fundus 503 of the eye.

Projection of the detector images will be precisely as before. Images of detector elements 41–45 will be projected centrally to the fundus by the prism array in the pattern of elements A–E. This projection will occur through a pupil in the central part of the eye lens and produce the pattern illustrated in FIG. 4. This FIG. 4 pattern will be in the same location on the eye fundus for both illustrated displacements of FIG. 5A and FIG. 5B.

In the above example for the "far sighted" eye, this detector has the characteristic that for an array of light emitting diodes all having the same 50% duty cycle, the detector segments will receive light signals in accordance with FIG. 5A which represents the relative displacement of LED 312 and FIG. 5B which represents the displacement of LED 323.

Let us suppose that the hypothetical eye illustrated in FIG. 10 is myopic or "near sighted". Such a condition has been illustrated on the eye of FIG. 10 by lengthening the distance between the eye lens 500 and the fundus 501. It can be seen that the central ray of light from LED 312 strikes the lower portion of fundus 501 at point 501'. The central ray of light from LED 323 strikes the upper portion of fundus 501 at point 501".

Remembering that each of the LEDs 312 and 323 is projected through the "basket weave" pattern of FIG. 3, it can be seen from the impingement upon the fundus beyond the point of convergence between the two central rays from the respective LEDs that relative displacement will exist between the two patterns, this relative displacement being the opposite of that previously illustrated. I will suppose for the purpose of the present discussion that the projected "basket weave" pattern of FIG. 5B results from LED 312; similarly I will suppose for the purpose of the present discussion that the projected "basket weave" pattern of FIG. 5A results from LED 323. These differing displacements will result from the refractive power of the eye lens deflecting the pupiled image of each LED at the eye lens 500 to the differing locations on fundus 501 of the eye.

The reader will realize that the displacements of FIGS. 5A and 5B illustrate an oversimplification of the various displacements that an eye having other than perfect refractive characteristics will generate. For each individual LED in an array of LEDs, differing displacements will result. Consequently, and in the absence of some adjustment, there will be no predictability at any of the elements 41–45 as to when signal will be received and from what discrete diode signal will be

received. Realizing this detection problem, attention will now be devoted to the diagram of FIG. 5C.

In the review of FIG. 5C, three separate principles will be addressed. First, an order of detector sequencing will be disclosed. This order will be illustrated for movement of the patterns relative to one another in the X direction. The case of the displacement in the Y direction will not be considered completely as it is precisely analogous to the X direction.

Second, the duty cycle of the LED 312 and 323 will be considered. It will be seen that each of the LEDs can be adjusted in duty cycle relative to the displacements of FIGS. 5A and 5B to obtain a maximum signal and a minimum signal. For the purposes of this demonstration, the preferred 40% duty cycle will be used.

Finally, it will be proposed to vary duty cycle of LEDs in an array in accordance with a predicted prescription. Such a variation will be seen to give at the detectors cumulatively the strongest signal. The received signal will be seen to have a highly desirable signal to noise ratio.

Referring to FIG. 5C, a detector timing diagram is shown. The timing diagram includes a circle 600 with ten equally divided arc segments. These arc segments are ordered in the counterclockwise direction.

The vector diagram of FIG. 5C assumes a continuing displacement of the rectangles of FIG. 3 in the X direction of FIG. 4. The displacement occurs from the relative displacements illustrated in FIG. 5A to the relative displacements in FIG. 5B and returning to the displacements of FIG. 5A. In other words, a full "revolution" of displacement is illustrated in the vector diagram of FIG. 5C.

The vector diagram is sequentially labeled. It includes the section 5A—5A for the detection of the displacement of FIG. 5A and section 5B—5B for the detection of the displacement of FIG. 5B. Assuming X axis displacement upwardly and to the right of that illustrated in FIG. 4, counterclockwise vector rotation will result.

For the displacements given, there will be two classes of detector elements. There will be a first class of detector elements illuminated. These are shown at each circle segment representing one tenth of the overall detector duty cycle. At 5A—5A the sequence CBA appears. This means that when displacement of the patterns to the relative position of FIG. 5A occurs, elements C, B, and A are illuminated. Similarly at 5B—5B, the sequence DE appears. This means that when displacement of the patterns to the relative position of FIG. 5B occurs, elements D and E are most likely to be illuminated.

In each position of rotation, some elements are most likely to be vignetted or obscured from illumination. At 5A—5A these elements are elements DE. These elements are shown in brackets (DE). Likewise, at 5B—5B elements CBA are vignetted obscured from illumination. These elements are shown in brackets (CBA).

I have found that it is preferable to actuate the optical segments in the order illustrated by the counterclockwise rotating vector of FIG. 5C. This sequence establishes the desired X axis sensitivity to displacement and enables activation of all communicated light detectors.

It will be remembered that I utilize synchronous light sensitive rectifiers. These elements can be activated in the positive (light receiving) and the negative (nonlight receiving) modes. Accordingly, it will be understood that in any position of vector rotation, all elements 41–45 will be activated—some will be present for the reception of light and will emit signal as light is received; other will be preset for the absence of light and will emit a negative signal when light is received. This much has been previously set forth in the circuitry of FIG. 8.

The next consideration is LED duty cycle timing relative to the established detector cycle. Using the preferred 40% duty cycle, the question becomes for the displacement illustrated in FIG. 5A, what duty cycle illumination of an LED will produce that maximum signal and what LED illumination will produce the minimum signal? These respective LED duty cycles are illustrated. The duty cycle of LED 1 will produce maximum signal; the duty cycle of LED 2 will produce minimum (i.e., negative) signal.

For the displacement illustrated in FIG. 5B, the opposite is true. LED 2 will produce maximum signal and LED 1 will produce minimum signal.

The reader will realize that as the duty cycle of the LEDs is shifted relative to the sequence of interrogation illustrated in the timing diagram of FIG. 5C, signal will decrease. For example, shifting each of the LED duty cycles by one quarter of a full detector cycle will produce an intermediate result in particular, nearly a zero signal.

It will therefore be understood that for each particular displacement along the X direction of FIG. 4 of the pattern of FIG. 3 there will be an LED duty cycle that will result in both a maximum signal being received and another LED cycle that will result in a minimum signal being received.

Realizing that by the shifting of the duty cycle of each of the interrogating LEDs 14 to a duty cycle required by a particular prescription, it will be understood that duty cycles for an array of LEDs can be varied for the determination of prescriptions. As will hereinafter be set forth, these respective various timings for various prescriptions are set forth in a look up table. A microprocessor accesses the look up table. When the correct prescription is interrogated in the look up table, a very strong cumulative signal appears from detectors 41–45. This strong signal enables the correct prescription component to be flagged.

Realizing this much, the case of an LED array can be considered. If an array of LEDs are all given discrete phases which anticipate a predicted prescription, an extremely strong signal will result. The reader will recognize that this "tuning" of the duty cycle is an extremely powerful technique for achieving high signal to noise ratio. By way of example, using an array of 24 LEDs and effecting timing of the LEDs to predict a realized prescription, a signal 24 times that for a single LED will be realized while the detector noise is little changed: more than 500 single LED determinations would be required to achieve this result from 24 cooperating LED sources

Having set forth the relative displacement of the patterns upon incidence to the fundus, the use of an entire array of interrogating light sources can now be understood.

First, reference will be made to such an array as illustrated in FIG. 12A. Thereafter, and with reference to the timing diagrams illustrated in FIGS. 9A and 9B, I will set forth how the duty cycle of each interrogating LED can be temporally shifted for given optical conditions of the eye that are not emmetropic. This temporal shift will enable the detector array of FIG. 8 to receive

an additive signal from an entire array of LEDs to indicate generation of a correct prescription by the apparatus disclosed herein.

Referring to FIG. **12A** an array of **24** light emitting diodes is illustrated. This array includes diodes **301–306**, **307–310** and **311–312** on the upper portion of dividing line **400** and light emitting diodes **313–318**, **319–322** and **323–324** on the bottom of the dividing line **400**.

For a given predicted prescription of sphere and cylinder for each of the light emitting diodes **301–324** a specific displacement can well occur. This displacement will be associated with a temporal shift of the light emitting diode duty cycle which will be shifted to a particular interval of the synchronous sampling of the detector array as illustrated in FIGS. **9A** and **9B**. It can be seen that assuming the temporal duty cycle of each light emitting diode is individually varied, a maximum sensitivity for the incidence together of all light emitting diodes **301–324** on a detector operating in the temporal pattern of FIG. **9A** can be attained. Specifically, and by the expedient of predicting displacement for a suspected prescription and varying the duty cycle as shown in FIG. **9A** discretely for each of the 24 light emitting diodes **301–324**, all detectors in the array illustrated in FIG. **8** can receive an optimal signal with simultaneity.

I prefer for each prescription component I detect to utilize look-up tables in a microprocessor. These prescriptive components can usually signal the start of the temporal phase of each LED in accordance with suspected prescription.

Thus, by the simple expedient of varying the time period of the 40% duty cycle of each of the light emitting diodes, a reinforced signal simultaneously received from all 24 light emitting diodes can signal correct prescription. It will be understood that the 24 light emitting diodes reinforce one another. In such reinforcement, a signal of unique strength indicating the presence of a correct prescription is attained.

Having set forth the possibility of an LED array being phased for reception of a tuned signal, a digression will be made. Specifically, the digression will refer to FIGS. **14A–14E**. A set of equations will be derived to describe standard eye prescription in terms of sphere 0°–90° cross cylinder and 45°–135° cross cylinder. These equations will relate the power of the eye at any particular point to values of sphere and cross cylinder.

Once this determination is made it will be emphasized that to determine sphere, cylinder and axis, measurement of at least three points on the surface of the eye is required. Thereafter, three discrete methods of measuring the power of correction necessary for an eye will be disclosed.

A first method will constitute scanning a group of light emitting diodes with duty cycles anticipating displacement. It will be shown that by scanning in meridional power for both the X and Y directions, sphere and 0°–90° cylinder may be measured.

Second, the use of a charge coupled device will be briefly considered. It will be shown that by using the derived equations, computation of optical prescription is possible. Specifically, by illuminating the eye sequentially through each of the "detector" elements and storing each corresponding video image, computations can be made resulting in the determination of a prescription.

Finally, an additional technique including scanning for error will be disclosed. This technique will be shown to give an indication of error both in sense and magnitude which enables rapid determination of the correct optical prescription.

Referring to FIG. **14A** an optical schematic is disclosed. An eye lens L is shown which lens L is subject to spherical correction. The correction here is positive sphere. This positive sphere is represented by a series of vectors which include a series of inwardly directed radial vectors **700**.

Referring to FIG. **14B**, an eye lens is schematically illustrated having required negative spherical correction. Accordingly a vector format of outwardly directed radial arrows **702** is illustrated for the negative spherical correction.

Referring to FIG. **14C**, a cross cylinder is illustrated. The cross cylinder has positive power along the X axis and negative power along the Y axis. Accordingly, it includes inwardly directed spherical vectors **700** aligned to the X axis and negatively directed vectors **702** aligned to the Y axis. Vectors in each of the respective quadrants of the graphical representation are shown. These vectors are a resolution of the vector deflections in the respective quadrants. Accordingly, vectors **705** and **706** respectively resolve the vectors of the respective lower left and lower right quadrants. Similarly vectors **707**, **708** respectively resolve the vectors of the respective upper right and upper left quadrants.

Referring to FIG. **14B**, a second cross cylinder is shown. This cross cylinder has positive cylindrical power on the 45° axis and negative cylindrical power on the 135° axis. Accordingly, a positive radial vector **700** can be seen on the 45° axis and a negative vector **702** on the 135° axis.

Each of the quadrants are here shown with vector resolution. These quadrants, however, appear on 0°, 90°, 180°, and 270° axis. Specifically, vectors **705'**, **706'**, **707'**, and **708'** resolve the vector powers in each of their respective quadrants of the **45**, **135** cross cylinder power here shown.

It is known to those skilled in the art that by varying cross cylinder powers as shown in FIGS. **14C** and **14D**, an overall cylinder of any power and any axis can be generated. I have discussed such a technique in my U.S. Pat. No. 3,822,932 entitled "Optometric Apparatus and Process Having Independent Astigmatic and Spherical Inputs" issued Jul. 9, 1974. Incorporation of that patent is herein made by reference.

I further wish to adopt a convention that will render more clear the terminology which I hereafter adopt. Specifically, for cylinder which is aligned on the 0°–90° axis, I will adopt the symbol C_+. For cylinder which is aligned to the 45°–135° axis, I will adopt the symbol C_x. It can thus be seen that the C standing for cylinder and the subscript + for 0°–90° and the subscript x for 45°–135° render the disclosed symbols quite understandable.

I now turn to the illustration of a hypothetical eye at FIG. **14E**. The eye is shown with three respective points, P_1, P_2, and P_3. For a power of sphere, cylinder and axis (or sphere and pair of cross cylinders) to be determined, at least measurement in three such points must occur.

In order to set forth equations by which such a three part solution can be rendered, it is necessary to establish the variables for any given point. Taking the point P_1 and referring to the above diagrams **14A–14D** can be instructive.

It will be remembered that my measurement technique is sensitive to X direction displacement only and Y direction displacement only. Therefore it is necessary for any point P_1 to write an equation which will measure the X axis displacement between the interrogating and reference patterns and the Y axis displacement between the interrogating and reference patterns.

Taking the case of a point P_1 and worrying only about the X axis displacement, it can be seen that for the X displacement of P_i the X axis displacement will be generated by any spherical power present such as illustrated in FIG. **14A** combined with any C_+ power present as illustrated in FIG. **14C**. In actual observation, when these two powers combine, they will not be distinguishable. I therefore choose to call these powers meridian power S_{bx} denoting that they are power resulting in pattern displacement in the x direction due to an aperture displacement of "base leg" b.

Referring to FIG. **14D**, it can further be seen that as a function of the point P_1 in distance above the b axis by a distance b_y another contribution to x axis displacement will occur. This x axis displacement is described by the term

$$\left(\frac{C_x}{2}\right)b_y$$

Thus, the equation for displacement in the x axis direction is as follows:

$$\phi_x = S_{bx}b_x + \left(\frac{C_x}{2}\right)b_y \quad [1]$$

Following exactly similar logic the equation for displacement in the Y axis direction due to the location of the point P_1 is defined by the equation

$$\phi_y = S_{by}b_y + \left(\frac{C_x}{2}\right)b_x \quad [2]$$

I have previously demonstrated that the terms S_{bx} (x axis meridian power) and S_{by} (y axis meridian power) are a combination of sphere and 0°–90° cylinder (see subscript +). The correct equations for these displacements are

$$S_{bx} = S + \frac{C_+}{2} \quad [3]$$

$$S_{by} = S - \frac{C_+}{2} \quad [4]$$

Having these equations, three discrete methods of determining prescription for the eye can now be determined.

First, and by the utilization of the foregoing equations, it is a matter for the reader to determine the expected displacement at any of the points P_1, P_2 or P_3. Indeed, I prefer to compute displacement for a matrix of such points. The matrix having the number of light emitting diodes illustrated in FIGS. **12A–12D**. It has been found that by varying the temporal relationship of the diode duty cycle with respect to the detector duty cycle (see FIG. **5C**) first for x sensitive sequencing and thereafter for y sensitive sequencing, a scanning mode results in a peak signal being determined for the values of ϕ_x and ϕ_6 corresponding to the correct refractive correction. This peak signal plots out with a well defined maxima at the point where meridional power is correctly chosen. Thus, and assuming a first X sensitive sweep for meridional power and a second y sensitive sweep for meridional power, two points of strongest signal will be received.

Referring to FIG. **15A** I include herewith an actual plot of signal produced by scanning in so-called meridian power. The meridian power was varied by varying the duty cycle of light emitting diodes. The diodes were varied to emulate a spherical prescription ranging from +44 dropters to −44 dropters.

Observing FIG. **15A**, it can be seen that there is present a peak **400**. This peak coincides to that portion of the scan that is closest to the required correction for a patient. Adjacent peaks **401** and **402** may also be observed. These respective adjacent peaks are false maxima. It is because of these false maxima I prefer to conduct (at least initially) a full scan of the possible ranges of sphere and cylinder. This full scan prevents the apparatus from determining a prescriptive component has been reached at peaks **401**, **402**.

It can be seen that the graph of FIG. **15A** is obtained by having the detectors interrogate the respective pattern of FIG. **4** using the X direction sensitivity. It will be remembered that X direction sensitivity is obtained by scanning the photosensitive elements **41–45** as communicated through the prism element **34** of FIG. **2B** to the pattern of FIG. **4** in the order A, C, D. B, E, A, etc.

As similar graph is obtained for Y direction sensitivity, it will be remembered that Y direction sensitivity is obtained by scanning the photosensitive elements **41–45** as communicated through the prism element **34** of FIG. **2B** to the pattern of FIG. **4** in the order A, D, E. C, B, A, etc.

We now make the assumption that there is no cross cylinder C_x. It can be seen from equations **3** and **4** above that if the curves are coincident, the term for 0°–90° cylinder C_+ will be 0. If the maxima of the spherical sweep curves are separated one from another by a distance, it has been found that distance is an approximation to the cylinder component C_+.

Referring to FIG. **15C**, I illustrate a plot having the intensity of the X interrogation plotted with respect to the intensity of the Y interrogation. It can be seen that two peaks appear; one peak **405** appears for the X direction interrogation and one peak **406** appears for the Y direction interrogation. It further can be seen that these respective peaks are separated one from another by a distance. This distance has been found to be magnitude directly proportional to the value of 0°–90° cylinder C_+.

It may be further seen that using equations [4] and [5] we may determine a value for sphere. At this juncture, values will be known for sphere S, and for the 0°–90° cylinder C_+. By the simple expedient of maintaining the two known maxima for Sx and Sy, a sweep for so-called 45°–135° cylinder can be made. Specifically, one sweep for Cx will be made for the X direction of interrogation and one scan for Cx will be made for the Y direction of interrogation. When the maximum function is found, very close estimates for sphere S, and cylinders C_+ and C_x will be present. By the simple expedient of iteration, the true prescription may be generated.

With respect to FIG. **16**A, a microprocessor embodiment of this invention is disclosed. In this microprocessor embodiment I disclose the use of four look up tables for scanning the eye to determine eye prescription. These look up tables are set forth with respect to FIG. **16**B and include spherical power in the X direction, spherical power in the Y direction. Cx in the X direction and Cx in the Y direction. From the foregoing explanation, the reader will understand that these look up tables will be all that is required to determine the prescriptive power of the eye in sphere S and cross cylinder C+ and Cx.

The reader can understand that the disclosed computations could as well be made by a charged coupled device (CCD) receiving the images from the eye. Specifically, in such a protocol, each discrete light emitting diode would be cycled in turn. The CCD would view the intensity variations in the pupil plane resulting from retinal pattern taking each element of the CCD image as an aperture at the pupil of the eye, the image intensities for a series of 5 image exposures provides sufficient information to define the phases ϕ_x and ϕ_y displacements from each diode. The CCD element position and its estimated values for ϕ_x and ϕ_y allow equations 1–4 will be solved. The solution, a function of numeric processing, will yield the correct sphere, cylinder and axis for the eye.

I at present do not prefer the use of the charge coupled device to the assignment of the discrete duty cycles to the LEDs. This being the case, I include the foregoing summary only for completeness of the disclosure and to note that the use of a charge coupled device is possible.

I further have made it clear that an array of light emitting diodes is preferred. Such an array can be patterned after those arrays illustrated in FIGS. **12**A through **12**B. In such arrays 24 light emitting diodes are utilized. These diodes are labeled **301–324**. The reader will understand that in a look up table, the discrete timing of the duty cycles for all of the LEDs can be set forth for the full range of each of the prescription components to be scanned.

Having set forth the usefulness of using 24 discrete light emitting diodes, all with varying timing to give unique reinforcing signals in both X and Y sensitive modes, two useful characteristics of the disclosed displacement interrogation will be set forth.

First, and with respect to FIGS. **11**A and **11**B, the problem of harmonics will be addressed. Thereafter, and with attention first to FIG. **10** and thereafter to the diagrams of FIGS. **12**A–**12**D an interrogating sequence will be set forth.

Referring to FIG. **11**A, a "ripple" effect of the utilization of five time periods is illustrated. In FIG. **11**A, it is presumed that each of the detectors B, A, D, C, E has a 50% positive duty cycle and a 50% negative duty cycle. As before, these respective duty cycles are averaged over a time period of 10 units for half or 5 of the ten units of time. The detectors are in the positive state half the time. For the remaining 50% of the 100% duty cycle, the synchronous rectifiers are in the negative state.

As before, the temporal phasing of the detectors is illustrated for sensitivity in the X direction. Displacement is one time unit out of a total of 10 time units between the leading edge of the successive sensitivity of each of the detector units B, A, D, C, and E. Here detector B is negative for time period 2 through time period and positive from time period 7 through time period **1**. The sequence continues with respective two unit displacements for the detector sequence B, A, D, C, E.

Assuming that a light source is given a 50% duty cycle and is illuminated from time period **2** through time period **6** for five discrete units, addition of the state of each of the total of five detectors is instructive. Specifically, during time period **2** one excessive negative state will be present. During time period **3** one excessive positive state will be present. During time period **4** one excessive negative state will be present. During time period **5** one excessive positive state will be present and finally at time period **6** one excessive negative state will be present.

For the entire time periods **2** through **6**, it can be seen that this is a total of three negative states and two positive states. Thus, the negative states will for the light source illustrated at **404** predominate by one negative state. (See FIG. **11**A)

Assume an elemental shift of the time period and illumination of a light source in a 50% duty cycle commencing at time period **3** and ending at time period **7**, it can be seen that there will be an excessive positive state by the addition process just illustrated. The negative state of time period **2** will be eliminated. The positive state of time period **7** will be added. Positive states from time periods **3**, **5**, **7** will exceed by one negative states from time periods **4** and **6**.

Referring to the lower portion of FIG. **11**A it can be seen that as displacement occurs, oscillation will occur from a negative state to a positive state at a frequency of approximately five times the total time required for one-half of a complete detector cycle.

I have dubbed this phenomena a "five omega ripple"; two solutions suggest themselves.

First, by the simple expedient of adapting a 40% duty cycle, this ripple can be eliminated. This is preferred and is illustrated in FIG. **5**C.

Second, successive duty cycles of each LED can be displaced by 1/20th of a cycle. Displacement in one direction (for example forward in time) by 1/20th of a cycle followed by displacement in an opposite direction (for example, retardation in time) by 1/20th of a cycle in the opposite direction will eliminate this "five omega" ripple phenomena when the results are combined.

Referring to FIG. **11**B, an additional ripple phenomena is therein illustrated. Referring to FIG. **11**B, I have discovered that a second so-called "three omega ripple" is present. Simply stated, the Fourier series includes a harmonic contributor of three omega. Again, two solutions are present. The first solution is to alter successive interrogating time periods by 1/12th, commencing one lighting state at a positive 1/12th time period and the remaining state at a negative 1/12th time period.

I have discovered that a timing count which is a multiple of **2**, **3**, and **5** is to be preferred. For example, instead of using the normal binary count of 256 I prefer to utilize a timing count of 240. Taking a 40% duty cycle, it can be seen that 96 counts comprise precisely 40% of a 240 time period cycle. Likewise by advancing or retarding an illuminating diode in the order of 20 of the total of 240 time units, the "three omega" ripple phenomena just discussed can likewise be eliminated.

An additional method of generating eye prescription once the gross prescription is estimated involves dividing the field of interrogating light emitting diodes into sectors, the sectors can be shifted in phase to produce an

error function or discriminator function. This error function can be understood by first utilizing and understanding the diagrams of FIGS. **12A** through **12D**.

Referring to FIG. **12A**, an array of **24** LEDs **301–324** is set forth. These LEDs include LEDs **301–312** above horizontal dividing line **400** and LEDs **313–324** below horizontal dividing line **400**. The reader will remember that by setting the discrete timing of each of the LEDs **301–324**, a vector signal of relatively great magnitude over the background illumination would be simultaneously received at each of the individual detectors A–E in the array of FIG. **8**.

Two phenomena rise from the division concept illustrated in FIGS. **12A–12D**. It will be first demonstrated that assuming optimum signal has been received and the prescription detected by the instrument is correct, by shifting the phase on one side of the dividing line **400** by plus 90° and simultaneously shifting the phase on the opposite side of the dividing line **400** by −90°, the signal at the detector apparatus of FIG. **8** will disappear for original phases appropriate to the refractive error.

Second, and assuming the same kind of phase shift but further assuming that the prescription is not correct, a vector function which I call a "discrimination" function will be generated. This "discrimination" function will have a magnitude and sign indicating the required sense and approximate magnitude required for correction of an estimated prescription to a correct prescription.

Referring to FIGS. **9A**, **9B** and **12A**, and assuming the emmetropic eye of FIG. **10** at fundus **501**, the reader will remember that there is no relative displacement from the vector configuration of FIG. **9B** for each of the LEDs **301–324**. That is to say, all of the LEDs can be timed to give the vector addition seen in FIG. **9B**, which vector will have relatively great strength over ambient background illumination.

It will be seen with respect to FIG. **12A**, sensitivity is in the "X" direction. It can further be seen that phase dividing line **401** for the phase shift is normal to the direction of shift sensitivity.

Now assume that LEDs **301**, **302**, **303**, **307**, **308**, **311**, **313**, **314**, **315**, **319**, **320**, **323** are each shifted positively 90° in phase. Assume that the remaining LEDs are each shifted negatively 90° in phase. As these groups of LEDs are on opposite sides of the dividing line **401**, the equal and opposite shift in phase in the amount of 90° will cause the detector array of FIG. **8** to go from a maximum signal to no signal at all for either of the two groups of LEDs. A zero signal will indicate by its null signal that the test prescription of the moment is correct. If the estimated retractive error was incorrect, the signal will be non-zero, and increase in strength in proportion to the size of the misestimate.

I have assumed in the description generated thus far that the meridional component measured by the light array divided on dividing line **401** and phase shifted in opposite 90° components to left and right of dividing line **401** was correct for the prescription being measured. It is a surprising result of my invention that if the component is other than correct, by the phase shifting process described with respect to FIG. **12A**, a signal indicating the component error will originate. This signal will indicate in both sign and magnitude the sense and magnitude required for correction of the particular component being measured.

It will be understood that the phase shifting process of FIG. **12A** must be repeated for each of the suspected components being tested. Specifically, and for each component of prescription measured, shifting will occur on opposite sides of a dividing line to opposite 90° phase differentials.

Shifting as indicated in FIG. **12B** along a dividing line **402** parallel to the direction of X sensitivity will give a sensitivity to 45°–135° components—useful in the determination of astigmatism.

Shifting as indicated in FIG. **12C** along a dividing line **403** normal to the direction of Y shift sensitivity will give the second and remaining meridional component of prescription.

Finally, shifting as indicated in FIG. **12D** along dividing line **404** parallel to the direction of Y shift sensitivity will give a second and redundant 45°–135° component of sensitivity.

In each case, should an error be present in the particular component being detected, a signal indicating both the sense and magnitude of the required correction will be generated. By the expedient of applying this vector indicated correction to the next iteration for the indicated component of prescription, the total prescription for the eye can be rapidly generated.

Referring to FIG. **13**, it can be seen that the optical arrangement of the instrument particularly lends itself to the addition of targets T useful in keratometry. Referring to FIG. **13**, two targets T1 and T3 of four preferred keratometry targets T1 through T4 are illustrated. These keratometry targets are measured in their apparent separation in reflection from the patient's cornea K by a video imaging device such as charge coupled device **600**. By the expedient of having the charged coupled device read out the apparent separation of the targets T1–T4, the curvature of the cornea K in sphere, cylinder and axis can be readily determined.

Referring to FIG. **16A**, a microprocessor embodiment of this invention is disclosed. The microprocessor includes three main operative functions for the practice of this invention. These functions are a look up table for communicating to the LED array the various duty cycles for sweeping the eye in prescription. Secondly, two sequencers which control two multiplexers. These respective multiplexers initiate interrogation in the X direction and the Y direction by the respective photosensitive elements. Finally, the microprocessor recognizes the various signal peaks when they are encountered. From the recognition of the signal peaks, eye prescription in sphere and cylinder can be computed.

Regarding the duty cycle communicated to each of the light emitting diodes, microprocessor **500** addresses through address bus **501** a look up table **502**. Look up table **502** is divided into four sections, these sections having been previously described with respect to the preferred protocol for locating the prescription of the eye. These sections of the look up table are schematically illustrated in FIG. **16B**.

Referring to FIG. **16B**, it can be seen that a first portion of the look up table **506** includes information corresponding to values of sphere dependent upon variations of LED position with respect to X displacement. These values are computed using the relationships of equation [1].

A second portion **507** of the look up table includes information corresponding to values of Cx for displacement in the X direction. These values will be computed utilizing the relationships of equation [1].

A third portion **508** of the look up table includes information corresponding to values of sphere dependent upon variations of the LED position with respect

to Y displacement. These values can be computed utilizing the relationships of equation [2].

Finally, a fourth portion **509** of the look up table includes information corresponding to values of cross cylinder Cx with respect to variations of the LED position with respect to Y displacement. These values can be computed utilizing the relationship of equation [2].

Each of the tables preferably contains information corresponding to ranges of sphere and cylinder which encompass the vast majority of possible refractive errors likely to be encountered.

Having set forth the layout of the look up table **502**, the sequence of examination can now be set forth. For the determination of prescription, the eye will typically be swept in one component of sphere power. This component of sphere power can include Sx for meridional power sensitivity related to displacement in the X direction.

Typically microprocessor **500** will address memory **502** at portion **506** on a block by block basis, each block corresponding to a value of sphere. I will assume that a full duty cycle will comprise a count of 240. For the preferred 40% duty cycle, the ON-time of each diode will be 96 counts long. Further, a separate starting count for each LED will be required. It will thus be understood that each block of memory will contain at least information indicating the count corresponding to the start of the ON-time for each of the separate LEDs **301–324**.

The value of the starting count of the microprocessor clock for each of the LEDs will be output on the data bus **510**. The microprocessor **500** will add 96 to the value of the starting count to determine the value of the stop count. Thereafter the clock count will be compared with these values. The result will be output to the LED register **512**. This command register will reflect whether a discrete LED is to be in the ON or OFF state.

LED register **512** will receive from the microprocessor **500** in a bit-mapped form. Each bit in the register will address an discrete LED. One bit in this register will be a gate enable signal for the LED gates. When this bit is set, LED illumination information will be gated from LED register **512**, by LED gates **518**, to LED drivers **515**. There is a LED driver for each discrete LED. Each driver furnishes the power to illuminate its associated LED when the corresponding bit in the LED register is set and the LED gates are enabled.

In use, and for each scan of a selected prescription to be scanned, the LED register will be loaded with ON or OFF data for each of the LEDs. Assuming the preferred complete cycle of 240 counts, each scan at a particular prescription will consume at least a full 240 counts. Scan will occur on a block by block basis through the look up table **502** at portion **506**.

Having set forth the cycling of the individual LEDs, the simpler case of the cycling of the detectors can now be set forth.

For the cycling of the detectors, sequencers **520** and **521** will be utilized. Sequence **520** will cycle detectors **41–45** (see FIG. 2A) for detection in the X direction. Sequencer **521** will cycle detectors **41–45** for detection in the Y direction.

Each of the sequencers **520** and **521** will be selected on an alternate basis by the multiplexer **529** under control of the microprocessor **500**. For sweep of Sx and for Cx related to displacement in the X direction, sequencer **520** will command the sequence of interrogation. For sweep of Sy and for Cx relating to displacement in the Y direction, sequencer **521** will command the sequence of interrogation. Control will occur through clock signal at line **525** and be initialized by a reset **526**.

As set forth in FIG. **8**, the cumulative output of the detectors will be utilized. Specifically, the detector array will output through an analog to digital converter **531**. An output for each value swept from the table **502** will occur.

Once sweeping of a portion of look up table **502**—say a portion **506** occurs, the values of signal output from the detectors **41–45** are compared for each prescription value swept. As the reader will undoubtedly recognize, the peak illustrated in FIG. **15A** can be easily identified and recorded to appropriate memory.

This process will be repeated for each portion of the memory **502** in the order **507**, **508** and **509**. Respective maxima for each of the values swept will be recorded.

The sequence of the microprocessor interrogation and computation has been previously set forth. It will be repeated only in summary format herein.

Specifically, Sx will be swept and the maximum recorded. Thereafter Sy will be swept and its maxima recorded. The two values Sx and Sy will most likely occur at differing values. The difference between these values will directly relate to cylinder C+. From C+, the actual values of sphere S can be computed using the relationship of equations [3] and [4].

Thereafter, as assuming a value for sphere S and C+, cross cylinder Cx will be swept. This cross cylinder will first be swept as it relates to X displacement and second will be swept as it relates to Y displacement. From these two sweeps, a value of Cx will be determined.

At this juncture, the reader will understand that tentative values for S, C+ and Cx will be present. Naturally, by assuming these values and iterating the process through sweeps reduced in scope based to the determined values, more accurate prescriptive data can be generated.

What is claimed is:

1. An optical instrument for objectively refracting the eye on the eye fundus, said instrument comprising:

an interrogating pattern of elements configured for projection to the eye fundus;

a reference pattern of elements configured for projection to the eye fundus for overlying said interrogating pattern for determining displacement of said interrogating pattern with respect to said reference pattern;

one of said patterns including a first array of elements including at least five distinct and repeating elements, said elements distinct in being distinguishable one from another, said elements being repeating in that the same distinguishable element appears more than once in each said array;

the other of said patterns including a second array of elements including at least two repeating elements, said elements being repeating in that the same element appears more than once in each said array;

optics for relaying respective images of said interrogating pattern along a first optical path through the lens of said eye and onto said eye fundus and relaying the respective images of said reference pattern along a second optical path through a different portion of the lens of said eye and onto the fundus of said eye;

at least one light source for illuminating one of said respective first or second arrays for projection as

said interrogating pattern onto fundus of the eye and at least two photosensitive elements optically communicated to the other of said respective second or first patterns for reading light as said reference pattern from the fundus of said eye; and,

means for detecting the signal at said photosensitive elements to determine the relative displacement of said patterns on the fundus of the eye.

2. The invention of claim **1** and wherein said photosensitive elements are five in number and communicated directly to at least five distinct and repeating elements.

3. The invention of claim **1** and including means for synchronously switching said photosensitive elements.

4. The invention of claim **1** and including a light source having a plurality of light emitting diodes for illuminating one of said patterns on said eye, said light emitting diodes arrayed for projection at spaced apart locations across the lens of said eye.

5. The invention of claim **4** and wherein said light emitting diodes are temporally phased to produce at said detector an additive signal.

6. The invention of claim **1** and wherein said first array of elements includes at least five distinct and repeating elements of square area with each distinct element bordered on every side by differently distinct elements and said second array includes at least first and second rectangles, said rectangles having an area equal to 5/2nds of the area of the squares of said first array and having a length equal to twice the width elongate dimension of said first rectangle at 90° to the elongate dimension of said second rectangle.

7. The invention of claim **1** and wherein said optics pupil respective images of said interrogating pattern and said reference pattern at said eye lens with said interrogating pattern being projected through at least three points on said eye lens and said reference pattern being projected through one point on said eye lens.

8. The invention of claim **1** and including means for providing a keratometry target projected adjacent said eye, said keratometry target positioned for reflection from a cornea of said eye along the center optical path of said instrument; and

means for measuring the dimension of said keratometry target attached to said instrument whereby at least the curvature in sphere, cylinder and axis of said eye may be measured.

9. The invention of claim **1** and including the prism array, said prism array disposed in the array of one of said pattern of elements.

10. The optical instrument of claim **1** and wherein:

said photosensitive elements include a charge coupled device.

11. A process for objectively refracting the eye, said process comprising:

providing an interrogating pattern of elements configured for projection to the eye;

providing a reference pattern of elements configured for projection to the eye, said reference pattern for overlying said interrogating pattern for determining the displacement of said interrogating pattern with respect to said reference pattern;

providing to said respective patterns a first array of at least five distinct and repeating elements, said elements distinct in being distinguishable one from another, said elements repeating in that the same distinguishable element appears more than once in said array;

providing to said respective patterns a second array having at least two repeating elements, said elements repeating in that the same element appears more than once in said pattern;

providing relay optics for relaying respective images of said interrogating pattern and said reference pattern to and from the eye;

projecting said interrogating and reference patterns to the eye through said relay optics;

providing a light source;

illuminating said interrogating patterns with said light source along a path for projection of either said respective first or second arrays through said optics to the eye and onto the fundus of the eye;

providing photosensitive elements,

projecting said reference pattern with said photosensitive elements optically communicated to the other of said respective second or first arrays along a path for projection through said optics from the eye and onto said photosensitive elements; and,

measuring the difference of signal between said respective photosensitive elements to determine the relative displacement of said interrogating pattern relative to said reference pattern whereby varying displacements of said image on the fundus of said eye may be measured for determining the prescription of the eye.

12. The invention of claim **11** and wherein said provided photosensitive elements are provided synchronous switches; and

switching said provided synchronous switches between positive polarity and negative polarity for detecting the presence and absence of light.

13. The process of claim **11** and wherein said provided light source includes a plurality of light emitting diodes, said diodes having a duty cycle in the range of 20% to 50%.

14. The process of claim **13** and including the step of varying the duty cycle of said diodes temporally one with respect to another to provide at said detectors additive signals.

15. The process of claim **11** and wherein the first of said provided arrays includes five distinctly different elements, each said element being square in shape and having an infinitely stackable array wherein each one of said distinct elements is surrounded by differing ones of said distinct elements on said four sides of said square and providing to said other array first and second rectangles, the major axis of said first rectangle aligned at 90° to the major axis of said second rectangles.

16. The process of claim **11** and including the step of projecting said reference or interrogating pattern through at least at one point on the eye lens, and

projecting said interrogating or reference pattern through at least three points on said eye lens, pupiled at each point of incidence on said eye lens.

17. The process of claim **11** and including providing a keratometry target surrounding said eye; and

projecting an image of said keratometry target to means for measuring the dimension of said keratometry target whereby the curvature of said eye may be detected.

18. The process of claim **11** and wherein the step of providing a light source includes the step of providing an array of light emitting diodes, said provided array of light emitting diodes for projecting through an area exceeding the dimension of the iris of said eye whereby

vignetting of said light emitting diodes by the iris of said eye indicates the dimension of said iris of said eye.

19. The process of claim **11** and wherein said step of providing a light source includes the step of providing a plurality of light sources selected to overlie a preselected portion of the optic being examined, said preselected portion being less than the total expanse of said optic.

20. The process of claim **11** and wherein said providing photosensitive elements step includes the step of:

providing a charge coupled device.

21. A process for objectively refracting the eye through projection optics, said process comprising the steps of:

providing an interrogating pattern of elements for projection to the eye;

providing a reference pattern of elements configured for projection to the eye for overlying said interrogating pattern to determine displacement of said interrogating pattern with respect to said reference pattern;

projecting both said patterns to the eye with a pupil of said projected patterns passing through the lens of said eye at distinctly different points;

providing to one of said patterns an array of five distinct and repeating elements, said elements being distinct in being distinguishable one from another, said elements repeating in that the same distinguishable element appears more than once in each pattern;

providing to the other of said patterns an array of at least two repeating elements, said elements repeating in that the same element appears more than once in each said pattern;

providing a plurality of light sources;

providing a plurality of photosensitive elements;

illuminating said respective first or second array by said plurality of light sources;

optically communicating said respective second or first array to said photosensitive elements; and,

timing the duty cycle of said light emitting sources to provide at said photodetectors an additive signal upon displacement of said patterns on the fundus of said eye.

22. The invention of claim **21** and including dividing said light emitting sources into first and second groups;

shifting the temporal illumination of said first group by 90° in a first and positive direction; and,

shifting the temporal illumination of said phase of the remaining half of said light sources in the opposite direction;

measuring the sensitivity at said detectors to determine the magnitude and sense of the resultant received signal.

23. The process of claim **21** and including the step of utilizing five photosensitive elements to said five distinct and repeating elements of said first pattern;

illuminating light sources on a 40% duty cycle said distinct and repeating elements of said second pattern.

24. The process of claim **21** and including successively advancing and retarding alternate duty cycle duration on each said light source.

25. The process of claim **24** and wherein said advance and said retard of said duty cycle moves advancing said duty cycle by 5% and retarding said cycle by 5% in sequential illumination of each said light source.

26. The process of claim **21** and wherein said providing photosensitive elements step includes the step of:

providing a charge coupled device.

27. A process for objective refracting a human eye, said process comprising the steps of:

providing an interrogating pattern of elements configured for projection through said eye;

providing a reference pattern of elements configured for projection overlying said interrogating pattern through said eye, said projection pattern and said interrogating pattern having relative sensitivity one to another upon relative displacement one to another;

providing one of said patterns with a first array of elements with at least five distinct and repeating elements, said elements distinct in being distinguishable from one another, said elements repeating in that the same element appears more than once in each pattern;

providing the other of said patterns with a second array of elements of at least two repeating elements, said elements repeating in that the same element appears more than once in each said array;

projecting a plurality of light sources through one said array through said eye to pupil said sources at said eye and to project said resultant pattern beyond said eye to an imaging surface on the regina;

projecting a second of said arrays to photosensitive elements, each element of said array communicated to one of said photosensitive elements;

interrogating said eye with an estimated prescription including a component of corrective cylindrical lens power provided by providing differing timing to differing ones of said plurality of light sources;

shifting the phase f half said light sources on one side of said array of said light sources 90° in duty cycle in a first temporal direction;

shifting the phase of the other half of said light sources in said array of said light sources in duty cycle 90° in the opposite temporal direction;

receiving at said photosensor said shifted phase to determine the sense and magnitude of optical change required for said estimated corrective prescription in an iterative procedure.

28. The process of claim **27** and including the step of sequencing the detectors in a first sequence to sensitize said detectors to displacement along a first axis across the imaging surface; and

sequencing said detectors to a second sequence, said second sequence for sensitizing said detectors for displacement of said pattern along and towards a direction normal to said first axis across said imaging surface.

29. The process of claim **27** and wherein said projecting the second of said arrays to photosensitive elements includes the step of projecting the second of said arrays to charge coupled devices.

[57] **ABSTRACT**

In an apparatus for detecting the relative positional relation between light intensity distributions relating to an object image and detecting the focus-adjusted state of an objective lens, a pair of stop openings for limiting an off-axis light flux forming light intensity distributions entering a pair of secondary imaging lenses are provided so as to be symmetrical with respect to a meridian centered at the optic axis of the objective lens so that the influence of the residual aberrations of the objective lens becomes uniform.

FOCUS DETECTING APPARATUS IN WHICH MATCHING WITH THE IMAGE PERFORMANCE OF AN OBJECTIVE LENS IS ACHIEVED

This application is a continuation of application Ser. No. 281,326 filed Dec. 8, 1988, now abandoned.

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to a focus detecting apparatus suitable for a single-lens reflex camera.

2. Description of the Related Background Art

As one of the focus detecting systems for single-lens reflex cameras, there is known the image correlation system. FIGS. 7 and 8 of the accompanying drawings illustrate focus detection by the image correlation system, FIG. 7 showing the optical path of a focus detecting optical system, and FIG. 8 showing the light amount distribution on a light detecting element (hereinafter referred to as a sensor) in which photo-electric elements are arranged in the form of a line. In these figures, the reference numeral **1** designates a film-equivalent surface, the reference numeral **2** denotes a field lens, the reference numeral **3** designates secondary imaging lenses, the reference numeral **4** denotes sensors, and the reference numeral **5** designates a photo-taking lens.

An on-axial light beam emitted from a point source of light P on the optic axis a (in the figure, parallel to the x-axis) of the photo-taking lens **5** is imaged near the film-equivalent surface **1** through the photo-taking lens **5**. The object light is transmitted through the field lens **2**, is converged by the secondary imaging lenses **3** and is projected onto the sensors **4**. Here, the secondary imaging lenses **3** have their focal length and arrangement set so that the image on the film-equivalent surface **1** is imaged on the sensor **4** at a predetermined magnification. Also, the secondary imaging lenses **3** are disposed as one set of two at locations symmetrical with respect to the optic axis of the photo-taking lens **5**, and cause part of the object light to be imaged on the one set of two sensors **4**. The sensors may be a row of sensors divided into two areas.

FIG. 7A shows a state in which the positional relation between the object P (which is the point source of light) and the photo-taking lens **5** and the film-equivalent surface is in the in-focus state. FIG. **8A** shows the light amount distributions on the sensors **4** at this time, and a light amount distribution having a sharp peak substantially at the central position of each sensor A, B is created, and the interval between the peak positions is l_0. l_0 is an independent value determined by the construction of the focus detecting optical system.

FIG. 7B shows the optical path in the forward focus state in which the photo-taking lens **5** has been moved to the object side, and the light amount distributions on the sensors **4** present distributions low in the degree of sharpness, as shown in FIG. **8B**, and the internal l between the peak positions of the light amount distributions on the sensors is narrower than the interval l_0 in the in-focus state. The difference $\Delta l(=l-l_0)$ between these peak-position intervals corresponds to the defocus amount and therefore, focus detection is accomplished using this amount Δl.

FIG. 7C shows the optical path in the rearward focus state after the photo-taking lens **5** has been moved to the film surface side, and the light amount distributions on the sensors **4** present distributions low in the degree of sharpness, as shown in FIG. **8C**, and the interval l between the peak positions on the sensors is wider than the interval l_0 in the in-focus state. The difference Δl $(=l-l_0)$ between these intervals corresponds to the defocus amount and therefore, focus detection is accomplished using this amount Δl. Also in the case of an ordinary object having a brightness distribution, the correlation between the object images on the sensors is taken and focus detection is accomplished from the amount of deviation l between the two images. Also, the field lens **2** is disposed near the film-equivalent surface (including the film-equivalent surface), and is set to such a focal length that the positional relation between the exit pupil P of the photo-taking lens **5** and the entrance pupils of the secondary imaging lenses **3** satisfies the imaging relation. Also, a stop **6** usually having two openings is disposed near the pupil positions of the secondary imaging lenses **3**, and this stop is set to such a size that two light fluxes transmitted through the openings thereof are separated and not eclipsed in the photo-taking lens **5**.

However, in the above-described focus detecting system, when an attempt is made to effect focus detection of an object lying at a location in the photo-taking picture plane which is off the optic axis of the lens, if the disposition of the sensors is done arbitrarily, the openings of the stop at the focus detecting position must be made small and the interval between the openings of the stop must be made narrow so that the focus detecting light flux entering the sensors may not have its focus detecting performance deteriorated under the influence of the residual aberrations of the photo-taking lens or the focus detecting light flux may not be eclipsed in the photo-taking lens, and this has led to the disadvantage that the focus detecting performance is deteriorated.

FIG. **9** of the accompanying drawings illustrates how the focus detecting light flux is influenced by the aberrations of the photo-taking lens, and shows the optical path of the focus detecting optical system. The reference numeral **1'** designates the film-equivalent surface, the reference numeral **2** denotes the field lens, the reference numeral **3** designates the secondary imaging lenses, the reference numeral **4** denotes the sensors, the reference numeral **5** designates the photo-taking lens, the reference numeral **6** denotes the stop, and the reference characters **9A** and **9B** designate focus detecting off-axial light fluxes.

An object P_1 is in the direction $-y$ relative to the optic axis of the photo-taking lens **5** in a plane x-y containing the optic axis, and the object light is transmitted through the photo-taking lens **5**, whereafter it is imaged at a position of height h in the direction of the y-axis on the film-equivalent surface **1'**. The stop **6** and the secondary imaging lenses **3** divide the object light into two and direct the divided light fluxes onto the two sensors **4**, and the direction of division of the light fluxes is the direction of the y-axis and is coincident with the direction of deviation of the object image from the optic axis. At this time, the two divided focus detecting light fluxes **9A** and **9B** are asymmetrical with respect to the optic axis of the photo-taking lens **5** and therefore, aberrations having asymmetry are created in the respective object images on A and B of the sensors **4**. As a result, in an apparatus wherein the correlation between the images on A and B of the sensors **4** is taken to thereby accomplish focus detection, it becomes difficult to take the

correlation between the two images and the focus detecting performance is deteriorated.

FIG. **10** of the accompanying drawings shows the vignetting in the opening of the stop **6** which corresponds to the focus detecting light flux **9B**. The solid line indicates the opening of the stop **6**, and it is set to a shape in which no vignetting occurs when the image height h=0 [mm] (which corresponds to a in FIG. **10**). As the image height h becomes higher to 6 [mm] (the dotted line b in the figure), 9 [mm] (the dot-and-dash line c in the figure) and 12 [mm] (the broken line d in the figure), eclipse of the light flux occures from the direction −y in the figure. Here, the area in the direction +y of the areas demarcated by the respective lines is an effective light flux area, and as the image height becomes higher, the light fluxes entering the sensors become less and the performance of the brightness of the focus detecting apparatus is reduced Also, as the image height becomes higher, the position G of the center of gravity of the light flux comes near to the optic axis of the photo-taking lens (the x-axis in the figure) and the distance L between the position G of the center of gravity of the light flux and the optic axis of the photo-taking lens becomes smaller. Here, the value of 2*L is a value corresponding to the length of the base line in triangulation, and if L becomes smaller, there arises the difficulty that the focus detecting performance is reduced.

On the other hand, an apparatus designed to effect focus detection for an object lying at an off-axis position off the optic axis of the photo-taking lens is known from Japanese Laid-Open Patent Application No. 62-47612 and Japanese Laid-Open Patent Application No. 62-189415. Particularly, one of the examples of the arrangement of sensor arrays disclosed in Japanese Laid-Open Patent Application No. 62-189415 is such that respective sensor arrays disposed off the axis are provided so as to be symmetrical with respect to a meridian centered at the optic axis. However, the other examples of the arrangement are such that the off-axis sensor arrays are not symmetrical with respect to the radius, and it is apparent that these examples do not take into account the aberrations caused in the imaging light flux by the objective lens.

SUMMARY OF THE INVENTION

It is a first object of the present invention to mitigate the reduction in detection accuracy caused by the residual aberrations of an objective lens when detecting the focus-adjusted state of the objective lens for an object lying off the central position in the field of view.

It is a second object of the present invention to mitigate the reduction in detection accuracy caused by the vignetting of an objective lens.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a perspective view showing an embodiment of the present invention.

FIGS. **2A** and **2B** are optical cross-sectional views for illustrating the optical action of the embodiment.

FIG. **3** is a plan view for illustrating the optical action.

FIG. **4** is a cross-sectional view showing the present invention as it is applied to a single-lens reflex camera.

FIG. **5** is a perspective view showing another embodiment of the present invention.

FIGS. **6A** and **6B** are optical cross-sectional views for illustrating the optical action of the FIG. **5** embodiment.

FIGS. **7A**, **7B** and **7C** are optical cross-sectional views showing an example of the prior art.

FIGS. **8A** to **8C** illustrate the optical actions.

FIG. **9** is an optical cross-sectional view for illustrating problems peculiar to the prior art.

FIG. **10** is a plan view for illustrating the optical action.

FIG. **11** illustrates the action of a constituent member.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

FIGS. **1** to **4** show a first embodiment of the present invention, FIG. **1** being a perspective view of a focus detecting optical system. The x-axis in the figures is coincident with the optic axis of a photo-taking lens, not shown. The reference numerals **21–23** designate field lenses, the reference numerals **31–36** denote secondary imaging lenses, the reference numerals **41** and **42** designate line sensors, the reference numeral **6** denotes a stop, the reference numerals **61–66** designate the openings of the stop, and the reference numeral **1** denotes a field mask comprised of a liquid crystal element or the like. The regions of the field mask which are indicated by rectangles can be made transparent and the remaining portion thereof is opague. The field mask **1** is disposed near the film-equivalent surface of the photo-taking lens and is capable of arbitrarily selecting a field of view for effecting focus detection by a driving device, not shown. That is, that portion of the field mask **1** which is indicated by a solid-line rectangle is the off-axis opening, and the center thereof is G. The field lens group **2** is disposed immediately rearwardly of the field mask **1** in the direction +x and one-dimensionally in the direction of the z-axis. The secondary imaging lens group **3** is set so that the film-equivalent surface of the photo-taking lens, not shown, and the line sensor group **4** satisfy the imaging relation. The stop **6** is disposed near the secondary imaging lens groups **3** and toward the field lens group **2**, and the stop openings **61** and **63**, **63** and **64**, and **65** and **66** substantially satisfy the imaging relation with the exit pupil of the photo-taking lens by the field lenses **21**, **22** and **23**. However, the off-axis field lenses **21** and **23** are of a shape suitable for inwardly refracting light. The stop openings **61**, **62**, the secondary imaging lenses **31**, **32** and the line sensors **41**, **42** form pairs, respectively, and effect the focus detection of a light flux forming an image near the location at which the field lens **21** off the optic axis of the photo-taking lens, not shown, is disposed, while the stop openings **61** and **62** which are in a conjugate relation with the exit pupil of the photo-taking lens are disposed symmetrically with respect to a plane passing through the center G of the opening of the field mask and containing the optic axis of the photo-taking lens (in the figure, the plane z-x). A system for forming an image near the position of the field lens **23** is similar to what has been described above. Also in a light flux which forms an image near the location at which the field lens **22** is disposed, the stop openings **63**, **64**, the secondary imaging lenses **33**, **34** and the line sensors **41**, **42** form pairs, respectively, and the stop openings **63** and **64** are disposed symmetrically with respect to a plane passing through the center G' of the on-axis opening of the field mask **1** which is

indicated by dotted line and containing the optic axis of the photo-taking lens (in the figure, the plane z-x).

The optical action will hereinafter be described.

FIG. 2 shows the optical path of the focus detecting optical system, FIG. 2A being a top plan view, and FIG. 2B being a side view. In FIG. 2, the letter L designates a photo-taking lens, the reference numeral 1 denotes the field mask comprised of a liquid crystal element or the like, the reference numeral 2 designates the field lens group, the reference numeral 3 denotes the secondary imaging lens group, the reference numeral 4 designates the line sensor group, the reference numeral 6 denotes the stop, and the reference numeral 8 designates an operation processing circuit, although it is not shown in FIG. 2A. The origin of the axis of the coordinates x-y-z is an arbitrary point on the optic axis of the photo-taking lens L.

In FIG. 2, the light flux from an object P, lying in the direction +Z off the optic axis of the photo-taking lens L is transmitted through the photo-taking lens L, whereafter it is imaged at a position of h on the field mask 1 in the direction −z relative to the optic axis of the photo-taking lens L. At this time, only the portion of the field mask 1 comprised of a liquid crystal element which is near the image point of the object P_1 is in a transmitting state. Part of the object light is transmitted through the field lens 21, and is thereafter limited by the stop openings 61 and 62 and is re-imaged on the line sensors 41 and 42 by the secondary imaging lenses 31 and 32. In the operation processing circuit 8, the correlation between the object images on the line sensors 41 and 42 is taken to thereby effect focus detection, and the resulting signal is supplied to the photo-taking lens L, whereby focus adjustment is effected. Now, the object light of the object P_1 lying in the direction +z relative to the optic axis of the photo-taking lens L is transmitted through the field lens 21, whereafter it is divided in the direction of the y-axis orthogonal to the z-axis by the stop openings 61 and 62, and light fluxes concerned in focus detection are symmetrical in the photo-taking lens L with respect to a plane passing through the center G of the opening of the field mask 1 and perpendicular to the direction of division (the direction of the y-axis) of the stop openings 61 and 62 including the optic axis of the photo-taking lens L (or a meridian about the optic axis) and therefore, no asymmetrical aberration occurs between the object images re-imaged on the line sensor 41 and the line sensor 42. This also holds true for the object light transmitted through the area corresponding to the field lens 23.

FIG. 3 shows the vignetting in the stop opening 61 when, in FIG. 2A, the image height h of the object image has varied. The solid line in FIG. 3 indicates the stop opening when the object is on the optic axis. The dot-and-dash line c indicates the boundary of the vignetting when the image height h=9 [mm], and the broken line d indicates the boundary of the vignetting when the image height h=12 [mm], and the eclipse of the light flux is small. Also, the eclipse of the light flux occurs from the direction −z in FIG. 3, and since the direction of travel thereof is substantially orthogonal to the direction of a base line (parallel to the y-axis), setting of the stop opening is possible without, reducing the value 2*L relative to the length of the base line in triangulation.

FIG. 4 shows the arrangement of a focus detecting apparatus in a single-lens reflex camera. In the figure, the letter L designates the photo-taking lens, the reference numeral 1 denotes the field mask, the reference numeral 2 designates the field lens group, the reference numeral 3 denotes the secondary imaging lens group, the reference numeral 4 designates the line sensor group, and the reference numeral 6 denotes the stop. The reference numeral 10 designates a movable mirror having a light-transmitting portion, the reference numeral 11 denotes a sub-mirror, the reference numeral 12 designates a focusing screen, the reference numeral 13 denotes a condenser lens, the reference numeral 14 designates a pentadach prism, the reference numeral 15 denotes an eyepiece, and the operation processing circuit is not shown.

The focus detecting optical system is disposed at the bottom of the camera body, and the center axis x of the focus detecting optical system is coincident with the optic axis of the photo-taking lens L through the half-mirror 10 and the sub-mirror 11.

In the present embodiment, the field lenses 21 and 22 have been shown as plano-convex lenses, but alternatively may be biconvex lenses.

FIGS. 5 to 6 show a second embodiment of the present invention, FIG. 5 being a perspective view of a focus detecting optical system. In FIG. 5, the reference numerals 20 and 21–24 designate field lenses, the reference numerals 31–36 denote secondary imaging lenses, and the reference numerals 41–44 designate line sensors. The reference numeral 6 denotes a stop, the reference numerals 61–66 designate the openings of the stop, and the reference numeral 1 denotes a field mask comprised of a liquid crystal element. The x-axis in these figures is coincident with the optic axis of a photo-taking lens, not shown. The field mask 1 is disposed near the film-equivalent surface of the photo-taking lens, and is capable of arbitrarily selecting a field of view for focus detection by a driving device, not shown. The portion of the field mask 1 which is indicated by a rectangle is an opening, and the center thereof is G. The field lens group 2 is disposed immediately rearwardly of the field mask 1 in the direction +x. The secondary imaging lens group 3 is set so that the film-equivalent surface of the photo-taking lens, not shown, and the line sensor group 4 satisfy the imaging relation. The stop 6 is disposed near the secondary imaging lens group 3 and toward the field lens group 2, and the sets of stop openings 61 and 62, 63 and 64, 65 and 66, 61 and 65, 62 and 66 substantially satisfy the imaging relation with the exit pupil of the photo-taking lens by the field lenses 21, 20, 23, 22 and 24, respectively.

Table 1 below shows the relations of correspondence between the members constituting the focus detecting optical system.

TABLE 1

No.			(1)		(2)		(3)		(4)	
Field lens	20		21		22		23		24	
Stop opening	63	64	61	62	61	65	65	66	62	66
Secondary imaging lens	33	34	31	32	31	35	35	36	32	36
Line sensor	41	42	41	42	43	44	41	42	43	44

In the combination represented by No. (1), the stop openings 61 and 62 are disposed symmetrically with respect to a plane passing through the center G of the opening of the field mask 1 and containing the optic axis of the photo-taking lens (in the figure, the plane x-y). In the combinations represented by Nos. (2), (3) and (4), this relation holds true.

The optical action will now be described.

FIG. **6** shows the optical path of the focus detecting optical system, FIG. **6A** being a side view, and FIG. **6B** being a top plan view. In FIG. **6**, the letter L designates the photo-taking lens, the reference numeral **1** denotes the field mask, the reference numeral **2** designates the field lens group, the reference numeral **3** denotes the secondary imaging lens group, the reference numeral **4** designates the line sensor group, the reference numeral **6** denotes the stop, and the reference numeral **8** designates an operation processing circuit, although it is not shown in FIG. **6A**. In FIG. **6**, the origin of the axis of the coordinates x-y-z is an arbitrary point on the optic axis of the photo-taking lens L.

In FIG. **6**, a description will be given with respect to an object P_1 lying in the direction $-y$ off the optic axis of the photo-taking lens L taken as an example. The object light is transmitted through the photo-taking lens L, whereafter it is imaged at a position of h on the field mask **1** in the direction $+y$ relative to the optic axis of the photo-taking lens L. At this time, only the portion of the field mask **1** comprised of a liquid crystal element which is near the image point of the object P_1 is in a transmitting state. Part of the object light is transmitted through the field lens **21**, and is thereafter limited by the stop openings **61** and **62** and is re-imaged on the line sensors **41** and **42** by the secondary imaging lenses **31** and **32**. In the operation processing circuit **8**, the correlation between, the object images on the line sensors **41** and **42** is determined to thereby effect focus detection, and the resulting signal is supplied to the photo-taking lens L, whereby focus adjustment is effected. Now, the object light of the object P_1 lying in the direction-y relative to the optic axis of the photo-taking lens L is transmitted through the field lens **21**, whereafter it is divided in the direction of the z-axis orthogonal to the y-axis by the stop openings **61** and **62**, and light fluxes concerned in focus detection are symmetrical in the photo-taking lens L with respect to a plane passing through the center G of the opening of the field mask **1** and perpendicular to the direction of division (the direction of the z-axis) of the stop openings **61** and **62** including the optic axis of the photo-taking lens L and therefore, no asymmetrical aberration occurs between the object images re-imaged on the line sensor **41** and the line sensor **42**.

In FIG. **6**, the example in the combination of No. (1) in Table 1 has been shown, and this also holds true of the combinations of Nos. (2) to (4). Also, the field mask **1** has been shown as being comprised of a liquid crystal element whose transmitting and light-intercepting areas are controllable, but it may be an electrochromic element whose action will be described later, and a stop plate having an opening can also be mechanically moved. Also, the field lenses **21**, **22**, **23** and **24** have been shown as plano-convex lenses each having one surface thereof made into the form of a prism, but alternatively, they may be biconvex lenses.

FIG. **11** illustrates the passage and interception of light by an electrochromic element.

The electrochromic element comprises a transparent substrate **51**, and first electrodes **52** and **52'** formed of a transparent conductive film, first electrochromic layers **53** and **53'** which are oxidation reaction color forming layers, intermediate insulating layers **54** and **54'** formed of a dielectric film, second electrochromic layers **55** and **55'** which are reduction reaction (non-color forming) layers, and second electrodes **56** and **56'** formed of a conductive film, all successively layered on the front and back surfaces of the substrate **51**.

In the above-described construction, the substrate **51** is generally formed of a glass plate, whereas this is not restrictive, but the substrate may be a plastic plate or a transparent substrate of synthetic resin such as polyimide. The intermediate insulating layers **54** and **54'** need not always be formed of a dielectric material, but may also be a solid electrolyte.

The transparent conductive film may be tin oxide SnO_2 doped in ITO film (indium oxide In_2O_3), Nesa film (SnO_2) or the like.

The first electrochromic layer **53** which is an oxidation reaction color forming layer is formed of iridium oxide (IrOx), nickel hydroxide ($Ni(OH)_2$) or the like. The intermediate insulating layer **54** is formed by the use of an oxide represented by tantalum pentoxide (Ta_2O_5), zirconium dioxide (ZrO_2) or the like, or a fluoride represented by lithium fluoride (LiF), magnesium fluoride (MgF_2) or the like. Also, as the second electrochromic layers **55** and **55'** which are reduction reaction (non-color forming) layers, use is made of polycrystalized porous tungsten trioxide (WO_3).

The total solid electrochromic element having such structure has an electro-chemical reaction induced by a voltage being applied between the first electrodes **52**, **52'** and the second electrodes **56**, **56'** and effects coloring and discharge.

Assuming that the IrOx side is plus (+) and the WO_3 side is minus (−), on the IrOx side, a reaction

$$IrOx + yH_2Oad \rightarrow IrOx(OH)y + yH^+ + ye^- \quad (1)$$

where H_2Oad is adsorbed H_2O contained in cells, progresses, and on the WO_3 side, a reaction

$$WO_3 + yH^+ + ye^- \rightarrow HyWO_3 \quad (2)$$

(non-color forming)

progresses, and coloring stuff IrOx(OH)y is considered to be formed, and neutral light absorption is exhibited in the visible range. Also, by reversing the electric field, reverse reactions of (1) and (2) are induced and color is discharged. These reactions progress by water content (indicated as H_2Oad) contained in the cells.

According to the present invention described above, even when focus detection of an object off the optic axis is effected, the influence of the aberrations of the objective lens can be eliminated and vignetting can be mitigated and therefore, the focus detecting performance is improved and particularly, even where the present invention is adopted in a single-lens reflex camera, a performance which can be practically used can be achieved.

What is claimed is:

1. An apparatus for detecting the focus-adjusted state of an objective lens, comprising:

field lens means, having a plurality of field lenses, disposed near a predetermined imaging plane of the objective lens;

a plurality of light intensity distribution forming means for forming light intensity distributions relating to an object from a light flux passed through said objective lens and said field lens means, said light intensity distributions moving relative to each other;

light receiving means for receiving said light intensity distributions and forming a signal indicative of the

focus-adjusted state of said objective lens based on the relative positional relation between said light intensity distributions; and

masking means disposed near said predetermined imaging plane for selectively forming an opening at any one of a plurality of different locations in said masking means.

2. An apparatus according to claim 1, wherein said masking means is made of an element having a property of matter which takes the selected opening light-transmissive.

3. An apparatus for detecting a focus-adjusted state of an objective lens having an optic axis, comprising:

field lens means disposed near a predetermined imaging plane of the objective lens;

a plurality of light intensity distribution forming means for forming light intensity distributions relating to an object from a light flux passed through said objective lens and said field lens means, said light intensity distributions moving relative to each other;

light receiving means for receiving said light intensity distributions and forming a signal indicative of the focus-adjusted state of said objective lens based on the relative positional relation between said light intensity distributions;

masking means disposed near said predetermined imaging plane for masking said light receiving means except for the light receiving areas thereof and having openings at a plurality of different locations therein; and

stop means provided with a plurality of sets of stop openings for separating a light flux entering said tight intensity distribution forming means at the pupil position of said objective lens and disposed between said field lens means and said light receiving means; and

the stop openings which form the set for receiving the light flux passed through an off-axis opening of said masking means being all determined so as to be symmetrical with respect to an imaginary plane passing through the center of the off-axis opening of said masking means and containing the optic axis of said objective lens so that the influence of the abberations of said objective lens becomes uniform, said plurality of sets of stop openings including an on-axis set of stop openings disposed parallel to an off-axis set of stop openings wherein said light receiving means comprises at least one pair of line sensors, and wherein said light receiving means comprises at least one pair of line sensors, and wherein said intensity distribution forming means comprises a number of pairs of lenses, the number of pairs of said light intensity distribution forming means being greater than the number of pairs of said line sensors.

4. An apparatus for detecting the focus-adjusted state of an objective lens, comprising:

field lens means disposed near a predetermined imaging plane of the objective lens;

a plurality of light intensity distribution forming means for forming light intensity distributions relating to an object from a light flux passing through the objective lens and said field lens means, the light intensity distributions moving relative to each other;

a plurality of pairs of line sensors for receiving the light intensity distributions, each pair of said line sensors forming a signal indicative of the focus-adjusting state of the objective lens based on the relative positional relation between the light intensity distributions; and

masking means disposed near the predetermined imaging plane for selectively forming an opening at a predetermined location in said masking means.

[57] **ABSTRACT**

A stereoscopic objective lens system for video endoscopes and borescopes includes two full-diameter doublets and a double set of two half-diameter identical doublets. The full-diameter doublets collimate object points, imaging object points to infinity. The large collimator doublets present equal-angle pairs from symmetrically disposed object points to the small stereo doublet pairs. This equal-angle property enables accurate object/image mapping onto the final stereo image pair, such that all parts of each left/right image can be mapped to within a fraction of a video pixel to each other.

STEREO VIDEO ENDOSCOPE OBJECTIVE LENS SYSTEM

BACKGROUND OF THE INVENTION

This invention relates generally to optical lens systems, and, more particularly, relates to stereoscopic objective lens designs adapted for use in stereo video endoscopes.

Medical endoscopes are widely utilized to view internal regions of the human body during diagnostic, surgical, and other medical procedures. Endoscopes typically include a long, thin, rigid or semi-rigid optical cylinder affixed to a viewing mechanism. The cylinder is sufficiently narrow to be inserted through a small opening in the body, which may be natural or surgical. When the endoscope is inserted and positioned for use, an image of the object being viewed is formed at an inserted end of the endoscope by an objective lens. The image passes through a series of relay lenses down the cylinder to an eye lens or video camera at a viewing end of the endoscope.

In recent years, researchers have attempted to improve the imaging available through endoscopic devices by developing stereoscopic video endoscopes. These endoscopes present an apparently three-dimensional image on a video monitor The stereoscopic effect is created by producing two optical images—a left image and a right image—through the endoscope. The left and right optical images are presented by the endoscope to left and right image sensors, which may be charge-coupled device (CCD) cameras or other image sensing devices. The sensing devices convert the left and right optical images into left and right video images which are then presented as alternating left-right images on a monitor, at a switching rate higher than the flicker-sensing limit of the human eye, so that observed images appear flicker-free.

The images are alternately switched from a left-hand polarization mode to a right-hand polarization mode, such that. for example, the left image has a left-hand polarization and the right image has a right-hand polarization. In accord with this example, the observer wears polarized glasses in which the left lens has the left-hand polarization and the right lens has the right-hand polarization. Thus, the left eye sees only images from the left channel of the endoscope system and the right eye sees only images from the right channel, resulting in stereoscopic viewing.

The following U.S. and foreign patents disclose examples of stereo endoscopes, some of which utilize video imaging and display elements:

U.S. Pat. No. 4,061,135
U.S. Pat. No. 4,615,332
U.S. Pat. No. 4,651,201
U.S. Pat. No. 4,862,873
U.S. Pat. No. 4,873,572
U.S. Pat. No. 4,895,431
EP 211,783

In particular, U.S. Pat, No. 4,061,135 discloses a binocular endoscope in which images are transmitted from the viewed object to the viewing station through an optical system utilizing a dove prism and mechanical linkage to compensate for rotation effects.

U.S. Pat. No. 4,615,332 discloses a binocular endoscope having flexible light guides and binocular eyepieces.

U.S. Pat. No. 4,651,201 discloses a stereoscopic video endoscope including two image guides and an illumination light guide. The image guides are optically coupled to a stereoscopic viewer for three dimensional viewing. The viewer includes couplings for attaching miniature video cameras that can be connected to a head-mounted stereoscopic video display.

U.S. Pat. No. 4,862,873 discloses a stereo endoscope having two light guides for carrying images of an object to an electro-optical imaging assembly. A lens system directs light from the object to the objective end of the light guides. Illuminating light is transmitted to the object from the opposite end of one light guide, thereby illuminating the object. Simultaneously, the image transmitted through the other optical guide is conducted to the imaging assembly.

U.S. Pat. No. 4,873,572 discloses a stereo endoscope having a CCD camera module and two image-forming lens systems that form two object images. The object images are integrated and directed to the CCD camera to provide a stereoscopic output. The lens systems include red, green, and blue color filters disposed at the camera imaging surface.

U.S. Pat. No. 4,895,431 discloses an endoscope apparatus that generates a three-dimensional image of an object from overlapping images recorded by a camera. The endoscope includes an insertion module and a movable end section capable of being deflected through an angle. A first image is recorded with the end section positioned at a first angle. A second image, partially overlapping the first image, is recorded after moving the end section to a second angle. The relative position of the movable end section is detected by an encoder that generates position signals for input to a microprocessor, which utilizes the position signals to generate a three-dimensional image of the object.

European Patent No. 211,783 discloses a stereo video endoscope in which two light pipes deliver two images of the same object. These images are presented by a binocular device to the user's eyes to show a three dimensional image of the target. The apparatus includes two television cameras and video recorders for recording the images. The recorded images can be displayed on separate screens and viewed by a binocular viewing system.

Most conventional stereo endoscopes, however, share a number of deficiencies associated with their objective lens systems. These problems include a bulky and unwieldy configuration; high cost and complexity of fabricating the objective lens system; and the mediocre optical performance afforded by conventional objective lens systems.

An additional problem associated with conventional stereo video endoscope objectives involves the requirement that all portions of each left/right image be mapped to within a fraction of a video pixel to each other. This pixel mapping condition is a significant optical design constraint, because the object-to-image ray paths through the lens system are quite different for the left and right image points associated with a common object point.

Accordingly, it is a general object of the present invention to provide improved stereo endoscope objective lens systems that overcome the problems associated with conventional designs.

A more specific object is to provide an improved stereo endoscope objective lens system having optical elements that facilitate assembly of the system.

It is another object of the invention to provide an improved stereo endoscope objective lens system having elements that are substantially less expensive to manufacture than the elements of conventional systems.

A further object is to provide an improved stereo endoscope objective lens system having optical performance characteristics that are substantially superior to the performance characteristics of conventional systems.

Another object of the invention is to provide a stereo objective lens system affording a pixel mapped image.

The above and other objects and advantages of this invention will become more readily apparent when the following description is read in conjunction with the accompanying drawings.

SUMMARY OF THE INVENTION

The foregoing objects are attained by the invention, which provides an improved stereo endoscope objective lens system for video imaging in medical endoscopes and industrial borescopes.

One aspect of the invention includes two full-diameter doublets and a double set of two half-diameter identical doublets. The full-diameter doublets substantially collimate object points, i.e., image them substantially to infinity.

In accord with this aspect of the invention, most of the optical power necessary to accomplish this collimation is provided by in the first or outer doublet, while the second collimator doublet is of low power.

In a further aspect of the invention, the smaller doublets are identical, so that they can be most economically fabricated in production quantities. This is advantageous because these small lenses are inherently difficult to manufacture.

In another aspect of the invention, the large collimator doublets present equal-angle pairs from symmetrically disposed object points to the small stereo doublet pairs. This equal-angle solution provides accurate object/image mapping onto the final stereo image pair. In this design, the larger, and hence easier to fabricate, doublets carry the corrective burden, so that the smaller, more difficult to manufacture lenses can be made as simple as possible.

The invention will next be described in connection with certain illustrated embodiments; however, it should be clear to those skilled in the art that various modifications, additions and subtractions can be made without departing from the spirit or scope of the claims.

BRIEF DESCRIPTION OF THE DRAWINGS

For a fuller understanding of the nature and objects of the invention, reference should be made to the following detailed description and the accompanying drawings, in which:

FIG. **1** is a schematic diagram depicting a stereo video endoscope utilizing an objective lens system constructed in accordance with the invention;

FIG. **2** is an optical schematic diagram depicting an objective lens system constructed in accordance with the invention, showing light rays transmitted through the system; and

FIG. **3** is an optical schematic diagram depicting the objective lens system of FIG. **2** in combination with relay lenses for transmitting the optical images.

DESCRIPTION OF ILLUSTRATED EMBODIMENTS

FIG. **1** depicts the invention, an endoscope objective system **100**, utilized in a stereo video endoscopy system **1** for generating stereoscopic images of an object **12**. The system **1** includes a stereoscopic endoscope **10** containing objective system **100**; sensing modules **152, 154**; switching module **156**; and a monitor **158**. In addition to objective lens system **100**, the endoscope **10** includes conventional relay lenses or optical fibers **150** for transmitting light collected by the endoscope objective system **100** to light sensing modules **152, 154**.

The endoscope objective system **100** generates left and right optical images of the object **12** that are processed by sensing elements **152, 154** and video switching module **156** in a known manner to display an apparently three-dimensional image of the object **12** on video monitor **158**.

The stereoscopic effect is created by producing two optical images—a left image and a right image—through the endoscope objective system **100**. The left and right optical images generated by the objective system **100** are presented by the relay lens or optical fiber system **150** to left and right image sensors **152, 154**, which can be conventional charge-coupled device (CCD) cameras or other image sensing devices. The CCD elements operate in a known manner to convert the light collected by the objective system **100**, and transmitted by the relay lenses or optical fibers **150**, into electrical signals representative of the left and right optical images of the object **12**.

Conventional video switching circuitry **156** transmits the electronic signals representative of left and right video images as alternating left-right images on the monitor **158**. In accord with known video practice, these alternating images are presented at a switching rate higher than the flicker-sensing limit of the human eye, so that observed images appear flicker-free.

Moreover, the images can be alternately switched from a left-hand polarization mode to a right-hand polarization mode, such that, for example, the left image has a left-hand polarization and the right image has a right-hand polarization. The observer wears polarized glasses in which the left lens has the left-hand polarization and the right lens has the right-hand polarization. Thus, when the observer views the monitor **158**, the left eye sees only images from the left channel of the endoscope system and the right eye sees only images from the right channel, resulting in stereoscopic viewing. Video switching and display equipment of this type is commercially available from Stereographics, Inc. of San Rafael, Calif.; and from Tektronix Corp., of Beaverton, Oreg.

The accuracy and quality of the image displayed on monitor **158** is controlled by the performance of the endoscope objective system **100**, which is the subject of the present invention. FIGS. **2** and **3** depict an objective lens system **100** constructed in accordance with the invention, showing light rays transmitted through the system. FIGS. **2** and **3** depict the same system, with two elements being omitted from FIG. **3** for purposes of clarity.

As indicated in FIG. **2**, one embodiment of the objective system **100** includes two full-diameter doublets **110, 112** and a double set of two half-diameter identical doublets **114, 116, 118, 120**. The full-diameter doublets collimate object points, i.e., image them to infinity. In

accordance with the invention, most of the optical power required to accomplish this collimation is provided by the first collimator doublet **110** closest to the object **12**, while the second collimator doublet **112** can have a very low optical power.

Those skilled in the art will appreciate that the lenses of the objective system **100** depicted in FIG. **2** define a sequence of sixteen optical surfaces. A working example of a set of lenses for objective system **100** is set forth below in Table A.

TABLE A

SURFACE	RADIUS	THICKNESS	APERTURE	GLASS
1	—	−4.002608	0.225000	AIR
2	6.211875	2.500000	3.000000	SK5
3	4.462623	1.500000	3.000000	SF8
4	53.596342	0.400000	3.000000	AIR
5	−11.075366	1.600000	2.500000	SK5
6	−3.318618	1.500000	3.000000	SF8
7	−31.896589	−1.200000	2.500000	AIR
8	—	1.900000	0.464074	AIR
9	2.747539	1.600000	1.500000	SSKN8
10	−3.153676	0.700000	1.500000	SF1
11	4.815753	0.250000	1.500000	AIR
12	2.747539	1.600000	1.500000	SF1
13	−3.153676	0.700000	1.500000	SSKN8
14	4.815753	0.400000	1.500000	AIR
15	—	0.001000	1.400000	BK7
16	—	—	1.400000	AIR

In Table A, the numerical value in the "RADIUS" and "THICKNESS" columns are set forth in millimeters. The "GLASS" descriptions are standard optical glass characterizations as found in the product catalog of the Schott Glass Company of the Federal Republic of Germany. The "THICKNESS" column refers to the distance to the next optical surface. For example, in connection with surface **3**, the number 1.5000 signifies 1.5 millimeters to surface **4**. The column "RADIUS" refers to the radii of curvature of the respective curved surfaces. In this working example, the lens diameters are 6 millimeters for the large doublets and 3 millimeters for the small doublets. The overall object-to-image distance is 28.3 millimeters. The image diameter is 2.5 millimeters.

The system **100** is designed so that all parts of each left/right image are mapped to within a selected distance of each other such that stereoscopic image quality is maintained. For video applications, this selected distance is typically a fraction of a video pixel. This is a difficult condition to satisfy, because the object-to-image ray paths through the lens system are quite different for the left and right image points of a common object point. FIG. **2** clearly illustrates this path difference. The ray paths shown in FIG. **2** demonstrate how differently an object point is imaged through the lens elements for the left and right images.

The objective system **100** depicted in FIG. **2** is able to map all parts of each left/right image to within a fraction of a video pixel to each other, because the large collimator doublets present equal-angle pairs from symmetrically disposed object points to the small stereo doublet pairs.

This exact equal-angle solution results in an accurate object/image mapping onto the final stereo image pair. Accuracy is also enhanced by the combination of a first high power collimator doublet **110** and a second, lower power collimator doublet **112**. This second doublet **112** strongly influences the optical solution to the image-mapping problem.

A further advantage is provided in that the smaller doublets **114**, **116**, **118**, and **120** are identical, so that they can be most economically fabricated in production quantities. This characteristic tends to offset the inherent difficulty of manufacturing small lenses. The larger, and hence easier to fabricate, doublets carry the corrective burden, so that the smaller, more difficult to manufacture lenses can be as simple as possible.

As indicated in FIG. **1**, the endoscope objective system **100** can be utilized in connection with optical fiber elements or a set of relay lenses **150** to conduct light from the objective system to the sensing elements **152**, **154**. An example of a relay lens system **150** that can be employed with the objective system **100** is depicted in FIG. **3**.

The relay lens system of FIG. **3** includes a plurality of rod relays **160**, **162**, **164** utilized in combination with objective system **100**. Those skilled in the art will recognize that a wide range of relay lens systems can be employed with an objective system constructed in accordance with the invention.

Alternatively, an endoscope constructed in accordance with the invention can employ a conventional CCD array mounted within the same housing as the objective system. As indicated in FIG. **2**, the CCD array can include left and right sensing elements **152**, **154**, disposed to receive the optical images generated at the output of doublets **118** and **120**. The design and construction of CCD elements having more than one photosensitive region in a monolithic package is well known in the art. The electrical signals generated by the CCD array can be conducted from the housing by a conventional conduit. This configuration eliminates the requirement for a relay lens system or optical fibers.

The system **100** depicted in FIGS. **2** and **3** offers advantages for use in medical endoscopes and industrial borescopes. The configuration offers the advantage of being adaptable to fit into a small tube diameter, as small as **3** millimeters. The design also affords high resolution and low distortion for diagnostic and surgical use, and for high-accuracy industrial measurement applications.

It will thus be seen that the invention efficiently attains the objects set forth above, among those made apparent from the preceding description.

It will be understood that changes may be made in the above construction and in the foregoing sequences of operation without departing from the scope of the invention. It is accordingly intended that all matter contained in the above description or shown in the accompanying drawings be interpreted as illustrative rather than in a limiting sense.

It is also to be understood that the following claims are intended to cover all of the generic and specific features of the invention as described herein, and all statements of the scope of the invention which, as a matter of language, might be said to fall therebetween.

Having described the invention, what is claimed as new and secured by Letters Patent is:

1. A stereoscopic objective lens system for a stereo video endoscope, the objective lens system converting optical images of an object generated at an objective end of the objective system to pixel-mapped left and right optical images at an image plane end of the objective system, the objective lens system comprising

A. a first collimator doublet lens element proximate the objective end for collecting light from points on the object, said first doublet lens having a first

optical axis, a selected diameter and a selected optical power,

B. a second collimator doublet lens for collecting light from said first collimator doublet lens,

said second collimator doublet lens being situated adjacent said first collimator doublet lens

so that the optical axis of said second collimator doublet lens is substantially collinear with the optical axis of the first collimator doublet lens,

said second collimator doublet lens having a selected diameter and a selected optical power,

wherein said first and second collimator doublet lenses cooperate to image the object points substantially to infinity so that light transmitted by the second collimator doublet lens from the object points is substantially collimated,

C. a first right/left pair of stereo doublet lenses

situated adjacent said second collimator doublet lens for collecting light from said second collimator doublet lens,

said first right/left pair of stereo doublet lenses including

a first right doublet lens and

a first left doublet lens,

the optical axis of said first right doublet lens and the optical axis of said first left doublet lens being substantially parallel to the optical axis of the second collimator doublet lens,

wherein said first and second collimator doublet lenses and said first right/left pair of stereo doublet lenses cooperate so that the first and second collimator doublet lenses present equal-angle light ray pairs from symmetrically disposed object points to the first right/left pair of stereo doublet lenses, and

D. a second right/left pair of stereo doublet lenses,

said second pair of stereo doublet lenses being situated adjacent said first right/left pair of stereo objective system

so that the optical axis of said second right doublet lens is substantially collinear with the optical axis of said first right doublet lens and

the optical axis of said second left doublet lens is substantially collinear with the optical axis of said first left doublet lens,

said second right doublet lens collecting light from said first right doublet lens to generate a right image at the image plane,

said second left doublet lens collecting light from said first left doublet lens to generate a left image at the image plane, such that corresponding portions of each left/right image are mapped to within a selected distance of each other.

2. A lens system according to claim 1 wherein the diameter of said second collimator doublet lens is approximately equal to the diameter of said first collimator doublet lens.

3. A lens system according to claim 2, wherein said first right doublet lens, said first left doublet lens, said second right doublet lens, and said second left doublet lens are substantially identical.

4. A lens system according to claim 3 wherein the diameter of said first right doublet lens, said first left doublet lens, said second right doublet lens, and said second left doublet lens are approximately one-half the diameter of said first collimator doublet lens.

5. A lens system according to claim 4 wherein said first collimator doublet lens has a higher optical power than said second collimator doublet lens.

6. Stereoscopic video endoscope apparatus for displaying stereoscopic video images of an object, the apparatus comprising

A. a stereoscopic objective lens system,

the objective lens system converting optical images of the object generated at an objective end of the objective system to pixel-mapped left and right optical images at an image plane end of the objective system, the objective lens system including

(i) a first collimator doublet lens element proximate the objective end for collecting light from points on the object,

said first doublet lens having a first optical axis, a selected diameter and a selected optical power,

(ii) a second collimator doublet lens for collecting light from said first collimator doublet lens,

said second collimator doublet lens being situated adjacent said first collimator doublet lens so that the optical axis of said second collimator doublet lens is substantially collinear with the optical axis of the first collimator doublet lens,

said second collimator doublet lens having a selected diameter and a selected optical power,

wherein said first and second collimator doublet lenses cooperate to image the object points substantially to infinity so that light transmitted by the second collimator doublet lens from the object points is substantially collimated,

(iii) a first right/left pair of stereo doublet lenses situated adjacent said second collimator doublet lens for collecting light from said second collimator doublet lens, said first right/left pair of stereo doublet lenses including

a first right doublet lens and

a first left doublet lens,

the optical axis of said first right doublet lens and the optical axis of said first left doublet lens being substantially parallel to the optical axis of the second collimator doublet lens,

wherein said first and second collimator doublet lenses and said first right/left pair of stereo doublet lenses cooperate so that the first and second collimator doublet lenses present equal-angle light ray pairs from symmetrically disposed object points to the first right/left pair of stereo doublet lenses, and

(iv) a second right/left pair of stereo doublet lenses, said second pair of stereo doublet lenses being situated adjacent said first right/left pair of stereo doublet lenses and proximate the image plane end of the objective system

so that the optical axis of said second right doublet lens is substantially collinear with the optical axis of said first right doublet lens and

the optical axis of said second left doublet lens is substantially collinear with the optical axis of said first left doublet lens,

said second right doublet lens collecting light from said first right doublet lens to generate a right image at the image plane,

said second left doublet lens collecting light from said first left doublet lens to generate a left

image at the image plane, such that corresponding portions of each left/right image are mapped to within a selected distance of each other, and

B. right and left optical sensing means, situated at right and left regions of the image plane, respectively, for converting said right and left optical images to electrical signals representative of right and left video signals in response to said right and left optical images, respectively.

7. Apparatus according to claim **6**, further comprising video monitor means, in electrical communication with said first and second optical sensing means, for displaying right and left video images in response to said electrical signals generated by the first and second optical sensing means.

8. Apparatus according to claim **6** wherein said right and left optical sensing means include at least on CCD element.

9. Apparatus according to claim **8** wherein

said objective lens system is contained within a housing, and

said at least one CCD element is disposed within said housing in proximity to said objective lens system so that optical images generated by said objective lens system are transmitted to said at least one CCD element.

[57] **ABSTRACT**

A wide-angle objective for a picture-taking lens of an aerial mapping camera, consisting of 11 lenses and 14 glass-air surfaces, the first optical element of which after the center aperture on the picture side is a converging fluorspar or fluorspar-like lens. Due to the large refractive index difference between this lens and the following meniscus lens and due to the provision of a triple group of high refractive index on the object side before the center aperture, a high resolution, low residual distortion and minimal lateral chromatic aberration are achieved.

FIG. 1

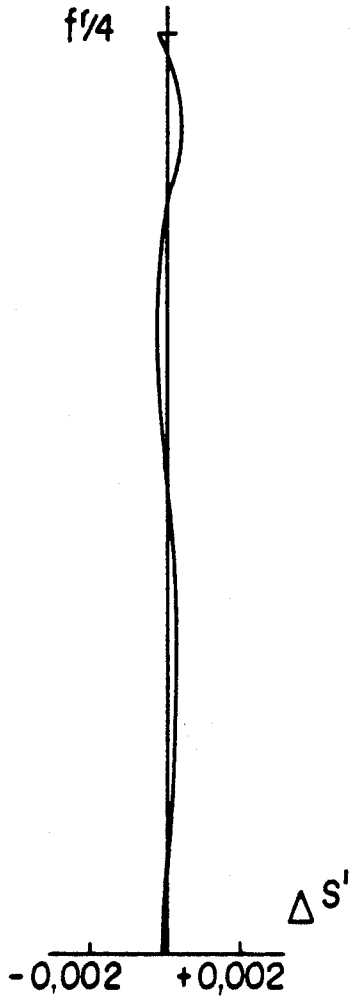

FIG. 2

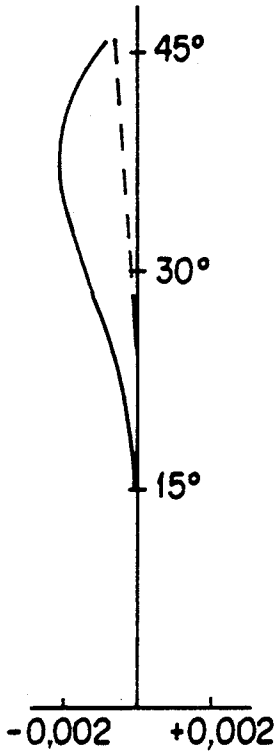

FIG. 3

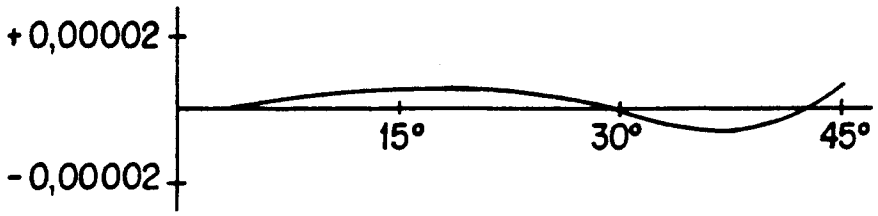

FIG. 4

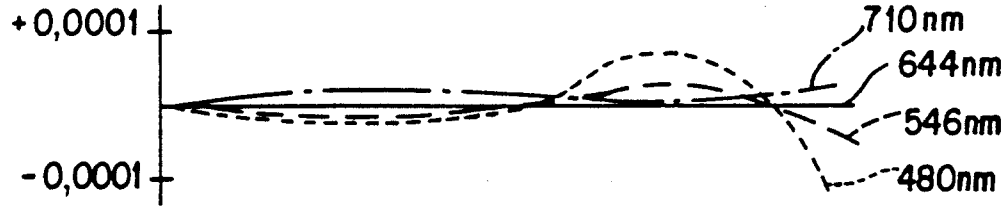

FIG. 5

WIDE-ANGLE OBJECTIVE

BACKGROUND OF THE INVENTION

The invention relates to a picture-taking lens for an aerial mapping camera.

In objectives for aerial photographic technology, the surface weighted resolution capability (AWAR), the resolution at the worst picture site, distortion and lateral chromatic aberrations are the main characteristic performance data that are used to describe the optical imaging performance. They must be considered in relation to the technological degree of difficulty of making the lens, to the material used and to the mass and dimensions of the objective. At the present time, there are three picture-taking lenses of comparable quality for aerial mapping cameras:

The universal Aviogon 15/4 UAg (f:4), with an AWAR of 75 L/mm, a resolution of 40 L/mm at the worst picture site and a distortion of ±3 microns measured at the overall length of 372 mm and the maximum lens diameter of about 234 mm. The lens has a 13-lens objective construction with a 3-fold and a 4-fold wring group, and relatively low performance data. This characteristic performance data for the AWAR and the resolution of the worst site of the picture, moreover are not attained for the full opening of k=4, but only when the aperture is stopped down to 5.6. As a result the maximum opening is practically not usable if the highest possible resolution is required. For this objective, approximately 550 nm has been selected as the achromatization wavelength. As a result, the lateral chromatic aberration in the short wave region for 480 nm is less than 20 microns. In the longwave range of the spectrum, lateral chromatic aberrations of up to 20 microns occur at 650 nm because of the relatively large secondary spectrum.

The Pleogon A 4/150 has an AWAR of 80 L/mm, a resolution of 67 L/mm at the worst site of the picture and a distortion of ±5 microns. Moreover, it is known that the best examples of this type achieve an AWAR of up to 96 L/mm and a distortion of ±1 micron. For the achromitization of the lateral chromatic aberration, a wavelength of 610 nm was selected. Because of the relatively large secondary spectrum, a lateral chromatic aberration of about 60 microns remains for a wave length of 480 nm and a lateral chromatic aberration of about 5 microns remains for a wave length of 650 nm. Nothing is known of the mass and dimensions of the objective. The material outlay with 9 lenses is relative low. However, the lenses of the objective have an extreme shape, with an center thickness ratio of about 30:1 and extreme deflections. The objective is therefore difficult technologically to produce.

The Lamegon 4.5/150 DM has an AWAR of 90 L/mm, a resolution of 70 L mm at the worst site of the picture and a distortion of ±1 microns. With this objective, however, the lateral chromatic aberration limits the performance in optical representation. For 470 nm, based on the wavelength of 640 nm at which the achromatization lies, it amounts to 30 microns. In the longwave region of the spectrum of 768 nm the lateral chromatic aberration is 30 microns. The relative large secondary spectrum of all known technical solutions does not ensure that the distortion is independent of the spectral sensitivity of the film. In color photographs, it necessarily leads to clearly identifiable color fringes and disadvantageously affects the resolution capability of broad-band sensitized black-and-white films. The AWAR achieved and the resolution capability at the worst site of the picture do not satisfy the highest requirements of photogrammetric recording techniques.

SUMMARY OF THE INVENTION

It is an object of the invention to provide a wide-angle objective as a picture-taking lens for aerial mapping cameras with demanding characteristic performance data and advantageous manufacturing parameters, while avoiding the disadvantages of the state of the art.

The invention is directed to the provision of a high resolution wide-angle lens with a picture angle $2\delta=90°$, a relative aperture of k=4 and a focal length of 150 mm, which has an AWAR of 115 L/mm on internationally customary high-resolution aerial photography films a resolution at the worst picture site of 80 L/mm and a residual distortion of less than ±1 micron. The maximum resolution capability is to be attained for a relative aperture of k=4.5 and the decrease in performance is to be small for a full aperture. Moreover, the lateral chromatic aberration in the broad-band spectral range of 480 nm to 770 nm in the picture field is to be less than 10 microns and the maximum lens diameter is to be smaller than $\frac{2}{3}$ of the picture diagonal and the overall length is not to be larger than the picture diagonal.

Pursuant to the invention, this object is accomplished by providing a wide-angle objective with a high resolution and a low residual distortion, comprised of 11 lenses and 14 glass-air interfaces. 6 lenses are disposed before a center aperture in the direction of the light and centrically to the optical axis, including diverging meniscus lens, a diverging double composite group and a converging composite groups 5 lenses are disposed after the center aperture, including a converging group, a converging double composite group and finally a diverging meniscus lens, one of the lenses after the center aperture being formed of a fluorspar or a fluorspar-like. The converging before the aperture is comprised of composite group a conlverging lens of high refractive index, a diverging lens and a further converging lens. The converging group after the center aperture includes the converging fluorspar or fluorspar-like lens and a diverging meniscus lens, which are separated from one another by a small thickness of air.

The use of a strongly converging lens of extremely low dispersion and high relative partial dispersion such as fluorspar or fluorsparlike glass in the immediate vicinity of the aperture makes is possible to realize, at the same time, a slight secondary spectrum for the longitudinal and lateral chromatic aberrations without interfering zones of the lateral chromatic aberration. The very large refractive index difference between the fluorspar lens and the subsequent meniscus lens in conjunction with very narrow air gap that is present between the two lenses satisfies the prerequisite of very good correction of the apertural error for the large relative aperture. The disadvanatageous effect of the low reflecting flurospar lens on the coma is compensated for by the high refracting converging lens of the triple group on the aperture space side.

The lenses selected have a maximum center thickness ratio of 1:10 and are therefore easily produced.

BRIEF DESCRIPTION OF THE DRAWINGS

The invention is explained in greater detail by means of the accompanying the following description of an drawings and of the operation.

In the drawings:

FIG. 1 is a sectional representation of the lenses of an objective in accordance with the invention.

FIG. 2 shows the sperical aberration as a function of the opening and of the distance between the back lens and the image $\Delta s'$.

FIG. 3 shows the meridianal (broken line curve) and sagittal (solid line curve) curvature of the image as a function of the angle of the image.

FIG. 4 shows the distortion as a function of the angle of the image.

FIG. 5 shows the chromatic distortion, the lateral chromatic aberration, as a function of the angle of the image for 4 different wavelengths.

DETAILED DESCRIPTION OF A PREFERRED EMBODIMENT OF THE INVENTION

In FIG. 1, lenses L1 to L11 are disposed in the following manner along the optical axis 0—0' in the direction of the light:

Before a center aperture B, a diverging meniscus lens L1, a diverging double composite group L2, L3 and a converging triple composite group L4, L5, L6 and, after the aperture B

a converging group including a converging lens L7 and a diverging menicus lens L8, which are separated by a small thickness of air, and a converging composite group L9, L10 and finally a diverging meniscus lens L11.

The lenses L1 to L11 are labeled by the radii of curvature r1 to r18 of their lens surfaces by numbering them continuously in the direction of the light. The lens thicknesses d1 to d11, measured along the optical axis, and the thicknesses of air 11 to 16 between the axial apexes of the lenses are labeled with the same numbering system.

The refractive indexes of the glasses used are likewise marked in a known manner n1 to n11, and the Abbe numbers are marked V1 to V11, these numbers being related to the e line, that is, to the wavelength of 546.0740 nm.

The following data Table contains the construction data wide-angle objective in accordance with the invention the length data being normalized for a focal length of 1.

FIGS. 2 and 3 show the good geometrical and optical correction of the lens that are prerequisite for a good resolution. The distortion of the objective is shown in FIG. 4 and the lateral chromatic aberration of the objective is shown in FIG. 5.

Lens	Radii	Thickness/ Thickness of Air	Refractive Indexes	Abbe Numbers
	r1 = +4.2149

L11		d 11 = 0.0722	n 11 = 1.51859	V 11 = 63.86
	r18 = −1.2586			

We claim:

1. A wide-angle objective with a high resolution and low residual distortion, comprising 11 lenses and 14 glass-air interfaces, wherein, in the direction of light and centrically to the optical axis, 6 lenses are positioned before a center aperture, including a diverging meniscus lens, a converging double composite group and a first converging composite group, in that order, and 5 lenses are positioned after the center aperture, including a second converging group, a converging double composite group and finally a diverging meniscus lens, in that order, said first converging composite group comprising a converging lens of high refractive index, a diverging lens and a further converging lens, the second converging group, after the center aperture including a converging lens consisting of fluorspar or of a material of optical properties like those of flurospar and a diverging meniscus lens separated from one another by a small air gap.

[57] **ABSTRACT**

In an electronic still camera employing a CCD, an automatic exposure control and an automatic focusing control are carried out by utilizing an image signal derived from CCD to photograph a subject. A liquid crystal display unit is provided within a viewfinder. A designation is performed on a subject image to be automatically controlled for the exposure and focusing operations by utilizing a frame displayed on the liquid crystal display unit. The automatic exposure control and automatic focusing control are executed with respect to the subject positioned within the frame displayed on the liquid crystal display unit.

CAMERA APPARATUS CAPABLE OF FREELY SETTING OBJECTIVE AREA WITHIN VIEWED SUBJECT

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to a camera apparatus equipped with an automatic focusing control function, and/or an automatic exposure control function.

2. Description of the Related Art

Recently, most of the camera apparatuses are equipped with either an automatic focusing control function, or an automatic exposure control function, or with both functions.

In such an automatic focusing control function, a focusing area is defined at a central part within a viewfinder, and then a focusing control is performed with respect to a viewed subject within this focusing area.

Furthermore, a so-called "focusing lock function" is provided with the automatic focusing control function. In accordance with the focusing lock function, a photograph focused on a subject which should be focused can be obtained even if this subject is not positioned within the focusing area while viewing the image through the viewfinder.

That is, this focusing lock function is performed as follows. Even when a change occurs in the once focused subject positioned within the focusing area, the lens position set to obtain the focused subject is locked without performing a further focusing function. In general, the focusing lock function is operable when the release switch is held under such a condition that this switch is depressed over a half travel length thereof, or the focusing lock switch is depressed.

In, on the other hand, the automatic exposure control function, the light quantity of the entire subject is generally measured so as to perform the exposure control.

When the focusing lock function is not equipped with the camera apparatus, the subject to be focused must be continuously positioned on the center of the viewfinder in order to perform the above-described automatic focusing control function, since the focusing area is fixed. Accordingly, such a camera apparatus has a drawback that a freedom on designation of an image is restricted. Furthermore, even if the automatic focusing control function is performed in conjunction with the focusing lock function, cumbersome operations are required, resulting in the incorrect operation of the camera apparatus. Also, in a still camera, there is another drawback that a lengthy photographing operation is required.

Furthermore, the above-described conventional automatic exposure control function has the following drawbacks. That is, in case that a dark portion and a light portion, the luminance of which is extremely different from that of the dark portion, are present within an overall subject to be photographed, the exposure control is executed based upon an average value of the respective luminance. As a consequence, the resultant image has different luminance from the respective luminance of both the dark and light portions. In particular, the above-described problem is emphasized when an image requiring the optimum luminance is positioned at either the dark portion, or the light portion.

SUMMARY OF THE INVENTION

The present invention has been made in an attempt to solve the above-described problems of the conventional camera apparatuses equipped with the automatic focusing function and/or automatic exposure function, and therefore, has an object to provide a camera apparatus capable of obtaining a subject image to be focused, or exposure-measured, from an arbitrary portion within the subject which is being observed through a viewfinder, while performing, for instance, the automatic focusing control function, or the automatic exposure control function.

To achieve the above-described object, a camera apparatus according to the present invention comprises:

optical image forming means for forming an optical image:

image sensing means having a photoelectric converting area comprised of a plurality of frame areas, for producing electric signals in response to said optical image formed by said optical image forming means;

area designating means for designating a desired frame area from said plurality of frame areas;

selecting means for selecting from the electric signals produced by the whole electric converting area, electric signals produced by said desired frame area designated by said area designated means; and,

producing means for producing a video signal based on said electric signals produced by said image sensing means and said selecting means.

In accordance with the camera apparatus of the present invention with the above-described arrangements, the operational capabilities for performing automatic focusing control and also automatic exposure control can be improved, and furthermore the desirable images can be acquired irrespective of the designation of the subject, and the conditions of the luminance of the subject.

BRIEF DESCRIPTION OF THE DRAWINGS

The above-described aspects and other features of the present invention are explained in the following description, taken in connection with the accompanying drawings, in which:

FIG. **1** is a schematic block diagram of a general arrangement of an electronic still camera according to a first preferred embodiment of the invention;

FIG. **2** is a schematic block diagram of a detailed arrangement of the electronic still camera shown in FIG. **1**;

FIG. **3** is a schematic diagram of a detailed arrangement of an image sensor shown in FIG. **2**;

FIG. **4** is a schematic block diagram of a detailed arrangement of a photometric area control unit represented in FIG. **2**;

FIG. **5** is a schematic block diagram of a detailed arrangement of an automatic exposure control unit represented in FIG. **2**;

FIG. **6** represents display conditions of a liquid crystal display unit employed within the viewfinder shown in FIG. **2**;

FIG. **7** is a flowchart for explaining operations of the automatic focusing control in the electronic still camera shown in FIG. **2**;

FIGS. **8A** to **8D** are timing charts for representing output conditions of signals derived from the major circuit portions of the electronic still camera while obtaining the luminance signal of the designated exposure-measuring area;

FIG. 9 is a schematic block diagram of an automatic exposure control unit shown in FIG. 2 according to a second preferred embodiment of the present invention;

FIG. 10 is a schematic block diagram of an automatic exposure control unit shown in FIG. 2 according to a third preferred embodiment of the present invention; and,

FIGS. 11A to 11D are timing charts for representing output conditions of signals derived from the major circuit portions of the electronic still camera while performing the exposure control in the automatic exposure control unit shown in FIG. 10.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

GENERAL ARRANGEMENT OF ELECTRONIC STILL CAMERA

Referring now to FIG. 1, an overall arrangement of an electronic still camera according to a first preferred embodiment of the present invention will be described in detail.

In the first electronic still camera shown in FIG. 1, an optical section 1 is employed so as to focus an image of an object (not shown in detail) being photograph with a desirable light level onto a predetermined plane of an image signal producing section 2. Under the control of a control section 3, the image signal producing section 2 produces an electronic still image signal in response to the object image focused by the optical section 1. Then, the electronic still image signal produced by the image signal producing section 2 is supplied to an image signal processing and selecting section 4.

The function of the image signal producing and selecting section 4 is to produce both a luminance signal and a color difference signal based on the electronic still image signal derived from the image signal producing section 2. Furthermore, the luminance signal is supplied from this image signal processing and selecting section 4 to both an image signal storage and output section 5, and an exposure and focusing control section 6, whereas the color difference signal is furnished therefrom to the image signal storage and output section 5. The image signal processing and selecting section 4 selects the luminance signal to be supplied to the exposure and focusing control section 6 in conjunction with the image signal producing section 2. That is, both the image signal processing and selecting section 4 and image signal producing section 2 produce a luminance signal with respect to an electronic image signal constituting a portion within a photographing range which is designated by a switch and key section 7, under the control of the control section 3, and thereafter supplies this selected luminance signal to the exposure and focusing control section 6.

The function of the above-described image signal storage and output section 5 is to store therein both the luminance signal and color difference signal supplied from the image signal processing and selecting section, and also to produce a color television signal, for instance, the NTSC (National Television System Committe) color TV signal in response to these luminance and color difference signals, which will be then furnished to an image signal output terminal.

Furthermore, the function of the exposure and focusing control section 6 is to detect an on-focusing condition of the object image focused by the optical section 1 based upon the luminance signal supplied from the image signal processing and selecting section 4, and to control the optical section 1 in such a manner that the above-described on-focusing condition of the object under imaging can be achieved. Moreover, this exposure and focusing control section 6 senses the light quantity of the object via the optical section 1, and controls both the optical section 1 and image signal producing section 2 in response to the sensed light quantity in such a way that the object image is converted into the electronic still image signal with a proper exposure level.

The switch and key section 7 outputs to the control section 3, an instruction signal for instructing a commencement of a photographing/recording process, instruction signals for instructing commencement of an exposure control process and a focusing control process, and an instruction signal for instructing an output of the recorded image signal. This switch and key section 7 further outputs a switching signal for switching an entire photometric mode and a spot photometric mode in connection with an exposure/focusing control during the photographing mode, and also a designation signal for designating a photometric region during the spot photometric mode.

In the arrangement of the electronic still camera shown in FIG. 1, a finder section 8 is provided, which is so constructed that the image of the object under photograph within the range focused by the optical section 1 can be observed, and also a photometric region designated by the switch and key section 7 can be indicated.

PARTICULAR ARRANGEMENT OF ELECTRONIC STILL CAMERA

A detailed arrangement of the respective sections shown in FIG. 1 will now be described with reference to FIG. 2.

First, the optical section 1 is constructed of an optical block 11, a lens driving block 12 and a diaphragm drive block 13.

The optical block 11 is provided to obtain the optical image of the object being photographed, and is arranged by lenses 14 and 15 and a diaphragm 16.

Then, the lens driving block 12 is constructed of a lens driving motor 17 and a motor drive control unit 18. The lens driving block 12 drives the lens 14 of the optical block 11 under the control of the exposure and focusing control unit 6.

The diaphragm drive block 13 is constituted by a diaphragm drive motor 19 and a motor drive control unit 20, and opens/closes the diaphragm 16 employed in the optical block 11 under the control of the exposure and focusing control unit 6. The optical image of the subject is focused by the optical block 11 on a predetermined position of the image signal producing section 2 at which an image sensor 21 constructed of a solid-state imaging element (CCD and the like) is provided. The image sensor 21 is, for instance, an area sensor having 380,000 picture elements (pixels). Color filters (not shown in detail) are provided on the light receiving plane of this area sensor from which an electric color image signal can be obtained. Then, the above-described image sensor 21 outputs an electric image signal corresponding to an optical image of the subject which has been formed by the optical block 11 under the control of an H driver 22 and a V driver 23.

Both the H driver 22 and V driver 23 control the operations of the sensor 21 based on the exposure time

data stored in the exposure time data memory unit **25** under the control of the control unit **24** (control section **2**). It should be noted that the above-described sensor **21**, H driver **22**, V driver **23**, transfer control unit **26** and exposure time data memory unit **25** constitute the image signal producing section **2** shown in FIG. **1**.

DETAILED ARRANGEMENT OF IMAGE SENSOR

In FIG. **3**, there is shown a detailed arrangement of the above-described image sensor **21**.

In this image sensor **21**, a plurality of photoelectric converting units (i.e., pixels) **50** are arranged along both a vertical direction and a horizontal direction. Vertical transfer units **51** are provided with each row of the vertical photoelectric converting unit **50**. Vertical transfer clocks ϕ_{V1}, ϕ_{V2}, and ϕ_{V3} are supplied from the V driver **23** to the vertical transfer unit **51** so that charges produced by the photoelectric converting unit **50** are transferred in response to these vertical transfer clocks ϕ_{V1}, ϕ_{V2}, and ϕ_{V3}. It should be noted that in this vertical transfer unit **51**, the transfer directions of the charges obtained by the photoelectric converting unit **50** are changed in accordance with the output sequence of the vertical transfer clocks ϕ_{V1}, ϕ_{V2}, and ϕ_{V3}.

A drain **52** is provided above the vertical transfer unit **51**. The drain **52** drains out the charges transferred from the vertical transfer unit **51**.

Under the vertical transfer unit **51**, an accumulating unit **53** is formed. The function of this accumulating unit **53** is to temporarily store the charges transferred from the vertical transfer unit **51**.

A horizontal transfer unit **54** is provided under this accumulating unit **53**. Horizontal transfer clocks ϕ_{H1}, ϕ_{H2}, and ϕ_{H3} are supplied from the H driver **22** to the horizontal transfer unit **54**. In response to the horizontal transfer clocks ϕ_{H1}, ϕ_{H2}, and ϕ_{H3}, this horizontal transfer unit **54** transfers the charges which are supplied from the vertical transfer unit **51** via the accumulating unit **53**.

Then, the charges transferred from the horizontal transfer unit **54** are output via an amplifier **55** to an external circuit.

When the image signal is acquired, the image sensor **15** with the above-described arrangements performs an interline transfer in response to the transfer clocks ϕ_{V1}, ϕ_{V2}, ϕ_{V3}, ϕ_{H1}, ϕ_{H2}, and ϕ_{H3} which are supplied from the V driver **17** and H driver **16**, respectively, and on the other hand, drains out the charges obtained by the photoelectric converting unit **50** to the drain **53** when the vertical transfer clocks ϕ_{V1}, ϕ_{V2}, and ϕ_{V3} are supplied in accordance with a supply sequence opposite to that of the above operation.

It should be noted that the above-described image sensor **21** or an equivalent element may be constructed by employing, for instance, the charge-coupled device type TC-245 of Texas Instruments Inc.

The image signal output from the image sensor **21** is supplied to an image signal process circuit **27** of the image signal processing and selecting section **4**, as represented in FIG. **2**.

The above-described image signal processing and selecting section **4** includes a sync signal generating unit **28**, a switching circuit **29**, and a photometric area control unit **30** in addition of the above-mentioned image signal process circuit **27**, and further includes the transfer control unit **26**. To the image signal process circuit **27**, the above-described transfer clocks from the H driver **22** and V driver **23**, and also a vertical sync signal Vsync and a horizontal sync signal Hsync from the sync signal generating unit **28** are supplied. The image signal processing unit **27** fetches the image signal supplied from the image sensor **21** in synchronism with the transfer clocks from the H driver **22** and V driver **23**, and produces a luminance signal Y from the image signal and also a luminance/sync signal (Y+S) and color difference signals (R−Y), (B−Y) by adding the vertical sync signal Vsync and horizontal sync signal Hsync to this luminance signal Y. The image signal processing circuit **27** outputs the luminance signal Y via the switching circuit **29** to an automatic exposure control unit **31** and an automatic focusing control unit **32** of the exposure and focusing control section **6**, and further outputs both the luminance/sync signal (Y+S), and color difference signals (R−Y), (B−Y) to an image data memory unit **33** of the image signal storage and output section **5**. In addition, the above-described image signal processing unit **27** supplies the sync signal Ysync corresponding to the output of the luminance signal Y to the photometric area control unit **30** and the automatic exposure control unit **31**.

The photometric area control unit **30** controls the switching operation of the switch circuit **39** under the control of the control unit **24**, and is so arranged as shown in FIG. **4**.

In FIG. **4**, a counter **90** is employed to perform a counting operation in response to the sync signal Ysync of the luminance signal Y outputted from the image signal processing unit **27**. When the counter **90** counts a quantity of sync signal Ysync outputted from the image signal processing unit **27** until all of the luminance signals Y corresponding to the pixels along **1** horizontal scanning period of the image sensor **1** have been outputted therefrom, a carry signal is outputted and is supplied to the counter **90** for reset operations. Then, the count value of this counter **90** is supplied to a coincidence detecting circuit **91**.

Furthermore, there are provided a head pixel position data memory unit **92** and a last pixel position data memory unit **93**. The head pixel position data memory unit **92** stores data on a head pixel position of a photometric area in the horizontal scanning direction which is outputted from the control unit **24** in accordance with the photometric area designated by the switch and key section **7**, whereas the last pixel position data memory unit **93** stores therein data on a last pixel position of the above-described photometric area. The memory data stored in the pixel position data memory units **92** and **93** are supplied via corresponding gate circuits **94** and **95** to the coincidence detecting circuit **91**.

On the other hand, when there is a coincidence between the count value derived from the counter **90** and the pixel position data read out from either the head pixel position data memory unit **92**, or the last pixel position data memory unit **93**, the coincidence detecting circuit **91** outputs a coincidence detecting signal. The coincidence detecting signal outputted from the coincidence detecting circuit **91** is supplied via either a set terminal S of a flip-flop **97**, or an AND gate **98** to a reset terminal R of the flip-flop **97**. Then, a set output Q of the flip-flop **97** is furnished via an OR gate **99** to a switching circuit **29**, and to an AND gate **98** and also a gate circuit **95**. Further, this set output Q is supplied via an inverter **100** to the AND gate **96** and gate circuit **94**. To this OR gate **99**, the overall photometric mode signal designated by the switch and key section **7** in the

overall photometric mode is supplied from the control unit **24**.

In the photometric area control unit **30** with the above-described circuit arrangement, first, both the count value of the counter **90** and the pixel position data of the head pixel position memory unit **92** are supplied to the coincidence detecting circuit **91**. When there exists a coincidence between the count value and pixel position data, the flip-flop **97** is set to close the switching circuit **29**. At the same time, in response to the set output Q from the flip-flop **97**, the gate circuit **95** is closed and the pixel position data from the last pixel position data memory unit **93** is supplied to the coincidence circuit **91**. Then, when the coincidence is again detected in the coincidence detecting circuit **91**, the flip-flop **97** is caused to be reset so that the switching circuit **29** is closed.

Now, the operations of the exposure and focusing control section **6** will be described.

The exposure and focusing control section **6** is constructed of an automatic exposure control unit **31** and an automatic focusing control unit **32**.

The functions of the automatic exposure control unit **31** are to obtain exposure time data, an open degree of the diaphragm **16**, and open degree control data for controlling this open degree in response to the luminance signal Y which has been supplied via the switching circuit **29** under the control of a control unit **24**.

AUTOMATIC EXPOSURE CONTROL UNIT

FIG. **5** represents a detailed arrangement of the above-described automatic exposure control unit **31**. This automatic exposure control unit **31** is constructed of an A/D converting unit **61**, a high speed adding circuit **62**, and a diaphragm/time converting circuit **63**.

The A/D converting circuit **61** has such a function that the luminance signal Y supplied via the switching circuit **29** from the image signal processing circuit **27** is sequentially converted into digital data corresponding to the value of this luminance signal Y in synchronism with the sync signal supplied from the image signal processing circuit **27**. Thus, the digital data obtained from the A/D converting unit **61** is sequentially supplied to the high speed adding circuit **62** so as to be added to each other. Furthermore, the addition data obtained from the high speed adding circuit **62** is fetched into the diaphragm/exposure time converting circuit **63** in synchronism with a transfer end signal output from a transfer control unit **26**.

The diaphragm/exposure time converting unit **63** includes a table (not shown) from which a proper open degree of the diaphragm **16** and a proper exposure time based upon the addition data of the high speed adding circuit **62** which are obtained by adding all of the luminance signals supplied via the switching circuit **29** thereto, and data on the distance between the subject and the electronic still camera, which are supplied from the automatic focusing control unit **32**.

Then, the diaphragm/exposure time converting unit **63** supplies the exposure time data to the exposure time data memory unit **25**, and also furnishes the diaphragm open degree control data to the motor drive control unit **20** for controlling a diaphragm drive motor **19** to vary the open degree of the diaphragm **16**, based upon either the data obtained from the table, or the control data supplied from the control unit **24**.

Referring again back to the automatic focusing control unit **32** shown in FIG. **2** detects an on-focusing condition of an image of a subject in response to the luminance signal Y supplied via the switching circuit **29** from the image signal processing circuit **27** so as to supply a control signal to the motor control unit **18** for controlling the lens drive motor **17** by which the positions of the lens **14** is varied. It should be noted that the above-described automatic focusing control unit **32** commences the detecting operation of the on-focusing condition in synchronism with a transfer control unit **26**. For instance, the automatic focusing control unit **32** detects the differences in the luminance between the respective pixels based upon the luminance signals in order to detect the on-focusing condition of the subject. The automatic focusing control unit **32** acquires data on the distance between the subject and camera based upon the position of the lens **14** when the on-focusing condition of the subject is just detected, and thereafter furnishes this data to the automatic exposure control unit **31**.

Then, the above-described image signal storage and output section **5** will now be described as follows. This image signal storage and output section **5** is arranged by the above-mentioned data memory unit **33** and stored image signal processing unit **34**.

The function of the image data memory unit **33** is to perform a predetermined process to both the luminance/sync signal (Y+S) and the color difference signals (R−Y), (B−Y) supplied from the image signal processing circuit **27**, and thereafter to store the processed signals into a preselected memory medium. In case that, for instance, the luminance/sync signal (Y+S) and color difference signals (R−Y), (B−Y) are recorded on a video floppy disk, the luminance/sync signal (Y+S) is sequentially superimposed with the color difference signals (R−Y), (B−Y), whereby the recording process is performed.

The image data memory unit **33** supplies both the luminance/sync signal (Y+S) and color difference signals (R−Y), (B−Y) which have been stored in the recording medium to the stored image signal processing unit **34**.

Then, this stored image signal processing unit **34** produces, for instance, an NTSC (National Television System Committee) color signal based on the luminance/sync signal (Y+S) and color difference signals (R−Y), (B−Y) supplied from the image data memory unit **23**, and thereafter outputs the color signal to an image signal output terminal **35**.

To the control unit **24**, predetermined signals A, B, S_1 and S_2 are supplied from the switch and key section **7** which provide a photometric area designation unit **36**, mode switch **37**, and release switch **38**.

The photometric area designation unit **36** is constructed of, for example, keys for designating upper, lower, right, and left directions, and supplies signals in response to the key operations to the control unit **24**.

The control unit **24** outputs display control signal C to an LCD (liquid crystal diode) drive unit **35** based upon the signal A supplied from the photometric area designation unit **36**.

As illustrated in FIG. **6**, the LCD drive unit **39** displays a designation frame **42** at a position in the LCD display unit **41** provided within a viewfinder **40**. This position corresponds to the operation of the photometric area designation unit **36**. The portion of the LCD display unit **41** except for the portion displayed by the designation frame **42** is transparent, through which the subject can be observed.

In response to the operation conditions of the mode switch **37** and release switch **38** (will be described later), the control unit **24** supplies to both the photometric are control unit **30** and transfer control unit **26**, pixel position data and mode signals D and E corresponding to the display positions of the designation frame **42** on the LCD display unit **41** which are designated by the photometric area designation unit **36**.

Then, in accordance with the pixel position data E, the transfer control unit **26** outputs only the image signal containing the subject existing in the designation frame **42** within **1** horizontal scanning period, and controls the H driver **22** and V driver **23** so as to feed out other image signals.

On the other hand, the photometric area control unit **30** controls the switching circuit **29** based upon the pixel position data D supplied from the control unit **24** and the sync signal Ysync of the luminance signal Y supplied from the image signal processing unit **27** in such a manner that only the luminance signal "Y" output from the image processing circuit **27**, which contains the subject present in the designation frame **42**, is supplied to the automatic exposure control unit **31** and automatic focusing control unit **32**.

The functions of the mode switch **37** are to switch a recording mode and an output mode, and also charge a spot photometric mode during the automatic exposure control and an entire photometric mode, and furthermore set a manual mode and also an automatic mode of a focusing control/an exposure control.

The release switch **38** outputs a first release signal "S_1" when being depressed along a half traveling path thereof, and also output a second release signal "S_2" when being depressed over a full traveling path thereof.

Under the conditions that the recording mode is set by the mode switch **37** and further the exposure/focusing control is set to the automatic mode, the control unit **24** outputs either the control signal or control data to the automatic exposure control unit **31**, automatic focusing control unit **32**, photometric area control unit **30** and transfer control unit **26** in order to perform the automatic exposure/focusing control when the first release signal S_1 is output from the release switch **38**.

That is, when the entire photometric mode is designated by the mode switch **37**, the control unit **24** supplies the pixel position data D and E corresponding to the designation made by the photometric area designation unit **36** to the photometric area control unit **30** and transfer control unit **26** only when the automatic focusing control is carried out. When the automatic exposure control is carried out, the control unit **24** supplies the pixel position data D and E to the photometric area control unit **30** and transfer control unit **26** in such a way that the luminance signals Y with respect to all of the image signals obtained by the image sensor **21** are supplied to the automatic exposure control unit **31**.

When the second release signal S_2 is output from the release switch **38** during the recording mode, the control unit **24** outputs the storing control signal F to the image data memory unit **33** so as to perform the storage process, and also outputs the transferring control signal E to the transfer control unit **26** in such a manner that the image sensor **21** produces the output signal in response to the data stored in the exposure time data memory unit **25**.

In addition, when the second release signal S_2 is output during the output mode, the control unit **24** outputs the output control signals F and G to the image data memory unit **33** and the stored image signal processing unit **34**, and outputs the image data which has been stored in the image data memory unit **33**, to the image signal output terminal **35**.

OPERATIONS OF ELECTRONIC STILL CAMERA

The electronic still camera with the above-described arrangements will now be described.

When the image data is recorded, the recording mode is set by operating the mode switch **37**.

Furthermore, a selection is made whether or not the exposure/focusing control is set to the manual mode or automatic mode by way of the mode switch **37**. In case that the automatic exposure mode is selected, another selection is made that the spot photometric mode, or entire photometric mode is chosen.

AUTOMATIC EXPOSURE CONTROL/AUTOMATIC FOCUSING CONTROL MODES

A description will now be made to such a case that the automatic exposure control/automatic focusing control modes are selected.

The designation frame **42** which is being displayed on the liquid crystal display unit **41** within the viewfinder **40**, is moved to a major portion of a subject (e.g., a person who is wanted to be photographed) by the photometric area designation unit **36**.

When the release switch **38** is operated so as to output the first release signal S_1, the automatic focusing control is first performed.

Then, the control unit **24** outputs the pixel position data D, E corresponding to the display position of the designation frame **42** which is being displayed on the liquid crystal display unit **41**, to both the photometric area control unit **30** and transfer control unit **26**. Thereafter, the control unit **24** outputs the control signal to the automatic exposure control unit **31**.

As represented in a flowchart of FIG. **7**, to entirely open the diaphragm **16**, the automatic exposure control unit **31** outputs the control signal to the motor drive control unit **20** (step A_1), and also outputs predetermined exposure time data (i.e., 1/250 sec in the preferred embodiment) to the exposure time data memory unit **25**.

On the other hand, the transfer control unit **26** controls the V driver **23** so as to drain out the charges accumulated in the image sensor **21** in response to the automatic exposure control starting signal E supplied from the control unit **24** (step A2). That is to say, the transfer control unit **26** control the V driver **23** in order to output the vertical transfer clocks ϕV_1, ϕV_2, and ϕV_3 having a frequency higher than the normal frequency at a timing reverse to the normal timing, and causes the charges obtained by the photoelectric converting unit **50** to be drained out via the vertical transfer unit **51** to the drain **52** (see FIG. **2**).

Thereafter, the charges are accumulated in the image sensor **21** for 1/250 seconds (step A3). In this step, the transfer control unit **26** counts the exposure time based upon the data which has been stored in the exposure time data memory unit **25**, and starts to control both the H driver **22** and V driver **23** after this exposure time has passed in order that the image signal is output from the image sensor **21**.

It should be noted that the transfer control unit **26** controls both the H driver **22** and V driver **23** in accordance with the control data which has been previously supplied from the control unit **24** and corresponds to the display position of the designation frame **42**. This designation frame **42** is being displayed on the liquid crystal display unit **41**.

For instance, in case that the designation frame **42** is being displayed at the position indicated by a solid line shown in FIG. **6**, the charges of the photoelectric converting unit **50** corresponding to the portion of the photographing area "L" represented in FIG. **6** are drained out at a high speed (step A4).

The transfer control unit **26** controls the charges of the photoelectric converting unit **50** corresponding to the portion of the photographing area "M" which contains the portion corresponding to the subject designated by the designation frame **42** in such a manner that the V driver **23** and H driver **22** perform the normal drive operation, whereby these charges are output to the image signal processing unit **27** (step A5). In addition, the transfer control unit **26** sweeps out the charges of the photoelectric converting unit **50** corresponding to the remaining photographing region "N" to the drain **52** in the similar manner (step A6).

It should be noted that the time chart of the V driver **23** is represented in FIG. **8**A.

As previously described, only the image signal corresponding to the photographing region "B" is output to the image signal processing circuit **27**.

Then, in this image signal processing circuit **27**, the luminance signal "Y" is produced from the image signal and supplied to the switching circuit **29**. The sync signal Ysync corresponding to the output of this luminance signal "Y" is furnished to the photometric area control unit **30** (see FIGS. **8**B and **8**C).

It should be understood that the sync signal Ysync supplied from the image signal processing unit **27** to the photometric area control unit **30** is a signal formed in response to the clock output from the H driver **22**.

It should be noted that although the clock output from the V driver **23** is completely synchronized with the output of the luminance signal Y in the time charts shown in FIGS. **8**A and **8**B, for the sake of simplicity, such a synchronization between the luminance signal and the clock signal does not occur in the actual case because there is a time shift in order to employ the image signal which has been delayed for 1 horizontal scanning period while producing the luminance signal Y.

On the other hand, when the first release signal **S1** is outputted from the release switch **38**, the photometric area control unit **30** causes the pixel position data memory units **92** and **93** to store the head pixel position data and last pixel position data supplied from the control unit **24**, respectively (see FIG. **4**). It should be noted that the above-described head pixel position data and last pixel position data represent positions of the pixels corresponding to both end portions of the designation frame **42** in the horizontal direction. Then, the pixel position data which have been stored in the head pixel position data memory unit **92** are supplied via the gate circuit **94** to the coincidence detecting circuit **91**. The sync signal Ysync outputted from the image signal processing unit **27** is supplied to the counter **90** for the counting purpose. The count value of this counter **90** is continuously supplied to the coincidence detecting circuit **91**. The coincidence detecting circuit **91** judges a coincidence between the pixel position data supplied from the head pixel position data memory unit **92** and the count value from the counter **90**, and supplies a coincidence signal when the coincidence is established therebetween. The coincidence signal outputted from the coincidence circuit **91** sets the flip-flop **97** via the AND gate **96**, so that the switching circuit **27** is brought into the ON-state and also the gate circuit **94** is turned OFF as well as the gate circuit **95** is turned ON.

Then, the pixel position data which have been stored in the last pixel position data memory unit **93** is supplied to the coincidence circuit **91**, and the above-described coincidence comparison process of the count value of the counter **90** is carried out therein.

Thereafter, when the count value of the counter **90** is coincident with the pixel position data which has been stored in the last pixel position data memory unit **93**, which is detected by the coincidence detecting circuit **91**, the coincidence detecting circuit **91** again outputs the coincidence signal. The coincidence signal outputted from the coincidence detecting circuit **91** causes the flip-flop **97** via the AND gate **98** to be reset, the switch circuit **29** to be turned OFF, and the AND gate **95** to be turned OFF, and also the AND gate **94** to be turned ON. Then, the pixel position data which have been stored in the head pixel position data memory unit **92** is again supplied to the coincidence detecting circuit **91**. When all of the sync signals Ysync during 1 horizontal scanning period have been outputted, the counter **90** outputs the carry signal, whereby the counted value is reset in response to this carry signal.

As previously described, the photometric area control unit **30** causes the switching circuit **29** to be in the ON-state in response to the pixel position data D which has been previously supplied from the control unit **24**, and also the sync signal Ysync furnished from the image signal processing circuit **27** at a timing when the luminance signal Y corresponding to a photographing area "0" shown in FIG. **6** is output from the image signal processing circuit **27** (see FIG. **8**D).

As previously explained, only the luminance signal "Y" corresponding to the subject which has been designated via the switching circuit **29** by the designation frame **42**, is supplied to the automatic focusing control unit **32**.

The automatic focusing control unit **32** commences the on-focusing condition detecting operation in response to the luminance signal Y in synchronism with the transfer end signal supplied from the transfer control unit **26**. When the off-focusing condition is detected, the automatic focusing control unit **32** outputs the control signal to the motor control unit **18** so as to move the lens **14** along the proper direction. In this case, the transfer control unit **26** repeates the processes defined at the steps A2 to A7.

When, on the other hand, the on-focusing condition is detected by the automatic focusing control unit **32**, an automatic focusing control end signal is output to the control unit **24** by the automatic focusing control unit **32**.

Thereafter, once this automatic focusing control end signal is supplied to the control unit **24**, the automatic exposure control process is commenced.

When the spot photometric mode is designated by operating the mode switch **37**, the luminance signal Y is supplied to the automatic exposure control unit **31** under the control similar to that of the above-described automatic focusing control process.

To the contrary, when the entire photometric mode is designated by operating the mode switch **37**, the control unit **24** furnishes new control data to both the photometric area control unit **30** and transfer control unit **26** in order that the luminance signal Y corresponding to all of the image signals obtained from the image sensor **21** is supplied to the automatic exposure control unit **31**.

Then, the luminance signal Y supplied to the automatic exposure control unit **31** under the either control is furnished to the A/D converting unit **61** of this automatic exposure control unit **31**.

In the A/D converting unit **61**, the above-described luminance signal "Y" is sampled based upon the sync signal Ysync supplied from the image signal processing circuit **27** so as to obtain digital data. This digital data is output from this A/D converting unit **61** to the high speed adding circuit **62**.

The added data obtained from the high speed adding circuit **62** is fetched by the diaphragm/exposure time converting unit **63** in synchronism with the transfer end signal output from the transfer control unit **26**.

It should be noted that the control data corresponding to the designated entire photometric mode or spot photometric mode is supplied from the control unit **24** to the diaphragm/exposure time converting unit **63**.

In the diaphragm/exposure time converting unit **63**, both proper exposure time data and proper diaphragm open degree data are obtained based upon the above-described added data, control data, and furthermore distance data output from the automatic focusing control unit **32**, and are supplied to the exposure time data memory unit **25** and motor control unit **20**, respectively.

The motor control unit **20** drives the diaphragm drive motor **19** in response to the diaphragm open degree data so as to set the proper open degree of the diaphragm **16**.

When the above-described automatic exposure control process is accomplished, the automatic exposure control unit **31** outputs the automatic exposure control end signal to the control unit **24**.

When the second release signal S_2 is output from the release switch **38** after the above-described exposure control process is completed (in case that the second release signal S_2 has been output, at the same time when the exposure control process is completed), the control unit **24** outputs such a control signal that the normal image signal is obtained at the transfer control unit **26**, and also outputs to the image data memory unit **33** another control data F for designating the memory operation. In other words, after the transfer control unit **26** clears the charges of the image sensor **21**, this control unit **26** counts the time based upon the exposure time data which has been stored in the exposure time data memory unit **25**. Then, the transfer control unit **26** sequentially outputs the charges accumulated in the image sensor **21** after the time determined by the above-described exposure time data has passed.

Subsequently, the image signal output from the image sensor **21** is supplied to the image signal processing circuit **27** so as to be converted into the luminance/sync signal (Y+S) and color difference signals (R−Y), (B−Y).

The luminance/sync signal (Y+S) and color difference signals (R−Y) and (B−Y) are then supplied to the image data memory unit **33** and recorded as single still image data in the image data memory unit **33**.

When the image data recorded in the image data memory unit **33** is reproduced, the output mode is set by the mode switch **37** and the release switch **38** is operated.

Once the second release signal S_2 is output from the release switch **38**, the control unit **24** outputs the control data F and G to both the image data memory unit **33** and stored image signal processing unit **34**.

Then, the image data memory unit **33** repeatedly supplies the image data corresponding to a single still image which has been recorded in the image data memory unit **33**, to the stored image signal processing unit **34**. The function of this stored image signal processing unit **34** is to produce an NTSC color TV signal from the image data supplied from the image data memory unit **33**, and delivers the NTSC color TV signal to the image signal output terminal **35**.

Furthermore, when the release switch **38** is operated, the control unit **24** instructs the image data memory unit **33** such that image data with respect to a next still image is output. As stated above, the control unit **24** sequentially updates the output still image every time the release switch **38** is operated.

SECOND AUTOMATIC EXPOSURE CONTROL UNIT

Referring to FIG. **9**, an automatic exposure control unit according to a second preferred embodiment will now be described.

First, the luminance signal Y which is derived from the image signal processing circuit **27** via the switching circuit **29** to the second automatic exposure control unit **110**, is input into an operational amplifier **70**. A voltage V_1 is applied via a resistor **71** to one terminal (i.e., minus terminal) of the operational amplifier **70**. An output from the operational amplifier **70** is input to a base electrode a PNP transistor **72**. The voltage V_1 is applied via the resistor **71** to an emitter of this PNP transistor **72**. A collector of the transistor **72** is connected to a capacitor **73**. Both terminals of this capacitor **72** are connected between an emitter and a collector of an NPN transistor **74**. One junction between one terminal of the capacitor **73** and the emitter of the NPN transistor **74** is grounded, whereas the other junction between the other terminal of the capacitor **73** and the collector thereof is connected to an A/D converting unit **75**. A transfer end signal output from the transfer control unit **26** is supplied to a base electrode of this NPN transistor **74**.

The above-described operational amplifier **70**, resistor **71**, PNP transistor **72**, capacitor **73** and NPN transistor **74** charge the charges corresponding to the luminance signal Y which has been supplied via the switching circuit **29** into the capacitor **73**, and discharge the charges from the capacitor **73** when the transfer end signal is output from the transfer control unit **26**.

That is, at the plus terminal of this capacitor **73**, a voltage is produced which is proportional to a sum of the charges accumulated in the respective photoelectric converting units **50** of the image sensor **21** corresponding to the range designated by the photometric area designation unit **36**.

The function of the A/D converting unit **75** is to obtain digital data corresponding to the voltage value appearing at the plus terminal of the capacitor **73**. This digital data is supplied to a diaphragm/exposure time converting unit **76**.

It should be noted that since the arrangement of this diaphragm/exposure time converting unit **76** is substantially identical to that of the above-described diaphragm/exposure time converting unit **76** represented

in FIG. 3, no further explanation thereof is made in the specification.

In accordance with the second automatic exposure control unit **110** with the above-described arrangement, in response to the luminance signal Y output from the image signal processing circuit **27** via the switching circuit **29**, the voltage proportional to the sum of the luminance of the pixels which have been designated by the photometric area designation unit **36** is produced at the plus terminal of the capacitor **73**. Then, the produced voltage is A/D-converted by the A/D converting unit **75** into the corresponding digital data, both the proper exposure time and proper diaphragm open degree are obtained.

THIRD AUTOMATIC EXPOSURE CONTROL UNIT

In FIG. **10**, there is shown another arrangement of an automatic exposure control unit according to a third preferred embodiment of the invention.

It should be noted that the same reference numerals shown in FIG. **9** will be employed for indicating the same or similar circuit elements shown in FIG. **10**, and no further explanation thereof is made.

Similar to the above-described second automatic exposure control unit **110**, a operational amplifier **70**, a resistor **71**, a PNP transistor **72**, a capacitor **73** and an NPN transistor **74** constitute such an arrangement that charges proportional to luminance of the respective pixels in an image which has been designated by the photometric area designation unit **36**, are charged into the capacitor **73**.

A plus terminal of the capacitor **73** is connected to a minus terminal of a first comparator **80** and also a plus terminal of a second comparator **81**.

On the other hand, to a plus terminal of this first comparator **80**, either a voltage V_2, or V_3 is applied via a switch circuit **82**.

The function of the switch circuit **82** is to select the voltage V_2, or V_3 in response to the designated photometric mode (i.e., spot photometric mode, entire photometric mode) based upon the control signal output from the control unit **24**. That is, the voltage V_2 is set to be greater than V_3, and a selection is made that the voltage V_3 is set when the spot photometric mode is designated, and the voltage V_2 is set when the entire photometric mode is designated.

Either a voltage V_4, or V_5 is applied via a switch circuit **83** to a minus terminal of the second comparator **81**.

The function of this switch circuit **83** is similar to that of the switch circuit **82**. That is, when the proper photometric mode is designated, the voltage V_4 or V_5 is selected in response to the control signal output from the control unit **24**. In other words, the voltage V_4 is set to be greater than the voltage V_5. The first voltage V_4 is selected when the spot photometric mode is designated, whereas the second voltage V_5 is selected when the entire photometric mode is selected.

Also, the voltage V_4 is selected to be larger than the voltage V_2, whereas the voltage V_5 is selected to be greater than the voltage V_3.

The outputs from the first and second comparators **80** and **81** are supplied to a judgment unit **84**. This judgment unit **84** is to output control signals to a diaphragm control unit **85** and an exposure time control unit **86** in response to the outputs derived from the first and second comparators **80** and **81**, control unit **24**, and automatic focusing control unit **22**.

In other words, when the first and second comparators **80** and **81** output both "High" signals, the judgment unit **84** judges that the measured exposure is over the proper value. To the contrary, when "Low" signals are output from the first and second comparators **80** and **81**, the judgment unit **84** judges that the measured exposure is under the proper value.

Based upon the judgment results (i.e., under exposure and over exposure), the judgment unit **84** outputs the control signals to the diaphragm control unit **85** and exposure time control unit **86**. At this time, the judgment unit **84** obtains both diagram open degree information and exposure time information which have been set by the exposure control unit **85** and exposure time control unit **86**, and also obtains information on a distance from the camera to the subject from the automatic focusing control unit **32**. As a result, the judgment unit **84** outputs the control signals to the diaphragm control unit **85** and exposure time control unit **86** in such a manner that the proper open degree is combined with the proper exposure time.

Then, the diaphragm control unit **85** outputs the control signal to the motor control unit **20** in response to the control signal supplied from the judgment unit **84**.

On the other hand, the exposure time control unit **86** obtains the exposure time data based upon the control signal supplied from the judgment unit **84**, and supplies this data to the exposure time data memory unit **25**.

AUTOMATIC EXPOSURE CONTROL

Automatic exposure control operations of the automatic exposure control unit **120** with the above-described arrangements will now be described.

In FIGS. **11A** to **11D**, there are shown time charts for representing output conditions of this automatic exposure control unit **120**.

First, the luminance signal Y which has been supplied via the switch circuit **29** from the image signal processing unit **27**, is furnished via the operational amplifier **70** to the PNP transistor **72**, so that the charges corresponding to the voltage value of this luminance signal "Y" are charged into the capacitor **73**, and therefore the voltage corresponding to the charges appears at the plus terminal of the capacitor **73** (see FIG. **9B**).

On the other hand, both the first and second comparators **80** and **81** output the signal corresponding to the voltage value appearing at the plus terminal of the capacitor **73**, to the judgment unit **84**.

In other words, the first comparator **80** outputs the "High" level signal when the voltage appearing at the plus terminal of the capacitor **73** exceeds the voltage V_2 or V_3 (see FIG. **11D**). The second comparator **81** outputs the "High" level signal when the voltage appearing at the plus terminal of the capacitor **73** exceeds the voltage V_4 or V_5 (see FIG. **11C**).

When both the outputs from the first and second comparators **80** and **81** become high levels, the judgment unit **84** judges that the measured exposure is over the proper exposure value so that the diaphragm **16** is closed, or the exposure time is shortened, or both controls are carried out. These controls are performed by sending the control signal to either the exposure control unit **81**, or exposure time control unit **86**, otherwise both control units **85** and **86**.

To the contrary, when both the outputs from the first and second comparators **80** and **81** become low levels,

the judgment unit **84** judges that the measure exposure is under the proper exposure value. Under this judgment, the judgment unit **84** transfers the control signal to either the diaphragm control unit **85**, or the exposure time control unit **86**, otherwise both control units **85** and **86**, whereby either the diaphragm is opened, or the exposure time is prolonged.

Furthermore, when the high level signal is derived from only the first comparator **80**, the judgment unit **84** judges that the measured exposure is proper, and then outputs the automatic exposure process end signal to the control unit **24**.

What is claimed is

1. A camera apparatus comprising:

optical image forming means for forming an optical image;

image sensing means having a photoelectric converting area comprised of a plurality of frame areas, for producing electric signals in response to said optical image formed by said optical image forming means;

area designating means for designating a desired frame area from said plurality of frame area;

selecting means for selecting from the electric signals produced by the whole electric converting area, electric signals produced by said desired frame area designated by said area designated means; and,

producing means for producing a video signal based on said electric signals produced by said image sensing means and said selecting means.

2. The camera apparatus of claim **1**, further comprising:

on-focusing detecting means for detecting whether or not said optical image formed by said optical image forming means is just focused on said image sensing means, based on said electric signals selected by said selecting means; and,

focusing control means for controlling said optical image forming means based on an on-focusing detecting signal obtained by said on-focusing detecting means, so as to focus said optical image formed by said optical image forming means just on said image sensing means.

3. The camera apparatus of claim **1**, further comprising:

luminous energy determining means for determining a level of a luminous energy of said optical image formed by said optical image forming means, in response to said selected electric signals selected by said selecting means; and,

luminous energy control means for controlling the level of the luminous energy of said optical image formed by said optical image forming means, based on a luminous energy determining signal obtained by said luminous energy determining means, so as to set a predetermined exposure condition.

4. The camera apparatus of claim **3**, further comprising:

diaphragm means for controlling the level of the luminous energy of said optical image; and,

diaphragm control means for controlling said diaphragm means based on said luminous energy determining signal obtained by said luminous energy determining means, so as to set the predetermined exposure condition..

5. The camera apparatus of claim **4**, further comprising:

exposure means for exposing the optical image incident upon said image sensing means for enabling said image sensing means to produce said electric signals; and,

exposure control means for controlling said exposure means, based on said luminous energy determining signal obtained by said luminous energy determining means.

6. The camera apparatus of claim **1**, further comprising:

on-focusing detecting means for detecting whether or not said optical image formed by said optical image forming means is just focused on said image sensing means, based on said electric signals selected by said selecting means;

focusing control means for controlling said optical image forming means based on an on-focusing detecting means obtained by said on-focus detecting means, so as to focus said optical image formed by said optical image forming means just on said image sensing means;

luminous energy determining means for determining a level of a luminous energy of said optical image formed by said optical image forming means, in response to said selected electric signals selected by said selecting means; and,

luminous energy control means for controlling the level of said luminous energy of said optical image formed by said optical image forming means, in response to a determining signal obtained by said determining means, so as to set a predetermined exposure condition.

7. The camera apparatus of claim **1**, further comprising:

viewfinder means for displaying a subject to be formed into said optical image by said optical image forming means and for indicating a part of said subject to be formed into said optical image corresponding to said photoelectric converting area designated by said area designating means.

8. The camera apparatus of claim **7**, wherein said viewfinder means includes display means for indicating said part of said subject to be formed into said optical image corresponding to said photoelectric converting area designated by said area designating means.

9. The camera apparatus of claim **8**, wherein said display means includes a liquid-crystal display device.

10. A method of operating a camera apparatus constructed of image sensing means having a photoelectric converting area comprised of a plurality of frame area, the method comprising the steps of:

forming an optical image;

producing first electric signals in response to said optical image;

designating a desired frame area from said plurality of frame area;

selecting second electric signals produced from said designated desired frame area from the first electric signals;

producing a video signal based on said second electric signals produced by said image sensing means.

11. The method of claim **10**, further comprising the steps of:

detecting whether or not said optical image is just focused on said image sensing means, based on said selected second electric signals; and,

controlling said optical image based on an on-focusing detecting signal obtained by said detecting step,

so as to focus said optical image just on said image sensing means.

12. The method of claim 10, further comprising the steps of:

determining a level of a luminous energy of said optical image, based on said selected second electric signals; and,

controlling said optical image based on a luminous energy level determining signal obtained by said determining step, so as to set a predetermined exposure condition.

13. The method of claim 10, further comprising the steps of:

focus-detecting whether or not said optical image is just focused on said image sensing means, based on said selected second electric signal;

controlling said optical image based on an on-focusing detecting signal obtained by said focus-detecting step, so as to focus said optical image just on said image sensing means;

luminous-determining a level of a luminous energy of said optical image, based on said selected second electric signals; and,

controlling said optical image based on a luminous energy detecting signal obtained by said luminous-detecting step, so as to set a predetermined exposure condition.

[57] **ABSTRACT**

In an objective lens assembly for an optical instrument comprising inner and outer tube members with outer and inner engaged helicoidal screws, respectively, the normal trapezoidal-section main ridge of the helicoidal screw of the outer tube member is modified to provide one or more wall surfaces that reflect stray light from the object side of the objective lens assembly to prevent such light from reaching the image side of the assembly. The wall surface or surfaces are provided by one or more sub-ridges or grooves at the top of the trapezoidal-section main ridge. Bottom portions between successive elements of the main ridge may be angulated to prevent stray light reflected therefrom from reaching the image end of the assembly.

DEVICE FOR PREVENTING GENERATION OF HARMFUL LIGHT IN OBJECTIVE LENS ASSEMBLY

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to a lens assembly for an optical instrument such as a camera. More specifically, the present invention is directed to an improvement in the structure of a helicoidal screw adapted for driving an objective lens in the direction of an optical axis.

2. Related Background Art

In an optical instrument with an objective lens assembly there is often produced the problem of harmful stray light. The stray light generated within the lens tube has various undesirable effects on the performance of the optical instrument.

A typical solution to the problem is to prevent the reflection of light on the inside circumferential surface of the lens tube. For example, in the case of a conventional picture-taking lens assembly comprising a plural lens groups designed for a camera, the inside circumferential surface of the lens tube is usually coated with a light-absorbing black paint. This black coating serves to prevent any scattered stray light from entering the film plane of the camera.

As well-known to those skilled in the art, a lens tube of a conventional camera lens assembly is usually composed of two tubes, namely an inner tube and an outer tube. Lenses are held in the inner tube and moved in a direction along the optical axis for focusing or zooming. To this end, the inner tube is provided with a male helicoidal screw formed on the outside circumferential surface. The male helicoidal screw is in mesh with a female helicoidal screw formed on the inside circumferential surface of the outer tube.

FIG. **1** shows an example of such a structure in a lens assembly for a camera.

Referring to FIG. **1**, a lens tube is composed of an inner tube **8** and an outer tube **3**. The inner tube **8** holds a lens **7** and has a helicoidal screw **8***a* formed on its outside circumferential surface. The outer tube **3** has a helicoidal screw **9** formed on its inside circumferential surface. The helicoidal screws **8***a* and **9** are in mesh with each other to couple the inner tube **8** with the outer tube **3**.

The inner tube **8** is allowed to move in an axial direction only and its rotation relative to the camera body **1** is inhibited by stop means not shown.

The outer tube **3** is engaged in a stationary portion **1***a* of the camera body **1** through a screw **2**. The outer tube **3** has also a gear **4** formed on the outside surface of the tube. The gear **4** is rotationally driven by a driving gear **5** which is in turn driven by a motor **6**.

When the driving gear **5** is driven into rotation by the motor **6**, the outer tube **3** is also rotated through the gear **4**. While rotating, the outer tube **3** moves axially in accordance with the pitch of the screw **2**. As the result, the inner tube **8** is moved together with the lens **7** linearly along the optical axis to attain focusing.

In the above-shown lens assembly, the problem of harmful stray light arises from the fact that the helicoidal screw **9** formed on the inside surface of the outer tube **3** is exposed to a beam of photo-taking light from the lens **7**. As seen in FIG. **1**, a portion of the photo-taking light from the lens **7** runs in a direction away from the optical path of the photo-taking light as represented by a beam A_1. The off-optical path beam A_1 falls on the helicoidal screw **9** and is reflected by it toward a film plane **13**. As stray light, the reflected beam A_2 enters the film and has an undesirable effect.

The effect of the harmful stray light is larger and more significant when the inner tube **8** is moved out toward the object side. This is because the number of exposed ridges of the helicoidal screw **9** is increased when the inner tube **8** is moved out.

FIG. **2** is a section view of a prior art helicoidal screw showing the conventional form of the screw.

As seen from the figure, the sectional form of the prior art helicoidal screw is trapezoidal. The ridge of the screw has a flattened apex **10**. The flat portion **10** tends to reflect the off-optical path beam A_1. The reflected light A_2 passes through an aperture **12** (FIG. **1**) and reaches the image-forming plane or film plane **13**. Thus, the reflected light A_2 constitutes harmful stray light which degrades the image-forming performance of the lens.

SUMMARY OF THE INVENTION

Accordingly, it is an object of the present invention to provide an objective lens assembly provided with means for preventing the generation of harmful light therein.

It is another object of the present invention to provide an improved structure of helicoidal screw which does not reflect off-optical path rays to the image-forming plane side or to the eye side when the screw is exposed to the optical path.

It is a further object of the present invention to provide a camera in which the generation of harmful light is prevented by employing the above-mentioned structure of a helicoidal screw.

These and other objects, features and advantages of the invention will become more apparent from reading the following description.

According to the present invention, in order to prevent the harmful light, a shading wall surface is provided on the top of the main ridge of the helicoidal screw opposed to the optical path of the photo-taking light. The shading wall surface is formed substantially continuously along the spiral of the screw and is disposed facing the object side of the lens.

The wall surface is inclined to reflect stray light coming from the object side of the lens. The inclination angle of the shading wall surface is so determined that the stray light incident on the wall surface may be reflected in a direction substantially orthogonal to the optical axis or in direction somewhat turned toward the object side.

In an embodiment of the present invention, the shading inclined surface is provided by additionally forming a sub-ridge portion on the top of the main ridge of the helicoidal screw. The sub-ridge portion has a triangular section and is formed along the spiral of the helicoidal screw.

In another embodiment of the invention, the shading inclined surface is provided by engraving a groove in the flat top of the conventional helicoidal screw. The groove is formed substantially continuously along the spiral of the screw and in such manner that no flat portion remains on the top of the screw after engraving.

In a further preferred embodiment, the bottom of the helicoidal screw is inclined relative to the inside circumference parallel to the optical axis and is formed as a

conical surface facing the object side and centered on the optical axis or image side.

In the lens tube according to the present invention, it is preferable to form the above-mentioned slant face over all the length of the helicoidal screw. However, it is to be understood that the object of the present invention may be attained, to some extent, by forming such slant face at only a portion of the screw where the harmful stray light is apt to be generated most frequently.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a sectional view of a prior art lens assembly for a picture taking camera;

FIG. **2** is an enlarged sectional view of a portion of a prior art helicoidal screw;

FIG. **3** is an enlarged perspective view of a portion of a helicoidal screw showing a first embodiment of the present invention;

FIG. **4** is an enlarged sectional view of the first embodiment;

FIGS. **5** and **6** are enlarged fragmentary sectional views showing modifications of the first embodiment;

FIG. **7** is an enlarged sectional view of a portion of a helicoidal screw showing a second embodiment of the invention; and

FIGS. **8** to **11** are enlarged fragmentary sectional views showing modified forms of the second embodiment.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

A first embodiment of the present invention is shown in FIGS. **3** and **4** as fragmentary enlarged views of a helicoidal screw of a lens tube.

A helicoidal screw is formed on the inside circumferential surface of the lens tube **2**. The main ridge of the helicoidal screw has a sub-ridge portion **21** formed on the top of the main ridge along the spiral of the screw. The sub-ridge portion **21** has a triangular form in section. The top of the sub-ridge portion is shaped into a sharp edge.

The function of the sub-ridge portion will be seen best from FIG. **4**. A light beam B_1 coming from a lens **7** (FIG. **1**) and running away from the optical path of the lens impinges on the flat top **22** of the main ridge and is reflected by the latter. The reflected light runs first toward the film plane. But, it is then reflected by a slant face **23** of the sub-ridge portion **21**. This reflected light beam B_2 runs upwardly in the plane of the drawing and does not enter the film plane.

Another off-optical path light beam C_1 falls upon the bottom **24** of the screw and is reflected by it. The reflected light is again reflected by a slant face **25** of the main ridge and then runs upwardly as the reflected beam C_2 in the plane of the drawing.

It is most desirable to make the reflected light beams B_2 and C_2 run in a direction normal to the optical axis or in a direction rather inclined toward a object side from the plane normal to the optical axis. However, such direction of reflection is not always necessary for the construction of the present invention. Since, as previously mentioned, the surface of the helicoidal screw is coated with light-absorbing black paint, almost all of the reflected rays B_2 and C_2 may be absorbed after several reflections within the lens tube. Therefore, the inclination angle of the slant faces **23** and **25** is not critical. The slant faces may also have an inclination angle by which the reflected rays B_2 and C_2 run in a direction somewhat inclined toward the image side providing that the reflected rays B_2 and C_2 never run into the film plane directly.

In the shown embodiment, the top end of the sub-ridge portion **21** is shaped into a sharp triangular edge. Though such sharp edge is preferable, the shape of the top end of the sub-ridge portion **21** is not limited to triangular form only. Another form such as semicircular also may be selected for the top end of the sub-ridge portion without reducing the effect for the prevention of harmful light too much.

Referring to FIG. **4**, the male helicoidal screw **8***a* of the inner tube **8** is engaged with the female helicoidal screw of the lens tube **20**. The bottom of the male screw **8***a* is not required to have a particular shape. It may have any conventional form. The thing required for the bottom of the male helicoidal screw **8***a* is only that it should have a sufficient depth so as not to be touched by the sub-ridge portion **21**.

In view of the need to reflect the incident light C_1 as described above, the ridge of the screw should be as high as possible. However, in practice, we must take into consideration a case where the height of the ridge of the screw is small for the pitch of the screw.

In this case, it is advisable to dispose the bottom of the screw inclined relative to the optical axis as shown in FIGS. **5** and **6**.

In a lens tube **30** shown in FIG. **5**, which is a modification of the first embodiment, the bottom of the helicoidal screw is formed by an inclined surface facing the image side or view-finder side. The beam C_1 falling on the bottom **31** is reflected in a direction of a relatively obtuse angle and impinges upon a slant face **32** of the main ridge. Again, the slant face **32** reflects the beam C_1 upwardly in the plane of the drawing.

In a lens tube **40** shown in FIG. **6**, which is a second modification of the first embodiment, the bottom **41** of the screw is formed by an inclined surface facing the object side in contrast with the first modification shown in FIG. **5**. In this second modification, the incident light C_1 is reflected by the bottom **41** not in a direction toward the slant face **42** but in a direction somewhat toward the object side or upwardly in the plane of the drawing.

The first embodiment described above is featured by the sub-ridge portion additionally formed on the flat top of the original ridge of a helicoidal screw.

A second embodiment of the invention shown in FIG. **7** is featured by a groove formed on the flat top of the original ridge of a helicoidal screw. The groove is formed by cutting out the flat top along the spiral of the screw in such manner that no flat portion is left after engraving.

More specifically, in the lens tube **50** shown in FIG. **7**, the helicoidal screw has a groove **51**. The groove has a V-shaped cross section. It is formed by cutting out the original flat portion at the top of the ridge of the screw. After engraving the V-shaped groove **51**, no original flat portion is left as such.

In this embodiment, the beam of light B_1 incident upon the top of the ridge is reflected back by a slant face of the V-shaped groove **51**. The direction of reflection can be controlled by suitably selecting the depth of the V-shaped groove **51**. Therefore, it is possible to reflect the incident beam B_1 in a direction much more deflected toward the object side.

The second embodiment has a particular advantage in that the height of the ridge of the helicoidal screw can be reduced as compared with the first embodiment in which a sub-ridge portion has been formed additionally on the top of the original ridge (main ridge). According to the second embodiment, therefore, one can reduce the size of the total structure of the helicoidal screw without substantially reducing the effect of the present invention for preventing harmful light. Further, this enables to realization a smaller lens tube than the prior art.

FIGS. **8** to **11** illustrate various modifications of the second embodiment.

In the modification shown in FIG. **8**, the helicoidal screw in a lens tube **60** has a plurality of V-shaped grooves **61** formed on the top of the ridge. A beam of incident light B_1 is reflected first by a slant face of one of the V-shaped grooves **61** and then reflected by an opposite slant face of the groove. Finally, the beam runs upwardly in the plane of the drawing.

In the second modification shown in FIG. **9**, the helicoidal screw in a lens tube **70** also has V-shaped grooves **71**. But, the distance between the grooves is longer than that in the first modification. In this second modification, therefore, because of the longer distance between the V-shaped grooves **71**, the beam B_1 is reflected in the direction toward the object side directly by a slant face of the first groove without being directed to an opposite face of the groove.

In further modifications shown in FIGS. **10** and **11**, each the V-shaped is formed by two slopes having different inclination angles.

More specifically, referring to FIG. **10**, each of the V-shaped grooves **81** in the lens tube **80** is formed by two slant faces having different inclinations. The inclination of the slant face on the image side is far sharper than that on the object side. In this modification, the incident beam B_1 is reflected three times between the two slant surfaces of the V-shaped groove **81**. Finally, the beam B_1 runs back toward the object side along approximately the same optical path as the incident beam. During the repeated reflections in the V-shaped groove **81**, the incident light B_1 is markedly attenuated. Thus, the effect for eliminating harmful light can be further increased by employing this modification.

Referring to FIG. **11**, the V-shaped groove **91** in the lens tube **90** also has two differently inclined slopes. But, in this embodiment, the slant face on the image side is more gently sloped than that on the object side so that the incident beam B_1 may be reflected upwardly in the plane of the drawing.

In the second embodiment where a plural number of grooves are engraved in the top of the ridge of a helicoidal screw, it is not always necessary to arrange the grooves at a constant pitch along the optical axis. In addition, the grooves may have different sectional shapes from each other. The grooves can be formed in a very simple manner.

For example, man can form such grooves by rotating a lens tube with a helicoidal screw preformed in a conventional shape as shown in FIG. **2** about the optical axis and scratching the flat top surface of the ridge with a rough sand-paper or the like thereby forming a plurality of scratched lines along the spiral of the ridge of the helicoidal screw.

We claim:

1. An objective lines assembly for an optical instrument, comprising:

an inner tube member surrounding an optical axis;

an outer tube member surrounding said inner tube member;

a helicoidal screw formed on the outside circumferential surface of said inner tube member;

a helicoidal screw formed on the inside circumferential surface of said outer tube member and engaged with the helicoidal screw on the inner tube member;

said helicoidal screws of said inner tube member and said outer tube member having each a main ridge of a trapezoidal form in section, respectively; and

means for forming a wall surface facing an object side of said objective lens assembly, said wall surface being formed at the top of the trapezoidal-section main ridge of the outer tube member and along the spiral of said screw, said wall surface being angulated relative to said optical axis so as substantially to prevent light incident on said wall surface from said object side of said objective lens assembly from reaching an image side of said objective lens assembly.

2. An objective lens assembly according to claim **1**, wherein said wall surface is provided continuously substantially the length of the spiral of said screw.

3. An objective lens assembly according to claim **1**, wherein said means for forming a wall surface comprises a sub-ridge portion formed along the spiral of said screw and on the top of the main ridge of the helicoidal screw on said outer tube member, and a side surface of said sub-ridge portion constitutes the wall surface.

4. An objective lens assembly according to claim **3**, wherein said sub-ridge portion has a triangular form in section and has a ridge-line along the spiral of said screw.

5. An objective lens assembly according to claim **1**, wherein said means for forming a wall surface comprises a plurality of sub-ridge portions formed in parallel with each other along the spiral of said screw and on the top of the main ridge of the helicoidal screw on said outer tube member, and side surfaces of the respective sub-ridge portions constitute the wall surface.

6. An objective lens assembly according to claim **1**, wherein a bottom portion of the helicoidal screw on said outer tube member is formed by a conical surface centered on the optical axis.

7. An objective lens assembly according to claim **1**, wherein said means for forming a wall surface comprises at least one groove formed in the top of the main ridge of the helicoidal screw of said outer tube member and along a spiral of said screw, and the side surface of the groove constitutes the wall surface.

8. An objective lens assembly according to claim **7**, wherein said at least one groove is formed by cutting out a flat top of the main ridge of said helicoidal screw in such manner that no flat portion remains on the top of the main ridge.

9. An objective lens assembly according to claim **7**, wherein said at least one groove has a substantially V-shaped sectional form.

10. An objective lens assembly according to claim **1**, wherein said means for forming a wall surface comprises a plurality of grooves formed in the top of the main ridge of the helicoidal screw of said outer tube member and along the spiral of said screw, and side surfaces of the grooves constitute the wall surfaces respectively.

11. A lens assembly for a camera with a picture-taking lens system for forming an image of an object on an image-forming plane comprising:

an inner tube member surrounding an optical axis;

an outer tube member surrounding said inner tube member;

a helicoidal screw formed on the outside circumferential surface of said inner tube member;

a helicoidal screw formed on the inside circumferential surface of said outer tube member and engaged with the helicoidal screw on the inner tube member, said helicoidal screws of the outer tube member being partly exposed to a picture-taking optical path extending between the picture-taking lens system and the image-forming plane when the inner tube member is moved relatively to the outer tube member, and each of said helicoidal screws of the inner and outer tube members has a main ridge which is approximately trapezoidal in section; and

shade means providing a wall surface at the top of the approximately trapezoidal-section main ridge of the helicoidal screw of the outer tube member, said wall surface being angulated relative to the optical axis so as substantially to prevent light incident thereon from the picture-taking lens system from reaching the image-forming plane.

12. A lens assembly according to claim 11, wherein said wall surface is formed continuously and over substantially the length of the spiral of said screw.

13. A lens assembly according to claim 11, wherein said wall surface is a surface of a sub-ridge portion on top of said main ridge.

14. A lens assembly according to claim 11, wherein said wall surface is a surface of a groove in the top of said main ridge.

CONTROL DEVICE FOR USE IN A CAMERA HAVING AN OBJECTIVE LENS

This application is a continuation of application Ser. No. 267,550, filed Nov. 7, 1988, now abandoned, which is a divisional of application Ser. No. 043,616, filed on Apr. 28, 1987, now U.S. Pat. No. 4,800,409.

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to a control device for use in a camera, and more particularly to a control device which controls both the focusing operation of objective lens of the camera and exposure operation of the camera.

2. Description of the Prior Art

There has been proposed, in U.S. Pat. No. 4,423,936, a control device in which distance detection for the focusing operation and a light measuring for the exposure operation are performed with respect to a plurality of regions in an object area to be photographed, and a distance is selected among the detected distances for the focusing operation. If the selected distance is detected with respect to a single region, a light measurement value measured with respect to the single region is used for exposure operation to control exposure value. On the other hand, if the selected distance is detected with respect to plural regions, plural light measurement values measured with respect to the detected plural regions are averaged to be used for the exposure operation to control exposure value.

However, in the conventional device as described above, since a primary object to be focused is not always positioned at the detected plural regions, the possibility for obtaining proper exposure for the primary object is relatively low.

Furthermore, in the conventional device, backlight condition is detected in the case that, difference between a first light measurement value measured with respect to the region in which the selected distance is detected and a second light measurement value calculated by averaging all of other light measurement values, is over a predetermined value. Here, if the selected distance is detected with respect to plural regions, the first light measurement value is calculated by averaging plural light measurement values of the plural regions. However, the difference is not always indicating whether the backlight condition or not in the latter case. For example, if the selected distance is detected in two regions arranged symmetrically with an optical axis of the objective lens, it is impossible to judge at which region a primary object is positioned in the device. In such case, it would be improper to detect the backlight condition.

There has been proposed, in Japanese Laid-Open Patent Application No. 60-129732, another control device in which a common light receiving device is used for the light measuring and for the distance detection. In the device, one calculating circuit for distance detection and the other calculating circuit for light measuring are provided, and the output of the common light receiving device is sent to the two calculating circuits in time-sharing manner or in time-dividing manner. The distance detection calculation and exposure calculation are performed in respective circuits. However, such device has disadvantages that the construction thereof becomes complex since two calculating circuits and a switching circuit for selectively transmitting the output of the light receiving device to the two calculating circuits are necessary, and that the operation of the entire device becomes complex since switching operation of the switching means is necessary.

SUMMARY OF THE INVENTION

Accordingly, an object of the present invention is to provide a control device for use in a camera having an objective lens wherein the probability of giving the proper exposure to the primary object photographed is high even when the selected distance is detected with respect to plural regions.

Also, another object of the invention is to provide a control device for use in a camera having an objective lens which is capable of more positively judging the backlight condition.

An additional object is to provide a control device for use in a camera having an objective lens which does not need a switching circuit for finding a range even when regions to be found in the range within the photographing distance are plural.

In accomplishing these and other objects, according to the present invention, there is provided a control device for use in a camera having an objective lens, comprising means for producing a plurality of distance signals necessary for focusing the objective lens on a plurality of first regions of an object area to be photographed; means for determining a distance on the basis of the plurality of distance signals to produce a determined distance signal for focusing the objective lens; means for driving the objective lens in accordance with the determined distance signal; means for measuring a plurality of brightnesses of second regions of the object area to produce a plurality of brightness signals each corresponding to the measured brightnesses respectively, each of the second regions being substantially similar to each of the first regions, respectively; means for counting the number of the distance signals used in the distance determining means for determining the distance; means for discriminating whether the number counted by the counting means is single or plural; means for determining a light measuring value by a first calculation when the discriminated number is single, while determining the light measuring value by a second calculation which is different from the first calculation and which is independent of the discriminated number when the discriminated number is plural; and means for calculating exposure value of the camera in accordance with the light measuring value, so that satisfactory exposure may be provided, judging from the experiences even when the selected distance is detected with respect to plural regions.

BRIEF DESCRIPTION OF THE DRAWINGS

These and other objects and features of the present invention will become apparent from the following description taken in conjunction with the preferred embodiments thereof with reference to the accompanying drawings, in which:

FIG. 1 is an illustrating view showing one arrangement of a light measuring optical system to be used in a first embodiment of the present invention;

FIG. 2 is an illustrating view showing the construction of a liquid-crystal filter of transmission wavelength switch type;

FIG. 3 is an illustrating view showing the light measuring range;

FIG. 4 is a block diagram showing a light measuring circuit employed in the first embodiment of the present invention;

FIG. 5 is a circuit diagram showing the switch groups in FIG. 4;

FIG. 6 is a further detailed block diagram of the light measuring circuit in FIG. 4;

FIG. 7 is a circuit diagram showing the construction of the light measuring circuit and the timing circuit thereof;

FIG. 8 is a block diagram showing the circuit construction of an electronic flashing apparatus in the first embodiment of the present invention;

FIG. 9 is a graph showing the relationship among the distance region of the photographed object, the focusing range and the aperture value (so-called lens opening);

FIGS. 15 and 16 are flow charts showing about the decision of the distance region for the photographing operation in the second embodiment of the present invention.

DETAILED DESCRIPTION OF THE INVENTION

Before the description of the present invention proceeds, it is to be noted that like parts are designated by like reference numerals throughout the accompanying drawings.

The embodiment wherein the present invention has been applied upon the lens shutter camera will be described with reference to the accompanying drawings. First, the distance detection and the light measurement to be used in the embodiment will be described in principle. The distance detecting apparatus is composed of a projecting means for projecting the light onto the entire region of the photographed field to be detected in distance, a light-receiving means for receiving the light to be reflected from the object, and a circuit for processing the signals from the light-receiving means to detect the distance.

The light-receiving means is composed of a plurality of light-receiving elements, by which the photographed field is divided into a plurality of regions to detect the respective distances. And one of the distances is selected as a distance where the photographing lens is focused, thereby the brightness of the selected region is detected as supposing that a primary object is positioned in the selected distance. In the present embodiment, the common light-receiving elements are used for both the distance detection and the brightness detection.

Referring now to FIG. 1, there is shown a concrete example of the optical system with the light-receiving element being provided for common use. An electronic flashing apparatus FL2 is the projecting means which projects the light on the entire region of the photographed field through the filter IRF1 provided on the front face, through which the infrared light of particular wavelength or wavelength range is transmitted. The light-quantity emitted by the electronic flashing apparatus FL2 is by far less than the light-quantity emitted by the electronic flashing apparatus for object illumination use to be employed in the photographing operation. A condenser lens LE collects the light reflected from the object OB to guide into the light receiving element SPC. A filter LCDF1 which is adapted to be capable of switching to a filter for transmitting the infrared light of particular wavelength or wavelength range through it, and a filter having the characteristics of visual sensitivity is provided between the condenser lens LE and the light-receiving element SPC.

This filter is constructed as shown in FIG. 2. Namely, the filter LCDF1 is composed of ,a guest-host type liquid crystal devices LCD1 and LCD2. When the signal of the "High" level (hereinafter referred to as "H") is outputted from a terminal OP1 of a microcomputer MC shown in FIG. 4, a predetermined voltage V2 is applied upon a first liquid crystal device LCD1 through a buffer BUF, and the first liquid crystal device LCD1 comes to let the infrared light of the particular wavelength or wavelength range pass through it. On the other hand, when the signal of the "Low" level (hereinafter referred to as "L") is outputted from the output terminal OP1 of the microcomputer MC, the predetermined voltage V2 is applied upon a second liquid crystal device LCD2 through a buffer BUF and an inverter IN2, so that the second liquid crystal device LCD2 comes to operate as a visible-sensitivity filter through which the light of the visible sensitivity range may pass. The buffer BUF and the inverter IN2 are adapted to be fed by the power voltage to be described later. Accordingly, when the release button (not shown) is not depressed, both the liquid crystal devices remain colorless in light transmission condition without application of the voltage.

The light-receiving element SPC shown in FIG. 1 is composed of a plurality of elements as described hereinabove and is adapted to measure each of a plurality of regions ① through ⑨ of the object field shown by a rectangular frame in FIG. 3. A plurality of the light-receiving elements are arranged to measure the region which is deviated a little downwardly of the object field as a whole, and are composed of nine elements in total arranged symmetrically, in the horizontal, vertical relation with the No. 1 light-receiving element as a center being provided to measure the region a little lower than the center of the object field. They are adapted to detect the distance and brightness of the regions ① through ⑨ shown in the oblique-line portions. The reason where they are arranged somewhat downwardly with respect to the field to be photographed is that the object or the person regarded as the primary object is often provided in the lower portion, but in the upper portion with the lens shutter camera having a comparatively wide-angle lens.

The camera system which performs the above-described distance detection and brightness detection will be described hereinafter. In the block diagram of FIG. 4 showing the circuit construction of the entire camera, a power battery E consists of direct connection of two lithium cells each producing 3V. A diode D1 is provided for preventing the voltage applied to the microcomputer MC from becoming lowered during the operation of the boosting circuit in the electronic flashing apparatus FL. A capacitor C0 is provided to prevent the noises and to hasten the charging operation to the main capacitor in the electronic flashing apparatus FL. A capacitor C1 has comparatively large in capacity for the back-up operation of the microcomputer MC. A resistor R1 and a capacitor C2 for resetting use are adapted to reset the microcomputer MC when the power battery E is mounted. A group of switches SW have a plurality of switches which are required for the

operation of the apparatus of the present embodiment. The group of switches will be described in detail with reference to FIG. 5.

A display circuit DI displays the photographing information. A liquid-crystal filter FI, which is shown in FIG. 2, becomes an infrared filter or a visible-light filter. The microcomputer MC is provided to control the entire circuit. A film sensitivity setting circuit IS converts the film sensitivity, which is read from the code pattern provided on the film container or is manually set, into the film sensitivity value represented by an A.P.E.X. system to output it into the microcomputer MC. A light measuring circuit LM is composed of a distance detection circuit for receiving the light, which is emitted from the electronic flashing apparatus FL for distance detection to be described later and are reflected from the object to detect the distance of the object, and a light measuring circuit for measuring the brightness BV of the object. An exposure control circuit AE for controlling the exposure in accordance with the exposure value EV to be outputted from the microcomputer MC outputs the flash starting signal X1 to the electronic flashing apparatus FL at a given timing. An AF controlling circuit AFC drives the objective lens to an in-focus position in accordance with the AF data to be outputted from the microcomputer MC. A motor controlling circuit MO controls the motor M for the winding operation of the film. The electronic flashing apparatus FL is composed of the electronic flashing apparatus FL2 for distance detection use and the electronic flashing apparatus FL1 for object illumination use during the exposure. A transistor Tr1 feeds the power voltage to the filter FI, the film sensitivity setting circuit IS, the light measuring circuit LM, the exposure controlling circuit AE, the AF control circuit AFC, and the motor control circuit MO in accordance with a signal from the microcomputer MC.

FIG. 5 shows the concrete example of a group of switches SW in FIG. 4. A lens cover switch S0 turns on and off through the operative cooperation of the opening, closing operations of a lens cover (not shown). The pulse signal is outputted into the interruption terminal INT0 of the microcomputer MC through a circuit composed of a delay circuit DEL and an exclusive OR circuit EOR by turning on and off of the switch SO. When it is inputted into the microcomputer MC, the microcomputer executes a given interruption routine INTO. A photograph preparing switch S1 turns on when the release button (not shown) is depressed as far as the first stroke. If the switch S1 is turned on when the lens cover is open, the interruption routine INT1 is executed. A release switch S2 turns on when the release button is depressed as far as a second stroke provided deeper than the first stroke. An exposure completion switch S3 turns off at the charging completion of the shutter charging member (not shown) and turns on at the exposure completion.

A one frame winding switch S4 turns off at the exposure completion and turns on at the completion of one frame winding completion. A switch S5 turns on when the objective lens is driven to the given position corresponding to the control signal and turns off at the charge completion of the shutter charging member.

The details of the light measuring circuit LM of the distance detection and the brightness detection to be used in the present embodiment will be described hereinafter with reference to the block diagram of FIG. 6.

The light measuring circuits LM1 through LM9 perform the distance detection and the brightness detection of the regions ① through ⑨ shown in FIG. 3, respectively. Each of the circuits for the distance detection latches the signals from the light-receiving element, i.e., the distance signal in response to a signal of the timing, circuit TM, so that the signals from the light-receiving elements are latched at the timing when the intensity of the light projected from the electronic flashing apparatus FL2 becomes maximum in the variation thereof, thereby to output the signal to the selector SEL. The selector SEL selects the signals from the light measuring circuits LM1 through LM9 by the signal from a decoder DE2, which is adapted to decode the signal from the microcomputer MC to output the selected signals to the encoder ED. The encoder ED converts the inputted signals into given forms to output them into the microcomputer MC. The distance signals of the light measuring circuits LM1 through LM9 are outputted to the microcomputer, by the signal from the microcomputer MC, sequentially through the selector SEL and the encoder ED1.

On the other hand, signals of the detected brightnesses are outputted as analog signals to the analog switch ANSW. The analog switch ANSW is composed of nine FETs, which are connected with the light measuring circuits LM1 through LM9 respectively, so that the respective brightness signals may be inputted, all the outputs being integrated into one, and are connected with the A/D converting circuit A/D. The selection of the analog switch ANSW is performed by the signal of the decoder DE2, which is adapted to decode the signal from the microcomputer MC as in the distance signal, and is sequentially performed from the light measuring circuits LM1 through LM9. The brightness signal which has been outputted to the A/D converting circuit A/D through the analog switch ANSW is converted into digital forms and is outputted into the microcomputer MC.

The details of the light measuring circuit LM1 and the timing circuit TM1 in the above-described diagram will be described in FIG. 7. The portion surrounded by the dotted lines in the drawing shows the timing circuit, and the portion except for it shows the light measuring circuit.

First, the timing circuit TM1 will be described. When the release button is depressed, the signal of "H" is outputted from the terminal OP8 of the microcomputer MC before the electronic flashing apparatus FL2 starts to emit the light, and the transistor Tr2 turns on to discharge the, capacitor C3. The transistor Tr2 is turned off immediately before the light emission to wait therefor. A phototransistor PHT1 which charges the capacitor C3 is disposed near the light emitting portion of the electronic flash apparatus FL2 and is adapted to directly receive the emitted light. When the electronic flashing apparatus FL2 emits the light in this condition, the current corresponding to the intensity of the light received by the phototransistor PHT1 is charged into the timing capacitor C3 through the phototransistor PHT1. When the voltage of the capacitor C3 exceeds a reference voltage Vr1, the comparator COMP1 is reversed to output the signal of the "H". The signal of the "H" is pulsed by the one-shot circuit OS1 and is outputted into the terminals T of the D flip-flops, to be described later, to latch the amplification signal from the light-receiving element SPC1. The reference voltage Vr1 is adapted to reverse the comparator COMP1 at the

time point when the intensity of light emitted by the electronic flashing apparatus FL2 is slightly lower from the maximum intensity.

The light measuring circuit LM1 will be described hereinafter. The voltage is applied through the power supply line V2 by the depression of the first stroke of the release button to feed the power to each circuit. At once, the signal of the "H" is outputted from the terminal OP9 of the microcomputer MC to turn on the analog switches AS1, AS2 so that constant current circuits I1, I2 start to flow constant currents, respectively. After the lapse of a predetermined time (as the lowest 20 msec is assigned to that time in the present embodiment), the light measuring circuit LM1 remains stable.

The circuit operation before the stability of the circuit LM1 will be briefly described. As the voltage of the capacitor C4 is extremely low when the constant current circuits I1, I2 start to flow constant currents, the transistor Tr3 does not turn on. Constant current I1 flown by the constant current circuit I1 and the photocurrent IP which corresponds to the brightness of the particular wavelength light passing through the filter flow to the base of the transistor Tr4 to be amplified there. The amplified current flows through the transistor Tr6, and the equivalent current flows through the transistor Tr7 which constitutes a known current mirror circuit with the transistor 6. One part of the current becomes current of the constant current circuit I2 and the remaining current flows through the diodes D2, D3 to cause the voltage VD corresponding to two steps of the diode. The operation amplification OP1 has a reference voltage Vref inputted into the inversion input terminal, and has the voltage VD inputted into the non-inversion input terminal, and the negative feedback is applied upon the transistor Tr3 so that the voltage VD may become always constant.

As the current flowing through the transistor Tr7 corresponds to the current which has amplified most of all the photocurrent IP and the constant current I1, the voltage VD to be caused by this current becomes higher than the reference voltage Vref. Accordingly, the operation amplifier OP1 charges the capacitor C4 to boost the base voltage of the transistor Tr3. This capacitor C4 is charged through the transistor Tr4. When the voltage of the capacitor C4 is boosted to turn on the transistor Tr3, the constant current I1 and the photocurrent IP flow through the collector of the transistor Tr3 to reduce the current flowing through the base of the transistor Tr4. Thus, the current flowing through the transistor Tr6 and Tr7 is reduced to lower the voltage VD, so that the above-described operation is performed until the voltage VD becomes equal to the reference voltage Vref. During this operation, the voltage VD may become lower than the reference voltage Vref. At this time, the operation amplifier OP1 operates for discharging the charge of the capacitor C4 to reduce the voltage thereof, which reduces the current through the transistor Tr3 within the constant current I1 and the photocurrent IP so as to increase the base current of the transistor Tr4. Accordingly, the current which flows through the transistors Tr6 and Tr7 increases to boost the voltage VD.

This circuit is stabilized by the above-described operation to flow the current almost equal to the total of the constant current I1 and the photocurrent IP through the transistor Tr3, so that the voltage of the capacitor C4 for becomes equal to the base voltage corresponding to the current.

When the electronic flashing apparatus FL2 emits the light, the light reflected from the object is received by the light-receiving element SPC1 to cause the photocurrent IP' (which is referred to as IP' hereinafter to distinguish it from the above-described ambient photocurrent IP) corresponding to the light including a reflected light component reflected by the object and the ambient light component. The current IP of the ambient light component within the photocurrent flows through the collector of the transistor Tr3, and the current IP'-IP corresponding to the reflected light component flow as the base current of the transistor Tr4. At this time, the capacitor C4 has the capacity, in which the transistor Tr4 does not respond by the current while the reflected light is received by the light receiving element. And the current IP-IP' is amplified by the transistor Tr4 to flow the diodes D2, D3 through the transistors Tr6, Tr7. Thus, the voltage VD is increased to compare the voltage VD with the reference voltage determined by the constant current circuit I3 and the resistors R11 through R14, so that the distance signal is represented as the outputs of the comparators COMP2 through COMP5. The output signals of the comparators COMP2 through COMP5 are latched into the D flip-flops DFF1 through DFF4 by the signal from the timing circuit TM to output the latch signal to the selector SEL.

After the distance detection has been performed in the above-described way, the filter arranged in front of the light-receiving element SPC1 is changed from a characteristic for permitting that the infrared light having the particular wavelength pass therethrough to the other characteristic for permitting that the visual light pass therethrough. Furthermore, the constant current circuit I1 is switched off to remove the voltage of the constant current I1 with respect to the charging voltage of the capacitor C4. The constant current circuit I2 is also turned off to cut off the route of the feedback of the transistor Tr3 through this constant current I2 so that the voltage of the capacitor C4 may become only the voltage which depends upon only the intensity of the ambient light component received by the light-receiving element SPC1. The voltage is outputted into the analog-switch ANSW through the buffer BUF1.

The other light measuring circuits LM2 through LM9 shown in FIG. 6 are also completely the same in construction as in FIG. 7.

The electronic flashing apparatus FL1 for photograph use and the electronic flashing apparatus FL2 for distance detection use to be used in the embodiment will be described hereinafter with reference to FIG. 8. Except for the point that the electronic flashing apparatus FL2 for distance detection use is much smaller (approximately 1/25 in the maximum light emitting amount) than the electronic flashing apparatus FL1 for photographing use, the former is completely the same in the circuit construction as the latter FL1, thus removing the illustration of the concrete construction of the former with the circuit being shown simply in block.

In the circuit of the electronic flashing apparatus FL1 for photographing use, a boost controlling circuit DCC receives the boost controlling signal FLC1 from the microcomputer MC and produces the changing completion signal B.C1 to be described later to control the transistor Tr8 for boosting circuit DC. The rectification diode is represented by D4. A charge detecting circuit B.C detects the charging condition of a main capacitor C5. An emission control circuit EC energizes a xenon

tube Xe in accordance with the emission signal X1 from the exposure control circuit AE to illuminate the object area. The emission signal X2 of the electronic flashing apparatus FL2 for distance detection use is fed through the buffer BUF10 from the microcomputer MC.

The operation of the electronic flashing apparatus FL1 for photographing use will be described. When the, charging operation to the main capacitor C5 has not been completed, the charge completion signal B.C1 is in the "L" level. When the boosting control signal FLC1 of the "L" showing the boosting start is sent from the microcomputer MC, the NOR circuit NOR1 outputs the signal of "H", and the boost controlling circuit DCC receives it to control the transistor Tr8 to turn it on and starts the boosting operation. When the charging completion signal B.C1 becomes "H" level by the completion of the charging operation to the main capacitor C5 or the boosting control signal FLC1 from the microcomputer MC becomes "H" level, the NOR circuit NOR1 outputs "L" level, so that the boost controlling circuit DCC turns off the transistor Tr8 to stop the boosting operation of the boosting circuit DC. It is to be noted that a neon tube showing this condition lights on independently of the control circuit and the microcomputer MC when the charging operation of the main capacitor C5 is completed.

The entire operation of the camera in the embodiment will be described hereinafter. Before it, the number of the distance zones detected by the distance detection, the in-focus range in each region, and how to determine it will be described.

The distances to the objects located at each of the regions are detected in accordance with the absolute amounts of the light reflected by the objects as described hereinabove. However, as each of the objects has a reflectance different from that of the other objects, the distance detected by the detection apparatus is not always equal to the distance to the object. In the present embodiment, the in-focus range of each region is provided wider or the range is provided across two regions so that the focusing operation may be performed without fail on the object. However, if the distance range from the nearest focusing distance such as 0.6 m to the infinity distance is divided into five ranges, it is impossible to achieve the in-focus condition of the objective lens with respect to any object located within the distance range in the condition in which the aperture of the objective lens is fully opened, due to the focusing performance of the objective lens. Thus, in the embodiment the maximum aperture value is decreased in accordance with the decrease of the distance. Therefore, an in-focus range of particular distance zone can be extended to achieve the in-focus condition with respect to any object within the distance range, by dividing the latter into five ranges.

Here, since the embodiment uses a shutter serving as an aperture diaphragm, the reduction of the aperture value causes the shutter speed to shorten. Therefore, the brightness range in which the natural light photographing may be performed becomes narrower, the underexposure is likely to be caused. In this case, the flash photographing operation is performed to compensate for it. The shutter, also serving as an aperture diaphragm, which is used in the present embodiment, is a type showing the triangular waveform in time-variation characteristics of the opening degree. The shutter gradually opens to reach the given aperture value, and is adapted to move to the closed operation.

Five ranges determined in accordance with the above-described idea and their in-focus ranges, the maximum aperture value of the use limit at this time, and the aperture value at the flash photographing operation will be described in FIG. 9.

In the drawing, the axis of ordinates shows the regions 1, 2, 3, 4, 5 arranged in order from the near distance side. The axis of abscissa shows the distance as far as 0.6 m through ∞. The focusing range of each region will be described. As shown in FIG. 9, in the region 1, the open aperture value is limited to F/8, and the object distance of the objective lens is set to 0.75 m. Thus, the object positioned within a distance range from 0.56 m to 1.1 m can be in in-focus condition on the predetermined focal plane by the objective lens. In the region 2, the open aperture value is limited to F/5.6, and the object distance is set to 1.0 m, thereby the objective lens is set to be in in-focus condition with respect to an object positioned within a distance range from 0.77 m to 1.5 m. In the region 3, the open aperture value is limited to F/4, and the object distance is set to 1.5 m, thereby the objective lens is set to be in in-focus condition with respect to an object positioned within a range from 1.1 m to 2.2 m. In the region 4, the open aperture value is limited to F/3.5, and the object distance is set to 2.1 m, thereby the objective lens is set to be in in-focus condition with respect to an object positioned within a distance range from 1.5 m to 3.6 m. In the region 5, the open aperture value is limited to F/3.5 and the object distance is set to 5 m, thereby the objective lens is set to be in in-focus condition with respect to an object positioned within a distance range from 2.7 m to ∞.

The aperture value used in flash photographing operation is determined as shown in "FM" in FIG. 9. The guide number of the flashing apparatus is determined to be 10 with respect to a film sensitivity of ISO=100. In the region 1, the aperture value in flash photographing operation is set to F/13, so that under- or over-exposure is provided by 1 step with respect to the object located at the nearest or farthest distance within the distance range of region 1. Only the same exposure amount is designed to become over or under with respect to both the ends. In the region 5, the flash photographing operation is adapted to be performed as far as possible with F/3.5 in the open aperture value.

FIGS. 10 through 14 show the flow charts of the microcomputer MC. The controlling operation of the camera will be described with reference to the flow charts.

The operation with the battery E being mounted on the camera will be described with reference to FIG. 10. When the battery E is mounted thereon, the signal which changes from "L" to "H" is inputted into the reset terminal RES, the microcomputer MC executes the flow to prohibit the interruption (#5) and to initially set (#10) the output terminals, the registers. Then, the signal of the terminal IP6 shown in FIG. 5 is inputted and the microcomputer MC allows the interruption to decide whether or not the lens cover is open. When it is closed, the interruption to the interruption terminal INT1 to be described later is prohibited to come to a stop (#25 through #27). On the other hand, the program proceeds to step #45 to be described later when the lens cover is open.

The interruption INT0 which is executed through the opening and closing operation of the lens cover will be described hereinafter. If the lens cover is opened or closed in the condition where the interruption to the

flow is allowed, the pulse is inputted into the terminal INT0, so that the microcomputer MC executes the interruption INT0 operation from the step #32. At first, the decision is made as to whether the lens cover has been opened or closed (#35). When the lens cover has been closed, the interruption to the flow of the interruptions INT1 to be described later is prohibited (#57) to proceed to the step #60 (#35, 37). When the lens cover has been opened, the interruption to the terminal INT1 is allowed (#40), the signals of "H" to the output terminals FLC1, FLC2 are outputted (#40 through 50) to start the boosting operation of the electronic flashing apparatuses FL1, FL2 for photographing use and distance detecting use so as to decide whether the charging operation of the main capacitor of the electronic flashing apparatus FL1 for photographing use has been completed through the output signal BC1 (#55). Even when the lens cover is open with the battery being mounted on, the program proceeds to the step #45. When the charging completion of the main capacitor is decided at the step #55, the signals of "L"are outputted to the terminals FLC1, FLC2 (#60, 65) to stop the boosting operation of both the electronic flashing apparatuses FL1, FL2 for photographing use and distance detection use. And all the flags are reset at the step #70. The counting timer started in the interruption flow of the INT1 shown in FIG. 11 is stopped to turn off the display, and the microcomputer MC becomes halt condition (#70 through 85).

Then, in FIG. 11, when the release button is depressed to the first stroke with the lens cover being opened, the signal which changes from "H" to "L" is inputted to the terminal INT1 and the microcomputer MC executes the flow of the interruption INT1 from the step #90.

In order to perform the distance detection and the brightness detection, the boosting operation of the electronic flashing apparatus FL1 for photographing use is stopped in this flow to prevent the noise caused by the boosting operation and the decrease in the battery voltage (#95). Then, the transistor Tr1 is turned on to supply the power supply to each control circuits (#100). The analog switches AS1, AS2 are turned on to flow the constant current for distance detection use (#105), and the output of the terminal OP1 is turned into "H" so that the filter is switched for infrared ray use to detect the distance (#110). The timer for counting the time required for the circuit stability is reset and started (#115), and the transistor Tr2 or timing use is turned on (#120) to discharge the timing capacitor C3 for the determination of the timing to latch the output of the distance detecting circuit. Then, the controlling operation is performed to start the boosting operation of the electronic flashing apparatus FL2 for distance detection use to wait for the completion of the charging operation of the capacitor C5 (#125, 130). After the charging operation of the capacitor C5 completes, the boosting operation is stopped (#132). And the decision is made whether or not 20 msec have passed from the timer start of the step #115. If they have not passed, the lapse is waited for. If they have passed, the transistor Tr2 for timing use is turned off (#135, 140). The signal of "H" is outputted into the terminal X2 to detect the distance and thereby the flashing apparatus FL2 for distance detection use is energized (#145). The signal from the timing circuit is inputted to detect whether or not the data of the result of the distance detection has been latched to wait for the data to be latched (#150). When the detection is performed that the data has been latched, the terminal OP1 is turned into "L" to detect the brightness to put the filter into the visible sensitivity use (#155). The analog switches AS1, AS2 are turned off (#160), and the subroutine for taking in the data for the latched distance detection use comes in preparation for the following brightness detection.

The subroutine will be described with reference to FIG. 12. The microcomputer MC sets variables N, N1, N2 into 0, and D0 into 5 (#1000 through 1015). This variable N is outputted into the decoder DE2 shown in FIG. 6 (#1020). The distance data detected by the light measuring circuit selected by the selector SEL which receives the output of the decoder DE2 are converted into a given coded data D1 by the encoder ED, and the coded data are inputted into the microcomputer MC at the step #1025. This data D1 corresponds to the detected distance region, that is either of the regions 1 through 5. For example, the coded data D1 shows 1 if the detected distance region is the region 1, while the data D1 shows 5 if the detected distance region is the region 5.

The nearest distance region among the distance regions detected by each of the light receiving circuits LM1 through LM5 is selected in accordance with the data D1. First, a decision is made as to whether or not the data D0, wherein the data corresponding to the distance region 5 is set, are equal to the input data D1. If they are equal to each other, 1 is added to the variable N1 (#1030, 1035). This variable N1 is provided for deciding if the number of the light measuring circuits which detect if the nearest distance region is single or plural. The data D0 are set in D1 to add 1 to the variable N (#1045, 1065). On the other hand, in the step #1030, the program proceeds to the step #1050 when the set data D0 are not equal to the input data D1 to decide whether not the input data D1 is in the distance region nearer than the set data D0. The program proceeds to the step #1045 when it is not in the nearer distance region. When it is in the nearer distance region, the variable N1 is set in 1, and the variable N2 is set to the variable N to proceed to #1040 (#1055, 1060). This variable N2 shows either of the light receiving regions ① through ⑨ shown in FIG. 3. In the step #1065, the decision is made whether or not the variable N is 9, i.e., whether or not the distance data of the light-receiving regions 1 through 9 have been inputted after the addition of 1 to the variable N at the step #1045. If the inputting operation of the distance data has not been finished, the step returns to the step #1020 to repeat the loop. If the inputting operation of the distance data has been finished, the program returns to the original flow of FIG. 11 at the step #1067 to proceed to the next light measuring data subroutine of the step #1070.

The subroutine is shown from the step #1070 of FIG. 12(*b*). In the step #1070, the decision is made as to whether or not the variable N1 is 1, i.e., the number of the light receiving regions in which the nearest distance region is detected is single. If it is single (N1=1), the program proceeds to the spot light measurement subroutine of the step #1075. When the number of the light receiving regions in which the nearest distance region is detected is plural, the proceeds to the step #1080 decide whether or not the light receiving region ① of the central portion is included in the plurality of regions in which the nearest distance region is detected. Even when it is included, the program proceeds to the step #1075. When the light receiving region of the central

portion is not included at the step #1080, the average light measurement flag AVRE is set at the step #1085. The program proceeds to the average light measurement subroutine, and returns to the original flow with BV2 (average light measurement value) as the light measurement data BV.

The spot light measurement and average light measurement subroutine among the light measuring data subroutine will be described with reference to FIG. 13. First, in the spot light measurement subroutine shown in FIG. 13(*b*), the microcomputer MC outputs the variable N2, showing the number of the light receiving regions, to the decoder DE2 (#1160). The decoder DE2 decodes the inputted variable N2, and controls to turn on one of the analog switches ANSW in order to output the analog light measuring signal which corresponds to the brightness of the region related to the variable N2, to the A/D converting circuit A/D. The microcomputer MC outputs the A/D conversion start signal from the terminal OP6 to convert the light measuring signal of this analog form into the digital form at the step #1165, and decides with the signal of the terminal OP7 whether or not this A/D conversion has been completed at the step #1170. After the completion of the A/D conversion, the A/D completion signal is outputted from the terminal OP6 at the step #1175 and the digital-converted light measuring data are inputted to the microcomputer MC as the brightness value BV.

The average light measurement subroutine shown in FIG. 13(a) will be described hereinafter. The variables BV2 and I are set to 0 (#1105, 1110) and this variable I is outputted to the decoder DE2. As in the case of the above-described spot light measurement operation, the light measuring output of the analog form showing the brightness of the light receiving region corresponding to this variable I is converted in digital form by the A/D converter A/D to input the light measuring data as BV1 (#1120 through 1135). The data BV1 are added to the data BV2 at the step #1180 and 1 is added to the variable I at the step #1145. And it is decided whether or not the variable I has reached 9 (#1150). If it reaches 9, it is assumed that the light measuring data showing the brightness has been inputted from all the light-receiving regions ① through ⑨, and the program goes to the next step. If it is not 9, the program returns to the step #1115 to repeat this loop to perform the data inputting operation. After the inputting operation of all the data is over, the microcomputer MC divides the data BV2, i.e.,. the light measuring data of all of the respective light-receiving regions, by 9 to obtain the average brightness data at the step #1155. It may be modified to obtain the average brightness data by averaging all of the light measuring data, even if a plurality of light receiving regions detect the nearest distance region. The step #1080 should be omitted for this modification.

Returning to the flow of FIG. 11, the film-sensitivity data SV from the film sensitivity setting circuit IS are read in A.P.E.X. system at the step #175 to add the brightness data BV to this value SV to obtain the exposure value EV (#180). The limited exposure value (EV) for switching from the natural light photographing mode to the flash photographing mode will be explained. The limited exposure value (EV) is changed in accordance with the detected distance region. In the step #185, the decision is made as to whether or not the distance region is region 1. If it is 1, the program goes to the step #190 to decide whether or not the exposure value EV is 13.5 or more. If the exposure value EV is less than 13.5, the exposure value EV is fixed to 13.5 (#235) to go to the step #270. If the distance region is region 2, the exposure value is secured to 11.5 when the exposure value EV is less than 11.5 at the step #230. If the distance region is region 3, the exposure value EV is secured to 9.5 when the exposure value EV is less than 9.5 at the step #225. If the distance region is region 4 or 5, the exposure value EV is fixed to 8.5 when the exposure value EV is less than 8.5 at the step #230. The program moves to the step #270 respectively to enter into the flash photographing mode (#195 through 235).

If the exposure value EV is 13.5 or more when the distance region is region 1, if the exposure value is 11.5 or more when the distance region is region 2, if the exposure value EV is 9.5 or more when the distance region is region 3, and if the exposure value EV is 8.5 or more when the distance region is region 4 or 5, the program moves to the step #240 to decide whether or not the average light measurement flag AVRF is set. When this flag AVRF is not set, the program goes to the step #245 to execute the average light measurement subroutine to obtain the average brightness data BV2 for getting the difference between the obtained spot brightness data BV and it so as to decide whether or not the difference is 2EV or more at the step #255. If this difference is 2EV or more, the daylight synchronous flag FILF is set because a primary object is in backlight condition. The program moves to the step #270 to enter the flash photographing mode (#250 through 260).

When the average light measurement flag AVRF is set in the step #240, or when the difference between the average brightness data and the spot brightness data value is less than 2EV, the program moves to the step #265, and moves to the step #390 to be described later to calculate the aperture value AV to move to the flow of the shutter release operation.

The flash photography mode from the step #270 will be described hereinafter. The decision is made as to whether or not the charging operation of the main capacitor of the electronic flashing apparatus FL1 for photographing use has been completed at the step #270. If it has been completed, the program moves to the step #310 to display the completion of the photograph preparation. If the charging operation has not been completed, the decision is made as to whether or not the release button is depressed to the first stroke. When the release button is depressed to the first stroke, it is displayed that the charging operation of the electronic flashing apparatus FL1 is not completed. Then, the removal of the depression of the release button is waited for (#275, 280). After the depression of the release button is removed, the microcomputer MC turns off the transistor Tr1 to cut out the power supply to the control circuit to start the boosting operation of the electronic flashing apparatus FL1 for photographing use (#285, 290). And the timer for battery check use is reset and is started to decide whether or not the charging operation has been completed within ten seconds. When the charging operation has not been completed within ten seconds, the boosting operation is stopped at the step #320, the timer for warning display use is reset and is started at the step #325, the battery check warning is performed for five minutes at the steps #330 and 335. Then, all of the displays are turned off at the step #340, and the flags are reset at the step #345. Thereafter, the microcomputer MC becomes in halt condition at the step #350. If the charging operation is completed

within ten seconds, the program moves to the step #310 to display the completion of the photographing preparation, and moves to the step #355.

In the step #355, the aperture value AV1 used in the flash photographing mode is calculated. The distance value DV in the step #355 is the value which becomes 5, 4, . . . 1 in response to the distance regions 1, 2, . . . 5. For example, supposing that the guide number of the electronic flashing apparatus FLI is 10 with respect to the film sensitivity of ISO 100, and that the distance region detected is the region 2, the distance value DV is 4 and the film sensitivity SV is 5, respectively, if the amount of light emitted by the flashing apparatus FL1. In the case, the calculated aperture value AV1 is 6.5, that is, the F-number of F/9.3. Then, the decision is made as to whether or not this calculated aperture value AV1 is less than 3.5 at the step #357. When it is less than 3.5, it is secured to 3.5 at the step #360 and the program goes to step #362. And the decision is made as to whether or not the daylight synchronous flag FILF is set. When the flag FILF is not set, the aperture value for exposure use is calculated from the exposure value EV fixed by each region to output the data of aperture value AV1 showing the light emitting timing of the flash photographing operation (#385). When the flag FILF is set, the aperture value AV2 based on the average brightness data BV2 is obtained at the step #370 to compare it with the aperture value AV1 of the flash photographing operation (#375). Here, the decision is made whether or not the exposure amount of the primary object becomes proper in the daylight synchronized flash mode.

Generally, the exposure amount of the primary object becomes proper by the flash light while the background thereof becomes in proper exposure by the natural light, in the daylight synchronized flash mode. In the case where the aperture value is determined for the natural light photographing condition, the aperture value AV1 for flash photographing should be compared with the aperture value AV for discriminating whether the primary object located at the detected distance region becomes in proper exposure by the flash light whose intensity is constant. Since the shutter serving also as an aperture diaphragm is gradually opening, the start of flash light emission can be performed at any timing during the opening. Therefore, if the aperture value AV1 is equal to or greater than the aperture value AV, proper exposure can be reproduced with respect to the primary object. Namely, when the aperture value AV1 for the flash photographing operation is equal to or greater than the aperture value AV for the natural-light photographing opera ron, the proper daylight synchronized flash photographing is performed. In the daylight synchronized flash mode, the microcomputer MC outputs the data of the aperture value AV1 as the light emitting timing data of the flash apparatus at the step #385 with the aperture value AV2 of the average light measurement as the control aperture value AV at the step #380. When the primary object is not exposed to the proper exposure by the flash photographing operation even in the backlight condition, the control aperture value AV is obtained in accordance with the brightness value in the spot light measurement to perform the natural-light photographing operation only (#390).

At this time, the microcomputer MC decides whether or not the release operation, i.e., the depression of the release button as far as the second stroke is effected at the step #392. When the release operation is not effected, the program moves to the step #395 to decide whether or not the release button is depressed as far as the first stroke. When the release button is in its depressed position, it returns to the step #390 to wait for the release operation. When the release button is not depressed as far as the first stroke, the program moves to the step #450 to be described later.

When the computer decides, at the step #392, that the release operation is affected, the program enters the release control operation to, first, prohibit the interruption to this flow at the step #397, and the microcomputer MC outputs the distance region data to the AF control circuit AFC at the step #400. Then, the microcomputer MC outputs the start signal to start the driving operation of the objective lens. When the objective lens is driven to the given position in accordance with the data, the switch (S5) showing the AF control completion is turned on, so that the microcomputer MC detects the AF control completion (#410). Then, the date of the control aperture value AV is outputted to the AE control circuit AE, and the AE control start signal is outputted (#415, #420) to the AE control circuit AE. When the light emitting timing data of the flash during the flash photographing operation is sent from the microcomputer MC in the AE control circuit AE, a flash signal is outputted to the electronic flashing apparatus FL1 for photographing use at the given timing in accordance with the data.

When the exposure control is performed in the AE control circuit and the switch S3 showing the exposure completion is turned on, the motor is driven to wind up one frame of the film. When the film is wound up by one frame, the motor is stopped (#425 through 440). The microcomputer MC permits the interruption to this flow at the step #445, and turns off the control circuit at the step #450. Then, the microcomputer MC starts the boosting operation of the electronic flashing apparatuses FL1, FL2 in preparation for the next photographing operation, and the timer for the boosting control use is reset and started at the step #470. The respective boosting operations are stopped when the charging operation is completed in five seconds or five seconds pass, and the display is turned off thereafter. Then, all the flags are reset and the microcomputer MC is in halt condition.

Though the first embodiment of the present invention is described hereinabove in such a manner that, the nearest distance region among the plurality of detected distance regions is provided as the distance region for the focusing operation, in the second embodiment described hereinafter, each light-receiving region is weighted when the distance region is obtained, and the weighted value is added for each distance region to detect which distance region is the most frequent. And the interval between the most frequent distance region and the nearest distance region, for example, in the case of the distance region 1 and the distance region 3 the intermediate distance region, that is, the distance region 2 in the above-described example, is applied as the distance for focusing operation. In the intervals except for it, the nearest distance is provided as the distance for the focusing operation. The brightness detection and the backlight detection are performed as in the first embodiment.

The flow chart for the operation of the microcomputer MC which executes the second embodiment is shown in FIG. 15, FIG. 16. This flow chart shows the

modified example of the AF data subroutine shown in FIG. 12(*a*), and the light measurement data subroutine shown in FIG. 12(*b*) with the entire flow being completely the same as FIG. 11, FIG. 13 and FIG. 14.

The flow chart will be described hereinafter. First, the microcomputer MC sets variables N0 through N4, N10 through N14, and N to 0 at all (#1500 through 1510). The variable N is outputted to the decoder DE2, and the data D1 of the distance region coming from the given light receiving region is inputted (#1515, 1520). Then" the microcomputer MC operates the weighting operation of 3, 2, 1 respectively to the light receiving regions 1, 2 through 5, 6 through 9 with respect to each light-receiving region. When the light-receiving region is 1 (N=0), the α as the weighting data is assumed as 3 (#1535) with this input data D1 being as the data D2 (#1530). If the light-receiving region is 2 through 5 likewise, the α is set to 2. If the light-receiving region is 6 through 9, the α is set to 1 (#1540 through 1550).

Then, the microcomputer MC adds the sum of the number of light receiving regions belonging to each distance region and the weighting data. When the distance region of the light receiving region is 1, 2, ... 5, the weighting data are added respectively to N0, N1, . . . N4, and the number of the light-receiving regions are added to N10, N11 . . . . N14 (#1555 through 1640). The decision is made as to whether or not N has become 9 through addition of 1 to the N. If the N has not become 9, the program returns to the step #1515 to repeat this loop until the N becomes 9. If the N is 9, the program moves to the step #1655 (#1645, #1650), considering that all the distance data have been inputted, and the microcomputer MC obtains the distance region including the light receiving region of the most frequent. In the step #1655, the value of the N0 showing the addition value of the weighted data of the distance region 1 is shifted to the N5, then the data showing that the distance region is 1 is inputted into the variable D3 and the variable I is set to 1 (#1660, 1665). Then, the weighted data N5 established is compared with the NI (I is the established value), for example, the addition value of the weighted value corresponding to the distance region 2 if I=1. If the NI is larger, the value of the N5 is changed to the value NI and the distance region at this time is inputted into D3 (#1670 through 1680).

Even when the NI is equal to or less than N5, the program goes to the next step #1685 to add 1 to the I. And the decision is made whether or not the I has become 5. If the I has not become 5, the program returns to the step #1670. If the I becomes 5, the -microcomputer MC obtains the nearest distance region and the distance between this region and the distance region of the most frequent value to obtain the distance region for the focusing operation. The microcomputer MC obtains the distance region where the value of the weighted data is not 0 in order from the distance region 1 to the distance region 4. The data showing this distance region at a time when the value of the weighted data not been 0 is inputted into D0 to input the number of the light receiving regions in that region into N7 (#1695 through 1760).

When the nearest distance region is one of the regions 1 through 3, the decision is made whether or not the distance between the nearest distance region and the distance region of the most frequent value is only one region. When the distance is one region, the data in the middle region is inputted into the D0 (#1765, #1770), and the program proceeds to the step #1775 of the light measurement data subroutine. When the nearest distance region is the region 4 or 5, the distance between the nearest distance region and the distance region of the the most frequent value does not become 1, the program moves to the step #1775 as soon as the inputting operation to D0, N7 is completed. In the light measurement data subroutine as compared with FIG. 12, the processed content of the microcomputer MC is completely the same except for the N1 being changed into N7.

The present invention is not restricted to this embodiment described hereinabove. The following modified embodiments may be applied.

(1) In the first and second embodiments, the brightness data obtained by the average light measurement of all regions are used for controlling the exposure amount, when the number of light receiving regions in which the nearest distance region is detected or when the central region is not included for detecting the distance region for the focusing operation. However, the exposure amount may be controlled in accordance with the average of the brightness data in all the light receiving regions showing the nearest distance region may be used. Thus, the number of the light receiving region in which the nearest distance region is detected is required to be memorized. The brightness data of the light receiving region are required to be inputted in accordance with this number to provided this average. Also, when the number of the light receiving regions in which the nearest distance region is detected are plural, the average light measurement value of all the regions may be used.

(2) Though the electronic flashing apparatus which is disposed separately from the electronic flashing apparatus for the photographing use is provided as the light emitting means for the distance detection means of the present embodiment, this may use the electronic flashing apparatus for photographing use in common. In the case of the distance detection, the infrared transmission filter of the particular wavelength is required to be provided on the entire face of the light emitting portion. In the case of the photographing operation, such mechanical construction as to remove this filter is required to be provided. Also, the light emitting means may be such a plurality of LEDs as shown in Japanese Patent Application Laid-open Publication Tokkaisho No. 59-146032. Also, one LED may be required with being sequentially scanned.

(3) If the primary object does not become proper with the flashing photographing operation only in the embodiment when the backlight light condition is detected, the photographing operation is switched from the flash photographing mode to the natural-light photographing mode. In addition, in the natural-light photographing operation, the light measuring operation is switched from the average light measurement to the spot one. However, since the film has a latitude, there is no necessity to provide the most proper exposure amount to the primary object. Concretely, if the exposure amount of the primary object is low by 1.5 steps than the most proper exposure amount, the image of the primary object can be reproduced sufficiently by the latitude of the film. Thus, it may be permitted that the exposure amount of the primary object by the flash light is lower by 1.5 steps than the calculated proper exposure amount in daylight synchronized flash photographing.

(4) In addition, the (1) through (3) of the above-described examples may be properly combined with the first, and second embodiments.

(5) Though the distance from the camera to the object is detected with a plurality of regions in the object area to be photographed in the embodiments, the defocus amount of the objective lens may be detected with the plurality of regions.

(6) Since the distance detection and the brightness detection use the common light measuring circuits LM1 through LM9 in the embodiments, the distance detection regions are completely similar to the brightness detection regions, respectively. However, both of the regions may.,be deviated from each other, or the size of both regions may be different from each other.

Although the present invention has been fully described by way of example with reference to the accompanying drawings, it is to be noted here that various changes and modifications will be apparent to those skilled in the art. Therefore, unless otherwise such changes and modifications depart from the scope of the present invention, they should be constructed as included therein.

What is claimed is:

1. Control device for use in a camera having an objective lens, comprising:

means for detecting a distance from the camera to an object to be photographed to produce a distance signal indicative of the detected distance;

means for driving the objective lens in accordance with the distance signal;

means for receiving light coming from a first; region which is a relatively small area in an object area to be photographed to produce a first light receiving signal indicative of the measured amount of light;

means for receiving light coming from a second region which is wider than the first region to produce a second light receiving signal indicative of the measured amount of light;

means for detecting whether a primary object to be photographed is in backlight condition or not, in accordance with the first and second light receiving signals;

means for illuminating the object area;

means for calculating a first aperture value on the basis of the second light receiving signal;

means for calculating a second aperture value on the basis of the distance signal;

means for calculating a third aperture value on the basis of the first light receiving signal;

means for comparing the first aperture value with the second aperture value; and

means for controlling exposure operation of the camera, if the backlight condition is detected, on the basis of the second light receiving signal with energizing the illuminating means when the first aperture value is smaller than the second aperture value, while controlling the exposure operation on the basis of the third aperture value when the first aperture value is equal to or larger than the second aperture value.

2. Control device for use in a camera having an objective lens, comprising:

means for receiving light coming from a first region which is a relatively small area in an object area to be photographed and for producing a first light receiving signal indicative of the measured amount of light;

means for receiving light coming from a second region which is wider than the first region and for producing a second light receiving signal indicative of the measured amount of light;

means for detecting whether or not a primary object to be photographed is in backlight condition on the basis of the first and second light receiving signals;

means for detecting a distance from the camera to an object to be photographed to produce a distance signal indicative of the detected distance;

means for determining an aperture value on the basis of the second light receiving signal and for producing an aperture value signal indicative of the determined aperture value;

means for illuminating the object area;

means for controlling exposure of the camera;

means, if the backlight condition is detected, for discriminating whether or not the primary object will be photographed in under-exposure condition in a flash photograph condition in which the photographing operation is performed by using the illuminating means, on the basis of the distance signal and the aperture value signal; and

means for controlling the illuminating means and the exposure controlling means so that the exposure amount of the camera is determined in accordance with the aperture value signal by energizing the illuminating means if the discriminating means discriminates that the primary object will not be photographed in under-exposure condition, and that the exposure amount of the camera is determined in accordance with the first light receiving signal if the discriminating means discriminates that the primary object will be photographed in under-exposure condition.

3. Control device as claimed in claim 2, wherein the controlling means includes means for prohibiting the operation of the illuminating means if the discriminating means discriminates that the primary object will be photographed in under-exposure condition.

[57] **ABSTRACT**

An optical scanning head (**10**) for measuring the surface of a work-piece (**12**) contains an integrated microscope. For this purpose, a deflecting mirror (**38**) located in the wall of the housing (**14**) of the scanning head is constructed as a dielectric mirror, which is impermeable for measured light, on the other hand is permeable for observation light and is also machined to optical quality on its rear side. Seated behind this deflecting mirror (**38**) are a tube lens (**70**) and an ocular lens (**72**), which together with the objective (**24**) of the scanning head (**10**) form a microscope.

Fig. 3

OPTICAL SCANNING HEAD WITH OBJECTIVE POSITION MEASURING AND MIRRORS

Optical scanning heads according to this invention are intended for incorporation in CD-players and serve for reading the optical information stored on the CD (compact disc). Due to the fact that the measuring light source is not located on the objective axis, on the contrary on an axis at right angles thereto and the measuring light is focussed by way of a deflecting mirror from the measuring light source by way of the objective on the surface to be scanned, one obtains a particularly low overall height of the scanning head, which makes it possible to produce CD-players with such a low overall height that they correspond to the standard dimensions of car radios.

This type of construction of the scanning head has the further advantage, which is not relevant for use in motor vehicle CD-players, that the path of rays between the measuring light source and objective is accessible for manipulations, since the deflecting mirror is inserted in an opening in the housing of the scanning head.

It was already proposed (DE-OS 35 36 700), to use such scanning heads of CD-players also for the high resolution measurement of the profiling and of the surface roughness of work-piece surfaces. In this case it would occasionally be advantageous if one could also visually inspect the surface section just measured.

It was then recognised that by slightly varying the deflection mirror on an optical scanning head, such as is used in motor vehicle CD-players at very low costs one could provide the additional possibility of direct observation of the point of the work-piece surface just measured.

For this purpose, it is proposed according to the invention to use a deflection mirror, which is indeed impermeable to the measured light, but is permeable for at least one wavelength in the visible region of the spectrum and has optical quality not solely on the reflecting front side, but also on its rear side. One can then position an observation device directly behind this deflecting mirror. Since the deflecting mirror is frequently originally a dielectric mirror, thus comprises a basic member (generally of glass) permeable to visible light, in many cases it is sufficient to remove the easily accessible deflecting mirror, already located on the scanning head intended for CD-players, to additionally polish it to optical quality on its rear side and then to re-install it. The observation optical system may be a commercially available microscope-eye-piece.

The modification according to the invention of the optical scanning head thus allows a visual observation of the respectively measured point of the work-piece surface, with very low additional costs. The additionally provided optical parts do not need to be manufactured specially, they do not require a great deal of space and do not considerably increase the weight of the scanning head.

Since the objectives used in CD-scanning heads have a very short focal length (in practice 4.5 mm) and also have a small diameter (in practice 6–8 mm), these objectives correspond very closely to microscope objectives. Thus, together with a commercially available microscope-eye-piece, according to the invention one obtains a microscope integrated in the scanning head.

With the development another embodiment of the invention a visual inspection of the measuring point is then possible even if the ambient light is very poor and the scanning head casts shadows. The observation device containing the scanning head and illumination device forms a compact, smooth-surfaced unit. Furthermore, the observation light falls exactly onto the measuring point, so that the illumination device requires only low power.

The development of the invention according to another embodiment is an advantage with regard to a solely low overall height even of the modified scanning head.

The development of the invention according to another embodiment ensures that one can carry out the visual observation of a point of the work-piece surface and the measurement of this point simultaneously, without the measurement result being adulterated and indeed even if the photoelectric transducer arrangement is sensitive per se to visible light, as is generally the case.

It is frequently necessary to measure work-piece surfaces at points which are not easily accessible and in this case the development of the invention according to another embodiment facilitates the visual inspection with the microscope integrated in the scanning head in a manner which is not tiring for the operator. Very compact solid state image converters with extremely good resolution can be obtained at relatively low prices as a vidicon replacement in television cameras. They can be connected simply to a monitor by way of the electronics developed for this camera.

The development of the invention according to another embodiment is an advantage with regard to the simple equipping of such scanning heads, which originally offer no possibility for direct observation of the measuring point.

The development of the invention according to another embodiment facilitates convenient observation of the measuring point from a distance.

With the development according to another embodiment it is ensured that the observation light source can be separated spatially from the scanning head, which is an advantage with regard to protection from heat, without additional measures as regards apparatus having to be taken for guiding the observation light to the measuring point.

The invention is described in detail hereafter by means of two embodiments, referring to the drawings, in which:

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a diagrammatic, vertical section through an optical scanning head for the high-resolution measuring of a work-piece surface;

FIG. **2** is a diagrammatic view of a modified ocular insert with integrated image converter and a monitor connected thereto, for use with the scanning head according to FIG. **1**; and

FIG. **3** is a similar sectional view to FIG. **1** through a modified scanning head.

DESCRIPTION OF PREFERRED EMBODIMENTS

In FIG. **1**, a scanning head is designated generally by the reference numeral **10**, which serves for the high accuracy measurement of surface roughnesses and surface structures on the surface of a work-piece **12**.

The scanning head **10** has a housing **14**, which is substantially cup-shaped. Securely inserted in a lower opening **16** in the housing **14** is a toroidal coil **18**, which produces an axial magnetic field. The toroidal coil **18** co-operates with an annular permanent magnet **20**, which is stuck to the outside of an objective ring **22**. The objective ring **22** retains an objective **24**. The unit formed by the permanent magnet **20**, the objective ring **22** and the objective **24** penetrates the toroidal coil **18** with radial clearance and is supported by two leaf springs **26, 28** extending parallel to each other, the section of which located on the left in FIG. **1** is constructed in the form of spectacles, so that the objective **24** remains free, whereas the section located on the right-hand side is in the form of a strip and is fixed at its outermost end by screws **30** to a cross-piece **32** of the housing **14**. The leaf springs **26, 28** thus form a resilient parallelogram suspension for the objective **24**.

Fixed in the section of the peripheral wall of the housing **14** located on the right in FIG. **1** is a semi-conductor laser **34** operating in the red. The laser beam emitted by the latter penetrates a semi-permeable measuring mirror **36** and reaches a deflecting mirror **38**. The latter consists of a glass backing member **40** and a dielectric layer **42** applied to its under side, which is chosen so that the deflecting mirror **38** reflects the laser beam. The latter then passes through the objective **24** and is focussed by the latter on the surface of the work-piece **12**.

The laser light reflected by the work-piece surface is focussed by the objective **24** and passes by way of the deflecting mirror **38** back to the measuring mirror **36**. The latter separates part of the reflected measuring light and directs it to a photoelectric transducer arrangement **44**, the centre of which is indicated at **46**. The photoelectric transducer arrangement **44** produces an output signal, which depends on the position of the incident light with regard to the centre line **46**. This output signal passes to an input amplifier **48** of an operating circuit associated with the scanning head **10** and designated generally by the reference numeral **50**.

The operating circuit **50** contains switching circuits not shown in detail, which ascertain the deviation of the instantaneously obtained output signal of the transducer arrangement **44** from that signal which is obtained at the time of incidence of the measuring light upon the centre line **46**. Corresponding to the difference between these two signals, the operating circuit **50** produces a fault signal for a power amplifier **52**, which supplies the toroidal coil **18**. The feed current for the toroidal coil **18** is increased or reduced until the measuring light spot on the transducer arrangement **44** again lies on the centre line **46**. This is the case when the distance between the objective **24** and the illuminated point of the surface of the workpiece **12** corresponds exactly to the objective focal length.

From the description given so far, it can be seen that when the scanning head **10** moves over the surface of the workpiece **12**, the objective **24** travels axially as this corresponds to the surface profile of the work-piece **12**. Due to position-measuring means co-operating with the objective ring **22** or by measuring the feed current for the toroidal coil **18** necessary for balancing, an electrical signal changing with the surface profile is thus produced. For the purposes of the present description it is assumed that this signal (possibly after correction for non-linearities in the drive system formed by the toroidal coil **18**, the permanent magnet **20** and the leaf springs **26, 28**) is derived from the magnitude of the toroidal coil feed current. This measuring signal is made available on a lead **54**.

The scanning head described so far corresponds in its construction to scanning heads as they are used in CD-players for motor vehicles.

However, in the scanning head illustrated in FIG. **1**, a device for the visual observation of the point of the work-piece surface measured is also provided by way of addition. For this purpose, the rear side of the glass backing member **40** is polished to optical quality. This can take place simply due to the fact that the deflecting mirror present in the commercially available CD-scanning head is removed from the housing **14** and is polished to optical quality on its rear side, whereupon the deflecting mirror **38** is then re-introduced into the housing **14**.

The observation device designated generally by the reference numeral **56** has a housing **58**, which defines a tube **60** and a lamp chamber **62**. Located in the lamp chamber **62** is a halogen lamp **64**, the coiled filament of which is focussed by way of a lens **66** on the end of a bent light guide **68**. The latter penetrates the tube **60** and lies with its light guide section extending vertically downwards on the axis of the objective, thus also on the axis of the tube **60**.

Inserted in the tube **60** is a tube lens **70**, which may be a plastic lens. In order to achieve the lowest possible overall height of the total arrangement, the tube lens **70** may be drilled in the centre and the lower end of the light guide **68** may be guided therethrough, as shown in the drawing. An ocular lens **72** is inserted in the upper end of the tube **60**.

The light emitted by the halogen lamp **64** passes by way of the light guide **68**, through the deflecting mirror **38** and by way of the objective **24** to the work-piece surface, where it is focussed. The observation light reflected by the work-piece surface passes partly through the deflecting mirror **38** again and passes through the tube lens **70** and the ocular lens **72** into the eye of an observer. For this, the objective **24**, the tube lens **70** and the ocular lens **72** form a microscope, through which details of the work-piece surface can be observed with magnification. The point of the work-piece surface observed in this way is exactly that which is also measured using the laser light.

Part of the observation light reflected by the work-piece surface also passes by way of the deflecting mirror **38** and the measuring mirror **36** to the transducer arrangement **44**. This light could disturb the subsequent guidance of the objective **24** and thus the measurement of the work-piece surface, if the visual observation and the measurement take place simultaneously. In order to prevent this, the semi-conductor laser **34** is excited in pulses by an associated feed circuit **74** of the operating circuit **50** and the input amplifier **48** is constructed as a phase-sensitive rectifier, so that non-modulated portions of light, which likewise fall onto the transducer arrangement **44**, do not impair subsequent adjustment of the objective position.

FIG. **2** shows an ocular member **76**, which can be inserted in the upper end of the tube **60** in place of the ocular lens **72**. The ocular member **76** contains a solid state image converter **78** in such an axial position, as it is used in television cameras, that the real image of the work-piece surface produced by the tube lens **70** lies on the light-sensitive surface of the image converter **78**. The image converter **78** is connected by way of camera

electronics **80**, which may correspond completely to the commercially available electronics of portable television cameras, to a monitor **82**. On this monitor, the microscope image of the region of the work-piece surface just measured may thus be observed at the same time as measuring of the work-piece surface. This observation is thus conveniently possible, without there being any risk that when looking into the ocular, the observer accidentally comes into contact with the scanning head **10** and thus mechanically influences the very precisely predetermined path along which the scanning head is drawn over the work-piece surface. Furthermore, in this way, a convenient visual inspection of the work-piece surface is also possible if the scanning head operates in poorly accessible places, for example measures cylinder bores or the like.

In the embodiment according to FIG. **3**, parts which have already been described above, are given the same reference numerals; they are not described in detail hereafter.

The housing **58** is separated from the housing **14** and in its place an adaptor plate **84** is screwed on, which defines a tube **86**. Fixed in the latter by means of a resilient clamping sleeve **88** is one end of a flexible, coherent fiber cable **90**. The latter comprises a plurality of glass or synthetic fibers bunched in an orderly manner and can thus transmit an image. The other end of the fiber cable **90** is fixed by a resilient clamping sleeve **92** in the lower end of the tube **60** of the housing **58**.

Also inserted in the tube **60** is a mirror **94** which is semipermeable to the observation light, which mirror deflects the observation light produced by the halogen lamp **64** and converted by the lens **66** into a beam of parallel rays, into the fiber cable **90** and allows the light reflected back by the work-piece surface to travel to the ocular lens **72**.

What is claimed is:

1. An optical surface scanning head which includes a measuring light source defining a light source axis, preferably a solid state laser, with an objective for focusing the measuring light source on a work-piece surface and having an objective axis which is inclined with respect to said light source axis and preferably intersects the latter at right angles, a deflecting mirror which is impermeable for the measuring light which is located at the intersection point of the objective axis and light source axis and has a light receiving front side and an opposing rear side, a measuring mirror which is semi-permeable for the measuring light and which is located between the measuring light source and the objective, preferably between the measuring light source and the deflecting mirror, a photoelectric transducer arrangement which is acted upon by the measuring light deflected by the measuring mirror returning from the work-piece surface and produces an output signal dependent on the incidence point of this measuring light, an adjusting device for axially moving the objective, a control circuit by which the adjusting device is actuated depending on the output signal of the transducer arrangement so that the output signal of the transducer arrangement assumes a given value, and means for producing a measuring signal corresponding to the objective position characterized in that the deflecting mirror (**38**) is permeable for at least one light wave length not contained in the measuring light spectrum and also has optical quality on its rear side, and in that an observation optical system (**70, 72**) is located behind the deflecting mirror (**38**).

2. A scanning surface head according to claim **1** characterized in that an illuminating device (**64–78**) makes available observation light with at least one wavelength not contained in the measuring light spectrum, on the axis of the objective (**24**).

3. A scanning surface head according to claim **2** characterized in that the illuminating device comprises an illuminating light source (**64**) located laterally beside the objective axis and means (**68**) for deflecting the observation light onto the objective axis, in particular a curved light guide (**68**).

4. A scanning head according to claim **1** characterized in that the measuring light source (**34**) produces modulated measuring light and the output signal of the transducer arrangement (**44**) is processed by a phase-sensitive rectifier (**48**).

5. A scanning head according to claim **1** characterized in that the observation optical system comprises a tube lens (**70**) and an ocular lens (**72**).

6. A scanning head according to claim **1** characterized in that the observation optical system comprises a tube lens (**70**) and a solid state image converter (**78**).

7. A scanning head according to claim **2** characterized in that the observation optical system (**70, 72, 78**) and optionally the illuminating device (**64–78**) are located in an additional housing (**58**) attached to the housing (**14**) of the scanning head.

8. A scanning head according to claim **1** characterized in that the observation optical system comprises a coherent fiber cable (**90**).

9. A scanning head according to claim **8** characterized by means (**94**) for introducing observation light (**64**) into the fiber cable (**90**).

[57] **ABSTRACT**

A scanning confocal optical microscope using a Nipkow disc having a plurality of pinholes to project light and an objective lens to receive the light and illuminate points on an object to be viewed. Rotation of the disc scans the points across the object. The object is viewed by viewing the reflected light focused on the pinholes by the ojective lens.

SCANNING CONFOCAL OPTICAL MICROSCOPE INCLUDING AN ANGLED APERTURED ROTATING DISC PLACED BETWEEN A PINHOLE AND AN OBJECTIVE LENS

This application is a continuation-in-part of copending application Ser. No. 031,516 Filed Mar. 27, 1987 now abandoned.

FIELD OF THE INVENTION

This invention relates generally to confocal optical microscopes and more particularly to a scanning confocal optical microscope.

BACKGROUND OF THE INVENTION

Conventional confocal optical microscopes are known for their extremely short depth of focus and improved transverse resolution. The main drawback with conventional confocal scanning optical microscopes is that they illuminate only one point on the object at a time. To scan the object either the sample or beam must be mechanically moved to form a raster image of the object. Mechanical scanning is time consuming.

In a paper appearing in The Journal of the Optical Society of America, Vol.58, No.5, May 1968, there is described a tandem-scanning reflected-light microscope. In the described microscope both the object plane and the image plane are scanned in tandem so that only light reflected from the object plane is included in the image. The object to be viewed is illuminated with light passing through plurality of holes in a rotating disc which are focused onto the object by an objective lens. Thus, a large number of points on the object, corresponding to the holes which are illuminated, are illuminated at one time. The holes themselves are located along spiral paths. By rotating the disc a raster scan of the object is obtained. Reflected light from the illuminated spots is directed to the opposite side of the same apertured disc and passes through optically congruent holes on diametrically opposite sides of the rotating disc. The image obtained had better contrast and sharpness than possible with the usual reflected-light microscope. This is due to the fact that reflected light from within the microscope and other stray light coming from other points is intercepted by the opaque portions of the disc and the image only comprised reflection from the illuminated spots. The system of the prior art is extremely complex and difficult to align because of the necessity of assuring that the light reflected from the illuminated spots must pass through congruent holes on the opposite side of the rotating disc.

The present invention employs the principals of a confocal optical microscope such as illustrated schematically in FIG. **1**. Light input from a laser, arc lamp or other light source impinges upon a plate **11** which includes a pinhole **12**. The light travels through the pinhole to the objective lens **13** and is focused on the object plane **14**. Light reflected from the object plane travels back through the pinhole as shown and can be viewed. Reflection from out of focus planes such as plane **16** does not converge at the pinhole and is therefore blocked by the plate **11**. In operation the reflected light passing through the pinhole impinges upon an associated detector. The detector output is maximum when the object is located at the focus of the lens, otherwise the light received at the pinhole is defocused and the amplitude of the signal falls off rapidly as the position of the object is changed on either side of the object plane. The system has a very short depth of focus in addition to excellent transverse definition.

As previously described, such a microscope can be mechanically scanned to form a raster image by moving the object or pinhole in a raster pattern.

OBJECTS AND SUMMARY OF THE INVENTION

It is a general object of the present invention to provide a scanning confocal microscope which overcomes the mechanical alignment problems of the prior art Tandem Scanning Microscope and which presents a total image of the object without the necessity of mechanical scanning of the light beam or object.

It is another object of the present invention to provide a confocal microscope employing a rotating apertured scanning disc in which reflections from the disc and other stray light is eliminated from the image making it possible to observe weakly reflecting objects.

In accordance with the invention there is provided a scanning microscope for viewing an object which comprises a scanning disc with a plurality of holes arranged in a predetermined pattern and a light source for illuminating a portion of said disc. A polarizer receives the light from the source and polarizes the light prior to the light illuminating the disc. A lens focuses light diffracted through said plurality of illuminated holes onto an objective lens which focuses a plurality of spots on the object. The objective lens receives light reflected from the object spots and focuses the light on the corresponding pin hole. A quarter wave plate is interposed between the objective lens and the disc.

A beam splitter receives the reflected light traveling through the holes and directs the light to a polarizer. Means are provided for rotating the disc to scan the spots across the object in a raster scan to provide an image of the region of the object illuminated by the spots.

In other embodiments the disc is tilted to deflect reflections from the rotating disc so that they do not impinge on the image of the object.

BRIEF DESCRIPTION OF THE DRAWING

The foregoing and other objects of the invention will be more clearly understood from the following description taken in connection with the drawings of which:

FIG. **1** shows a prior art confocal optical microscope.

FIG. **2** shows a scanning confocal optical microscope in accordance with the present invention.

FIG. **3** shows another embodiment of the scanning confocal microscope in accordance with the invention.

FIG. **4** is a perspective view of a Nipkow disc used in the present invention.

FIG. **5** is an enlarged view of a section of the disc of FIG. **1** showing its construction.

FIG. **6** shows an embodiment of the invention with tilted disc.

FIG. **7** shows an embodiment similar to that of FIG. **6** with analyzer, polarizer and quarterwave plate.

FIG. **8** shows an embodiment similar to that of FIG. **7** with a split field lens.

FIG. **9** shows an embodiment of the invention with dark field imaging.

FIGS. **1O***a* and **10***b* illustrate how the dark field stop of FIG. **9** operates.

FIG. 11 shows another embodiment of the present invention.

FIG. 12 shows an embodiment of the invention using a polarizing beam splitter.

DESCRIPTION OF THE PREFERRED EMBODIMENT(S)

Referring to FIG. 2, the microscope includes a circular disc 21, known as a Nipkow disc, which has holes 4 disposed in a pattern of several interleaved spirals 6 of several turns each, FIGS. 4 and 5. The holes are spaced approximately ten hole diameters apart. In one example the average radius of the spiral was five centimeters and the spiral extended over a radial distance of 1.8 centimeters with a total of 200,000 holes of 20 micrometer diameter formed in the periphery of the disc. Preferably the disc is of transparent material 7 with a layer 8 of black emulsion or black chrome in which the holes 4 are formed by photo masking techniques.

A suitable light source, for example, either a mercury arc lamp or a laser 22, is used to illuminate an area of 1.8 centimeters by 1.8 centimeters containing about 4,000 holes. The light from the light source is polarized by a polarizer 23 and passes through a beam splitter 24 before striking the disc 21. The holes diffract the impinging light and the incident beam converges on objective lens 26. For example, the incident beam converges to a five millimeter diameter on the back of the objective lens 26 so that 4,000 points on the object 27 are simultaneously illuminated. Because of the spacing of the image points there is negligible interference between the different illuminated points.

The disc is rotated, for instance, at 2,000 rpm and since the holes are arranged along the spiral path the rotation of the disc forms a raster scan across the object, thus forming 7,000 lines 500 frames per second.

The light focused on the object is reflected and focused at the same pinholes by the objective lens after traveling through a quarter wave plate 28. The light passing through the holes strikes a beam splitter 24 and is directed at right angles there from to an analyzer 31 and thence can be viewed by the naked eye through a transfer lens 32 which focuses on the pinholes.

In the embodiment of FIG. 3, where like reference numerals are applied to like parts, the image travels through a relay lens to a camera 33 and to a TV monitor 34 which provides a display. Alternately the camera may be a photographic camera which takes a picture of the object. It is to be noted that no precise alignment is needed. The same holes are used for transmission and reception of the light making it relatively simple to align the microscope. The eyepiece, or camera, is focused on the pinholes illuminated by reflected light from behind the pinholes. Centering of the spiral is not critical. Vibration is not a severe problem provided that disc vibration has an amplitude much less than the depth of focus of the lenses at the pinholes, typically a distance greater than 1 millimeter.

The use of the polarizer, analyzer and a quarterwave plate reduces interference from reflections from the disc as well as the surfaces of the microscope elements by a factor of the order of 10^{-4} intensity and provide a clear visual image.

With reference to FIG. 3 the apparatus also includes a light stop which is located at the focal point of the incident light reflected from the surface of the Nipkow disc.

The purpose of this stop is to completely remove all remaining reflected light from the disc When a laser source is employed, the stop is placed at the focus of the reflected converging beam. With a lamp source, an image of the source is focused on the stop. With an incoherent light source of finite diameter, the stop must be larger than it would need to be with a coherent light source. Nevertheless the stop would only intercept a very small fraction of the area of the beam passing through the pinholes to the observer. The microscope can be constructed with solely a light stop, and this may be disadvantageous when an object having a low reflectivity is being viewed.

The object or the objective lens can be moved up or down in order to focus on various planes in a translucent object such as a biological material like bone, or at various levels of a sample such as an integrated circuit. A very similar system can be used as a range sensor in robotic applications.

In the robotic application the Nipkow disc is illuminated by a collimated laser beam with, perhaps, as much as several watts in the beam. The pinholes in the disc are viewed as described in FIG. 3. Images of the pinhole are focused on a distant plane by a camera lens. The beam, after leaving the pinhole, may be expanded by a telescope to give a larger beam at the lens pupil. This is to make it possible to use a lens of larger aperture so as to obtain the optimum transverse and range definitions.

When the Nipkow disc is rotated a region at the focal plane of the lens is imaged. Thus a direct real time image of a plane at a fixed distance from the lens is obtained in real time. Images of other cross sections are easily obtained by moving the lens back and forth. This can be used to control a robot.

In the embodiments to be described, the rotating disc is tilted to eliminate reflections from the rotating disc making it possible to observe weakly-reflecting objects.

Referring to FIG. 6, light from a light source 22*a*, such as a mercury arc lamp, a filament lamp or a laser, is focused onto a pinhole P whose diameter is made small enough to get a fairly good point source consistent with providing sufficient illumination of the sample. The diameter of the pinhole is typically in the range from 100 μm to 1 mm. The light emerging from the pinhole passes through a beamsplitter 24 and through the pinholes in the rotating disc 21*a*. It then proceeds through a field lens 36 and through the objective lens 26*a* and strikes the sample. In FIG. 6, the dashed lines indicate the ray paths if the disc were not present, similar to a standard microscope; without the disc, the pinhole would be imaged onto the center of the objective lens. When the rotating disc is present, the light passes through the pinholes in the disc. The light from an individual pinhole in the disc is diffracted into an Airy pattern at the pupil of the objective lens. The center of this Airy pattern is always located at the center of the objective lens, due to the focusing of the image of the pinhole P by the field lens onto the objective, as already described. Thus, the shape and intensity of the illumination at the objective lens does not vary very much from one pinhole to another. Therefore, the definition and the intensity of the illumination of the sample is approximately uniform over the field of view.

The spacing of the rotating disc from the objective is typically of the order of 200 mm and the diameter of the pinhole is chosen so that the illumination of the objective by one pinhole in the disc is fairly uniform. This implies that the pinhole diameter should be small

enough so that the pupil of the objective lens is smaller than the diameter of the zeroth order lobe of the pinhole at the pupil. In turn, this implies that light passing through the pinhole, reflected from the sample through the objective lens, is focused to a spot at the pinhole which is larger than the diameter of the pinhole. Typically, this spot also has the form of an Airy pattern. Thus, this pinhole also acts like a spatial filter to the reflected light. If h is the distance from the objective to the rotating disc, a is the radius of the pinhole, and b is the radius of the pupil of the objective lens, then, without the field lens present, the ratio of the amplitude of the field at the edge of the pinhole to that at its center is $J_1(2\pi ab/h\lambda)/(2\pi ab/\lambda h)$ where $\lambda$is the wavelength and J_1 is a first order Bessel function. For best definition, the pinhole should be infinitesimal in diameter. However, to pass enough light through the pinhole, the pinhole size must be finite, and for optimum performance, $ab/h\lambda < 0.61$ and preferably $ab/h\lambda$ is of the order of 0.25.

With the spacings used, this implies that the pinhole diameter is typically in the range of 10–20 μm. When the pinhole diameter is infinitesimal, the beam passing through the pinhole is diffracted into a 2 λ solid angle. In this case, the objective lens is illuminated uniformly by the diffracted beam from the pinhole. As the pinhole diameter is made larger, the diffraction angle of the beam passing through the pinhole becomes smaller and the objective lens is nonuniformly illuminated. With too large a pinhole diameter, the intensity of illumination at the pupil of the objective lens is largest at its center, falls off towards its edges, and includes higher order sidelobes so that the effective aperture of the objective lens is reduced from its value with uniform illumination. Therefore, the definition of the microscope image is deteriorated when the pinhole size is too large. A further major disadvantage of using too large a pinhole is that the variation of the intensity of the output, when there is a plane reflecting sample present, is not as rapid with distance from the focus as it is with an infinitesimal pinhole. Put another way, if the pinhole diameter is made too large, then the short depth-of-focus dictated by the principle of the confocal microscope is no longer obtained and the device behaves more like a standard microscope.

It should be noted that it is not advisable to make the pinhole diameter too small, for then not enough light passes through the pinhole. In order to eliminate interactions between the light passing through individual pinholes, particularly when using a laser source, it is necessary to have the pinhole spacing on the disc of the order of ten pinhole diameters apart. Thus, less than one percent of the light reaching the disc passes through the pinholes. Therefore, it is vitally necessary to eliminate the reflected light from the disc itself.

One technique for doing this was described above with reference to FIGS. **2** and **3**. A preferred technique is shown in FIG. **6**. The disc is tilted sufficiently far so that the light reflected from the disc hits an aperture plate **37** in front of the relay lens **38** and is eliminated. This is schematically illustrated by the dotted area showing the reflections from the disc. The plane of this aperture plate is placed at the mirror image position of the plane of the pinhole P with respect to the beamsplitter. The image of a pinhole on the disc is focused on the eyepiece **39**, which in turn implies than an image of the sample can be seen at the eyepiece. The tilt angle of the disc θ can be compensated by tilting the sample by an angle θ/M, where M is the magnification of the objective lens **26***a*.

In the embodiment of FIG. **7**, polarizer **23**, analyzer **31**, and $\lambda/4$ plate **28** as in the embodiments of FIGS. **2** and **3** are added. Light from the light source is polarized, and when reflected from the disc and the beamsplitter, passes through an analyzer rotated at 90 degrees to eliminate the polarized light reflected from the disc. The polarization of the beam passing through the objective lens through the $\lambda/4$ plate and reflected back through it again is rotated by 90 degrees, and hence passes through the analyzer. Hence, the image of the sample can be observed, but the light from the disc is eliminated by two strategems, tilt and polarization.

A further improvement on this system is to split the field lens into two parts, **41** and **42**, one between the disc **21** and the sample and the other on the top side of the disc **21**, as shown in FIG. **8**. The upper lens **41** collimates the beam from the pinhole P to produce a parallel beam at the disc. Without the disc present, the lower lens focuses the collimated beam to a point on the pupil plane of the objective lens. The beam reflected from the disc is now focused by the upper field lens **41** to a point on the aperture **37** in front of the relay lens **38**. This aperture is placed in a plane which is the mirror image in the beam splitter of the plane of the pinhole P. The reflected light passing through the pinhole of radius a is diffracted so that the first zero of the Airy pattern of the diffracted beam from the pinhole is of radius $R=0.61\ \lambda L/a$, where L is the distance of the pinhole P from the upper field lens. Typically L is 75 mm, a=10 micrometers and R=2.5 mm. with λ=0.54 mm. This implies that the focused spot corresponding to the reflection from the disc should be placed a distance slightly greater than R from the center of the aperture pinhole. Thus the tilt angle of the disc need only be of the order of $\theta=R/2L$ or 1 degree.

This makes it still easier to eliminate the reflected light, in particular to eliminate any stray light due to diffraction of the light beam and the granularity of the film on the rotating disc. By this means, it is only necessary to tilt the rotating disc by one or two degrees instead of the order of five degrees, as in FIGS. **6** and **7**, since the diameter of the beam that must be eliminated at the aperture in front of the relay lens is relatively small. This has the further advantage that with a small tilt, the depth of focus is much larger than the change in height of the disc from one side of the beam to the other.

In the embodiments shown in FIGS. **6** and **7**, the quality of the image tends to deteriorate at the edges of the field because of the large tilt of the rotating disc that is required. The polarizer and analyzer, along with the $\lambda/4$ plate, are still used to improve the signal-to-noise ratio of the wanted signal to the reflected light from the disc still further. With this system, reflected light from the disc is below the level of all other sources of light in the defocused beam. For example, when the beam is badly defocused as the sample is moved out of the focal plane of the objective lens, it might be expected that approximately one percent of the reflected light from the sample would still pass through pinholes (their total area being assumed to be 1% of the illuminated area of the disc), and would give rise to background light, which is difficult to eliminate. This phenomenon dictates the lower level of the dynamic range of the system.

Another embodiment of this microscope which is useful for certain purposes is that of dark field imaging.

In FIG. **9** a stop is placed over half of the back of the objective. The presence of this stop eliminates light directly reflected from a specular reflector. For example, as shown in FIG. **10***a*, a ray A impinging on the objective lens of sample returns along a path like ray B. However, with the stop in place, no light returns along path B and hence a specular reflector cannot, in principle, be seen. However, light from a corner or a sharp edge scatters in all directions and some will go through the lens to regions where the stop is not present, as shown in FIG. **10***b*. Therefore, the system forms a dark field imaging system with the short depth-of-focus of the real-time scanning optical microscope. Such a system is particularly good for looking at holes in photoresist and other materials where the beam can enter through the region of the hole and not through the photoresist itself. In this case there is no aberration of the beam by the photoresist and the light reflected from the top and bottom corners of the hole makes it possible to make measurements of the depth and slope of the hole. In general, dark field imaging can be obtained if the shape of the stop is chosen so as to eliminate light directly reflected from a specular reflector.

A problem, and sometimes an advantage, of this type of microscope is the chromatic aberration of the objective lens. The depth-of-focus of this microscope can be of the order of 0.5 micrometers or less with a 0.9 aperture lens. When a white light source is used, however, different colors tend to be focused at different depths due to the chromatic aberration of the lens and the chromatic aberration in the focal plane can be as much as several micrometers with a white light source. This has the advantage that the microscope can be useful for inspection because different depths appear in different colors. On the other hand, for quantitative measurements, it is better to observe a beam focused on a given surface by determining when the intensity is maximum. This is best done by placing an optical filter in front of the pinhole or in front of the relay lens so that a relatively narrow band of light reaches the eye or the TV camera.

A further version of this microscope is suitable for polarization imaging. In this case, shown in FIG. **11**, the polarizer **23** and analyzer **31** are used with the analyzer rotated so that its plane of polarization is at 90 degrees to the polarizer. However, the $\lambda/4$ plate shown in FIGS. **2**, **3**, **7**, **8** and **9** is omitted. Therefore, a dark field image is obtained from a reflector which does not rotate the plane or polarization. Edges and dielectric materials rotate the plane or polarization of the beam upon reflection and therefore show up in polarization image. The system is also useful for observing reflections from magnetic materials such as a magnetic disc of the type used for computer storage. It is also apparent that the system will have the same depth-of-field as the standard confocal microscope.

Another embodiment of the microscope which can provide the advantage of less light loss than with the use of a plate beamsplitter, is to employ a polarizing beamsplitter **42**, as illustrated in FIG. **12**. Light from a laser source, mercury arc lamp or filament lamp is first linearly polarized by the polarizing beamsplitter **42** then passes through the apertures, field lens **36** and quarterwave plate **28** to the objective lens **26**. The light returning from the object has it polarization rotated by 90 degrees after passing back through the quarterwave plate and therefore is reflected by the beamsplitter **42** to the relay lens and then to the eyepiece, while the light reflected from the disc passes back to the illuminator, since its plane of polarization has not been rotated. In order to further suppress the background reflection from the disc and from the surfaces of the beamsplitter, a polarizer **23** and an analyzer **31** is used in this embodiment. The advantage of the beamsplitter is that very little light is lost in passing through it. In a normal beamsplitter, half the power is wasted on each transit through it. Furthermore, the polarizing beamsplitter also acts as a polarizer and an analyzer itself, so the overall background reflections can be lower compared to the other embodiments.

We claim:

1. A scanning microscope for viewing an object comprising:

a light source;

a pinhole for receiving light from said light source;

an objective lens disposed to focus light from said pinhole onto said sample surface area;

an apertured rotating disc placed between said pinhole and said objective lens with the axis of rotation of said disc at an angle with respect to the axis of the light from said pinhole passing through apertures in said apertured rotating disc to said objective lens and sample, said objective lens serving to focus light reflected at said sample surface onto said rotating disc whereby light reflected from said surface is transmitted through said apertures; and

means for directing said transmitted light onto an image plane and for eliminating from said image plane light from the pinhole reflected by said rotating disc.

2. A scanning microscope as in claim **1** wherein said means for eliminating from said image plane light reflected by the rotating disc comprises an apertured member which interrupts the reflected light and passes transmitted light through the aperture.

3. A scanning microscope as in claim **2** wherein said means for eliminating light reflected from said rotating disc from the image plane includes additionally a polarizer for polarizing light from said pinhole;

a quarterwave plate for receiving the light from said pinhole and the light reflected by the sample surface and an analyzer for receiving the transmitted light.

4. A scanning microscope as in claims **1**, **2** or **3** including a stop adjacent to and between said objective lens and the object being viewed to stop light specularly reflected at said sample surface.

5. A scanning microscope as in claims **1**, **2** or **3** including a beam splitter for passing light from said pinhole to the objective lens and for reflecting and directing the transmitted light.

6. A scanning microscope as in claim **5** in which said beam splitter is a polarizing beam splitter.

7. A scanning microscope as in claims **1**, **2** or **3** including a field lens for receiving light from said pinhole and focusing it onto said objective lens.

8. A scanning microscope as in claim **7** in which said field lens is a split lens with one half on each side of said rotating disc to pass collimated light through said apertures.

9. A scanning microscope for viewing an object comprising a scanning disc with a plurality of pinholes arranged in a predetermined pattern;

a light source on one side of said disc for illuminating an area of said disc;

a first polarizer for polarizing the light which illuminates the disc;

an objective lens on the opposite side of said disc for focusing light diffracted by said pinholes onto the object to illuminate a plurality of points on said object;

means for mounting said disc with its rotational axis at an angle with respect to the axis of light from said source to said objective lens;

means for rotating said disc to scan the points across the object;

said objective lens serving to receive light reflected from the object and focus the light on corresponding pinholes;

a quarterwave plate interposed between said objective lens and disc to intercept the light traveling to and reflected from said object;

a beam splitter on said one side of said disc between said first polarizer and said quarterwave plate for receiving reflected light traveling through said quarterwave plate and said pinholes and directing it; and

a polarizer for receiving the directed light.

10. A scanning microscope as in claim **9** including a light stop disposed to stop light reflected from the disc.

11. A scanning microscope as in claim **9** in which the holes are disposed in a pattern of several interleaved spirals of several turns each.

12. A scanning microscope as in claim **9** in which the disc includes an apertured dark layer on the surface of a transparent disc.

13. A scanning microscope as in claim **9** wherein said means for eliminating from said image plane light reflected by the rotating disc comprises an apertured member which interrupts the reflected light and passes transmitted light through the aperture.

[57] **ABSTRACT**

The present invention relates to image-formation on any selected kind of objective body. The characterizing features reside in such that, based upon fed image data, required images are formed on an image-transferable sheet acting for imaging carry-over service and in reliance on sublimation image transfer technique, and then, by the use of said sheet with said images thus formed thereon, the formed images thereon are transferringly applied on the objective body. By adopting the above measures, the objective body can be formed sharply and clearly with any desired images, irrespective of kind and configuration thereof, with such superior results of highly improved unity and solidability between the formed images and the objective body to be decorated with.

IMAGE FORMATION ON OBJECTIVE BODIES

TECHNICAL FIELD

This invention relates to methods and apparatus for the formation of images as prints on objective bodies through transfer of images preformed by the sublimation transfer technique, and more specifically it relates to such systems as adapted for the formation of images on any selected objective body, such as cards, clothes, papers, and transparent sheets, although these are not limitative to the present invention.

BACKGROUND ART

Reliance is made generally upon the normal printing technique for formation of images on objective bodies. For the execution of the printing technique, provision and use of printing plates (forms or blocks) are requisite. No matter how simple the image-printing is, the plate-making is a very time-consuming the laborious procedure This is much more so in the printing of various and complexed image combinations, such as those of graphic or portrait images combined with characters, letters or bar codes, as an example, representing extremely complicated and troublesome work.

Further, in the normal printing operation, various operating conditions, including ink selection and the like, must be carefully considered, depending upon the kind and nature of the printing object, thus the best selection thereof is highly delicate and not as simple as expected.

The present invention is proposed upon careful consideration of the foregoing facts, and an object of the invention is to provide a unique process for the formation of sharp and clear images regardless of the kind and nature of the object to be printed upon, and usable and effective materials and apparatuses for carrying out this unique process.

The method of thermal image transfer (sublimation image transfer) on clothes or fabrics with the use of thermal transfer dyestuffs has been practiced for a long time. In this conventional process, a dyestuff picture layer carrying thermal transfer dyestuff is formed on a substrate sheet which is then subjected to heat in an overlapped state on a cloth or fabric, the dyestuff thereby being transferred thermally onto the latter for forming the desired images thereon. By utilizing this technique, and with recent development of the image forming technology concerning fine thermal printers and the like, various fine image forming processes have been proposed to provide fine images which are comparable to photographic images and are transferred onto plastic films from thermal transfer sheets carrying thermal transfer dyestuffs.

According to these recently proposed processes, various images of cameras, or TVs, graphic images of personal computers and the like can be reproduced easily in the form of hard copies on the surface of a transferred material such as a paper or the like sheet carrying thereon a fixedly attached layer of polyester resin, as an example. These images thus reproduced represent an amply high level comparable to those obtained by photography or fine printing arts.

The thermal transfer process so far set forth has an advantage in that it can form any image in a convenient manner yet entails a problem in that it is limited to image-transferred products preferably of polyester and the like materials which must be dyed with thermal transfer dyes. On the other hand, the image-transferred products must be limited to specifically selected shapes, preferably film, sheet or the like configuration, and thus, such materials as wood, metal, glass or ceramics cannot be formed with images in this way. Further, even if the material is plastics such as polyester or the like, and when the image-forming surface is curved or undulated, or physical body other than sheet, even if it represents a plane surface, it is almost impossible to reproduce images precisely thereon, which naturally constitutes a grave problem in the art.

With recent development and enlargement of utilizing fields of various card-style products, such as cash cards, telephone-cards, prepayment cards; and ID-cards, there are increasing demands for providing these cards with images, symbols and codes, so as to give various other functional and/or decorative effects. Most of these cards are of planar form, but they are frequently not pliable and/or have uneven rough portions due to provision of characters and symbols, resulting in great difficulty in the scheduled image formation relying upon the thermal image transfer process.

There is therefore an urgent demand among those skilled in the art for the provision of a unique technique capable of forming sharp and clear images of desired patterns on the surface of an objective body of any preferred kind of material and having any shape and configuration and surface condition of any kind, and indeed, for combining and unifying image- and decoration effects.

DISCLOSURE OF THE INVENTION

The present invention is basically based on such a principle that a first image transfer pattern is formed on an image transfer material, preferably an image transfer sheet, and in the form of dyestuff images through the sublimation image transfer process executed by first image transfer means, depending upon given image data, preferably including those of letters, characters, symbols, line images, graduated graphic representations, and then the first transfer pattern is transferred to second transfer means for retransferring the images onto an objective body so as to provide a final product.

Based upon the image data fed from various image data input means and at the first image-transfer means, a thermal head is actuated to execute printing operation through a dyestuff film (thermal image-transfer sheet) on an image-transfer material (or more specifically on an image-transferable material which means an image-transferable sheet. This image-printing is carried out according to the sublimation or sublimative image transfer technique. Thus, in this case, the dyestuff on the dyestuff film is transferred or shifted under the influence of heat energy from the thermal head onto the image-transfer material through sublimation, thus providing the first image-transferred means. Since this first image-transferred means has been thus formed with the images by the sublimated dyestuff, they are, then, transferred onto the second image-transferable means which will be brought into tight contact with the object to be decorated and subjected to heat and pressure for execution of further image-transfer operation to provide the final desired product.

In the present invention, the image-transfer material (image-transferable sheet) is, as above referred to, formed with images by the sublimative image transfer technique for providing first image-transfer means

which has highly sharp and clear images a the operation and results of the characterizing feature of the sublimation image-transfer technique. Therefore, because of the transfer of such sharp and clear images onto the object, it becomes possible to form the images thereon, and indeed, practically irrespective of the kind and nature of the object. In this way, thus, fine image-formation is assured onto practically any objective substance.

And further, by execution of control of the thermal energy applied during the sublimative image-transfer step, the resulting color effect is superior and the image quality is good.

The images sublimatingly applied and formed in the foregoing way are subjected to a further transfer, and onto a substrate product, for providing a final decorative product as desired. In this final product, it should be noted that the underlying layer underneath the images during the sublimative image-transfer stage appears now at the top, acting thus as a kind of protecting layer upon up-and-down positional conversion during execution of the second and final image transfer stage, resulting in realization of various and numerous effects. As an example, attainment of substantial reduction of contamination, improvement of light resistance, weather resistance and chemical resistance; substantial reduction of color fading; provision of glazing effect; easier and simpler introduction of granular and/or undulated image appearance.

The inventive process is carried into effect basically in such a manner that an image-reception layer provided on one surface of an image-transferable sheet is subjected to an image-forming step with the use of dyestuff capable of depositing therein depending upon the fed image data, so as to form the required images, and then, the image-reception layer of the image transferable sheet, having been image-fixed and thus now image-carrying, is stuck onto the surface of the object to be decorated upon.

As for the image-transferable sheet adapted for use in the image-transfer during execution of the inventive process, it consists basically of a sheet-like substrate and a reception layer attached, however, in a separable manner, onto one surface thereof. As a modification of the inventive process from the basic mode set forth above, the sheet-like substrate is caused to remain, even after completion of the image-transfer step, as may be occasionally required. In this modified case, it is unnecessary to make the image-reception layer of the image transfer sheet separable.

Under occasion, the inventive process may be brought into effect in such a wa that the image-reception layer of the image-transfer sheet is transferred upon execution of the image-forming step, and indeed, once onto an intermediate image-transfer substrate which is then retransferred, together with the once transferred image-reception layer, onto the surface of an object to be decorated on, and thus, in a retransferring manner.

BRIEF DESCRIPTION OF THE DRAWINGS

In the accompanying drawings:

FIG. **1A** is a block diagram, showing a preferred embodiment of the apparatus according to the present invention;

FIG. **1B** is a schematic view illustrating at (a), (b) and (c), several image-transfer steps for the execution of a process according to the invention;

FIG. **1C** is a schematic view of an image-transfer step, using a platen roll;

FIG. **1D** is a plan view of part of a multi-color dyestuff film adapted for use in an image-forming step;

FIG. **1E** is a schematic view for the illustration of several image-transfer steps;

FIG. **2** is a flow chart of successive operation steps with use of a data-processor, shown in FIG. **1**, functioning as an operating center;

FIG. **3A** is a schematic block diagram, showing a data-processor for the printer;

FIG. **3B** is a block diagram of a sublimative image-transferring printer adopted in the present invention, as a preferred embodiment thereof;

FIG. **4** is a schematic block diagram, showing a color correction unit shown in FIG. **3A**, and several related parts cooperating therewith;

FIG. **5** is a schematic block diagram of a comparator and several related parts cooperating therewith;

FIG. **6** is a circuit block diagram of an image-transfer head shown in FIG. **1B**;

FIG. **7** is a graph showing operational characteristics of a color tone or -gradation corrector unit shown in FIG. **3A**;

FIG. **8** is a table for the illustration, as an example, of picture- or image-elements, as expressed in binary signals;

FIG. **9** is a table showing a conversion operation, as an example, of a parallel/series converter shown in FIG. **3A**;

FIG. **10** is a flow chart, illustrating the operation of the sublimative image transfer printer;

FIG. **11** is a plan view of a final decorative product prepared according to the inventive technique;

FIG. **12** is a sectional view of the product card shown in FIG. **11**, and taken along a section line A—A shown therein;

FIGS. **13** through **31** are a series of sectional views, respectively illustrating several structural examples of image-transferable sheets, suitable for use in the invention; and

FIGS. **32** (*a*), (*b*), and (*c*) are sectional views, indicating final transfer steps.

BEST MODES FOR CARRYING OUT THE INVENTION

Referring now to FIG. **1A** and FIG. **1B**, (a), (b) and (c), a basic scheme of the inventive image data processing and image formation will be illustrated. First, in FIG. **1A**, numeral **101** represents an image input means which is adapted for forming image data based upon optical and the like inputs delivered from a TV-camera, line sensor or the like. Other than those above enlisted only by way of example, video; CD; TV; scanner; personal computer, captain system, capable of providing R.G.B.- and picture image and the like signals may also be utilized in a similar way. The image signal data delivered from the image input means are fed through a data processor **104** to a memory **105** for being stored therein. These stored data can be taken out from the memory and fed through data processor **104** to display means **102** for being displayed thereat.

To the data processer **104**, a mouth/tablet digitizer and/or the like position data processer **103** is electrically connected for introducing position data concerning displayed images appearing at the display **102**. In addition, key board and the like character data input means **106** and font generator **109** are provided for introducing character data. Still further, a barcode generator **110** is provided for introducing barcode when

necessary. By the use of these means and units, various additional processing modes can be executed.

The thus processed data are subjected to conversion at a data converter **107** into proper data adapted for operating a sublimation transfer printer and fed forward through a driver **108** to the thermal head.

In this case, by controlling the current duration period to the thermal element of the thermal head, the transfer quantity from the dyestuff film (thermal transfer sheet) is controlled depending upon the thermal energy of the element for realization of the desired gradation degree of concentration on the transfer sheet. There are two different modes of such control of current duration period as follows:

(a) A method for controlling the pulse length corresponding to the picture element in the impressed data to the thermal element of the thermal head or, more specifically, a series data introduced as input to the shift register shown in FIG. **6** and to be described more specifically hereinafter.

(b) A method for controlling the number of pulses of the pulse series corresponding to the picture elements of the data impressed upon the thermal element in the thermal head (in this case, the pulse length being constant).

The degree of gradation of the transfer image can be controlled in the above mentioned way by the regulation of the current-conducting period depending upon the desired gradation degree. On the other hand, the image concentration can be controlled by adjusting the pulse length or the number of pulses contained in the pulse series in correspondence to the picture elements contained in the data as introduced in the shift register and depending upon the driving mode of the thermal head. Further in this case, if the number of gradation of introduced image data is larger than that which can be expressed by the printer unit, a proper conversion operation can be performed by the known strobe control method As an example, in such case, the conversion of gradation number **256** to **64** may be executed by a ROM, and the thus reduced gradation number can be used as output.

Next, referring to FIG. **1B** at (a) and (b), reference numeral **121** represents a thermal head which receives signals from the driver **108** shown in FIG. **1A**. This thermal head **121** is arranged in opposition to platen roll **122**, forming the printing position therebetween. The dyestuff film (thermal transfer sheet) is fed from a delivery roll **123** to a winding roll **124** through this printing position, these structural and functional features being commonly employed in both the arrangements shown in FIG. **1B** at (a) and (b).

In the case of FIG. **1B**, (a), the mechanism is so arranged that card or sheet style transfer sheets are printed with dyestuff images.

On the other hand, in the case of FIG. **1B**, (b), the mechanism is so arranged that cards are continuously produced with the use of a film style transfer sheet and a dyestuff film in combination.

Now turning back to FIG. **1B**, (a), a number of transfer sheets (cards, sheets or the like) have been stacked and stored within a storage casing **125** and ar being thrust upward from below by a spring so that the uppermost sheet is kept in pressure contact with a take-out roll **126**. With the rotation of the roll **126**, the sheets are successively delivered from the casing **125** by conveyer belts **127**, **128** onto a platen roll **122**. Each one of the sheets is fixed on the peripheral surface of the platen roll, now positionally indexed, by means of a gripper or the like mechanical attaching and separating means, static attracting means, or electromagnetic attaching means. Then, the roll **122** is so rotated that the transfer sheet is positioned at the ready-for-printing-position.

Next, the thermal head **121** is brought into pressure contact with the transfer sheet through the intermediary of the dyestuff film, and then the thermal head **121** is energized with electric current while the dyestuff film and platen roll **122** are moved in synchronism for the execution of image transfer (first image transfer).

Upon execution of the image transfer, the platen roll **122** is rotated, the gripper is released and the take-out roll **129** is rotated and brought into pressure contact for taking out the image transfer sheet onto a tray **130**.

The thus taken out sheet is brought into overlapped state with a new image transfer sheet, not shown, and then, both the sheets are fusingly united together by pressure application of a heated roll, not shown, for execution of a second transfer step job. The whole operation has thus been completed. Before the fusion process, the sheets may be subjected to punching, trimming and/or the like processing, if necessary.

By execution of the foregoing operational steps, a monocolor printing operation has been completed. However, in the case of multicolor printing, use is made of tricolored or quadruple colored dyestuff film and the corresponding printing operations must be repeated. In this case, upon completion of a single monocolor printing procedure, the platen roll is rotated without contact of the take-out roll **129**, until it arrives again at the printing-initiation position, and so on.

In the following, a tricolor printing job will be illustrated with reference to FIG. **1B**, (b), and with use of three different series color zones, of cyan, magenta and yellow.

First, a platen roll **122** is positionally indexed, and an image transfer sheet taken out from the roll **131** and a dyestuff film taken out from the roll **123** are brought into pressure contact in an overlapped state. Then a thermal head **121** is pressed against the platen roll **122** through the intermediary of the overlapped sheets. At this stage, the platen roll **122** is rotated counterclockwise while synchronism is kept between the platen roll **122** and the dyestuff film, and the thermal head **121** is kept electrically energized. In this way, the first color printing is executed.

Further, the dyestuff film is fed to the second color zone position, and then, the platen roll **122**, the dyestuff film and the image transfer sheet are fed forward clockwise around the center roll **122**. Thus a second color printing step is executed.

Further, the print-serviced two color sections of the film is fed back counter clockwise around the center of the platen roll **122** for the execution of a third color printing step. Then, each card sheet is taken out from the stack **200** under the action of take-out rolls or the like, not shown, towards and between a pair of thermal transfer rolls **132**, **133**, brought into overlapping state with the image transfer sheet positionally indexed and already subjected to image transfer steps as was described above, and finally subjected to a picture printing operation by pressurizing application of the thermal image transfer rolls **132**, **133** from both sides of each taken-out card, and so on.

The color-printing step with the use of the thermal head is carried into effect in the following manner, as an example.

(First color printing)

Platen roll, image transfer sheet and dyestuff film perform the printing while they are moved in the counterclockwise direction.

(Second color printing)

Platen roll and image transfer sheet are moved in the clockwise direction while the dyestuff film is moved at the same speed and in the counterclockwise direction for performing the color printing under consideration.

(Third color printing)

Platen roll, image transfer sheet and dyestuff film are moved in the counterclockwise direction for execution of the color printing under consideration.

In the modified arrangement shown in FIG. **1B**, (c), thermal image transfer rolls **132, 133** have been replaced by a flat press type image transfer head having up-and-down movable flat printer elements **132'**, **133'**.

It should be noted that in the course of the foregoing first and second image transfer steps, image reversal phenomenon is necessarily brought about upon execution of each image transfer step. In other words and more specifically, when two successive image transfer steps in the foregoing sense are executed, reverse images which have once appeared will return to the original normal images. Therefore, when the printed-out products are to be provided upon execution of the first image transfer step, it is necessary to provide reversed image data in the signal processing system. For this purpose, it is only necessary to reverse the addressing order at the data introduction or readout stage into or from the memory.

In the modified arrangement shown in FIG. **1C**, the foregoing platen roll means has been replaced by a metal block **141** lined with a rubber plate **142** in an overlapped manner. The image transfer sheet and dyestuff film are fed out from respective rolls **131** and **123**. With the use of this modified arrangement, the dyestuff surface layer of the dyestuff film can be brought into tight contact with the image-receiving surface layer of the image transfer sheet, and thermal energy will be transferred evenly form the thermal head **121** to the dyestuff, film.

In this case, the image transfer sheet is delivered from the roll **131**, and the desired zone or region of the sheet is set underneath the rubber plate **142** (step **1**).

At the same time, the dyestuff film shown in FIG. **1D** on an enlarged scale is delivered from the roll **123** and a selected one of the different color regions is set underneath the rubber plate **142** (step **2**).

Next, the thermal head **121** is brought into the rear surface of the dyestuff film which is the opposite surface to the dyestuff-coated front layer, and the head **121** is driven while it is being translated in the direction shown by an arrow A, images thereby being formed at the specifically allocated zone(s) or region(s) of the image transfer sheet (step **3**).

Further, the thermal head **121** and rolls **416** and **418** are shifted downwards as shown by arrows B, so as to form an idle gap between the image transfer sheet and the dyestuff film for allowing the latter to shift towards the next following color region (step **4**).

Further, the thermal head **121** and rolls **416** and **418** are returned to their original positions, whereupon the third and further succeeding steps are repeatedly executed until a certain predesired number of color printings are completed.

As shown in FIG. **1D**, the dyestuff film is colored to have several different color regions denoted by Y (yellow), M (magenta), C (cyan) and Bk (black). However, the arrangement order is not limited to that shown: Y; M; C and Bk. In addition, as occasionally required, the Bk-region may be dispensed with. Further, as the color elements to be adopted in the Y, M, C-system may not be limited to the three primary colors provided by the subtractive color mixture. On occasion, a characterizing color which means such a color as preadjusted to provide an objective specifically selected one may be used to form the images concerned. As a further modification, the arrangement shown in FIG. **1C** may be so modified that the traveling direction of the image transfer sheet is selected to be perpendicular to that of the dyestuff film.

FIG. **2** is an operation flow chart for showing schematically operational modes taking the data processor **104** adopted in the embodiment shown in FIG. **1** as the centrum of description. The operational contents of several working parts downstream of the data converter **107** will be set forth separately hereinbelow. Now referring to FIG. **2**, in combination with FIG. **1** and at the step of **S101**, image pickup operation is carried out by means of the image pickup means **101**. For execution of this step, it may be better to pick up the face of a person per se which is to be represented on the card, or alternatively, a photograph, portrait or imagery product thereof will do. Depending upon the nature of the object, a TV camera, line sensor or the like instrument may naturally be selectively utilized.

The data taken by the image pickup means **101** are stored through the data processor **104** at a memory **105** (**S102**). By the use of these stored data, image or images is/are displayed at the display **102** (**S103**). Since this display image is not yet subjected to any processing, it is generally unsuitable for representing on the card. However, under certain circumstances, it may be represented thereon as it is.

Then, the operator observed the displayed image or images on the display unit **102** and adjudges whether additional processing is necessary or not (**S104**). If it is not necessary, he will manipulate the key board **106** to make a certain operation, resulting in the termination of processing at the data processing unit **104**, data being fed out therefrom to the succeeding data converter **107**.

On the contrary, when additional processing is necessary, the operator observes carefully the displayed image or images on the unit **102** and adjudges whether the picture image data, or character data or barcode data should be processed. If the picture image data should be processed, such an operation is made for selecting the proper mass of trimming or layout within the menu range of position-data input means **103**. By the execution of this operation, functions and operations at steps **S105** and **S106** can be executed at one stroke. If trimming is taken as an example, the next step is executed in such a way that position data are fed from the position input means **103** to the data-processer **104** with the use of a carsor. When a tablet digitizer is used as the position data input means, the carsor image displayed in an overlapped manner on the displayed picture image appearing at the display unit **102** by carsor manipulation is positionally specified beforehand in registration with the specified position on the card, for determining the trimming range. Then the operation is carried out in

such a way that the picture image data outside the specified trimming range are canceled. By completing these operations, data processing operations relating to step **107** are executed, and, then, the mass for completion of the menu range is selected out. By these measures, steps progress through **S109** to **S102**, and data storing is executed, and further, display representation is brought about through step **S103**. If there is no need for additional processing, an operation termination manipulation is carried out as before at key board **106**, and further operations will be made through data converter **107**.

As for the layout, the operation is carried out with the position data input means **103**, similarly as in the foregoing trimming operation. More specifically, layout is selected out in the menu range of position data input means **103**, and the overall configuration of the card and the display position of picture image are shown at display unit **102**. Then, image inclination correcting operation and the like are carried out so as to realize correspondence thereof with the displayed positional information, the processing operations relating to step **S108** thereby being brought about. After completion of these operations, the mass for the ending in the menu range is selected.

In this way, when selection is made from the menu range by reliance on the position data input means **103**, trimming or layout operation can be brought about. At this stage, when manual operation is carried out at the key board **106**, introduction of character data is executed (**S110**). As the character data in this sense, in the case of ID card, as an example, the name and/or birthday, month and year of the owner may be used. The data introduced from the key board **106** in accordance with the output character style from the font generator **109** are shown at the display unit **102** in the specified positions on the displaying surface and respectively arranged in accordance with display items. The operator acknowledges these items and detailed displays of the represented images. When he acknowledges them as being true, he will operate the key board **106** for showing the operation ending (**S111**).

Upon ending the operations as described above, the data are stored in memory **105** (**S102**) and represented at the display **102**. The operator will acknowledge again this fact, and upon the execution of this, the operations are terminated.

As for the barcode introduction, the data are subjected to inputing at steps **S112** and **S113**, as in a manner similar to the character data introduction as set forth above. The barcodes and the like data may be introduced separately through printing or other mechanical method.

In FIG. **3A**, a data processing circuitry usable in the sublimation image transfer printing method is shown only schematically. As shown, the circuitry **107** comprises a picture element density converter **3**; a color corrector **4**; a gradation corrector **10**; a memory **11**; a switch **12**; a buffer **13** and parallel/series converter **14**. The picture element density converter **3** is connected to a picture image input unit **100**.

The unit **100** serves for generation of three primary color data of R.G.B.- or Y.M.C.-mode from original picture images and is connected through the picture element density converter **3** to the color corrector **4**. The converter **3** converts the picture element density of the image data fed from the unit **100** to the desired one, by subtracting or supplementing, as the case may be, image data for each color element. It should be mentioned that for attaining high quality hard copies, conversion of the picture element density to at least **10** lines/mm or so is preferable.

Color corrector **4** consists preferably of a color decoder, level adjuster or color converter, and serves to correct three primary color data converted to those of a predetermined density of picture elements in consideration of characteristics of the image transfer ink in the image transfer sheet and in addition to provide black color data.

The data processing circuitry **107** is connected through a driver **108** to the sublimation image transfer printer.

In FIG. **4**, an example of the color corrector **4** is shown schematically in structure. As shown, it comprises adders **6Y**; **6M** and **6C**, a black color data calculator **7**, and primary and secondary color correction circuits **8** and **9**. Primary color correction circuit **8** serves for making correction of turbidity of the image transfer ink, while secondary color correction circuit **9** provides a capability of arbitrary and selective correction control relative to specifically selected color hue.

The gradation corrector **10** is so arranged as to make correction of the gradation of the data for each color Y, M, C or K (representing black color) fed from the foregoing color corrector **4** when necessary. For this purpose, the corrector **10** includes a gradation circuit (not shown) and the like, whereby a certain mode of highlight stressing or shadow stressing is introduced and realized.

The memory **11** functions to preserve temporarily the data of each color delivered from the gradation corrector **10**, a selection switch **12** being provided at the output side of the memory for selective writing-in of the data of each color to the buffer **13**. The buffer **13** is capable of writing-in the data of one line of the image transfer head **16** and kept in connection with the parallel/series converter **14** adapted for converting parallel data into series data. Additionally, in the simplified machine, black color data series is dispensed with in some instances.

In FIG. **5**, a schematic construction of the parallel/series converter **14** is shown. As shown, parallel data delivered from the buffer **13** are fed to an input side of a comparator **22**, while outputs from a counter **23** are fed to another input side of the comparator **22** which delivers the converted series data to the driver **15** for driving a thermal head **121**.

If necessary, however, the comparator **22** may be replaced by a converter table, not shown, utilizing a parallel/series converting ROM.

In FIG. **6**, a detailed circuit scheme of the thermal head **121** is shown. As shown, series data delivered from the comparator **22** are fed into a shift register SR and thence, after being subjected to latching at a latch circuit LT, fed to thermal elements HE through NAND gates NA which are fed at respective one side inlets with strobe signals.

Next, referring to FIG. **3A**, the operation of the data processing circuitry **107** will be described more specifically.

First, when three primary color image data are fed from the picture image inlet circuit **100** to the picture element density converter **3**, the latter converts these three primary color data to those which represent a predetermined picture element density and then are fed to the color correction unit **4**. In this case, it is assumed

that the unit **4** is fed with three primary color data expressed in respective concentration signals, which are of yellow: **Y0**; of magenta: **M0** and of cyan: **C0**, respectively, in the present example.

These data: **Y0**; **M0** and **C0** are, as shown in FIG. **4**, fed through respective adders **6Y**; **6M** and **6C** to the black color data calculator **7**, to provide a K-output as expressed mathematically by the following formula:

$$K=\min(Y, M, C)$$

wherein, "min" represents a function which provides a possible minimum value.

These data: **Y0**, **M0** and **C0** are fed from the converter **3** to the primary color correction circuit **8** to provide primarily corrected data **Y1**, **M1** and **C1** which are thence fed to the secondary color correction circuit **9** to provide, through calculation, secondarily corrected data: **Y2**, **M2** and **C2**, respectively. These are then fed to respective adders **6Y**, **6M** and **6C**, which add them to respective data **Y0**, **M0** and **C0**, to provide respectively added output data Y, M, and C to be fed to the gradation correcter circuit **10**, respectively, after being utilized for calculation of the K-output signal value.

The primary color correction circuit **8** serves to calculate primarily corrected data: **Y1**, **M1** and **C1** which are necessarily utilized for correct-out of transfer ink turbit. In this case, the original data: **Y0**, **M0** and **C0** are subjected to matrix calculation to provide the primarily corrected data **Y1**, **M1** and **C1**, as follows:

$$Y1=k_{11}.C0-k_{12}.M0+k_{13}.Y0$$

$$M1=k_{21}.C0+k_{22}.M0-k_{23}.Y0$$

$$C1=k_{31}.C0+k_{32}.M0-k_{33}.Y0$$

Where, k_{ij} represents weight coefficients:

$i=1-3$; and

$j=1-3$.

The secondary color correction circuit **9** serves to calculate secondary color correction data **Y2**, **M2** and **C2** from primary color correction data **Y1**, **M1** and **C1** by modifying the latter to make certain thereto by performing matrix calculations so as to provide a capability for making an arbitral and selective color control at a certain specifically selected-out color hue, in the following manner:

$$Y2 = Y1 + l_{11} \cdot \Delta B + l_{12} \cdot \Delta C + l_{13} \cdot \Delta G + l_{14} \cdot \Delta Y + l_{15} \cdot \Delta R + l_{16} \cdot \Delta M$$

$$M2 = M1 + l_{21} \cdot \Delta B + l_{22} \cdot \Delta C + l_{23} \cdot \Delta G + l_{24} \cdot \Delta Y + l_{25} \cdot \Delta R + l_{26} \cdot \Delta M,$$

and

$$C2 = C1 + l_{31} \cdot \Delta B + l_{32} \cdot \Delta C + l_{33} \cdot \Delta G + l_{34} \cdot \Delta Y + l_{35} \cdot \Delta R + l_{36} \cdot \Delta M$$

wherein, l_{ij} represents weight coefficients:

$i=1-3$;

$j=1-6$;

ΔB, ΔC, ΔG, ΔY, ΔR, ΔM:

characterizing color data.

Thus, when these secondary correction data **Y2**, **M2** and **C2** are added to the corresponding original data **Y0**, **M0** and **C0** by means of respective adders **6Y**, **6M** and **6C** and under proper selection of weight coefficients k_{ij} for primary color correction circuit **8**, any color discrepancy of the ideal color of the ink appearing on the printed picture images under the action of the sublimation transfer printer can be arbitrarily ammended. In this case, when the weight coefficients l_{ij} for the secondary correction circuit **9** are selected out properly, the color tone of the printing picture images can be modified to an arbitrary degree.

Further, as for the black color data K, correction data **K2** can be calculated by the following formula. With use of these correction data **K2**, which are added to the original black color data K, the desired correction can be executed in a similar manner.

$$K2=K+m1.\Delta B+m2.\Delta C+m3.\Delta G+m4.\Delta Y+m5.\Delta R+m6.\Delta M$$

wherein, Mi represents weight coefficients:

$i=1-6$.

In this way, output data: Y, M, C and K delivered from the color correction circuit **4** are introduced into the gradation corrector **10** as inputs thereof, and each constituent of these data can be subjected to correction as desired.

FIG. **7** shows several characteristic curves illustrating corrections by means of the gradation corrector **10**. More specifically, **f0** represents a standard characteristic curve; **f1** a highlight stressing operation curve; **f2** a shadow-stressing operation curve; **f3** a highlight-and-shadow stressing operation curve; and **f4** a medium tone stressing operation curve.

As indicated in FIG. **7**, by presetting, as necessary, the tone-reproducing characteristics, which determine the relationship between that concentration of color data and that of the prints printed by means of a sublimation image transferring printer, a color tone similar to that possessed by the original image can be reproduced. More specifically, when no correction is adopted, the curve **f0** is used, while in the case of correction, any selected one of these curves **f1** to **f4** may be utilized depending upon the part of gradation to be stressed. Further, it should be noted that the tone reproducing characteristic curves are not exclusively limited to those which have been specifically shown and described above. As an example, the control of gradation correction by color tone reproducing characteristic mentioned above is executed by a gradation circuit, not shown, and the setting of the color tone reproducing characteristic is brought about by manipulation of any selected one of the control knobs, not shown, which are provided separately for "highlight"; "medium tone" and "shadow".

Y.M C K. data subjected to correction by the gradation corrector **10** are once stored in the memory unit **11**. The thus stored data may be read out from the memory for each color by manipulation of the selection switch **12** and, after provisional storing, per one line of transfer head **16**, at the buffer **13**, introduced into the parallel/s-

eries converter **14** for conversion thereby into corresponding series data.

Another example of the data processing circuit for the sublimation transfer printer is shown only schematically in FIG. **3B**. As shown, the processing circuit in **107'** comprises a level regulator **503**; a color converter **504**; an A/D converter **505** and a parallel/series converter **14**.

As the image data introduced into the processing circuit **107'**, those which have been subjected to conversion into R.G.B.-signals in the color decoder **502** from composite video signals delivered from a T.V. camera, VTR or the like are used. On the other hand, R.G.B.-signals delivered from a personal computer, captain system or the like means are introduced as input into the level adjuster **503**.

As the color correction method with the use of the foregoing arrangements, it is possible, more specifically, to adjust the hue saturation and/or brightness in the color decoder **502**, or to adjust the signal level of each color light of R.G.B.-system in the level regulator **503**.

As an example, the color conversion from R.G.B.- to Y.M.C.-system can be executed in the color converter **504**. The simplest possible method in this color conversion is to procure the opposite color to each of the normal colors.

The thus produced color signals of Y.M.C.-system is subjected to A/D conversion and then fed successively through the parallel/series converter **14** and the driver **108** to the thermal head, not shown, to carry out printing in the sublimation transfer principle.

Additionally, in normal cases, with the use of the foregoing system composition, input image data must be of static mode. However, by provision of memory means in front of the color decoder or at an intermediate position between the A/D converter and parallel/series converter, animating images can be processed.

The series data converted in the foregoing manner in the data converter **107** or **107'** are fed to the shift register SR shown in FIG. **6** by n-image elements and then, upon being subjected to latching in the latch circuit LT are further delivered to NAND gate NA as its inputs. When a strobe signal ST is fed as input to the NAND gate NA, the foregoing n-image element data is fed to the thermal element HE.

FIG. **8** is a schematic diagram, showing signals for respective image elements. The gradation has been so selected that the first image element is at the highest gradation level, while the n-th image element corresponds to the lowest gradation level, and that the second to (n−1)th image elements vary linearly in gradation levels, so as to provide representatively a better understandable example of the invention.

Next, the operation of the parallel/series converter **14** will be described.

First, as shown in FIG. **5**, image elements data A, consisting of parallel data, more specifically, comprising parallel eight bit data **A0–A7**, are fed to one-side inputs of comparator **22**, while another side inputs thereof are fed with outputs B, comprising eight bit increment outputs **B0–B7**, of counter **23**. The counter **23** counts clock signals in increments, the outputs **B0–B7** being successively varied.

The comparator **22** performs comparison between the two inputs A and B, so as to deliver successively outputs of binary "1" until the increment output B is brought into coincidence with image elements data A, or more specifically, under the condition of A>B and A=B, while, thereafter, binary "0"-outputs are delivered therefrom. More specifically, comparator **22** will continue to deliver binary "1" until an increment value which corresponds to the weight of concentration of image element data A is given thereto. As an example, if the image element data A has a concentration of gradation 128 of a total 256, output "1" will be repeated to deliver 128 times first and then, output "0" will follow after again 128 times, so as to provide in total a specific series data peculiarly in this case.

These series data are taken out from the comparator **22** in the form of A>B- and A≧B-outputs and of A=B-outputs through an attributed OR-gate **24**, and in the present example, the gradation consists of 256 steps or increments. However, in practice, the gradation may represent a smaller number of steps. As an example, if the incrementing bit is **B1** instead of hitherto employed **B0**, the gradation will have 128 steps; and if **B2** is employed, it will have only 64 steps. In this way, the gradation setting may be varied in a simple manner.

When in the foregoing way, the output B from the counter **23** is stepwise incremented, such series data consisting of a first series of "1" will be delivered until the relationship between the image elements data A and the output B from counter **23** becomes A=B, and of a second series of "0" issued thereafter, as shown in FIG. **8**.

In FIG. **9**, a conversion mode at the parallel/series converter **14**, which, however, is different from that shown in FIG. **8**, as an example, is shown again in the form of a matrix. As shown, when the image data are of 8-bit parallel kind, as an example, the gradation data are ranged from 0 to 255, providing, therefore, binary series data from "00 . . . 00" to "11 . . . 11".

In this way, the data, per line in the transfer head **16**, kept preserved in the buffer **13** are fed to the parallel/series converter **14** for providing as outputs therefrom into corresponding series data which are then delivered through the driver **15** to the transfer head **16** and thus recorded on a print paper P supported on the transfer drum **17**.

FIG. **10** represents a flow chart illustrating the operation of the sublimate printer as employed in the present invention.

At the first step **S1**, print papers are set in position and the printing ribbon is also set in position ready for performing the required procedure.

At the second step **S2**, printing operation is initiated, and line printings are executed, line by line, accompanying necessary intermittent line shifts, with relation to any selected one of four colors: C (cyan); M (magenta); Y (yellow) and K (black) being carried out. Refer to **S3** and **S4**. When line printings with the selected-out single color have been completed (**S5**), the image transfer sheet is replaced by another color sheet (**S6**) and so on. In this way, line printings are completed in all four colors. In this case it is naturally most preferable to use a long extended single transfer sheet on which four color ink regions are repeatedly printed in a certain predetermined pattern. The image reception paper is initiated to make print from a certain prescribed position for each of these colors (**S8**). When all of the printing steps have been completed with the four colors, the paper is discharged from position (**S9**) and the printing operation is terminated to be repeated.

In FIG. **11**, a card style sample of the final products according to this invention is shown in front view at **200**. FIG. **12** is a sectional view thereof. Numeral **201**

represents the substrate material of the card; **202** a display layer; **203** a surface protecting layer; and **204** a display image as an example. Depending upon the kind of usage and when necessary, the protecting layer **203** may be dispensed with. It should be noted that the display image **204** on the display layer **202** is represented by a sublimative dyestuff, as a characterizing feature of the present invention.

As the main and substantial material of the image transfer sheet, various plain papers, converted papers, plastic resin sheets or the like may be used per se or in combination. When a plastic resin sheet which can be colored directly with a sublimative dye or dyes is used, these image transfer substrates (articles or objects) as at **201** can be united each with the display layer **202**. Each of these substrate materials, when it is of the card style, may have generally such dimensions: thickness of 0.68 to 0.80 mm and size: 11 to 8×8 to 5 cm.

As the material of the display layer **202**, various known materials which may be colored with sublimative dyestuffs, such as polyethylene, polypropylene, polyester, ABS, AS, polyvinylchloride, polyvinyl/vinyl acetate copolymer, polystyrene, polyacrylate, polyester, polyamide, polyurethane and the like plastic material, may be advantageously utilized. As will be more specifically described hereinafter, this material layer can be united with the substrate material layer **201**. In the case of such unified structure with substrate layer **201**, the thickness and size dimensions may be substantially as the same as before. However, when normal and/or converted papers or metals, which are practically impossible to color with sublimative dyestuffs, are used as the substrate layer **201**, various methods can be utilized for desired coloring. As an example, a solution including at least any selected one of plastic resin materials capable of coloring with sublimative dyestuffs may be coated on the substrate surface, or alternatively used in the form of a film which is laminated thereon. This kind of film preferably has a thickness of about 3 to 50 μm or so. One of main characterizing features represented in and by the final products **200** is that the appearing display image or images as at **204** is/are formed at least partially or wholly with a sublimative dyestuff or dyestuffs. Additionally, the process for formation of such images can be executed in the conventional art.

As an example, the processing method may be executed conventionally as follows.

As an example, a sublimative image transferable sheet, such as a paper sheet, plastic resin film or sheet capable of acting as the carrier is coated on its surface with any suitable binder resin carrier carrying sublimative a dyestuff or dyestuffs under heat, is overlapped on the display layer **202** and then subjected to heat from behind the heat-transferable sheet, preferably in the pattern mode, so as to transfer the dyestuff or dyestuffs into the display layer **202**. It is proper to select the molecular weight of 250 or larger of the dyestuff, for improving the fastness thereof. However, a molecular weight higher than 370 is more favorable. In the case of provision of the surface protecting layer, there is practically no limitation to the selectability of the dyestuff molecular weight.

The sublimative image transfer may be executed directly on the surface of substrate **201** provided with the display layer **202**. Or alternatively, a carrying, image transferable sheet is prepared separately and, after formation of the image **204** thereon, may be stuck onto or laminated on the substrate **201**.

Image-carrying and imaqe-transferable sheet

In the following, structure, material, usage and application purpose of the image transferable sheet to be employed in the present invention will be described in detail:

FIG. **13** illustrates only basically and in schematic sectional view the image-transferable sheet adopted in the present invention, while FIGS. **14** through **19** and **22** through **24** illustrate preferable embodiments thereof.

The basic structure of the image transferable sheet **310** is characterized in that, as shown in FIG. **13**, a sheet-like substrate **301** is provided at its one surface with an image-reception layer **302** capable of peel-off from the substrate. By adopting such a structural configuration of the image-transferable sheet, the image-reception layer **302** can be formed with the required image or images with the use of an image transferable sheet having thermally shiftable dyestuff, and then, the image-formed, image-reception layer **302** is peeled off from substrate **301** and attached firmly, preferably as by sticking, on the surface of any selected object or article with use of any suitable means. In this way, various conventional drawbacks inherent in the comparative conventional technique can be basically overcome.

More specifically, as the material of the aforementioned image reception layer **302**, limitation must be imposed to those which can be colored with thermally shiftable or transferable dyestuff. However, upon formation of necessary images and upon peel-off from the sheet like substrate **301**, the image reception layer **302** may be attached fixedly onto the surface of glass-made, metal-made or wooden-made products or plastic-resin made ones which are very difficult to color with thermally shiftable and transferable dyestuffs, indeed, by reliance on conventional sticking techniques as properly adopted in consideration of the specific nature and kind of the material of decorative products to be ornamented. Further, the image-formed and peeled-off, image-reception layer **302** from the sheet substrate **301**, is highly thin and thus sufficiently pliable so that it may be applied even onto any uneven and complicated surface of a product to be decorated or ornamented, having undulations, convexities, concavities, recesses and projections. Therefore, a maximum possible better fitness of the image-reception layer to be ornamented is attained and guaranteed by the present invention. Thus, practically no limitation in the attaching use thereof may be encountered. Further, in sharp contrast to conventional sealing seals and the like, the very thin image-reception layer bearing necessary images can be applied easily to the product per se in a very uniform manner, thus providing no raised and thickened feeling, and giving rise to no foreign feeling upon attachment.

FIG. **14** shows a further example of the image transferable sheet **310**. In this case, there is provided a parting agent layer **303** on the surface of image-reception layer **302**. Between the latter and the sheet substrate **301**, there is provided a parting agent layer **303'**. If necessary, however, any one of the two layers **303**; **303'** may be dispensed with.

The first parting agent layer **303** is provided for prevention of thermal fusion between the image-reception layer **302** and an image transferable sheet, not shown, as may occur during image transfer and formation on the first layer **302** through transfer of thermally transferable dyestuff from the said transferable sheet to the first

layer. If there is no risk of such thermal fusion of the above nature, or when the image-transferable sheet has been already provided with such a parting agent layer, the present provision thereof may be unnecessary. As for another parting agent layer **303'**, it is for the purpose of making the latter peel-off operation, to be executed after image-forming step, easier. When the sheet-like substrate **301** is made of polyester or the like material which has, as it is, sufficient separability from image-reception layer **302**, provision of parting agent layer may naturally be dispensed with.

FIG. **15** illustrates a still further example of image transferable sheet **310**. In this case, between the image-reception **302** and the sheet-like substrate **301**, an intermediate layer **304** and/or parting agent layer **303'** is/are provided. The laminating order is optional and thus not binding. The intermediate layer **304** will serve to assist the image formation to be rather firm and beautiful, the image formation being carried out by transferring the thermally shifting and transferring dyestuff from the image transferable sheet to the image-reception layer **302**. For this purpose, the intermediate layer **304** may take, for example, the form of a cushioning layer or heat insulating layer. When a cushioning layer is provided as the intermediate layer **304**, the cohesion between the image transferable sheet and th image reception layer **302** is greatly improved and the thermal shift and transfer of the dyestuff during image formation with the use of a thermal head is evenly executed, the image formation thereby being carried out amply in correspondence with the supplied image signals. Further, when a heat insulating layer consisting of a highly heat-insulative material is used as the intermediate layer **304**, ineffective release of the heat applied during shift and transfer of the dyestuff from the image transferable sheet to the image-reception layer **302** can be reduced to a minimum possible, the effective thermal efficiency thereby being correspondingly improved and ample image formation being accelerated. If necessary, however, these cushioning layer and heat-insulating layer can be prepared independently and arranged concurrently in any arranging order.

Additionally, when the intermediate layer **304** is arranged at a higher level than the parting agent layer **303'**, the intermediate layer **304** will be conjointedly peeled off in the case of peel-off of the image reception layer **302**. On the contrary, when the intermediate layer **304** is arranged at a lower level than the parting agent layer **303'**, the intermediate layer will remain on the sheet-like substrate **301** after execution of the separation of image-reception layer **302**. In this case, therefore, the intermediate layer **304** may be made preferably and at least substantially transparent, when the peeled-off image-reception layer **302** is stuck on a decorative product, while directing the surface of parting agent layer **303** towards the latter.

In the modifications shown in FIGS. **16**, **17**, and **18**, modified from the foregoing embodiment shown in FIG. **15**, a further protecting layer **305** is provided between the image-reception layer **302** and the sheet-like substrate **301**. This protecting layer **305** serves to prevent deterioration of the formed images in the image-reception layer **302** when the latter is stuck on the decorating product while directing the surface (more specifically the image-formed surface) towards the product. For example, this protecting layer **305** is prepared from a superior material which exhibits at least one of desirous properties such as antiwearing, light-fast, weather proofing and anti-chemical qualities. With the use of the protecting layer **305** having these superior qualities, the images can represent improved fastness in the above various aspects, even after execution of the foregoing sticking procedure.

In the modification shown in FIG. **16**, the protecting layer **305** is arranged between the intermediate layer **304** and the parting agent layer **303'**.

In the further modification shown in FIG. **17**, the protecting layer **305** is arranged between the image-reception layer **302** and the parting agent layer **303'**.

In still another modification shown in FIG. **18**, the intermediate layer **304** takes the role of the protecting layer **305**.

In each of these modifications, the protecting layer **305** is arranged in neighboring relationship with the partition agent layer **303'**, whereby the image-formed and remotely arranged, image-reception layer **302**, kept in its up-and-down reversed state, is capable of adhering securely to the decorative product, so as to be positioned as an uppermost layer, as may be required. In a still further modification shown in FIG. **19**, derived from that shown in FIG. **14**, a sticking layer **306** is further provided between the image-reception layer **302** and the partition agent layer **303**. It should be noted, however, that such a sticking layer as at **306** may be provided in any one of other foregoing examples and modifications, if necessary, in neighboring relationship with the parting agent layer **303'**.

The provision of such a sticking layer as at **306** is highly valuable when the image-formed and peeled off image-reception layer is adhering without position reversal onto the decorative product. With this arrangement mode, the protecting layer **305** shown in FIGS. **16**, **17**, and **18** may be dispensed with. If, however, the protecting layer **305** is composed of a material in the form of a sheet-like substrate, the part to be peeled off is thereby strengthened, the peel-off procedure thus being greatly facilitated.

By previous provision of the sticking layer **306**, the image-formed and peeled-off, image-reception sheet **302** can be caused to adhere as it is onto the decorative product without use of a separate sticking agent. As the sticking layer **306**, an ordinary sticking agent which is active at room temperature can be used. Or alternatively, a heat-sensible or light-sensitive sticking agent may be used, if necessary.

In the foregoing, the main structure of the image transferable sheet employed in the present invention has been described in detail. However, other structural modes than those set forth hereinbefore which occur easily to those skilled in the art may be employable in the invention, and thus they may be included within the scope of the invention without departing from the appended claims.

It should be further noted that, in the present invention, the sheet-like substrate may be provided on its one surface with an image transferable layer capable of peeling off through the intermediary of only one weakly sticking layer.

FIG. **22** shows only schematically in a sectional view a preferred embodiment of such an image-transferable sheet, denoted with same reference numeral **310**.

As shown in FIG. **22**, the image-transferable sheet **310** represents a basic structural characteristic such that any suitable sheet-like substrate **301** is provided on one of the surfaces with an image-reception layer **302** through an only weakly sticking intermediate layer **402**,

the layer **302** thus being easily peeled-off when desired. By providing the image-transferable sheet with such a structural characteristic as set forth above, desired positive or negative images are formed by transferring thermally shiftable and transferable dyestuff from the image heat transferable sheet to the image-reception layer **302**, and the thus image-formed layer is peeled off from the sheet-like substrate **301** and then attached onto any suitably selected product with the use of proper means or attached per se thereon without the peeling-off operation, the substrate then being peeled off, whereby an image-formed final product can be obtained.

In the foregoing example, it should be noted that the image reception sheet **302** per se has only a thin thickness and thus represents only poor feedability during the sheet-feeding period within the printer at the time of image formation, insufficient cushioning effect and only insufficient thermal efficiency during the printing operation, and further, it is very difficult to treat in advance of as well as after execution of the image formation. Therefore, the coexistence of the image-reception layer **302** and the sheet-like substrate **301** is absolutely necessary. In addition, it is a requisite requirement that the image reception layer **302** be easily peeled off from the sheet-like substrate **301** upon execution of the image forming operation, and thus, the layer **302** and the sheet **301** should not be stuck too strongly together. In order to satisfy this requirement, provision is made of weakly stuck layer **402** therebetween. Thus, it should be noted that the term "weakly stuck" employed in this specification and appended claims may be defined as "to be separable by finger's end and the like means from each other without entailing destruction or breakage of the parts originally stuck together". It is worthwhile to say, in considering the relative relationship between the image-reception layer **302** and the sheet-like substrate **301**, there is no necessity to provide the weakly-stuck layer **402** if the aforementioned peeling off is very easy to bring about.

FIG. **23** illustrates still another modification of the image-transferable sheet **310** denoted by the same reference numeral **310** only for simplicity and convenience, wherein a further parting agent layer **303** is provided on the surface of image-reception layer **302**.

This layer **302** is provided for occasional thermal sticking between the thermal image transferable sheet, not shown, and the image reception layer **302** in the progress of thermal shift and transfer of the dyestuff from the sheet to the layer **302**. This provision of the parting agent layer **303** may be dispensed with if there is no risk of occurrence of such disadvantageous sticking attachment or the sheet under consideration has already been fitted with such a parting agent layer.

A modification shown in FIG. **24** from that shown in FIG. **23** has such a modified structure that a protecting layer **305** is provided between the image-reception layer **302** and the weakly stuck layer **305**. This layer **305** serves to prevent otherwise occurring deterioration of the images at the image-reception layer **302** which has been formed with preferably reversed images and subjected to peeling-off, together with protecting layer **305**, preferably a plastic sheet layer, from the sheet-like substrate **301** and finally stuck onto the decorative product, while directing the image-formed surface of the image-reception layer towards the product. The protecting layer **305** is made of a material having various excellent physical properties, such as anti-wearing-, light-fastness and antichemical characteristics. Provision of such a protecting layer improves various fastness performances of the formed images after sticking attachment of the image-reception layer **302**.

When necessary, a separate parting agent layer, not shown, may be provided between the protecting layer **305** and the weakly stuck layer **402** for providing easy peel-off capability between these two layers **305** and **402**, as being applicable to the example shown in FIG. **24**. If the surface of the protecting layer **305** should have sufficient peel-off capability, it is natural to provide such an intermediate parting agent layer as above.

Further, in the case of the image-transferable sheet **310**, it is naturally easy to separate from each other through a peel-off operation, upon the formation of necessary images thereon and before practical use thereof as the image-transfer sheet, and a cut-out slit as at **407** in the sheet-like substrate **301** may be provided for attaining such an easy separation as stated above at a portion of the sheet **310** in proximity to one end thereof. Upon the provision of such a cut-out slit as at **407**, the thus formed flap-like portion can be easily folded out by the operator's finger-tip, thereby affording convenience in a peel-off operation.

The usable materials and composing methods of the foregoing image transferable sheets will now be described.

As a material usable for the sheet-like substrate may be any one or any combination of the following categories:

(1) synthetic paper (polyolefin series; polystyrene series and the like);

(2) fine quality paper; art paper; coated paper; cast-coated paper, wall paper; back-up paper; backing paper; resin-, emulsion- or synthetic rubber-impregnated impregnated paper; resin admixed paper; paper board; cellulose fiber paper;

(3) polyolefin-, polyvinyl chloride-, polyethylene terephthalate; polystyrene; polymethacrylate; polycarbonate and the like plastic film or sheet.

Use of the synthetic paper belonging to the foregoing category (1) is highly suitable for the purpose of the present invention since the surface thereof generally represents a microvoid layer which provides a low heat conductivity and thus a high heat-insulating performance. A laminated material representing any combination of the foregoing categories (1), (2) and (3) can be used in the present invention. A representative and recommendable example of such a laminate is that of cellulose fiber paper and synthetic paper or that of cellulose fiber paper and plastic resin film or sheet. Among others, use of the first mentioned kind of laminate will provide an advantage in that the thermal instability such as thermal elongation or shrinkage possessed by the synthetic paper component is compensated for by the cellulose fiber paper, whereby a high thermal sensibility is demonstrated during the printing step due to low thermal conductivity of the synthetic paper component. Further, in the case of the present paper combination, however, a further modified combination of a three-layer laminate: synthetic paper-cellulose fiber paper-synthetic paper may be more advantageously employed for making the frequently appearing lesser by providing a well-balanced structure between both the surfaces of the final laminate.

As the synthetic paper mentioned above, any suitable one usable as a synthetic paper substrate used as a component of the image-transferable sheet layer may be used. As a recommendable example thereof, having a

fine porous fine paper structure layer, the synthetic paper called "YUPO", manufactured and sold by Oji Yuka Goseishi Kabushiki Kaisha, Tokyo, may be mentioned. This paper layer having a fine pore structure may be prepared in such a way that a suitable plastic resin material containing a filler of finely divided state is subjected to a mechanical elongation step. When the image-transferable sheet composed of the synthetic paper sheet containing finely divided air as above mentioned is formed with images through a thermal image transfer setup, the concentration of the thus formed images is surprisingly high and no fluctuation of image configuration and concentration is encountered, thanks to the heat insulation effect provided by the very existence of fine air pores, in addition to the improved thermal energy efficiency. Especially, due to the advantageous cushioning effect provided by the air-filled fine pores, the image-receiving layer is supposed to be rather advantageously affected during the image formation step. As an alternative measure, the paper-like layer containing the above-mentioned fine air pores may be, if desired, provided directly with the core material consisting of the cellulose fiber paper or the like.

It is further possible to use plastic film in addition to the cellulose fiber paper in the laminate described above. Still further, a laminate of said cellulose fiber paper and plastic film composed together can be used.

As the method for co-sticking of synthetic paper and cellulose fiber paper, use of a known adhesive agent is naturally adopted, as an example. Or alternatively, the extrusion-laminating, heat-adhesion, or the like process may be relied upon, as the case may be. On the other hand, as the sticking-process between the synthetic paper and the plastic film, the lamination process to be carried out simultaneously with the formation of the film may be adopted. Calendering or the like method may be utilized for the same purpose. Selection of any suitable one of the several foregoing sticking processes depends upon the kind of material or the like condition of the partner member to be stuck together with the synthetic paper. As for the adhesive agent mentioned above, emulsion adhesive such as ethylene-vinyl acetate copolymer, polyvinyl acetate or the like, aqueous solution type adhesive polyester containing carboxyl radicals; or the like may be mentioned. On the other hand, as the laminating use adhesive, organic solvent solution type one such as polyurethane-, acrylic- or the like, may be mentioned.

The material for the image reception layer must be suitable for reception of heat-transfer dyestuff, such as sublimative disperse dye from the image transfer sheet and holding and maintaining the thus formed images thereon. From the view point of image-holding and blocking prevention, use of such synthetic resin as having glass transition temperature higher than 40° C. may be advantageous. For example, the synthetic resins set forth in the following items (a) through (e) may be used separately or in combination.

(a) Ester bond-bearing resins:
Polyester resin; polyacrylic ester resin; polycarbonate resin; polyvinyl acetate resin; styrene acrylate resin; vinyltoluene acrylate resin and the like.
(b) Urethane bond bearing resins:
Polyurethane resin and the like.
(c) Amide-bond carrying resins:
Polyamide resins (nylons).
(d) Urea-bond carrying resins:
Urea resins and the like.
(e) Other high polar-bond carrying substances:
Polycaprolacton resin; polystyrene resin; polyvinylchloride resin; polyacrylonitrile resin and the like.

The image-reception layer may be prepared from a resin mixture of saturated polyester and vinylchloridevinyl acetate copolymer. As the saturated polyester, such commercialized products: "Vylon 200"; "Vylon 290"; "Vylon 600"; "Vylon 103" and the like, manufactured and sold by Toyoboseki K.K., Osaka, Japan; "KA-1038C" (manufactured and sold by Arakawa Kagaku K.K., Osaka, Japan; "TP 220"; "TP 235", manufactured and sold by Nippon Gosei K.K., Osaka, Japan; may be advantageously used. The vinyl chloride-vinyl acetate copolymer may have preferably 85–97 wt. % of vinyl chloride component, the polymerization degree being between about 200 and 800. The vinyl chloride-vinyl acetate copolymer may further contain a vinyl alcohol component, maleic acid component within the purpose of the invention in addition to the main components. According to our experiments, it has been found that these modified copolymers should have rather superior compatibility with polyester resin. The image-reception layer may be, if necessary, composed of polystyrene resin, for example, in this case, styrene monomer, preferably styrene, α-methyl styrene, and vinyl toluene may be used separately or in the form of copolymer or saying in general sense polystyrene resin. Further, such styrene copolymer resin may be used as specifically recommendable material in the above sense, comprising said styrene monomer(s) with other monomer, preferably for example, acrylic acid ester, methacrylic acid ester, acrylonitrile, methacrylonitrile and the acrylic or methacrylic monomer, or further styrene copolymer resin comprising maleic acid anhydride.

It should be noted, however, that among others, polyester series resin is especially superior for the purpose of the present invention.

In any of the foregoing embodiments, however, white pigment is preferably admixed with the material of the image-reception layer for improving the whiteness thereof and further accentuating the sharpness and fineness of the images when transferred thereto and to provide a manually writing-on performance. As the white pigment for this purpose, the following materials may be used separately or in any combination: titanium oxide; zinc oxide; china clay calcium carbonate; finely divided silica and the like.

For further improving the whiteness fluorescent whiteness-increasing agent or -bleaching agent may be added to. Further, for improving the light fastness of transferred images, ultraviolet absorption agent and/or photostabilizing agent may be added to, preferably in a quantity of 0.05 to 10 and 0.5 to 3 weight parts per 100 weight parts of the material resin composing the image-reception layer.

The image-transferable sheet used in the present invention is preferably constituted for improving the separability from the image-transfer sheet in such a way that the surface of the image-reception layer is formed with a partition agent layer, or instead, such agent is admixed to the image-reception layer. As for the partition agent to be used for this purpose, polyethylene wax; Amido Wax, Teflon Powder or the like solid wax; surface active agents such as fluorine contained agent or phosphoric acid ester series surfactant; silicone oil or the like may be selectively used. Among others, silicone oil may be advantageously utilized.

The silicone oil may be used in oily state, but a hardenable type thereof may be rather advantageous. As the hardenable silicone oil, reaction hardening one, photohardening one, catalytically hardening or the like one may be used selectively according to necessity. However, use of the reaction-hardenable one is most highly recommendable. Silicone oil of this type may be obtained, as example, by reacting amino-modified silicone oil with epoxy-modified silicone oil to obtain a reaction-hardened product. As for the amino-modified silicone oil, "KF-394", "KF 857", "KF-858"; and "X-22-3680"; "X-22-3801C" (manufactured and sold by Shinetsu Kagaku Kogyo K.K., (Tokyo, Japan)) and equivalents thereof may be used. As for the epoxy-modified silicone oil, "KF-100T"; "KF-101"; "KF-60-164"; and "KF-103" (manufactured by Shinetsu, above mentioned) and equivalents thereof may be used. Further, as the catalytically hardenable and photohardenable silicone oils in the above sense, "KS-705F"; "KS-770" of the catalytic hardenable or hardened silicone oils, manufactured by Shinetsu; and "KS-720" and "KS-774" of the photohardenable or hardened silicone oils (manufactured equally by Shinetsu) and equivalents thereof may be used. The adding quantity of each of these hardenable or hardened silicone oils may advantageously range from 0.5 to 30 wt. % depending on the material of the resin composing the image-reception layer.

At least a part of the image-reception layer is coated with a solution or dispersion of any of the foregoing partition agents in a suitable solvent and dried and further treated, a suitable parting layer being provided thereon. A particularly suitable partition agent for the formation of this kind of partition layer is the aforementioned reaction type hardenable one obtainable by reaction of an amine-modified silicone oil with an epoxy-modified one. The thickness of the partition layer is 0.01–5 μ, preferably 0.05–2 μ.

It should be noted that when silicone oil is admixed during formation of the image-reception layer, the silicone oil will bleed out after coating and the parting agent layer can be formed by the hardening even after such bleeding. In order to improve the parting ability between the image transferable layer and sheet-like substrate, it is possible to provide a parting layer consisting of a heat-hardenable resin, preferably of the melamine series, and having better affinity for the image transferable layer compositions. For the same purpose as above, however, without special provision of the parting layer, a protecting layer consisting of polymethyl methacrylate resin or cellulose acetate propionate can be provided.

For the formation of the image transferable layer, a solution or dispersion of a material composition suitable for the purpose is applied on the sheet-like substrate through conventional coating or printing. As an alternative way, a separate film or sheet for the image transferable layer **302** is formed preparatorily on a provisional carrier sheet or film and then, as a succeeding step, subjected to an image-transfer onto the substrate.

The intermediate layer is made of either a cushioning or a porous material. In some cases, the intermediate layer may additionally function as the adhesive layer.

The cushioning layer is mainly composed of such a resin which has a value of 100%-modulus as defined at JIS-K-6031 (Japanese Industrial Standard) of less than 100 kg/cm^2. If this value should exceed the above prescribed value, the rigidity will become much higher than that recommended for the intermediate layer. When the layer is formed with such disadvantageous material resin, sufficient adhesion between the heat image-transfer sheet and the image-reception layer cannot be maintained during the printing step. The lower limit of the prescribed 100%-modulus is of the order of 0.5 kg/cm^2 in actual practice.

Preferable kinds of resin to be used for the above purpose, may be enlisted as follows:

polyurethane resin; polyester resin; polybutadine resin; polyacrylic acid ester resin; epoxy resin; polyamide resin rosin-modified phenol resin; terpene phenol resin; ethylene/vinylacetate copolymer resin; and the like.

These resins can be used independently or in combination of two or more kinds. Since these resins are rather viscous and tend to give rise to manufacturing troubles inorganic additives may be admixed, such as, for example, silica; alumina; clay; calcium carbonate; amide series substance such as amide stearate; and/or the like.

The cushioning layer is preferably formed with the use of one or more of the above specified resins, occasionally with the addition of suitable additive(s); solvent or diluent, prepared into a coating agent or printing ink which is then applied on, according to a known coating or printing process and then subjected to drying to provide a coating. The thickness of the coating should be between 0.5–50 μm, preferably 2–20 μm or so. With a thickness less than 0.5 μm, the coating will not be able to compensate for the surface irregularities on the substrate, thus being ineffective for the desired purpose. On the other hand, when the thickness exceeds the above specified maximum value or more specifically 50 μm, the overall thickness of the image-transferable layer becomes much too large, so that handling troubles may be encountered during wind-up and overlapping procedures, without attaining further effect as desired. In addition, in this case, a loss of production economy will be inevitably introduced.

The thus obtainable improvement of intimate adhesion between the heat image transfer sheet and the thermally image-transferable sheet by the provision of the above intermediate layer may be conceivably attributed to the lower rigidity of the intermediate layer per se, whereby it is liably to be deformed under the influence of the printing pressure, and further to the generally relatively low glass transition temperature and softening temperature of the aforementioned kinds of resin resulting in further lowering of rigidity and tendency to deform than at room temperatures upon reception of heat energy during the image printing step.

The porous layer may be formed generally in the following four ways: (1) through (4).

(1) Emulsion of polyurethane or the like resin, methylmethacrylate-butadiene series synthetic rubber latex is foamed by mechanical agitation, coated, and dried on the sheet substrate into a layer.

(2) The synthetic resin emulsion or synthetic rubber latex is admixed with a foaming agent and the liquid mixture is coated and dried on the substrate into a layer.

(3) Vinyl chloride plastisol, polyurethane or the like synthetic resin or styrene-butadiene series or the like synthetic rubber is added with a foaming agent and the liquid mixture is coated on the substrate and subjected to heating to provide a foamed layer formed thereon.

(4) A thermoplastic resin or synthetic rubber is dissolved in an organic solvent to provide a solution, and a non-solvent (including that containing aqueous main component), and the latter solution are mixed together to provide a liquid mixture, said nonsolvent being less volatile than the organic solvent and having a considerable mutual solubility with the solvent, and showing, however, non-solubility with the thermoplastic resin or synthetic rubber. The thus prepared liquid mixture is then coated on the sheet-like substrate and dried, to provide a porous membrane upon micro-coagulation of the constituents. The resulting microporous layer can be utilized for the above purpose.

It should be noted that the layers produced by any of the foregoing three processes (1) to (3) have rather large foams contained therein, and thus when the foaming solution for the image-transferable layer is applied thereon and dried, the latter may exhibit excessively coarse surface conditions. Therefore, in order to obtain an optimumly image-transferable smooth surface capable of providing transferred images of high uniformity, provision of the micro-porous layer prepared by the process as set forth in the forgoing item (4) is highly recommendable.

As the thermoplastic resin suitable for the formation of the above porous layer, saturated polyester; polyurethane; vinylchloride-vinylacetate copolymer; cellulose acetopropionate and the like can be used. Further, as the synthetic rubber usable for the same purpose, those of styrene-butadiene series, isoprene series, urethane and the like series may be used. Still further, as the organic solvent and non-solvent liquid used for the formation of the microporous layer, various known substances may be used. Generally speaking, however, methyl ethyl ketone; alcohol and the like are representatively used. On the other hand, as the non-solvent, water is mostly used.

The thickness of the porous layer usable in the present invention is preferably greater than 3 μm, especially preferably in the range of 5 to 20 μm. With the use of a porous layer having a thickness of less than 3 μm, the desired cushioning and heat-insulating effects cannot be attained.

As was referred to hereinbefore in the description stage for the formation of the image-transferable layer, the intermediate layer may act simultaneously as the sticking layer in some cases.

This kind of intermediate layer(s) may be provided on one or both of the surfaces of the thermally image-transferable sheet.

In practice, however, an electrostatic charge may accumulate in the material of the thermally image-transferable sheet during its processing step or during running through the printer. As a countermeasure, a proper antistatic agent may be applied on one surface of the image-transferable layer or on the bottom surface of the thermally image-transferable sheet or it can be included in the material of the image-transferable layer. As the antistatic agent in this sense, a surfactant such as a cation-exchange agent (for example, a quaternary ammonium salt, polyamide derivatives and the like) may be advantageously used. Further, an anion exchange type surfactant, such as alkyl sulfonate may be used. Otherwise, amphoteric ion type surfactants or even, non-ionic surfactants may be used for the same purpose.

On the other hand, the antistatic agents may be coated on the surface of image-reception layer by gravure-coating, bar-coating or the like process or alternatively, these agents may be kneaded with the material resin and then subjected to transfer towards the surface during the coating formation and drying step for preparing and providing the image-transferable layer. As the antistatic agents to be admixed with the image-transferable layer material resin, cation-type acrylic polymers may be employed.

The protecting layer is peeled off together with the image-transferred layer, from the sheet-like substrate, and then stuck, in inverted reversed state, onto any desired decorative object, the protecting layer thereby being positioned at the uppermost position, for improving the anti-wearing-light-proofing and anti-chemical performances of the image-bearing layer. As the material adapted for the formation of the protecting layer, for example, alkyd resin; phenol-modified alkyd resin; aminoalkyd resin; phenol resin; urea resin, melamine resin; silicone resin, thermosetting acryl resin, thermosetting polyurethane resin and the like thermosetting resin or normal temperature setting resin; further, ultraviolet hardenable resin; electron ray hardenable and the like activating energy flux hardenable resins or thermoplastic resins such as polyester-; polyurethane-; polyvinyl acetate resin; vinyl chloride-vinyl acetate copolymer resin; polyolefin resin, acryl resin and the like, can be used.

Preparation and use of a protecting layer comprising one or more of the above-mentioned resins are made in such a way that the material resin is dissolved in a properly selected solvent according to the necessity, so as to provide a coating liquid or ink, as the case may be, which is provided between the parting layer and the image transferable layer. The thickness thereof is generally 0.5 to 20 μm. It is also possible to form the protecting layer with the use of a resin film which consists of polyester-; acryl-; acrylpolyol-; polyvinyl chloride-; olefin resin or the like resin. It is further possible advantageously to admix an ultraviolet ray absorbing agent and/or photostabilizer to the material of the protecting layer.

The protecting layers prepared and formed in the foregoing way are thus not made integral with the sheet-like substrate or parting layer and, therefore, the peel-off operation of the sheet-like substrate upon execution of the image transfer is very simple and easy.

It is further recommendable, if necessary, to provide a slip-promoting layer on the bottom surface of the sheet-like substrate, which surface is naturally the one opposite to the image-transferable layer side, so as to properly adjust the friction between the image-transferable sheet and feed roll paper or carrier belt acting during passage through the printer and to improve the running performance of the thermally image-transferable sheet in the printer.

The slip-promoting layer can be formed by adding an organic powder such as polyethylene wax fluorine resin powder or an inorganic powder such as talc, according to necessity, to a resin such as polymethyl methacrylate resin; vinyl chloride-vinylacetate copolymer; vinyl chloride copolymer; cellulose acetate butylate; cellulose acetate propionate; styrene-acryl series or the like resin and kneading the resulting mixture to prepare a composition, applying this composition as a coating on the sheet substrate either directly or after application of a suitable primer treatment, and drying the coating thus applied. A suitable quantity of the slip promoting layer is 0.5 to 5 g/m^2 after drying.

In the embodiments shown in FIGS. **22**, **23**, and **24**, as the adhesive agent to be used in the slightly weak or weak adhesive layer, it should be noted that those conventionally used adhesives for adhesive tapes and seals can all be used. Preferred examples are polyisoprene rubber; polyisobutyl rubber; styrene butadiene rubber; butadiene acrylonitrile rubber and the like rubber-series resins (meth)acrylic acid ester-series resins; polyvinyl ether-series resins; polyvinyl acetate-series resins; vinyl-chloride-acetate copolymer series resins; polystyrene-series resins; polyester-series resins; polyamide-series resins; polychlorinated olefin-series resins; and polyvinyl butyrol series resins. To the suitably selected adherent may be added a proper quantity of a stickness improver, such as rosin; dammar; polymerized rosin; partially hydrogenated rosin; ester rosin; polyterpene-series resins, terpene-modified substances; petroleum-originated resins; cycropentadiene-series resins; phenol resins; styrene resins; xylene resins; and coumarone-indene resin. Further, when necessary, to the mixture may be added a softening agent, filler; antiaging substance or the like conventional agent(s). As the material for the formation of slightly or weak adherent layer said above, emulsion type adhesive, preferably of acryl acid ester series can be used. As for the parting function after a long time of preservation, emulsion type adhesives are highly recommendable. These adhesive agents are easily procurable from market.

When necessary, these adhesives are added with proper organic solvent(s) for the adjustment of the viscosity, and then applied by roll coating, die-coating, knife coating, gravure coating or the like conventional technique on the surface of the sheet-like substrate, image reception layer or protecting layer, so as to provide an adhesive agent layer. The thus formed adhesive layer is preferably of a thickness of 1–50 μm, although this is not limitative.

Formation of Images

In the following, the decorating process according to this invention will be set forth in detail. Utilization of the image-transferable sheet according to this invention constitutes an important main feature thereof.

In FIGS. **20** and **21**, basic practising processes will be described first.

The embodiment shown in FIG. **20** is a result of the use of the transferable sheet shown in FIG. **13**. First, a known transfer sheet **320** is applied onto the image-transferable sheet **310** in an overlapped manner such that the dye-carrying layer **321** is kept in opposition to the image-reception layer **302** of image-transfer sheet **320**, and heat energy is applied, as schematically shown by a plurality of arrows, in accordance with image signals fed at a thermal head, not shown, from the side of image-transferable sheet **310**, or preferably, from the side of the image-transfer sheet **320**, thereby forming the desired images as at **307** in the image-reception layer **302**. Next, the image-reception layer **302** formed therein with the desired images **307** is peeled off from sheet-like substrate **301** and stuck onto the decorative product **306**. Or alternatively, both the sheets **302**; **301** are stuck onto the product **306** without preparatory peeling-off. In the latter case, the peel-off step may be executed after execution of the stickingly attaching step. In the above former case, and in such a case where an adhesive agent layer **306** has preparatorily provided between image-reception layer **302** and sheet-like substrate **301** as was set forth hereinbefore, the sticking attachment is carried into effect in such a way that the adhesive layer **306** is kept in opposing contact with the product **330**, and then the sticking operation is brought about by application of heat and pressure or light and pressure, depending upon the nature and structure of the layer **306**. In this way, the decoration according to the present invention is completed as a preferred one mode thereof.

On the other hand, if there is no preparatory provision of the adhesive layer, either the surface of product **330** or of the peeled-off image reception layer **302**, may be coated with the adhesive agent, and the latter layer **302** per s or otherwise in the up-and-down reversed state may be stickingly attached onto the product **330** (refer to FIG. **21**).

Since the image-reception layer **302** is composed generally of such thermoplastic resin material as is liable to be colored with thermally transferable dyestuff, it can be thermally and fusingly attached to plastic resin-made formlings, clothes or metals even with provision of an adhesive layer, if necessary.

In this case, the image bearing layer **302**, the image thereof having been formed in the aforementioned way, is stuck on, through the intermediary of the adhesive agent layer **306** as shown in FIG. **25**, while retaining the sheet-like substrate **301** on the surface of the image-reception layer **302**.

A modification of the last-mentioned mode is shown in FIG. **26**. In this case, sheet-like substrate **301** is formed on the surface of the product **330** and the image-reception layer **302** is formed as the outermost layer. Further, in this case, sheet-like substrate **301** and product **330** may be stuck together, and, through the intermediary of a suitable adhesive layer, sticking layer or heat sealable sheet or the like.

As for the transparent film usable as the said sheet-like substrate, it must be transparent to such a degree as not to conceal the images formed in the image-reception layer, and, in addition, it must have superior surface properties such as, for instance, antiwearing characteristics. As an example, polyolefine; polyvinyl chloride; polyethylene terephthalate; polystyrene; polymethacrylate; polycarbonate and the like plastic resin-made films may be used upon variously surface conditioning. If these transparent films should be too thick, the images will be raised, and the unitary feelings may be lost when these are stuck on respective products to be decorated. Therefore, the film thickness is preferably of the order of 0.5 to 50 μm.

In the case of a further embodiment of the present invention, the image reception layer of image transferable sheet which has been, however, formed with necessary images is subjected to image transfer treatment onto an intermediate image transferable substrate, the latter is then subjected to an image-retransfer with the images, and the thus retransferred images are again transferred onto the surface of the product to be decorated. In the following, this image transfer mode will be set forth in detail.

Embodiments shown in FIGS. **27**, **28** and **29** represent such a process for execution of image transfer operation as by the intermediary of intermediate image transfer sheet **510**. First, as shown in FIG. **27**, a thermally image-transfer sheet **320** having a thermal transferable dyestuff layer **321** is overlapped to image-transfer sheet **510** which is, at this stage, not formed with images **307** and thus consists of a thermal image-transferable sheet, in such a way that the dyestuff layer **321** or more specifically the parting layer **322** is in opposi-

tion to the image-reception layer **302** of the foregoing sheet **510**. In such a case, however, that heat energy is supplied in accordance with image-forming signals delivered from the thermal head, not shown, and, indeed, preferably from the side of the sheet **320** as hinted by a plurality of double-line arrows for thermal formation of desired images (positive images) as at **307** in the image-reception layer **302**, it is highly recommendable to provide an adhesive layer **402** between the layer **302** and sheet-like substrate **301**.

Then, with the use of the image transfer sheet **510** formed with positive images **307**, the images of layer **302** are transferred, as shown in FIG. **28**, to a separate intermediate substrate **501**, which is, however, fitted with a protecting film layer **305**, thus, the transfer being carried out, in fact, onto the latter, and indeed, with the correspondingly inverted images, attached with same reference numeral only for convenience, from the foregoing layer **302**. In this case, it is preferable to subject the adhesive layer **402** of the image-transfer sheet **510** to the image-transfer operation, together with the image-reception layer **302**. Further, as for the intermediate image-transfer substrate **501**, it is recommendable to provide the protecting film layer **305** through the intermediary of a weak-adhesive layer **402'** as shown. The thus provided intermediate image-transfer. sheet **610** represents generally the image-transferable sheet. FIG. **29** illustrates the step for transfer of the image-reception layer **302** now carrying positive images onto the object **330** to be decorated and under utilization of the previously described intermediate image-transfer sheet **610**.

More specifically, the intermediate image-transfer sheet **610** is overlapped onto the said object **330** in such a way that the adhesive layer **402** of the former in opposition to the, surface of the object **330** and pressurized together. Then, the intermediate transfer substrate **501** together with the weak-adhesive layer **402'** is peeled off from the remainder of the thus-pressurized assembly, the now image-carrying layer **302** formed with positive images **307** covered with protecting the film layer **305** thereby remaining in the transferred state on the product **330**. In the case of no provision of the protecting film layer **305** on the intermediate image-transferable sheet **610**, the layer **302** remains in an exposed state. Therefore, an overcoat layer, if necessary, can be provided on the now image-carrying layer **302**.

The previously set forth process carried out by the use of said intermediate image-transferable sheet can be executed by means of the apparatus which is shown schematically in FIG. **1E**.

In this apparatus, more specifically, there is provided a carrier system comprising a series of rolls **11, 412, 413** and **414** for conveying the intermediate transfer substrate (sheet), arranged in addition to the apparatus shown in FIG. **1B**. More specifically, the substrate is drawn out from feed roll **414**, conveyed through successive rolls **413**; **412** and retransferred onto one of the products **200**. Other operations are same as set forth hereinbefore with reference to FIG. **1B**. Further, in the case of FIG. **1E**, the final product may take the form of a roll-like substrate which is subjected to an image transfer operation through the intermediate substrate, by transferring its image-carrying, image-transferable layer, for later being punched out properly. Alternatively, under occasion, it may be subjected to half-cut operations downstream of roll **122**.

As was set forth herein above, the preferable method for the formation of desired images on the image-transferable sheet is carried out by use of a heat image-transfer sheet comprising a sheet like substrate having a layer including a thermally transferable dye (evaporative dye). The heat image-transfer sheet which can be utilized in this method is known per se. And almost every kind of these known sheets can be useful in the practice of the present invention. It should be noted that by employing the foregoing image-transfer method, monocolor or full-color images can be easily formed as occasion may desire.

It should be further noted that details of such heat image-transferable sheet can be easily understood with reference to our U.S. patent application Ser. No. 833,039. As for the heat image transferable sheet usable in the present invention, the coating layer of the sheet (coating film) may include a parting agent. By adopting this measure, the image-reception layer of the image-transferable sheet or the surface thereof, to be subjected to sublimative image-transfer, must not have a separate parting agent layer, the adhesive ability between the image reception and the surface of object to be decorated can be still further improved upon execution of the sublimative image-transfer and image-formation at the image-reception layer and adherent attachment thereof to the object. As the parting agent to be included in the coating layer of the thermally image-transferable sheet (coating film), silicone oil; silicone resin; phosphoric ester or the like surfactant; and/or chelate- and the like agents, may be selectively utilized. These agents, upon mixed, will ooze out from inside to the outer surface of the coating layer, resulting in providing a better parting quality. However, it is preferable to properly select the kind and nature of the parting agent to be used for this purpose, being such that the agent cannot transfer to the image-reception layer of the image transferable sheet during the sublimating image transfer stage. The adding quantity of the parting agent may preferably be 3–25 wt. parts based upon the total amount of resin and coating composing the layer taken as 100 wt. %.

In practice, any kind of conventionally known heat transfer sheets is overlapped on the thermally image-transfer sheet employed in the present invention, and then necessary heat energy of 5–100 mJ/mm^2 is applied by use of a conventionally known heat transfer unit, for instance, "Video-printer: VY 100" manufactured and sold by Hitachi Seisakusho, Tokyo, or its equivalent machine, for the formation of necessary images on the image-reception layer of the image-transfer sheet as set forth hereinbefore.

Peel-off operation for removal of the image-reception layer formed with necessary images in the above manner may be carried into effect in a very easy manner, so as to provide it in a thin film carrying the images thereon. In case where the thus-peeled off film carrying the images is provided beforehand with an adhesive layer, composed of a suitable adhesive agent as was referred to, at the opposite surface to the image-carrying one, the peeled-off film can be, as it is, stuck on the object to be decorated. It is natural that this adhesive attachment procedure can be performed only partially and locally on selected part of the whole surface of the object, or totally thereon, as the case may be. On the contrary, if the peel-off film is provided beforehand with no adhesive layer, the film can be subjected occasionally to a heat fusion onto the surface of the object, if the physical properties or material kind thereof is suitable for such kind of thermal fusion. Or alterna-

tively, a properly selected adhesive agent can be preparatorily applied onto the surface of the film or object, and then, the stick-on job can be executed.

If the image-reception layer is provided preparatorily with a parting layer thereon, as was referred to, the latter layer can be removed off partially or wholly, by grinding or rubbing operation after execution of the sublimating image transfer job, for avoiding otherwise occurrence of ill effect by the very presence of parting layer in the adhesive attachment of the image-carrying layer film onto the decorative object.

In case of that where the image-transferable sheet is provided with a protecting layer and the latter is composed of a plastic resin film, this film may preferably be cut into pieces or subjected to punch-cuttings.

FIG. **32** illustrates successive die-cutting steps in sectional views, serving for the above purpose. In this case, as shown in FIG. **32** at (a), only image-reception layer **305** of the image-transferable sheet **310**, which has been image-formed through the way of the foregoing image-transfer step, are die-cut by operation of a cutter **801**. Next, as shown in FIG. **32** at (b), a pair of hot stamps **132'**; **133'** are used to execute a pressurizing job under heat from opposite sides, thereby the decorative product **330** being processed into a final product provided tightly with an image-reception layer and a protecting layer, as shown in FIG. **32** at (c).

Further, when occasion desires, the image-carrying film is reversed up and-down in position after execution of the peel-off job, and, the film is stuck onto the product to be decorated in such a state that the image-carrying surface of the film is kept in direct opposition to the product's decorating surface. In this case, however, it would be rather preferable that in advance of preparatory peel off of the image-reception layer, the image carrying transferable sheet is stuck onto the surface of the product to be decorated, and indeed, preferably with use of an adhesive agent, in such a way that the image-carrying layer is kept in direct opposition to the product surface and finally, the sheet-like substrate is peeled off, so as to leave the image-carrying surface on the product's surface.

As in the foregoing, when the images are once reversed and then stuck onto the object to be decorated, the forming images are preferable to reverse in mode (mirror-like relationship) the original to those of reversed mode.

It is further possible that the transfer or sticking-on of the image-carrying layer is carried out through the intermediary of a separate fusing sheet.

In FIG. **30**, use of such fusing sheet **701** for reimage-transfer operation of image-carrying layer **2** already formed with necessary images **307**, however, of reversed mode, and onto the surface of a product.

More specifically, the image-transferable sheet **310** is overlapped onto the product **330** to be decorated in such a way that the image-reception layer **302** carrying the necessary images **307** is kept in opposition to the surface of the product, and indeed, through the intermediary of a fusing seat **701** and then these three components are pressurized together. Further, sheet-like substrate **301**, together with parting layer **303'**, is peeled off, thereby the image-reception layer **302**, now having positive images **307** formed thereon, and protecting the latter, being transferred onto the product **330**. It will be seen in this case, that there is no need for this transfer job, to provide in advance on adhesive layer on the surface of image-reception layer **302** and/or on the surface of the product **330**, and further that a direct heat fusion onto the surface of the product **330** which may be composed of plastic resin, textile fabric, metal or the like common material, however, through the intermediary of a heat-fusible or heat-sealable sheet.

In case where the protecting layer **305** is of plastic resin, similar composing technique as mentioned above may be employed by substituting a weak-sticking layer **402'** for parting layer **303'**.

As the heat-fusible or heat-sealable sheet as at **701** employable in the present invention, it may be composed of one or other material capable of adhering under heat, pressure or both, especially suitable one of those which become soft to be adhesive upon heating. These heat adhering materials in the form of sheets will be, upon softening, charge the pores, meshes or stitches of the product material composed preferably of textiles, woven or non-woven; knits, rough-surface papers or meshed materials, thereby the surface of the product becoming highly smooth for well receiving the image-reception layer **302** for desired image-retransfer with trouble, which effect is superior in the art.

On the contrary, when such heat-fusible or heat adhesive sheet materials which may be called "heat bond sheets" as at **701** are not utilized, it is highly difficult to realize the image-retransfer operation onto certain kind of objects such as rough-surfaced or rough-meshed fabric or the like. Even if the retransfer job could be executed, the obtained images may be blurred and the adhesive may be insufficient, on account of the very thin thickness of the image-reception layer **302**, thus giving rise to technical and commercial troubles.

As for the heat fusible sheet **701** to be used in the foregoing manner, ethylene/vinyl acetate copolymer, nylon copolymer; epoxy/phenol copolymer; epoxy/vinyl copolymer; acrylic resin; polyester resin; or polyolefin resin and the like thermoplastic resins (heat sensible adhesive agents) which are formed into sheets or films may be used. These materials must be softened at 100°–250° C. or so to represent viscous adhesive characteristics. These materials are, when used, capable of being stuck to both the image-transferred product **330** and the image-carrying layer **302**.

These heat bond sheets **701** have generally thickness of 1–200 μm. When the surface of the product **330** to be decorated is relatively smooth, the sheet selected out may be of relatively thin thickness, while, on the contrary, when the surface of the decorative product **330** is relatively rough, as in the case of textile fabrics, unwoven fabrics, meshed fabrics or the like, use of thicker heat bond sheets is rather recommendable.

As set forth above, the use of heat bond sheets is highly recommendable in the decorative image-transfer onto rough surface products, such as those of rough fabrics, woven or non-woven, knitted clothes, meshed one or the like, thereby a better quality image-transfer being executed, in spite of the meshed or highly undulating surface conditions of the objects to be decorated.

Further in the present invention, during the adhering attachment of the image-reception layer already formed with necessary images onto the object or product, an additional processing step is preferably introduced for prevention of occasional interference in the foregoing adhering attachment step, by rubbing-off or grinding-off part or whole of the parting layer, provided on the surface of the now image-carrying layer, upon completion of the sublimating image-transfer step.

Still further, in such a case that the image-transferable sheet is fitted with a protecting layer which is composed of a plastic resin film, the latter must in advance be subjected to punching or the like cutting step for cutting the film into desirously sized pieces.

FIG. **32** represents such a die-cut (half-cut) process in sectional schema. In this case, at first, as shown at (a) of FIG. **32**, the image-reception layer **302** of an image-transferable sheet **310**, now formed with necessary images through a sublimative image-transfer step, and the protecting layer **305**, are subjected to a die-cutting process by means of a cutter **801** to shape a desired shape. And then, as shown at (b) in FIG. **32**, the cut-out piece is subjected to a pressurizing step under heat by means of a pair of hot stamps **132'**; **133'** to provide a final decorative object, as shown at (c) in FIG. **32**, which is composed of a product **330** to be decorated, however, now attached integrally and jointly with image-carrying layer **302** and protecting layer **305**.

Applied Products

The products applicable with the inventive process for decorating purposes are not limited to occasionally employed kind, shape and nature of the materials. Preferred examples of the usable product may be: cartons; vessels or packages; bags; cassette cases; cassette halves; floppy cases; paper packages and envelopes; stock certificates; personal and bank cheques; bills; bonds; certificates; notifications; car tickets; travel tickets; betting tickets; tax stamps; postage stamps; entrance tickets, money-exchangeable papers and documents; cash-cards, credit cards, orange cards, telephone cards; member's cards; greeting cards; postcards, name cards; driver's certificates; IC-cards; optical cards and the like various cards; accounting cards and documents-envelopes; tags; OHP sheets; slide films; bookmark slips; calendars; posters; pamphlets; menus; passports; POP-goods and articles; coasters; displays; nameplates; keyboards; cosmetics personal ornaments (watches; cigarette lighters); stationaries; construction materials; radio receiving sets; T.V.-sets; speakers; table calculators; automotive gauge boards; emblems., keys; clothes; wearing commodities; footwears; appliances; OA-instruments; sample books; tickets in general; albums; computer graphic and/or medicare graphic image printouts; and the like, where the material kinds, sizes and configurations are regardless for purposes of the invention.

The aforementioned goods and instruments may have printed or the like other images in advance of execution of the process of the invention. Or conversely, the goods and instruments can be formed with necessary images in accordance with the present process, and then, additional images may be formed in conventional printing or the like process.

As an example, when the invention is applied to a card style intermediate product, it is possible to combine image-forming means of the present invention with conventional recording means. As the latter, magnetic recording by use of a magnetic material layer; optical recording by use of an optical recording layer; preferably composed of a membrane having low melting point metal; application of hologram; embossing formation of characters and numerals; application of personal face photograph; engraved formation of personal face or the like; human signatures; recorded information with use of IC-memory; mechanical printing; formation of bar codes; formation of characters and patterns by use of printer, typewriter or pen plotter may be used independently or in any combination.

In the following, the present invention will be more fully described by way of preferred embodiments. In these embodiments, parts or % will be given by weight, not otherwise specifically referred to.

As the image transfer film (dye film) used for sublimating transfer onto the image-transferable sheets, a polyester film, 6 μm thick, subjected to a heat-resisting treatment on one surface thereof only, and bearing color ink composition areas of yellow, magenta and cyan, respectively, was used. The coating rate of the color ink composition was 1.0 g/m^2 when measuring at the dry state.

These color ink compositions were as follows.

These color ink compositions were as follows.

Yellow ink composition	
polyvinyl butyral resin ("Eslek-BX-1", manufactured and sold by Sekisui Kagaku K.K., Tokyo)	4.80 parts
dispersion dye ("PTY-52, Disperse Yellow-141", manufactured and sold by Mitsubishi Kasei Kogyo Co., Ltd., Tokyo)	5.50 parts;
methyl ethyl ketone	55.00 parts;
toluene	34.70 parts;
(parting agent)	1.03 parts
Magenta ink composition	
polyvinyl butyral resin (same as above in the case of yellow color ink)	3.92 parts;
dispersion dye ("MS Red G, disperse red 60", manufactured and sold by Mitsui Toatsu K.K.)	2.60 parts;
dispersion dye ("Macrolex Red Violet R, Disperse Violet 26", manufactured and sold by Beyer A.G., West Germany)	1.40 parts;
methyl ethyl ketone	43.34 parts;
toluene	43.34 parts;
(parting agent)	0.40 part
Cyan color ink composition	
polyvinyl butyral resin (same as in said yellow color ink composition)	3.92 parts;
dispersion dye ("Kayaset Blue-714, solvent blue-63", manufactured and sold by Nippon Kayaku K.K., Tokyo)	5.50 parts;
methyl ethyl ketone	68.18 parts;
(parting agent)	0.94 parts

Each of the foregoing color ink compositions was prepared with and without addition of parting agent.

As the parting agent occasionally used in each of the foregoing color ink compositions, any of the following specific agents may be employed:

(a) silicone alkyd parting agent, "KR-5206", manufactured and sold by Shinetsu Kagaku Kogyo K.K., Tokyo;

(b) graft polymer of silicone and acryl, "GS-30", manufactured and sold by Toa Gosei Kagaku K.K.;

(c) silicone graft polymer, "US-3000", manufactured and sold by the above company;

(d) phosphoric acid ester, natrium salt, "RE-410", manufactured and sold by Toho Kagaku Kogyo K.K.;

(e) natural phosphoric acid ester, "Lecytin", manufactured and sold by Ajinomoto Co., Ltd., Tokyo;

(f) silicone oil, "KF 412", manufactured and sold by Shinetsu Kagaku Kogyo K.K., Tokyo;
(g) aluminum chelate agent, "ALM", manufactured and sold by Ajinomoto; and
(h) titanium chelate agent, "TTS", manufactured and sold by Nippon Soda K.K., Tokyo.

EXAMPLE A-1

As the substrate, a laminate of a synthetic paper, "Yupo FPG 150 μm thick" manufactured and sold by Oji Yuka Co., Ltd., Tokyo, and a polyester film, 6 μm thick, was prepared and coated on the polyester film side surface by a wire bar with a mixture of pull-separating varnish, "Hakurinisu 45" manufactured and sold by Showa Ink Co., Ltd., Tokyo, with an ultra-violet absorbing agent, or more specifically, 2.5-bis(5'-tert-butylbenzoxazolyl (2))-thiofin, 0.5% based on the resin content of the varnish, and dried up to provide a protecting layer of 1 g/m^2, when weighed upon drying.

Then, on the surface of the foregoing protecting layer, an ink composition adapted for the formation of an image-reception layer was coatingly applied and dried up. The applied quantity amounted to 7 g/m^2 when measured upon drying.

Ink composition for the formation of image-reception layer	
polyester resin (manufactured and sold by Toyobo K.K.)	100 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu Kagaku Kogyo K.K., Tokyo)	5 parts;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu Kagaku Kogyo)	5 parts;
solvent (methyl ethyl ketone/toluene/cyclohexanon 4/2/2)	900 parts.

The ink composition was coated, dried up and cured one day under normal temperature. Then, the layer was kept at 100° C. for 30 minutes under heat, for letting the silicone to bleed up to the surface, to provide an image-transferable layer formed on its surface with a hardened silicone layer.

On the thus-provided image-reception layer, a sublimating image transfer film was overlapped which is composed of cyan color sublimative dye (molecular weight being higher than 250) carried by a proper binder resin and thermal energy is fed thereon from a thermal head adapted for receiving electric signals representing cyan color components obtained by a color analysis of a portrait photograph, as an example, for providing portrait images corresponding thereto. Then, two successive sublimative image-transfer jobs were executed with use of respective sublimating image-transfer films carrying sublimative magenta and yellow color dyes, each molecular weight being higher than 250, and substantially in the manner set forth above. In this way, after all, an overall combined display image composed of a full color portrait, in combination with several characters and graphics, was provided.

The image-reception layer of the sheet, now carrying these display images, was overlapped on the card substrate composed of a polyester resin sheet, 100 μm thick, which had been primed to white opaque state, and pressurized together at 160° C. by means of heated pressure rolls. Then, the polyester film was peeled off at the interface with the protecting layer, thereby providing a final product card transferrd with image-reception layer now carrying the desired image display.

It was found that the overall surface of the product card was generally smooth and showing no raised feeling of the thus-formed and displaying images. Even upon an accelerated testing of the product card for three months held in an atmosphere of 40° C., the images showed no blurrings as well as no interlayer separation. Further, according to an accelerated light-proof test carried out as prescribed in JIS-Standard with use of a carbon arc lamp, the results showed to be classified to JIS-4 or -5 corresponding to an acceptable superior performance. Additionally, a surface scratch test and the like showed also superior durability.

EXAMPLE A-2

The foregoing image-transferable sheet, now image-carrying, as processed in Example A-1, is then subjected to a peel-off operation for separating the image-carrying layer from the sheet. Then, an adhesive agent of polyester series was coated on the exposed surface of the peeled-off film, and stuck under pressure on a curved surface part of a telephone set. The images could follow up to the stuck curvature into a unitary solid mass, and indeed, without inviting any stuck-on feeling, contrary to the case when a sticky loose-leaf stamp should have been stuck on. In this way, miracle viewing feelings as obtainable with direct-printing operation only, were created and maintained.

EXAMPLE A-3

A white polyester film, baked on one surface thereof with melamine coating, "E 20", 100 μm thick, manufactured and sold by Toray Co., Ltd. Tokyo, is formed on the opposite surface with a slipping layer, same as in the following Example C-2, through application of polyurethane primer. And an identification mark was provided thereon through the way of regular printing technique. On the melamine resin-baked surface of the white polyester resin film, a layer of peeling varnish (of polymethyl methacrylate-series), manufactured and sold by Showa Inku. Co., Ltd., Tokyo) was applied in dry quantity of 2 g/m^2 and dried up to provide a definite layer.

On the thus-formed protecting layer, the following image-reception layer-forming composition was coated and dried up, so as to form an image-heat transferable sheet. The coated composition was in quantity of 6 g/m^2 by dry weight.

Image-reception layer-forming composition	
polyester resin ("Vylon 600", Tg: 47° C., manufactured and sold by Toyobo, Osaka	80 parts;
polyester resin ("Vylon 290", Tg: 77° C., manufactured and sold by Toyobo)	20 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu Kagaku Kogyo)	7 parts;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu Kagaku Kogyo)	7 parts;
solvent (methyl ethyl ketone/toluene = 1/1)	800 parts.

On the image-reception layer of the foregoing heat image-transferable sheet, reversed images composed of full color portrait images together with characters and graphics by use of a thermal head, as in the same way with Example A-1, were formed. Next, the image-reception layer, however, now carrying the reversed images formed in the foregoing manner was brought into contacting and overlapping state with the image displayable surface on a card style substrate made of white color polyester resin, 125 μm thick, preparatorily primer treated as before, and pressurized together under the action of thermal rolls, and the white polyester film, 100 μm, was peeled off between the protecting layer and the melamine-baked layer, thus providing a final card-style product transferred with the image-reception layer now carrying the necessary images.

The surface of the final card style product represented a smooth and slippery, without fear of interlayer separation and with superior light resistant power.

EXAMPLE A-4

A white foam polyester resin film, "Merinex", 125 μm thick, manufactured and sold by ICI, was provided with an identification mark on one surface thereof, with regular printing technique.

Then, on the opposite surface of the white foam polyester resin film to the foregoing surface formed with the identification mark, a coating of a polyurethane-series primer was applied and dried up. Further, the following protecting layer-forming composition was applied in dry quantity of 3 g/m^2 and dried up to form a protecting layer.

Protecting layer-forming composition	
acrylic polyole ("Acrit 6416MA", manufactured and sold by Taisei Kako K.K.)	41 parts;
toluene	36 parts;
methyl ethyl ketone	27 parts;
diisocyanate ("Colonate", manufactured and sold by Nippon Polyurethane K.K.)	6 parts.

On the above protecting layer, the following composition was applied in dry quantity of 3 g/m^2 and dried up, to provide an intermediate layer.

Intermediate layer-forming composition	
polyester resin ("Vylon 290", manufactured and sold by Toyo Boseki (Toyobo) K.K., Osaka)	15 parts;
toluene/methyl ethyl ketone = 1/1	85 parts.

On the thus-formed intermediate layer, an image-reception layer which is substantially same with that in the foregoing Example A-3 was provided, so as to form an image-transferable sheet. Then, as same in the foregoing Example A-3, correspondingly inverted images were formed on the image-reception layer and further then, subjected to transfer onto the card substrate by use of thermal rollers. In this way, a final product card, having an image transferable, yet now image formed layer, was provided.

This card showed favorable results of light-resisting test. Further, it showed a better scratch test result than the foregoing card obtained in Example A-3.

EXAMPLE A-5

Substrate

A white polyester film, "E-20", 100 μm thick, manufactured and sold by Toray Co., Ltd., Tokyo, was used.

Intermediate layer-forming composition	
Polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki K.K., Osaka)	15 parts;
toluene/methyl ethyl ketone = 1/1 (dry weight: 5 g/m^2)	85 parts.
Protecting layer-forming composition	
"Hakuri-Nisu" (acrylic resin varnish, manufactured and sold by Showa Ink K.K.) (dry weight)	2 g/m^2
Image-reception layer-forming composition	
polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki K.K., Osaka)	10 parts;
polyester resin ("Vylon 200", supplied by Toyo Boseki K.K.)	5 parts;
toluene/methyl ethyl ketone = 1/1	85 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu Kagaku Kogyo)	1 part;
epoxy-modified silicone ("X-22-343", supplied by Shinetsu Kagaku Kogyo) (coated quantity (dry) 5 g/m^2)	1 part.

With use of the foregoing composition and processed in similar was as in Example A-3, to provide a final card product, having an image-reception layer transferred with necessary images.

EXAMPLE A-6

Substrate

White polyester resin film, "E-20", 100 μm thick, manufactured and sold by Toray was coated with polyurethane-series primer and dried up.

Parting layer-forming composition	
melamine resin ("Meran 45", manufactured and sold by Hitachi Kasei)	100 parts;
hardener (para-toluenesulfonic acid) (coating quantity (dry), 2 g/m^2)	20 parts;
Protecting layer-forming composition	
vinylchloride-vinylacetate ("Vinylite VYHH", manufactured and sold by Union Carbide Corp.)	15 parts;
methyl ethyl ketone = 2/1 (coating quantity (dry): 2 g/m^2)	85 parts;
Intermediate layer-forming composition	
polyurethane resin ("Takelac T-3350", manufactured and sold by Takeda Pharmaceutical Company, Osaka, of 23%-concentration)	50 parts;
isopropyl alcohol	15 parts;
toluene	25 parts;
methyl ethyl ketone (coating quantity (dry) 5 g/m^2)	10 parts.
Image-reception layer composition	
polystyrene resin ("Picolastic D125" (Tg = 53° C.), manufactured and sold by Hercules	15 parts;
toluene/methyl ethyl ketone = 1/1	85 parts;
amino-modified silicone ("KF-393", manufactured and	1 part;

-continued

sold by Shinetsu Kagaku)	
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu Kagaku) (coating quantity (dry): 6 g/m^2)	1 part.

The foregoing composition was prepared and used as in the same manner with Example A-3, to provide a card with the image-reception layer subjected to image-transfer as desired.

EXAMPLE B-1

As the substrate, a polyester resin film, 6 μm thick, was used and a polyester resin-series primer was coated on one surface thereof and dried up. Further, the following ink composition was applied and dried up. The coating quantity of the composition was set to about 7 g/m^2.

Image-reception layer-forming composition	
polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki K.K.)	100 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu Kagaku)	5 parts;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu Kagaku)	5 parts;
solvent (methyl ethyl ketone/toluene/ cyclohexanone = 4/2/2)	900 parts.

The ink composition was coated, dried up and left standing for a full day, and then subjected to heat treatment at 100° C. for 30 minutes, so as to bleed the silicone towards the film surface for providing thereon an acceptable image-reception layer composing the active surface.

Then, a sublimative image-transferable film, composed of a resin binder evenly mixed with a proper amount of sublimative cyanic dye, the molecular weight being higher than 250, was overlapped on the above image-reception layer and applied with heat energy by means of a thermal head supplied with electric signals corresponding to cyanic color components of a portrait full color photograph as determined by regular color analysis, thus providing cyanic color component images.

Next, as for magenta and yellow color components, similar respective processings were executed and finally, full color display portrait images could be formed.

Then, the exposed surface of image reception layer of the thus display image-formed film was overlapped on a card substrate composed of a white opaque, hard vinyl chloride resin sheet, 100 μm thick and pretreated with a conventional primer, and then this assembly was subjected to heat and pressure by means of a pair of heated rolls. In this way, a card product stuck with an image-transferable and now carrying layer was provided.

The surface of this card was generally smooth and slippy, the thus-formed images thereon providing no raised feelings. In an accelerated test of these formed images in hot atmosphere of 40° C. for a continuous period of three months, there were no appreciable image blurring and interlayer separation. Upon execution of a light exposure test in accordance with prescribed conditions in JIS with use of an arc lamp, the results were classified to JIS-4 to 5 Classes which means as acceptable and better image quality. Scratch test results were also superior.

EXAMPLE B-3

A sticking layer, 1 μm thick, was formed with a polyamide resin sticking agent on the image-carrying surface of the image-transferable sheet, image-formed in the manner as described in foregoing Example B-1, and the thus provided sheet was stuck on the curved surface of a glass tumbler. These images express practically no stuck-on feelings, rather providing such a touch and viewing feeling as if they had been formed by the regular and direct printing technique.

EXAMPLE C-1

With use of the image-transferable sheet prepared in the foregoing Example A-1, images were formed substantially in accordance with procedures mentioned therein, however, with exception of the formation of reversed images, and then, the image-carrying layer was, without execution of the foregoing peel-off operation, stuck on a portion of curved outer surface of a glass tumbler, whereupon the sheet-like substrate was peeled off, together with the weak-sticking layer. The thus-applied images represent almost no sticking-on grip and viewing feeling, as if they should have been applied through regular and direct-printing technique.

EXAMPLE C-2

On the surface of a transparent polyester film, 12 μm thick, employed as a protecting film, the following image-reception layer forming composition was applied to form a coated layer (in quantity of 6 g/m^2 when measuring upon drying), dried up and left as it was for full one day. Then, it was held at 100° C. for 30 minutes, to form an image-reception layer. On the surface thereof, a parting surface layer was found to exist, which was composed of a combined hardened product of amino-modified silicone resin and epoxy-modified silicone resin.

Image-reception layer-forming composition	
polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki)	100 parts
amino-modified silicone resin ("KF-393", manufactured and sold by Shinetsu)	7 parts;
epoxy-modified silicone resin ("X-22-343", manufactured and sold by Shinetsu)	5 parts;
solvent (methyl ethyl ketone/toluene = 1/1)	800 parts.

As the substrate, on the other hand, white polyester resin film, "E-20", 75 μm, manufactured and sold by Toray, was used and coated on one surface thereof with a polyurethane-series primer and dried up. Then, the following composition (in the dried quantity of 1 g/m^2) and dried up, so as to provide a smooth and stick layer.

Smooth layer-forming composition	
polymethyl methacrylate resin ("Dianal BR-85", manufactured and	12 parts;

-continued

Smooth layer-forming composition	
sold by Mitsubishi Rayon Co., Ltd., Tokyo)	
polyethylene wax ("MF8F", manufactured and sold by Dulacon Co.)	0.5 part;
toluene/methyl ethyl ketone = 1/1	85 parts.

On the opposite surface of the white-polyester resin sheet to the smoothed surface there, a primer coating of polyurethane-series is applied and dried up, and further coated thereon with the following composition, in quantity of 3 g/m^2, so as to provide a weak-sticky layer.

Weak-sticky layer-forming composition	
weak-sticky adhering agent ("Esdyme AE-206", manufactured and sold by Sekisui Kagaku Kogyo K.K., Tokyo)	50 parts;
water	50 parts.

The weak-sticky adhering layer is brought into contact with the protecting film consisting of a polyester film, 12 μm thick, at the opposite surface to the image-reception layer, and then subjected to heat and pressure, to provide an image-transferable sheet. Upon bringing the image-reception layer of the image-transferable sheet and the dyestuff layer of the heat-image transfer sheet into contact with each other, heat energy was applied from a thermal head, as in the similar manner mentioned in the foregoing Example A-1, and thus heat image-transfer job was executed, so as to provide reversed mode images for expressing a full color portrait as well as characters and graphics.

Next, the image-reception layer formed with the reversed images thereon was overlapped onto the image-displayable surface of a card style substrate, 100 μm thick, made of a white color polyester resin material preparatorily applied with a primer layer by coating a composition, consisting of "Vylon **200**", 100 μm thick, manufactured and sold by Toyo Boseki K.K., and then subjected together to heat and pressure by means of at least a heated roll at 160° C. Then, the white polyester film, 75 μm thick, and the weak-sticky adhesive layer were peeled off in unison, for providing a final decorative product card having the image-reception layer transferred with images and carrying display images.

This card had a highly smooth surface and was not liable to invite any interlayer separation and showed superior light fastness.

In place of white color polyester-made card substrate preparatorily formed with a primer layer, such a modification was prepared and experimented that the white polyester sheet was formed on its rear surface with a magnetic layer, while, on its front surface there is formed with a write-on layer which consists of proper filler and resin as conventionally, so as to provide a telephone card. This processed telephone card had the write-on layer provided with display images formed by image-transfer.

EXAMPLE C-3

On the surface of a transparent polyester film, 9 μm thick, used as the protecting layer, an intermediate layer was provided by coating. The coated amount was 5 g/m^2 as measured upon being dried up.

Intermediate layer-forming composition	
polyurethane resin ("Takelack T-3350", solid content 23%, manufactured and sold by Takeda Pharmaceutical Co., Ltd., Osaka)	50 parts;
isopropyl alcohol	15 parts;
toluene	25 parts;
methyl ethyl ketone	10 parts.

Onto the intermediate layer, the following composition was applied for the formation of an image-reception layer. The coated quantity was 5 g/m^2 as measured upon being dried up.

Image-reception layer-forming composition	
polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki)	10 parts;
polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki)	5 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	1 part;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	1 part;
solvent (methyl ethyl ketone/ toluene = 1/1)	85 parts.

On the other hand, a white color polyester film, which was similar to that employed in the foregoing Example C-2 was formed with a slidingly smooth layer, as well as a weak-sticking adhesive layer, the latter being brought into intimate contact with a transparent polyester film, 9 μm thick, at the opposite surface to the image-reception layer and then, subjected to heat and pressure, for providing a heat image-transferable sheet. As further processed in the similar manner in the foregoing Example C-2, full color photographic images (reversed images) were thus formed on the image-reception surface. In this way, a final product card, having its image-reception layer transferringly formed with display images.

EXAMPLE C-4

Substrate

White color polyester sheet, "E-20", 100 μm thick, manufactured and sold by Toray was formed thereon with a polyurethane-series primer coating. Then, a weak-sticking layer was applied thereon with use of the following composition.

Weak sticking layer-forming composition	
weak-sticking agent ("Esdyne AE-206", manufactured and sold by Sekisui Kagaku Kogyo K.K., Tokyo)	50 parts;
water	50 parts.
Protecting layer-forming composition	
polyester resin ("Vylon-200", manufactured and sold by Toyo Boseki)	15 parts;
diisocyanate ("Colonate L", manufactured and sold by Nippon Polyurethane Co., Ltd.)	1 part;

-continued

toluene/methyl ethyl ketone = 1/1	84 parts.
Image-reception layer-forming composition	
polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki K.K.)	10 parts;
vinyl chloride-vinyl acetate copolymer resin ("Vinylite VAGH" (Tg = 79° C.), manufactured and sold by Union Carbide Corp)	5 parts;
toluene/methyl ethyl ketone = 1/1	85 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	1 part;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	1 part.

With use of the above composition and processed substantially same as in the foregoing Example C-2, a final card product was obtained.

EXAMPLE D-1

An image-transferable sheet was prepared as in the foregoing Example A-1 and thermally image-transferred with reversed mode images of a full color portrait photograph, to provide an intermediate image-transfer medium. The latter is overlapped by its image-reception layer onto the surface of a sheet of rough-textured cotton cloth, however, through the intermediary of an acrylic acid ester vinyl acetate copolymer sheet, 100 μm thick. Then, the assembly was subjected to heat and pressure. Then, the substrate sheet and weak-sticky adhesive layer, together, were peeled off. The thus transfered images have sufficient surface smoothness, showing superior surface conditions.

Without use of the bond-attaching sheet in the above process and when similar image-transfer job as above was performed, the resulted images followed the surface undulations appearing disadvantageously on the material product of the rough fabrics and thus were highly uneven, and further, on account of insufficient adhering performance acting between the image-receiving layer and the woven fabrics serving as product material, easy and frequent separations took place therebetween.

EXAMPLE D-2

In the similar way as was disclosed in the foregoing Example D-1, an intermediate image transfer medium carrying reversed images was prepared and overlapped on a polymethacrylate board preparatorily subjected to surface-roughening operation through a conventional sand-blasting step, and through the intermediary of a bond-adhering sheet pressurized together under heat, as was employed in Example D-1. Then, the sheet-like substrate was peeled off, together with the weak adhesive layer. The thus-provided images were highly smooth and even in spite of the highly rough and undulating conditions at the surface to be image-transferred. In addition, the image-carrying surface showed superior results in various resisting tests.

Without use of the foregoing bond-sticking layer, the similarly transferred images showed considerable undulations and distortions. Further, on account of insufficient adhering performance, easy and frequent peel offs of applied images were feared.

EXAMPLE D-3

On the surface of a polyester resin film, 25 μm thick, the following composition adapted for the formation of bond-sticking layer was coated and dried up, in dried quantity of 5 g/m^2, to provide a film formed thereon a bond sticking sheet.

Bond-sticking sheet-forming composition	
polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki)	15 parts;
methyl ethyl ketone/toluene = 1/1	84 parts.

The bond-sticking sheet surface, together the polyester resin film proper, was brought into contact with the image-representing surface of a white color polyester made-card substrate, 25 μm thick, and then, subjected to heat and pressure by means of at least a heat roll kept at 200° C., arranged to supply heat energy from the side of the polyester resin surface, thereby heat bonding the bond-sticking sheet onto the card surface, whereupon the polyester resin film being forcedly peeled off.

Further then, as in the similar way as adopted in foregoing Examples C-2; A-3; A-4 and C-3, use is made of the image reception layers representing reversed images thereon, the respective image-reception layers were whereupon brought into contact with the card's bond-sticking surface of the card and subjected to heat and pressure by use of at least a heat roll kept at 200° C. Then, the white color polyester resin substrate was peeled off, together with the weak-sticky adhering layer. In this way, a final product card displaying the portrait photograph was obtained.

EXAMPLE D-4

Substrate

A white color polyester resin sheet, "E-20", 100 μm thick, manufactured and sold by Toray Co. Ltd., was coated with a polyurethane-series primer. On the surface of the thus precoated sheet, the following composition was coated to form a weak-sticking adhesive layer.

Weak-sticking adhesive component	
weak sticking adhesive agent, ("Esdyne AE-206", manufactured and sold by Sekisui Kagaku)	50 parts.
Image-reception layer-forming composition	
polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki)	7.5 parts;
polyester resin ("Vylon 290", manufactured and sold by Toyo Boseki)	7.5 parts;
toluene/methyl ketone = 1/1	85 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	1 part;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	1 part.

The foregoing compositions were prepared. On the other hand, a polyester resin film, 25 μm thick, was coated on one surface thereof with a 15%-solution of polyester resin, "Vylon 200", manufactured and sold by Toyo Boseki, in toluene/methyl ethyl ketone=1/1 and dried up. The coating quantity was adjusted to 5 g/m^2

when measuring in dried state. In this way, a bond-sticking sheet was provided.

Then, the coated surface of the thus prepared bond-sticking sheet was brought into contact with the image display surface of a card style substrate of white color hard vinyl chloride or the like resin material preparatorily subjected to a primer coating treatment in overlapping state and then, the whole assembly was subjected to heat and pressure with use of at least a heated roll to 130° C., thus the bond-sticking layer being stuck on the card surface. Under this condition, the polyester resin film, 25 μm thick, was peeled off.

Then, the image-reception layer, now carrying thereon reversed images, was brought into contact with the bond-sticking sheet and the resulted whole was subjected to heat and pressure by use of at least a heated roll and the white color polyester resin substrate, together with the weak-sticking adhesive layer, was peeled off. In this way, the card, now displaying the portrait images, was provided.

EXAMPLE D-5

Substrate

Same as in the foregoing Example D-4.

Weak-sticking adhesive layer

Same as in the foregoing Example D-4.

Protecting layer-forming composition	
polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki)	15 parts;
diisocyanate ("Colonate L", manufactured and sold by Nippon Polyurethane)	1 part;
toluene/methyl ethyl ketone = 1/1	84 parts.
Image-reception layer-forming composition	
polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki)	10 parts;
toluene/methyl ethyl ketone = 1/1	85 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	1 part;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	1 part.

With use of the foregoing materials and compositions, the processings were carried out as in the foregoing Example D-4, to provide a final product card displaying portrait images as was desired.

EXAMPLE D-6

Substrate

Same as in the foregoing Example D-4.

Weak-stickinq adhesive layer

Same as in the foregoing Example D-4.

Image-reception layer-forming composition	
polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki)	10 parts;
vinyl chloride-vinyl acetate copolymer resin ("Vinylite VAGH", manufactured and sold by Union Carbide Corp.)	5 parts;
toluene/methyl ethyl ketone = 1/1	85 parts.

The foregoing materials and compositions were and processed in the similar way as in the foregoing Example D-4, to provide a final product card, displaying the desired portrait images as were desired.

EXAMPLE E-1

On a polyethylene terephthalate film, 9 μm thick, a solution of saturated polyester resin, "Vylon 600", manufactured and sold by Toyo Boseki, in toluene/methyl ethyl ketone = 1/1, was coated by reliance of the known reverse roll-coating process, and dried up. The coated quantity was 7 g/m^2 when measuring in dry condition. In this way, a weak-sticking adhesive layer could be formed. On the weak-sticking adhesive layer, the following composition, 3 g/m^2 (dry), was coated by means of an oblique-lined gravure roll for solid and full printing use and in the reverse roll-coating process, and then dried up, to provide an image-reception layer.

Image reception layer-forming composition	
polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki)	70 parts;
polyester resin, ("Vylon 290", manufactured and sold by Toyo Boseki)	30 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	5 parts;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	5 parts;
methyl ethyl ketone (wt. ratio 1/1)	700 parts.

On the opposite surface to the image-reception layer of the thus-prepared image-transferable sheet, a synthetic paper substrate, "Yupo FPG 110", 110 μm thick, manufactured and sold by Oji Yuka K.K, coated with "Vylon 600" as the adhesive agent in quantity of 10 g/m^2 (dry) was stuck intimately together.

On the other hand, a polyethylene terephthalate film substrate, 6 μm thick, preparatorily provided on one surface thereof with a heat-resisting layer was used and the following composition was applied on the opposite surface of the substrate with use of a wire bar and dried up, in the quantity of 1 g/m^2 (dry), so as to provide a dyestuff layer. In this way, a heat image-transferable **10** sheet was prepared and provided.

Dyestuff layer-forming composition	
dispersion dye ("Kayaseo Blue-136", manufactured and sold by Nippon Kayaku K.K.)	4 parts;
ethylhydroxyethyl cellulose	6 parts;
methylethylketone/toluene (wt. ratio: 1/1)	90 parts.

The dyestuff layer of the foregoing heat image-transfer sheet was brought into contact with the image-reception layer of the image-transferable sheet in overlapping manner, then, heat energy was applied from a thermal head from the side of heat-resisting layer of the heat image transfer sheet, thereby dyestuff being transferred to the image-reception layer of image-transferable sheet, and indeed, for the formation of positive images.

Then, the image transferable sheet, now carrying the required positive images was stuck together under heat

and pressure at 140° C. for 5 seconds on the intermediate image transfer substrate prepared in the following manner, in mutually opposed manner. Then, the synthetic paper "Yupo" was peeled off at the intersurface between the polyester resin film and the "Vylon 600" layer. In thus way, the inventive image-transfer sheet (intermediate image-transfer medium) carrying the corresponding reverse images was provided.

Method for the preparation of intermediate image-transfer substrate

A sheet of fine quality or stick paper, unit weight: 82 g/m^2 was applied with a coating, about 20 μm thick, of polyethylene resin through conventional extrusion coating process. Thereon, further, a catalyst-added toluene solution of a parting agent silicone, "KS-707", manufactured and sold by Shinetsu was applied and dried up in quantity of about 2 g/m^2 (dry), for the purpose of curing. Thereon, still further, the following coating liquid composition was applied by means of a conventional coating bar and dried up, to provide an intermediate image transfer substrate. The thus coated and dried resin quantity was measured to 7 g/m^2.

Coating liquid composition	
polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki)	100 parts;
methyl ethyl ketone/toluene (mixing ratio by weight: 1/1)	700 parts.

A sheet of coated paper, pretreated for pore-filling, was coated, in the similar manner as above, with the foregoing liquid composition, to provide an image-transferable medium. On and with the presently coated surface, the image carrying surface of the foregoing intermediate image-transfer medium is brought into opposing contact and stuck together under heat and pressure at 140° C. for 7 seconds. Finally, the laminate of fine quality paper and polyethylene was peeled off, to provide a final decorative .product now displaying the positive images as required.

It will thus be seen that by adopting the above processing steps, the positive images formed under the action of the thermal head are transferred, through the intermediary of intermediate image transfer medium, onto the final object to be decorated, and indeed, in the form of positive mode. It will be further seen that, since the dyestuff is well distributed within the image-reception layer, the transferred positive images are highly sharp and fresh, in addition to much profundities.

Since a resin layer was overlappingly applied on the thus-formed images, weather fastness, frictional durability and light-fastness of the finally formed images could be highly and amazingly improved. When suitable ultraviolet absorbing agent, antioxydant, quenching agent and/or radical scavenger is added to, further improvement of the light-fastness can be attained.

EXAMPLE E-2

The substrate of image-transferable medium adopted in the foregoing Example E-1 was replaced by a hard polyvinyl chloride card, 100 μm thick, and other processing modes were same as in Example E-1. In this way, a high quality, positive-image transferred, decorative final product was successfully provided. When the image include human portrait photograph, the final product was highly useful for ID-card.

EXAMPLE E-3

The substrate of image-transferable medium adopted in the foregoing Example E-1 was replaced by a transparent polyester film, and other processing modes were same as employed therein. In this way, a transparent film formed with the wanted positive images of better quality as before was obtained. This film was highly useful in OHP-services.

EXAMPLE E-4

A sheet of high quality paper, unit weight: 104 g/m^2, was coated with a layer of polypropylene resin, thickness: about 20 μm, through the way of conventional extrusion coating technique, then the coating was further coated with a silicone solution for use in parting service and hardenable under electron rays and dried up. The quantity of the coating silicone was about 1 g/m^2 upon drying. In this way, an electron hardened, provisional substrate was provided. On this substrate, the following, image-reception layer-forming composition was applied as a layer by use of a coating bar, and then dried up, for providing an image-reception layer. The coated resin quantity in the above last step amounted about 5 g/m^2.

Image-reception layer-forming composition	
polystyrene ("Picolastic D 150" (Tg = 69° C.), manufactured and sold by Rika-Hercules Co., Ltd.	100 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	7 parts;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	7 parts.

Further processing was carried out as was set forth in the foregoing Example E-2, for providing a final product card, carrying thereon the wanted positive images of same superior quality, as was in Example E-2.

EXAMPLE E-5

On the image transferable medium used in the foregoing Example E-4, however, in the present Example, a thermoplastic resin, adhesive, polyolefine series film, "Adwin 500", manufactured and sold by Showa Denko K.K., Tokyo, was applied as a layer. Other materials were used and processed as set forth therein. In this way, a decorative final product formed with necessary positive was obtained with superior results.

Industrial Availabilities

As will be well understood from the foregoing detailed description of the invention, it is possible according to the present inventive system, to form highly easily and evenly the desired images sharply and attractingly on any product and object to be decorated or graphically ornamented, substantially irrespective of material kind and configuration thereof, and indeed, with a surprising unitary touch and feeling with the substrate. Therefore, the invention can be utilized broadly and conveniently in such various industrial fields, where unitary formation of various images, characters, symbols, numerals and graphics, on and to the

articles, objects and substrate products to a sufficiently miracle and attracting degree.

We claim:

1. A process for forming sublimation transfer images on an objective body, said process comprising:

a first transferring step for sublimation transferring images on an image-transferable sheet comprising a sheet-like substrate and an image-reception layer provided on one surface of said sheet-like substrate, said sublimation transferring being carried out by means of a thermal printer on the basis of image data formulated by an image data processor; and

a second transferring step for transferring the images formed on the image-transferable sheet from the image-transferable sheet to the objective body.

2. The process of claim 1, wherein the images are formed on an image surface of said image-reception layer by the use of a dyestuff which is capable of depositing in or on said image-transferable sheet, and then during said second transferring step, said image-reception layer of said image-tranferable sheet is caused to adhere to said objective body.

3. The process of claim 2, wherein said sheet-like substrate is a transparent film, the image surface of said image-reception layer is caused to face the body, and the image-reception layer, accompanied by the transparent film, is caused to adhere to the objective body.

4. The process of claim 2, wherein after the images are formed on the image-reception layer, the image-reception layer being separable from the sheet-like substrate, said image-reception layer is separated from said sheet-like substrate and caused to adhere to said objective body.

5. The process of claim 4, wherein the image-reception layer which has already been formed with the images is subjected provisionally to an image-transfer procedure on an intermediate transfer substrate and then, the once transferred image-reception layer is re-transferred onto the objective body.

6. The method of claims 2, or wherein the step of causing the image-reception layer to adhere to said body is carried out with the use of an adhesive agent or sticking agent.

7. The process of claims 2, or wherein the step of causing the image reception layer to adhere to said body is carried out with the use of a heat bond sheet.

8. The process of claim 2, wherein the image-reception layer of the image-transfer sheet is formed with the images in positive or regular mode when viewed from the image surface of the image-reception layer.

9. The process of claim 2, wherein the image-reception layer of the image transfer sheet is formed with the images in reversed or negative mode when viewed from the image surface of said layer.

10. The process of claim 2, wherein the image-transferable sheet further comprises a protecting layer provided on one surface thereof such that said image-reception layer is separable between said protecting layer and said substrate, and said image-reception layer is subjected, together with said protecting layer, to said second transferring step.

11. The process of claim 10, wherein said protecting layer comprises a plastic film.

[57] **ABSTRACT**

A camera system comprising a camera body and an interchangeable lens assembly adapted to be coupled to the camera body. The interchangeable lens assembly has no manipulatable aperture adjusting ring, but has an aperture mechanism and a read-only memory both built therein. The read-only memory stores therein various data peculiar to such lens assembly. The camera body communicates with and power the lens assembly through a set of terminals connectable with associated terminals provided in the lens assembly. The terminals in each of the camera body and lens assembly are arranged in a generally arcuate row with the data transmitting terminal located at one extremity of the arcuate row on the leading side with respect to the direction of turn of the lens assembly which is effected when the lens assembly is to be completely coupled to the camera body.

CAMERA SYSTEM CAPABLE OF INTERCHANGING ITS OBJECTIVE LENS

This is a continuation of application Ser. No. 138,841, filed Dec. 23, 1987, now abandoned which is a divisional application of abandoned Ser. No. 000,198, filed Jan. 2, 1987, which is a divisional application of Ser. No. 632,405, filed on July 19, 1984, now U.S. Pat. No. 4,639,112 which is a continuation in part application of Ser. No. 478,910, filed on Mar. 25, 1983 (issued as U.S. Pat. No. 4,560,267, on Dec. 24, 1985).

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention generally relates to a photographic camera system utilizing interchangeable objective lens assemblies one at a time and, more particularly, to an improvement in coordination between the camera body and the interchangeable objective lens assembly then coupled thereto.

2. Description of the Prior Art

In a photographic camera system utilizable with interchangeable objective lens assemblies one at a time, one of the most important coordinations between the camera body and the lens assembly then coupled thereto lies in the manual aperture setting required to be performed at the time of manual exposure control, automatic exposure control under the aperture-priority mode, or the like. As is well known to those skilled in the art, interchangeable lens assemblies generally have a manipulatable aperture adjustment such as an aperture setting ring mounted exteriorly on the lens barrel for the access to a photographer.

On the other hand, there is also known a photographic camera system wherein the aperture adjustment is not provided on an interchangeable lens assembly, but on the body of a photographic camera so that the setting of the aperture adjustment can be transmitted to the lens assembly to control the aperture in such lens assembly. In this camera system, since the available aperture range, i.e., the available range from the maximum settable aperture (the smallest available f-stop number) to the minimum settable aperture (the largest available f-stop number), varies from one interchangeable lens assembly to another, a mechanism comprising a mechanical signaling element, provided in any one of the interchangeable lens assemblies and indicating the aperture range available in the respective lens assembly, and an engagement element provided in the camera body for engagement with the signaling element is employed to inhibit the aperture adjustment in the camera body to set the aperture of a value outside the available aperture range.

In either of the above described camera systems, there are many limitations and/or requirements imposed on the manufacture of the interchangeable lens assemblies such as, for example, a space for accommodating an arrangement necessary to permit the aperture setting ring to rotate, a precise arrangement of both the signaling element and the engagement element, the precise machining of the associated component parts and so on. These limitations and/or requirements often render the camera system as a whole to be complicated and expensive.

Another one of the most important coordinations between the camera body and the lens assembly lies in the transmission of various electric signals therebetween. Numerous techniques and arrangements have

hitherto been utilized for transmitting electric signals through terminals between the camera body and the lens assembly. As is well known to those skilled in the art, the utmost care is required to permit the electric signals to be correctly transmitted between the camera body and the lens assembly and, therefore, an improvement has long been desired to avoid any possible inadvertent transmission of one or more of the electric signals from the camera body to the lens assembly or from the lens assembly to the camera body which would result in the erroneous operation of the camera.

SUMMARY OF THE INVENTION

An essential object of the present invention is to improve the conventional camera utilizing an interchangeable lens assembly to permit the camera system as a whole to be reasonably constructed and also to simplify the interchangeable lens assembly.

Another important object of the present invention is to provide an improved camera system wherein the manipulatable aperture adjustment is not provided on the interchangeable lens assembly, but on the body of a camera to permit the setting of the aperture of the lens assembly to be carried out on the side of the camera body.

A further object of the present invention is to provide an improved interchangeable lens assembly having its utility in the camera system of the type referred to above.

A still further object of the present invention is to improve the system so as to avoid the possibility that the camera body may process erroneous information in the event of the incorrect mounting of the lens assembly to the camera body.

A yet further object of the present invention is to provide an improved interchangeable lens assembly having its utility in the system of the type referred to in the preceding paragraph.

The present invention provides a camera system that includes a compatible camera body and interchangeable lens assembly particularly adaptable for automatic focusing. The camera body has a series of terminals for providing electrical power, enabling signals and clock signals plus the ability to receive information from the interchangeable lens assembly. The interchangeable lens assembly has complementary terminals and can have the ability to store various data peculiar to the specific lens assembly such as aperture size.

BRIEF DESCRIPTION OF DRAWINGS

These and other objects and features of the present invention will be readily understood by those skilled in the art upon the reading of the following description taken in conjunction with a preferred embodiment with reference to the accompanying drawings, in which:

FIG. **1** is a perspective view showing an essential portion of the camera with an interchangeable lens assembly shown as separated therefrom;

FIG. **2** is a perspective view of the camera of FIG. **1** as viewed from a different direction;

FIG. **3**(*a*) is a circuit diagram showing an electric circuit incorporated in the camera body according to the present invention;

FIG. **3**(*b*) is a circuit diagram showing an electric circuit incorporated in the lens assembly according to the present invention;

FIG. **4** is a circuit diagram showing an essential portion of a circuit shown for the purpose of comparison

with the operation of the embodiment in FIGS. 3(*a*) and 3(*b*) according to the present invention;

FIG. 5 is a circuit diagram showing an essential portion of the embodiment in FIGS. 3(*a*) and 3(*b*) according to the present invention, shown for the purpose of comparison with the circuit of FIG. 4;

FIG. 6 comprises FIGS. 6(*a*) to 6(*c*) and altogether shows a flow chart of the sequence of operation of the camera system according to the present invention; and

FIG. 7 is a flow chart showing a subroutine executed during the process flow of FIG. 6.

DETAILED DESCRIPTION OF THE EMBODIMENT

Before the description of the present invention proceeds, it is to be noted that like parts are designated by like reference numerals throughout the accompanying drawings.

Referring first to FIG. 1 showing a combination of an interchangeable zoom lens assembly and the body of a photographic camera utilizable with the zoom lens assembly, the zoom lens assembly includes a distance setting ring 1 for setting the camera-to-object distance, and a zooming ring 3 for the adjustment of the focal length of the zoom lens assembly. When the zooming ring 3 is rotated, the focal length of the zoom lens assembly can be adjusted and, at the same time, a slide member provided in a focal length code plate FCP as shown in FIG. 3(*b*) slides a coded pattern in contact therewith to enable the code plate FCP to generate an output data indicative of the focal length to which the lens assembly has been set by the rotation of the zooming ring 3. The lens assembly has a rear end provided with a ring-shaped abutment plate 5 fixed coaxially thereto and carrying five electric terminals JL1 to JL5, said electric terminals JL1 to JL5 being arranged in a circle coaxial with the abutment plate 5 about the optical axis of the lens assembly. Rigidly mounted on the rear end of the lens assembly adjacent the abutment plate 5 is a coupling ring having a plurality of, for example, three, radially outwardly flanged bayonet pawls 7, the function of which will be described later. The lens assembly also has a stop-down pin 9 protruding axially outwardly from the rear end of the lens assembly and normally angularly biased by a spring in a direction shown by the arrow Z, said stop-down pin 9 being so operatively associated with an aperture control mechanism 100 built in the lens assembly that the aperture of the lens assembly can be adjusted to the minimum aperture size (the largest f-stop number) with the pin 9 located at the position shown by solid line and the full open aperture size (the smallest f-stop number) when the stop-down pin 9 is angularly moved to a position 9*a* shown by the broken line in a direction counter to the biasing direction Z.

The camera body 21 has a ring-shaped abutment plate 11 rigidly secured thereto for engagement with the abutment plate 5 fast with the lens assembly and carrying an equal number of electric terminals JB1 to JB5, said electric terminals JB1 to JB5 being so positioned and so arranged that, when and after the lens assembly has been completely coupled to the camera body 21 with the abutment plate 5 held in contact with the abutment plate 11, the terminals JB1 to JB5 on the camera body 21 can be electrically connected with the associated terminals JL1 to JL5 on the lens assembly, respectively. The camera abutment plate 11 has an equal number of bayonet flanges 13 extending radially inwardly therefrom and engageable with the lens bayonet pawls 7 when the lens assembly is mounted onto the camera body and subsequently turned in the direction Z so as to assume a locked position. It is to be noted that the complete coupling of the lens assembly to the camera body 21 is intended to mean that the lens assembly mounted onto the camera body 21 and then turned so as to assume the locked position is held in such locked position and that, although not shown because of the well known expedient in the related art, the camera body 21 is to be understood as provided with a releasable locking member for holding the lens assembly in the locked position. The camera body 21 also has an aperture stop-down control lever 15 having a side edge 15*a* engageable with the stop-down pin 9 when and after the lens assembly has been completely coupled. Accordingly, the aperture of the lens assembly depends on the position of the aperture stop-down control lever 15. Although in practice the aperture stop-down control lever 15 is spring-loaded so as to move in a direction shown by the arrow X, it is held in a position shown by the solid line during a period other than during the exposure control operation and, therefore, the aperture of the lens assembly is set to the maximum aperture size, i.e., the full open aperture size. When the exposure control operation takes place, the control lever 15 is disengaged from the solid line position to move in the direction X accompanied by the angular movement of the stop-down pin 9 in the direction Z with the aperture of the lens assembly consequently stopped down. After the control lever 15 has been moved in the direction X by a predetermined distance corresponding to the stopping-down degree to attain a required aperture size, the control lever 15 is brought to a halt and, at the same time, the stop-down pin 9 having been following to the control lever 15 is brought to a halt with the aperture of the lens assembly consequently set to the predetermined value. The camera body 21 also has a reflective mirror 17 supported for pivotal movement between an up position, at which the incoming light passing through the lens assembly is allowed to reach a photosensitive film, and a down position as shown and at which the incoming light is reflected towards a viewfinder of the camera.

To mount onto the camera body 21, the lens assembly is first inserted into the camera body 21 until the lens abutment plate 5 contacts the camera abutment plate 11 and then is turned in the direction Z to allow it to be held in the locked position. When the lens assembly is so locked, the bayonet pawls 7 are held in position between the bayonet flanges 13 and spring members (not shown) provided in the camera body 21 and positioned on one side of the bayonet pawls 7 opposite to the associated bayonet flanges 13 and, at the same time, the lens terminals JL1 to JL5 are aligned and electrically connected with the camera terminals JB1 to JB5, respectively. The paired terminals JB1 and JL1 are utilized to transmit data from the lens assembly onto the camera body; the paired terminals JB2 and JL2 are utilized to supply an electric power from the camera body onto the lens assembly; the paired terminals JB3 and JL3 are utilized to supply synchronizing clock pulses from the camera body onto the lens assembly; the paired terminals JB4 and JL4 are utilized to supply from the camera body onto the lens assembly a chip select signal necessary to activate a circuit built in the lens assembly; and the paired terminals JB5 and JL5 are utilized to make

the ground common to both the camera body and the lens assembly.

As can readily be understood from FIG. **1**, it is clear that, except for a mechanical linkage associated with the control of the lens aperture, no other mechanical linkage intended for the transmission of pieces of information is employed between the camera body and the lens assembly. Accordingly, not only can the lens assembly have enough space to spare, but also no substantial care is required in designing and machining component parts of the mechanical linkage necessitated to transmit a physical information concerned of the lens aperture.

In addition, since the paired terminals for the transmission of the electric signals are arranged in the manner as hereinabove described, the data transfer terminal JB1 on the camera body **21** contacts none of the lens terminals JL1 to JL5 during the mounting of the lens assembly and prior to the complete coupling of the lens assembly to the camera body, but contacts the associated lens terminal JL1 only when the lens assembly has been completely coupled to the camera body having been held in the locked position. Accordingly, as will be described later, even when the lens assembly is incompletely coupled to the camera body, there is no possibility that electric current may flow from any of the other terminals to this data transfer terminal through the circuit built in the lens assembly. This is advantageous in that the possibility is eliminated that the data may be destroyed by the current flowing from any of the other terminals while a microcomputer is in operation to transact the data with blocks other than the lens assembly, thereby permitting the data to be correctly read.

FIG. **2** illustrates the appearance of the camera body viewed from the rear. As shown, the camera body has a shutter release button **22**, a mode selector slide **23**, a liquid crystal display unit **24**, an aperture setting button **25**, an exposure time setting button **26**, an up-shift button **27**, a down-shift button **28** and a frame counter window **29** all arranged at convenient places readily accessible to and noticeable by the photographer. The shutter release button **22** when depressed is moveable in two stages between inoperative and operated positions past an intermediate position, and the first stage of movement from the inoperative position to the intermediate position results in the closure of a light measuring switch S1, shown in FIG. **3**(*a*), to initiate the light measurement, the calculation and the display operation, but the subsequent second stage of movement from the intermediate position to the operated position results in the closure of a release switch S2, shown in FIG. **3**(a), to initiate the exposure control if an exposure control mechanism has already been charged. The mode selector slide **23** is selectively movable to any one of the four click positions marked "A", "P", "S" and "M", respectively. When this mode selector slide **23** is in the A position, the camera is brought in position to operate under an aperture priority mode (hereinafter referred to as A mode) at which the exposure time is automatically controlled in reference to the preset aperture, but when the slide **23** is moved to the P position, the camera is brought in position to operate under a programmed mode (hereinafter referred to as P mode) at which a combination of the exposure time and the aperture are automatically controlled in dependence on the amount of light. It is to be noted that, during the P mode of operation, the program line varies dependent on the data fv fed from the lens assembly indicating the focal length, to which the zooming ring **3** has been adjusted, in such a way that, when fv>fvt, wherein fvt represents the data indicative of the focal length of, for example, 80 mm, a Pt mode is established in which a priority is given to the high shutter speed in determining the combination of aperture and exposure time, but when fvw>fv, wherein fvw represents the data indicative of the focal length of, for example, 35 mm, a Pw mode is established in which a priority is given to the small aperture in determining the combination of exposure time and aperture. However, when and so long as fvt>fv>fvw, a normal Pn mode is established. When the mode selector slide **23** is set at the S position, the camera is brought in position to operate under an exposure time priority mode at which the aperture is automatically controlled in reference to the preset exposure time, which mode is hereinafter referred to as S mode. On the other hand, when the slide **23** is in the M position, the camera is brought in position to operate under a manual mode at which both the exposure time and the aperture can be manually set according to the photographer's desire, which mode is hereinafter referred to as M mode.

The aperture setting button **25** is adapted to be depressed at the time of setting of the aperture, and the depression of this button **25** results in the closure of a switch ASS, shown in FIG. **3**(*a*), to initiate the light measurement, the calculation and the display operation and also to modify the aperture in dependence on the state of any one of the upshift and down-shift buttons **27** and **28**. The exposure time setting button **26** is adapted to be depressed at the time of setting of the exposure time, and when this button **26** is depressed, a switch SSS shown in FIG. **3**(*a*) is closed to initiate the light measurement, the calculation and the display operation and also to modify the aperture in dependence on the state of any one of the upshift and down-shift buttons **27** and **28**. When the up-shift button **27** is depressed, a switch UPS shown in FIG. **3**(*a*) is closed. When at this time the aperture setting button **25** is depressed while the camera is operable under any one of the A and M mode, the aperture size once set changes to a size smaller than it by 0.5 Ev. However, when at this time the exposure time setting button **26** is depressed while the camera is operable under any one of the S and M modes, the exposure time once set changes to a value shorter than it by 0.5 Ev. The repression of the down-shift button **28** results in the closure of a switch DOS shown in FIG. **3**(*a*). When at this time the aperture setting button **25** is depressed while the camera is operable under any one of the A and M modes, the aperture size once set changes to a size larger than it by 0.5 Ev, but when at this time the exposure time setting button **26** is depressed while the camera is operable under any one of the S and M modes, the exposure time once set changes to a value longer than it by 0.5 Ev. The liquid crystal display unit **24** is used to display various pieces of information such as, for example, the ISO value, the combination of the exposure time and the aperture both used for the control, a camera wobbling warning, and the out-of coupling range warning. The frame counter window **24** is used to display the count of film frames exposed.

FIGS. **3**(*a*) and **3**(*b*) altogether illustrate an electric circuit of the camera system as a whole embodying the present invention, wherein FIG. **3**(*a*) shows the circuit incorporated in the camera body while FIG. **3**(*b*) shows the circuit incorporated in the lens assembly. The circuit incorporated in the camera body, which is hereinaf-

ter referred to as camera circuit in contrast to a lens circuit which is the circuit shown in FIG. 3(*b*) and incorporated in the interchangeable lens assembly, includes a source BA of electric power which may be constituted by one or more batteries. This power source BA feeds, through a power supply line +E, a microcomputer, a display circuit DSP, a shift register SR, AND gates AN0, ANI, AN2, and NAND gates NA0 and NA1. The camera circuit also includes the switch S1, which is a light measuring switch adapted to be closed upon the first stage of depression of the release button 22; the switch SSS which is a Tv switch adapted to be closed when the exposure time setting button 26 is depressed, the switch ASS which is an Av switch adapted to be closed when the aperture setting button 25 is depressed; the switch UPS which is an up-shift switch adapted to be closed when the up-shift button 27 is depressed; and the switch DOS which is a down-shift switch adapted to be closed when the down-shift button 28 is depressed.

A transistor BTo acts as a power supply transistor and is adapted to conduct, when the microcomputer PC initiates its operation, to supply an electric power from the power supply line +V to a light measuring circuit LMC, a release magnet circuit RLM, an aperture stop magnet circuit APM, a mirror magnet circuit MRM, a leading curtain magnet circuit 1CM, a trailing curtain magnet circuit 2CM, an aperture stop-down pulse generator FEN, an ISO data detecting circuit CAD, and an exposure control mode data generator MOD. Moreover, when and so long as the transistor BTo is in conduction, an electric power is supplied to the camera terminal JB2 through a protecting resistor Ro and then to a power line vL of the lens circuit of FIG. 3(*b*) through the lens terminal JL2 then connected with the camera terminal JB2. The protecting resistor Ro is used to avoid any possible shortcircuiting which may happen to occur between the power supply line +V and the ground when, for example, forceps touch the camera terminal JB2. It is to be noted that, except for the circuits LMC, RLM, APM, MRM, 1CM, 2CM and FEN, the camera circuit is fabricated in C-MOS.

The operation of the camera system as a whole will now be described with reference to the flow charts of FIG. 6 and 7 showing the sequence of operation of the microcomputer PC. Assuming that the microcomputer PC is in the inoperative position, terminals P2, P3 and P4 are all in a low level state. When any one of the light measuring switch S1, the Tv switch SSS and the Av switch ASS is subsequently closed, an input to an interruption terminal itA sets down to a low level state and the microcomputer PC consequently starts its operation from the initial step #1. At step #1, a terminal P11 is rendered in a low level state wherefor the transistor BTo is caused to conduct to initiate the electric power supply from the power supply line +V and also the electric power supply through the resistor Ro. By rendering the terminals P2, P3 and P4 in a high level state, a terminal P14 is rendered in a high level state. When the terminal P14 is rendered in the high level state, ISO data and mode data are latched in the shift register SR in response to the positive edge of the high level signal emerging from the terminal P14. An ISO data output circuit CAD is a circuit operable to read a coded pattern indicative of the ISO data, which coded pattern is provided on a film container as is well known to those skilled in the art, whereas the mode data generator MOD is operable to generate the mode data from a coded pattern depending on the position of a slide member movable together with the mode selector slide 23 shown in FIG. 3(*a*). In addition, at the same time as the terminal P14 is rendered in the high level state, the NAND gate NA1 and the AND gates AN0 and AN2 are brought in position ready to be enabled. At step #4, the microcomputer PC undergoes a serial input and output operation with the consequence that eight clock pulses are output from a terminal CKO on the one hand and data fed to a data input terminal SIN are taken in a serial input/output register SIOR, provided internally of the microcomputer PC, in response to the negative edge of each positive edge of the eight clock pulses on the other hand. Substantially at the same time, the shift register SR sequentially outputs the data, which have been latched therein, on the basis of the eight clock pulses successively fed to the AND gates AN2. When the data so output are in the high level state, and output from both of the gates AN0 and NAl is in a low level state and, accordingly, a field-effect transistor To is brought in a conductive state thereby permitting a high level signal to be fed to the data input terminal SIN. On the other hand, when the data outputed from the shift register SR are in the low level state, an output from both of the gates AN0 and NAl is in a high level state and, accordingly, a field-effect transistor T1 is brought in a conductive state thereby permitting a low level signal to be fed to the data input terminal SIN. It is to be noted that, when and so long as the terminal P14 of the microcomputer PC is in a low level state, the NAND gate NAl and the AND gate AN0 generate high and low level signals, respectively, and therefore both of the field-effect transistors T0 and T1 are held in a non-conducting state, thereby avoiding any possible adverse influence which would otherwise occur when data taken from the lens circuit of FIG. 3(*b*) are fed to the data input terminal SIN. Upon termination of step #4, of the data taken in the serial input/output register SIOR, the mode data are set in a register MOR, and the ISO data are, after having converted the data taken in into data for the calculation, set in a register SVR. Then, the microcomputer PC renders the terminal P14 in a lower level state and proceeds to step #7.

At step #7, a decision is made as to whether or not data appropriate to the law of the coded pattern on the film container have been read out from the ISO data taken in the serial input/output register SIOR. If it proves that the data appropriate to the law of the coded pattern have been read out, the contents of the register SVR remain unchanged, but if it proves to the contrary, it can note that the film container having no coded pattern is loaded or any film container is not loaded and, in such case, data representative of the ISO sensitivity which is most often utilized, for example, ISO 100, can be set in the register SVR.

Subsequently, the microcomputer PC proceeds to the reading of data out from the lens circuit shown in FIG. 3(*b*). In the first place, the content of a register k is rendered "0" and a terminal P12 is rendered in a high level state. The register k serves to select one of the data setting registers LDR0 to LDR5 according to the content stored therein More specifically, when the content of the register k is "0", "1", "2", "3", "4" or "5", the register LDR0, LDR1, LDR2, LDR3, LDR4 or LDR5, can be selected, respectively. When the terminal P12 is rendered in the high level state as hereinabove described, this high level signal is fed to the lens circuit through the terminal JB4 and then the terminal JL4. By

this high level signal, all of the AND gates AN3 and AN4, the NAND gate NA2 and a decoder DE are brought in position ready to be enabled and, on the other hand, counters C00 and C01 are released from their reset states. Then, the microcomputer undergoes the serial input and output operation to sequentially read in the data, which are fed to the data input terminal SIN from the lens circuit through the coupled terminals JL1 and JB1, in response to the negative edge of the same clock signal as the clock signal outputed from the clock output terminal CKO, the data so read in being subsequently set in a register LDRK to add "1" to the register k. Then, a decision is made as to whether or not the content of the register k has become "6". If the content of the register k is determined "6", the process flow proceeds to step #15, but if it is not, the process flow proceeds to step #11 to read in the next succeeding data fed from the lens circuit. By repeating the above described process flow, six types of data can be read in the microcomputer PC and set in the register LDR0 to LDR5, respectively.

Referring to FIG. 3(*b*) showing the lens circuit, that is, the circuit built in the interchangeable lens assembly, a counter C00 is a 3-bit counter operable to count the number of negative edges of the respective clock pulses which have been fed from the clock output terminal through the coupled terminals JB3 and JL3 and then the AND gate AN3 and subsequently inverted by an inverter IN0, that is, the number of positive edges of the respective clock pulses outputed from the clock output terminal CKO. The decoder DE sequentially generates a high level signal from its left-hand terminal to its right-hand terminal in correspondence with an output from the counter C00, thereby bringing AND gates AN10 to AN17 in position ready to be enabled. Accordingly, each of the AND gates is held in position ready to be enabled during a period from the positive edge of one clock pulse to the positive edge of the next succeeding clock pulse, thereby generating one-bit data. On the other hand, when the outputs from the counter C00 are all rendered in a low level state upon completion of its counting operation up to eight clock pulses and an AND data AN5, therefore generates a high level output, a counter C01 receives the clock pulses, which have been outputed from an AND gate AN3 and subsequently delayed by a delay circuit DL, and counts the number of negative edges of the clock pulses so received thereby. The delay circuit DL is utilized to inhibit the AND gate AN6 from outputing a pulse in response to the positive edge of the first clock pulse. Accordingly, each time the eight clock pulses are fed thereto, one clock pulse is counted. Reference character DSL represents a data selector adapted to output the input data, which have been fed to an input section A, when and so long as the most significant bit of the counter C01 is in a low level state, but to output the input data, which have been fed to an input section B, when and so long as it is in a high level state. And, RO fixedly stores various data of the interchangeable lens assembly at respective addresses. When one of the addresses is specified by address data fed from the data selector, the data stored and fixed at such specified address are outputed and are then output through the AND gates AN10 to AN17 bit to bit from the least significant bit. The data output from the AND gates AN10 to AN17 emerges from an OR gate OR0 and, when and so long as the output from the OR gate OR0 is in a high level state, a field-effect transistor T2 is rendered conductive with the high level signal consequently fed to the data input terminal SIN through the coupled terminals JL1 and JB1. However, when and so long as the output from the OR gate OR0 is in a low level state, a field-effect transistor T3 is rendered conductive with the low level signal consequently fed to the data input terminal SIN through the coupled terminals JL1 and JB1.

Hereinafter, the reason will be discussed that, even if the lens assembly is incompletely coupled to the camera body, the transmission of various data between the lens assembly and the camera body will not be adversely affected. For this purpose, reference will now be made to FIGS. 4 and 5. It is to be noted that FIG. 4 illustrates the case employed only for the purpose of comparison, in which the power terminal on each of the camera body and the interchangeable lens assembly is positioned at one extremity of the arcuate row of the terminals and the lens assembly is incompletely coupled to the camera body. FIG. 5 illustrates the case in which the lens assembly incorporating the lens circuit of FIG. 3(*b*) is incompletely coupled to the camera body incorporating the camera circuit of FIG. 3(*a*).

Referring first to FIG. 4, the lens assembly is incorrectly coupled to the camera body such that a data terminal JB2' and a clock terminal JB3', both on the camera body, are electrically connected with a power terminal JL1' and a data terminal JL2' both on the lens assembly, respectively. At the outset, a discussion will be made as to what will happen when, in the incomplete condition, the clock pulses are generated from the clock terminal CKO to permit data from other data output sections, that is, the shift register SR, provided internally of the camera body, to be read in the data input terminal SIN. A high level signal of the clock is generated upon the conduction of a field-effect transistor T4. Then, a voltage from the power supply line +V is supplied through the field-effect transistor T4 and the coupled terminals JB3' and JL2' to the lens assembly and then to a power supply line VL in the lens assembly through a diode D2 which is essentially formed by a CMOS circuit. This signal is in turn fed to the data input terminal SIN in the camera body through the coupled terminals JL1' and JB2'. At this time, it is assumed that the data from the shift register SR in the camera body are in the low level state, an N-channel field-effect transistor T1 is conducting and the low level signal is to be read in the data input terminal SIN. However, when and so long as the field-effect transistor T1 is conducting, the potential at the data input terminal SIN is equal to the potential of the electric power +E divided by the on-resistance of a field-effect transistor T4, and the on-resistance of both the diode D2 and the field-effect transistor T1 and is not clear as to whether it becomes a high level state or whether it becomes a low level state. Accordingly, there is a possibility that incorrect data will be read in the data input terminal SIN. (It may be contemplated to employ a resistor of relatively high resistance between the terminal JB2' and the data input terminal SIN or between the clock output terminal CKO and the terminal JB3' to avoid the reading of the incorrect data. However, where such a resistor is employed, it may happen that a low-pass filter having a large time constant will be formed by the above described resistor and the parasitic capacitance of the data transfer line or the clock transfer line, in which case a high speed data transmission will be hampered.) On the contrary thereto, in the embodiment according to the

present invention, since the data terminal JL1 for transmitting the data from the lens assembly to the camera body is positioned on the leading extremity of the row of the lens terminals with respect to the direction of turn of the lens assembly which is effected when the lens assembly is coupled to the camera body, even if any erroneous connection between the terminals such as corresponding to that described with reference to and shown in FIG. 4, no voltage will be imposed on the data terminal JB1 on the camera body as shown in FIG. 5 and, therefore, no adverse effect will occur when the data input terminal SIN in the camera body reads in the output from the shift register SR. In general, in the case of the embodiment according to the present invention, the terminal JB1 for receiving the data of the camera is electrically connected with the terminal JL1 only when and after the interchangeable lens assembly has been completely coupled to the camera body and hence held in the locked position, and will not be connected to any one of the other terminals JL2 to JL5 during the mounting of the lens assembly. Accordingly, even if while the lens assembly is incompletely coupled to the camera body the ISO data are read in through the data input terminal SIN, there is no factor that adversely affect the data and the ISO data are, therefore, correctly read in by the microcomputer PC. It is to be noted that, in the case of the embodiment according to the present invention, although a current tends to flow in through the transistor BTo, the resistor Ro, the coupled terminals JB2 and JL1, the diode D2, a power source VL and the coupled terminals JL2 and JB3, the waveform of the clock signal will not be adversely affected because the impedance is increased by the protecting resistor Ro.

The relationship between the data stored and fixed in a read-only memory RO and the addresses of the read-only memory RO as well as the operation necessary to specify the addresses will now be described.

TABLE 1

Counter (CO1)	Addresses	Data	Registers
000	000 00000	Check data	LDR0
001	000 00001	AVo: Full Open Aperture Size	LDR1
010	000 00010	Avmax: Minimum Aperture Size (maximum F-number)	LDR2
011	000 00011	Wv: Error in Full Open Aperture Metering	LDR3
100	100 *****	Avz: Deviation in Effective Aperture Size from A Standard	LDR4
101	101 *****	fv: Focal Length	LDR5

Table 1 illustrates the relationship among the output from the counter C01, the address of the read-only memory RO to be specified, the data stored at the specified address, and the register to which the data are set within the microcomputer PC. Each time the eight clock pulses are fed to the counter C01, the latter increases its count by one increment. Accordingly, at the outset, the output from the counter C01 is "000". As a result, the data, "000 00000", from an input section A are outputed from the data selector DSL to the read-only memory RO. Subsequently, check data (for example, "10101010") common to all of the available interchangeable lens assemblies is transferred from the read only memory RO to the camera body. When the output from the counter C01 subsequently become "001", an address data "000 00001" from the input section A is outputed from the data selector DSL and a data Avo representative of the full open aperture size is outputed from the read-only memory RO. In the case of the zoom lens assembly having its effective aperture variable with change in focal length, a data representative of the full open aperture size at the shortest focal length, that is, the greatest aperture size available in the lens system, is outputed. When the output from the counter C01 becomes "010", an address data "000000010" from the input section A is output from the data selector DSL and a data Avmax representative of the minimum aperture size (the maximum f-stop number) is output from the read-only memory RO. Also, as for this minimum aperture size, in the case of the zoom lens assembly having its effective aperture variable with change in focal length, a data representative of the minimum aperture size at the shortest focal length is outputed. When the output from the counter C01 becomes "011", an address data "00000011" is output from the data selector DSL and a data Wv representative of an error in full open aperture metering is output. When the output from the counter C01 becomes "100", an address data "100*****" from the input section B is output from the data selector DSL. The five-bit data represented by "*****" is a data output from the focal length code plate FCP in correspondence with the focal length set by the zooming ring 1. At this address, a data representative of the deviation in effective aperture size from that at the shortest focal length is fixedly stored. It is, however, to be noted that, in the case of a zoom lens assembly having its effective aperture not variable with change in focal length, a data "00000000" is fixedly stored. In addition, in the case of a lens assembly of a fixed focal length, no focal length code plate is employed and, at the same time, no data selector DSL is employed, and the address in the read-only memory RO is specified "00000100" and, therefore, a data "00000000" is output from the read-only memory RO. When the output from the counter C01 become "101" a data "101*****" from the input section B is output from the data selector DSL and a data fv corresponding to the focal length set by the zooming ring 1 is output. In the case of the lens assembly of a fixed focal length, the address of "00000101" is specified and a data fv representative of the fixed focal length is output.

Referring to the flow chart of FIG. 6, the operation of the microcomputer PC will now be described. After the data has been taken in from the lens circuit, the analog-to-digital conversion of an output from the light measuring circuit LMC is carried out at step #15. The output from the light measuring circuit LMC is fed to an analog input terminal ANI so that a reference voltage created within the light measuring circuit LMC can be utilized as a reference voltage for a digital-to-analog converter built in the microcomputer PC for the analog-to-digital conversion and the output from the light measuring circuit LMC is subjected to the analog-to-digital conversion on the basis of this reference voltage. Subsequently, at steps #16 and #17, both the full open aperture size and the minimum aperture size at the focal length once set are calculated, the resultant data being designated by Avo and Avmax, respectively. Then, at step #18, the error Wv, included in the data of the output from the light measuring circuit LMC which has been subjected to the analog-to-digital conversion, and a factor of the full open aperture size Avo are subtracted on the basis of the data read out from the lens assembly to calculate Bv to which the film sensitivity

data set in a register SVR is added to calculate an exposure value EV.

Upon the completion of the above described operation, an exposure calculation operation starting from step #20 starts. At step #20, based on the data taken in a register MOR, a decision is made as to whether or not it is the P mode. If it is the P mode, the program flow proceeds to step #21 at which a decision is made as to whether or not the focal length data fv from the lens assembly is greater than fvt. If fv>fvt, the programmed calculation for the high speed shutter priority is performed at step #21 which is followed by step #35. However, if the determination at step #21 shows fv≦fvt, a decision is made at step #23 to find if fv<fvw. If fv≦fvw, the program flow proceeds to step #25 at which the programmed calculation for the small aperture priority is performed, which step #25 is subsequently followed by step #35. When the determination at step #23 shows fv≧fvw, the normal programmed calculation is performed at step #24 which is followed by step #35. On the other hand, if the determination at step #20 is such that it is not the P mode, a decision is made at step #26 to find if it is the A mode. If it is the A mode, the aperture is set in a register AVR1 depending on the states of the respective buttons 25, 27 and 28, and at subsequent step #26, the calculation for the A mode is performed, followed by step #35. If it is not the A mode as determined at step #26, a decision is performed at step #29 to determine if it is the S mode. If it is the S mode, an exposure time is set in a register TVR1 at step #30 in dependence on the states of the respective buttons 26, 27 and 28 and, after the calculation for the S mode has been performed at step #31, the program flow proceeds to step #35. If it is not the S mode as determined at step #29, this means the M mode and, therefore, at step #32, the aperture determined in dependence on the states of the respective buttons 25, 27 and 28, and the exposure time determined in dependence on the states of the respective buttons 26, 27 and 28 are set in registers AVR1 and TVR1, respectively, at step #32 which is followed by step #34 at which the calculation for the M mode is performed, the program flow thereafter proceeding to step #35.

The aperture for the control obtained from one of the above described calculations for the respective modes is set in a register AVR2 while the exposure time for the control obtained from one of the above described calculations for the respective modes is set in a register TVR2. Moreover, an over exposure warning, an under exposure warning, a camera wobbling warning and the data of the displacement from a proper exposure during the M mode are all set in a register DMR. The preset aperture and exposure time are set in the registers AVR1 and TVR1. If during the calculation for the S mode the calculated aperture AV is such that Av°Av-max, Avmax and the data on the preset exposure time are set in the registers AVR2 and TVR2, respectively, with the over exposure warning effected. On the other hand, if Av°Avo, Avo and the data on the preset exposure time are set in the registers AVR2 and TVR2, respectively, with the under exposure warning effected. During the P mode, if Avmax+Tvmax°Ev, Avmax and Tvmax are set in the registers AVR2 and TVR2, respectively, with the over exposure warning effected. Moreover, if the calculated Av is smaller than Avo, Avo is set in the register AVR2 and, if Tv which is obtained by Ev-Avo=Tv is higher than Tvmin, the Tv so obtained is set in the register TVR2, but if Tv<Tvmin, Tvmin is set in the register TVR2 with the under exposure warning effected. At step #35, the number of steps to be stopped-down is calculated from both the data on the aperture size for the control and the data on the full open aperture size, the calculated data beings et in a register PVR. At the subsequent step #36, data Avd on the aperture for the display, of which minimum unit is 0.5 Ev, is calculated from the data on the aperture for the control and is then set in a register AVR3. At step #38, data Tvd on the exposure time for the display, of which minimum unit is 0.5 Ev, is calculated from the data on the exposure time for the control and is then set in a register TVR3. After the above described operation has been completed, the program flow proceeds to step #39 at which a subroutine for the transfer of the data to be displayed is executed.

The subroutine for the transfer of the data to be displayed will now be described. At step #60, a terminal P13 is rendered in a high level state, the AND gate AN1 is brought in position ready to be enabled, and the display circuit DSP is set in position ready to receive inputs. The content of the register DMR is set in a serial input/output register SIOR and the serial input and output operation is performed. Thereby, the content of the register DMR is taken in the display circuit DSP. Subsequently, the content (ISO data) of the register SVR is set in the register SIOR and the serial input and output operation is performed. After the data in the register AVR3 on the aperture for the display and the data in the register TVR3 on the exposure time for the display have been fed to the display circuit DSP, the terminal P13 is rendered in a low level state, followed by the return to the main routine. Then, the display circuit DSP outputs a signal, corresponding to the data so read out, to a segment terminal SEG and a display corresponding to the data fed together with a signal from a common terminal COM is carried out by means of a liquid crystal display unit LQ.

After the completion of the transfer of the data to be displayed, and at step #40, interruption to a terminal itB is enabled. This is such that, if the release switch S2 shown in FIG. 3 is closed and, at the same time, the exposure control mechanism has been charged with the switch S4 consequently closed, the output from the NAND gate NA0 changes to a low level state with an interruption signal consequently fed to the terminal itB, and the microcomputer performs an exposure control operation from step #70 if the interruption to the terminal itB is in condition ready to be enabled, no matter what operation it has performed. When the interruption to the terminal itB is enabled, the terminals P2, P3 and P4 are rendered in a low level state and a decision is made as to whether or not an input terminal P0 is rendered in a low level state as a result of at least one of the switches S1, SSS and ASS having been closed. If the terminal P0 is rendered in the low level state, the program flow returns to step #2, thereby repeating the above described operation. On the other hand, if the terminal P0 is in the high level state, the program flow proceeds to step #43 at which the interruption to the terminal itB is disabled and a blank data BLD for turning off the display is set in the registers AVR3 and TVR3 and, further, the register DMR in which display data such as for warning is set is reset, followed by the subroutine for the transfer of the data to be displayed. After the completion of the data transfer starting from step #60 in the manner as hereinbefore described, the terminal PII is rendered in a high level state to interrupt

the power supply by means of the transistor BTo while the interruption to a terminal itA is enabled to interrupt the operation of the microcomputer PC. Accordingly, at the time of interruption of the operation of the microcomputer, the display unit LQ merely displays only the ISO data.

Hereinafter, a subroutine for the aperture setting will be described with reference to FIG. 7. At step #101, a decision is made to find if the switch ASS is closed. This is to determine if, while a terminal P4 is rendered in a low level state, the terminal P0 is rendered in a low level state and to render the terminal P4 in a high level state. If the switch ASS is not closed, a flag SEF is set to "0" at step #115 followed by step #116. On the other hand, if the switch ASS is closed, a decision is made at step #102 as to whether or not the switch UPS is closed. This operation is to determine if, while the terminal P3 is rendered in a low level state, the terminal Pl is rendered in a low level state and to render the terminal P3 in a high level state. If the switch UPS is closed, a decision is made at step #103 as to whether or not the down-shift switch DOS is closed. This operation is to determine if, while the terminal P4 is rendered in a low level state, the terminal Pl is in a low level state and to render the terminal P4 in a high level state. If the down-switch DOS is, too, closed, it means that the up shift button 27 and the down-shift button 28 are simultaneously depressed and, therefore, the program flow proceeds to step #116 with no set value altered. If it proves at step #103 that the switch DOS is not closed, a decision is made at step #104 to find if the flag SEF is "1". If the flag SEF has been found to be "1", this means that the up-shift button 27 is kept depressed and, therefore, the program flow proceeds to step #116. On the other hand, if the flag SEF has been found to be "0", this means that the up-shift button 27 is first depressed and, therefore, the flag SEF is set to "1" at the subsequent step #105 followed by step #106 at which 0.5 is added to the content of the register AVR1. At step #107, the minimum aperture size Avmax obtained at step #17 is compared with the content of the register AVRl. If (AVRl)° Avmax, Avmax is set in the register AVRl at step #108 followed by step #116. On the other hand, if (AVRl)≦Avmax, the data of the register AVRl remains unchanged and the program flow proceeds to step #116.

If the determination at step #102 is such that the switch UPS is not closed, step #102 is followed by step #109 at which a decision is made to find if the switch DOS is closed. If the switch DOS is not closed, too, the flag SEF is set to "0" at step #115 followed by step #116. On the other hand, if the switch DOS is closed, a decision is made at step #110 to find if the flag SEF is set to "1". If the result at step #110 indicates that the flag SEF is "1⇌, this means that the down-shift button 28 is kept depressed and, therefore, the program flow proceeds to step #116 without the data being altered. On the other hand, if the result at step #110 indicates that the flag SEF is "0", this means that the down-shift button 28 is first depressed and, at this time, the flag SEF is set to "1" at step #111 followed by step #112 at which 0.5 is subtracted from the content of the register AVRl. If the result of comparison carried out at the step between the content of the register AVRl and the data Avo of the full open aperture size obtained at step #16 shows (AVRl)≧Avo, the content of the register AVRl remains unchanged and the program flow proceeds to step #116. On the other hand, if it shows (AVRl)<Avo, the full open aperture size Avo is set in the register AVRl at step #114, followed by step #116.

At step #116, a decision is made as to whether or not the content of the register AVRl is greater than the value representative of the minimum aperture size Avmax, and if it not greater than Avmax, the content of the register AVRl remains unchanged, but if it is greater than Avmax, the minimum aperture size Avmax is set in the register AVRl at step #117 in place of the original content in the register AVRl. At step #118, a decision is made as to whether the content of the register AVRl is smaller than the value representative of fuller open aperture size Avo determined at step #16. If the result of comparison at step #118 indicates that the content of the register AVR1 is smaller than Avo, Avo is set in the register AVRl at step #119 in place of the original contents in the register AVRl, but if it shows the content of the register AVRl not smaller than Avo, the content of the register AVRl remains unchanged and the program flow subsequently returns to the main routine. The program flow from step #116 to step #119 is provided for the purpose of avoiding any possible departure of the data, set in the register AVRl prior to the lens assembly being interchanged, from a controllable range when the lens assembly is interchanged. In addition, as shown in the subroutine, a single depression of any one of the up-shift and down-shift buttons results in the change of the set value by 0.5 Ev.

The subroutine for the determination of the exposure time is similar to the subroutine shown in FIG. 7 except that step #101 is substituted by a decision step to determined if the switch SSS is closed; the register AVRl at each of the steps #106, 107, 108, 112, 113 and 114 is substituted by the register TVR1; Avmax is substituted by the data Tvmax on the shortest exposure time; Avo is substituted by the data Tvmin on the longest exposure time; and steps #116 to #119 are omitted because of no change occurring in any one of the shortest and longest exposure times.

Referring to FIG. 6, particularly to FIG. 6(*c*), the operation which takes place when an interruption signal is fed to the interruption terminal itB will now be described. At step #60, a decision is made as to whether or not the data of a register PVR associated with the number of f-stop steps to be stopped down is "0". If it is not "0", the content of the register PVR is set in an event counter ECO to enable the interruption by the event counter ECO. And, a low level pulse of a duration To is generated from a terminal P6 to activate the release magnet circuit RLM. Then, the engagement of the control lever 15 shown in FIG. 1 is released and the control lever 15 starts its movement in the direction X to initiate the aperture stop-down operation. In addition, in response to the movement of the control lever 15, the pulse generator FEN generates a pulse which is in turn fed to a clock input terminal of the microcomputer PC at which, in response to each pulse, the data of the number of f-stop steps to be stopped down, which is preset in the event counter ECO, is subtracted. The microcomputer, after the lapse of a time T1 subsequent to the generation of a low level pulse from the terminal P6, generates from a terminal P8 a pulse of a duration To necessary to activate the mirror magnet circuit MRM. When the mirror magnet circuit MRM is so activated, the engagement of the reflective mirror 17 shown in FIG. 1 is released and the reflective mirror 17 is therefore is pivoted upwards. After the lapse of a time T2 subsequent to the generation of the low level pulse

from the terminal P8, the program flow proceeds to step #81 at which a low level pulse of a duration To is generated from a terminal P9. During a period from the generation of the low level pulse from the terminal to step #81, the aperture spends time enough to allow it to be stopped down from the full open aperture size to the minimum aperture size regardless of the type of an interchangeable lens assembly, and during this time pulses equal in number to the number of f-stop steps to be stopped down are generated from the encoder FEN and the content of the event counter ECO is zeroed. By this operation, the interruption by the event counter ECO is effected and the operation starting from step #90 is initiated. In this program flow, a low level pulse of a duration To is generated from a terminal P7, thereby returning to the main routine. In this way, the aperture stop magnet circuit APM is activated to stop the movement of the control lever 15 so that the aperture can be controlled to a preset aperture. When a time T2 elapses subsequent to the generation of the low level pulse from the terminal P8, the upward pivotal movement of the mirror 17 has completed, and a low level pulse is generated from the terminal P9 to initiate the travel of the leading curtain.

Upon the initiation of the travel of the leading curtain incident to the generation of the low level pulse from the terminal P9, a time 2—Tvc based on the data Tvc of the exposure time for the control, set in a register TvR2, is counted, and upon the completion of the counting of this time, a low level pulse is generated from a terminal P10 to activate the trailing curtain magnet circuit 2CM so that the travel of the trailing curtain can be initiated. After the completion of the travel of the trailing curtain, and the subsequent closure of a switch S4, the program flow proceeds to step #41 with the subsequent operation taking place in a manner similar to that hereinbefore described.

As hereinbefore fully described, according to the present invention, except for the aperture stop-down quantity transmission means essentially required to control the aperture mechanism of the interchangeable lens assembly from the side of the camera body, neither the aperture adjusting ring in the interchangeable lens assembly nor mechanical component parts such as mechanical linkage members associated with the aperture between the interchangeable lens assembly and the camera body are employed. Therefore, not only can the number of component parts of one or both of the lens assembly and the camera body be minimized, but also they can have enough space to spare. In addition, in these component parts, neither the machining precision nor the accurate positioning, which have hitherto been considered important problems, need be required to be taken into consideration. Furthermore, although information to be transmitted between the interchangeable lens assembly and the camera body includes information in the error in full aperture metering, and, in the case of the zoom lens assembly, the focal length, changes in aperture resulting from the zooming as the case may be, and the like, if these pieces of information are stored in the read-only memory in a manner similar to information of the full open aperture size and the minimum aperture size, the construction of the present invention can be concurrently utilized to transmit these pieces of information between the lens assembly and the camera body. Yet, while in the case of the customary interchangeable lens assembly having an aperture adjusting ring and an aperture mechanism mechanically associated therewith, a manipulation to set the aperture adjusting ring to a particular position to prevent a mechanical control by the aperture adjusting ring from interfering with this is required even though the aperture is set on the side of the camera body, such complicated procedures are not required according to the present invention. What is more, according to the present invention, any possible confusion which would occur in transmitting electric signals between the lens assembly and the camera body in the event of the incorrect coupling therebetween can advantageously be eliminated.

Although the present invention has fully been described in connection with the preferred embodiment thereof with reference to the accompanying drawings, it is to be noted that various changes and modifications are apparent to those skilled in the art. Such changes and modifications are to be understood as included within the true scope of the present invention as defined by the appended claims unless they depart therefrom.

We claim:

1. In a camera system capable of selectively functioning in a manual exposure control mode or an automatic exposure control mode having a camera body and an interchangeable objective lens removably coupled with the camera body, the improvement which comprises:

means, located in the interchangeable objective lens, for adjusting the aperture size of the lens without any source of manually controlling the adjusting means within the interchangeable objective lens;

a common electric terminal for data transmission from the interchangeable objective lens to the camera body;

means, located in the interchangeable objective lens, for transmitting a first electric data representative of the fully open aperture size and a second electric data representative of the minimum available aperture size peculiar to the objective lens, through said common electric terminal to the camera body;

means, located in the camera body, for manually setting exposure time including means for retaining the manually set exposure time regardless of a selection between the manual and automatic exposure control modes;

means, located in the camera body, for manually setting aperture including means for retaining the manually set aperture regardless of a selection between the manual and automatic exposure control modes;

means, located in the camera body, for restricting the manual aperture value setting within an aperture value range defined between the first and second electric data transmitted from the interchangeable objective lens;

means, located in the camera body, for performing a calculation for the manual exposure control mode in response to said manual exposure time setting means and said manual aperture value setting means;

a shutter means located in the camera body;

first means, located in the camera body, for controlling said shutter means in response to said manual exposure time setting means in the manual exposure control mode, and

second means, located in the camera body, for controlling said adjusting means in response to said manual aperture setting means in the manual exposure control mode.

2. The improvement according to claim 1, wherein said second controlling means includes means for calculating an aperture stop-down degree from the fully open

aperture size in response to said manual aperture value setting means and said first electric data received from the interchangeable objective lens.

3. The improvement according to claim 1, further comprising means for measuring light through the interchangeable objective lens with its aperture kept fully open.

4. The improvement according to claim 3, further comprising means for selecting between the manual exposure control mode and a program exposure control mode in which both exposure time and the aperture size are automatically controlled, means for calculating both the exposure time and aperture value in the program exposure control mode in response to said measuring means and said first and second electric data so that the calculated aperture value is restricted within the aperture value range defined between the first and second electric data, wherein said first controlling means is further responsive to the calculated exposure time in place of the manually set exposure time with the program exposure control mode selected, and said second controlling means is further responsive to the calculated aperture value in place of the manually set aperture value with the program exposure control mode selected.

5. The improvement according to claim 4, further comprising means, located in the interchangeable objective lens, for transmitting a third electric data representative of the focal length of the interchangeable objective lens through said common electric terminal to the camera body, wherein said exposure time and aperture value calculating means includes a plurality of exposure programs and means for adopting one of the programs in response to the third electric data, the first and second electric data being effective to restrict the calculated aperture value regardless of the selection of the program.

6. The improvement according to claim 4, wherein said mode selecting means is adapted to be capable of further selecting a shutter priority mode or an aperture priority mode, and further comprising means for calculating an aperture value in the shutter priority mode in response to said measuring means, said manually set exposure time and said first and second electric data so that the calculated aperture value is restricted within the aperture value range defined between the first and second electric data, and means for calculating an exposure time in the aperture priority mode in response to said measuring means, said manually set aperture value and said first electric data, wherein said first controlling means is responsive to the manually set exposure time in the shutter priority mode and responsive to the calculated exposure time in the aperture priority mode, and said second controlling means is responsive to the manually set aperture value in the aperture priority mode and responsive to the calculated aperture value in the shutter priority mode.

7. In a camera system having a camera body and an interchangeable objective lens removably coupled with the camera body, the improvement which comprises:

means, located in the camera body, for manually setting exposure time;

means, located in the camera body, for manually setting aperture value;

means, located in the camera body, for restricting the manual aperture value setting within an aperture value range;

means, located in the camera body, for measuring light through the interchangeable objective lens with its aperture fully open;

means, located in the camera body, for selecting one of manual, shutter priority, aperture priority and program exposure modes;

means for retaining the manually set exposure time and the manually set aperture value regardless of a selection among the manual, shutter priority, aperture priority and program exposure modes;

means, located in the camera body, for practicing an automatic exposure control calculation in one of the shutter priority, aperture priority and program exposure modes in response to at lest necessary one of the measuring means, the manually set exposure time and the manually set aperture value so that the calculated aperture value is restricted within the aperture value range;

first means located in the camera body, for controlling the shutter speed in response to the manually set or calculated exposure time;

second means, located in the camera body, for controlling the aperture size in response to the manually set or calculated aperture value;

a common electric terminal located in the interchangeable lens;

means, located in the interchangeable objective lens, for transmitting a first electric data representative of the fully open aperture size and a second electric data representative of the minimum available aperture size peculiar to the objective lens, through said common electric terminal to the camera body for the use in the restriction of manual aperture value setting in the camera body and for the use in the automatic exposure control calculation, and

means, located in the interchangeable objective lens, for adjusting the aperture size always in response to the second controlling means in any one of the manual, shutter priority, aperture priority and program exposure modes without any source of manually controlling the adjusting means within the interchangeable objective lens.

8. In a camera system capable of a manual and an automatic exposure control having a camera body and an interchangeable objective lens removably coupled with the camera body, the interchangeable objective lens comprising:

a camera electric terminal;

means for transmitting a first electric data representative of the fully open aperture size and a second electric data representative of the minimum available aperture size peculiar to the objective lens, through said common electric terminal to the camera body for the use in a restriction of manual aperture value setting in the camera body within an aperture value range defined between the first and second electric data and for use in an automatic exposure control calculation in the camera body;

means for transmitting a third electric data representative of the focal length of the interchangeable objective lens, through said common terminal to the camera body;

means for transmitting a fourth electric data representative of an error in fully open aperture metering which is to be caused by using the interchangeable objective lens, through said common terminal, and

means for adjusting the aperture size always under the control of the camera body in any one of the

manual and automatic exposure control mode without any source of manually controlling the adjusting means within the interchangeable objective lens.

9. In a camera system capable of a manual and automatic exposure control having a camera body and an interchangeable objective lens removably coupled with the camera body, the interchangeable objective lens comprising:

a common electric terminal;

means for transmitting a first electric data representative of the fully open aperture size and a second electric data representative of the minimum available aperture size peculiar to the objective lens, through said common electric terminal to the camera body for use in a restriction of manual aperture value setting in the camera body within an aperture value range defined between the first and second electric data and for use in an automatic exposure control calculation in the camera body;

means for transmitting a third electric data representative of the focal length of the interchangeable objective lens, through said common electric terminal to the camera body;

means for transmitting a predetermined data common to all of the available interchangeable objective lenses in the system, through said common terminal to the camera body, and

means for adjusting the aperture size always under the control of the camera body in any one of the manual and automatic exposure control modes without any source of manually controlling the adjusting means within the interchangeable objective lens.

10. In a camera system capable of a manual and automatic exposure having a camera body and an interchangeable objective lens removably coupled with the camera body, the improvement comprising:

means, located in the interchangeable objective lens, for adjusting the aperture size of the lens without any source of manually controlling the adjusting means within the interchangeable objective lens;

a common electric terminal for data transmission for the interchangeable objective lens to the camera body;

means, located in the interchangeable objective lens, for transmitting a first electric data representative of the fully open aperture size and a second data representative of the minimum available aperture size peculiar to the objective lens, through said common electric terminal to the camera body;

means, located in the interchangeable objective lens, for transmitting a third electric data representative of the focal length of the interchangeable objective lens through said common electric terminal to the camera body;

means, located in the camera body, for measuring light through the interchangeable objective lens with its aperture kept fully open;

means, located in the interchangeable objective lens, for transmitting a fourth electric data representative of an error in the fully open aperture light measurement which is inevitable depending on the interchangeable objective lens coupled with the camera body;

means, located in the camera body, for selecting between the manual exposure control mode and a program exposure control mode in which both exposure time and the aperture size are automatically controlled;

means, located in the camera body, for manually setting exposure time;

means, located in the camera body, for manually setting aperture value;

means, located in the camera body, for restricting the manual aperture value setting within an aperture value range defined between the first and second electrical data transmitted from the interchangeable objective lens;

means, located in the camera body, for calculating both the exposure time and aperture value free from the fully open aperture light measurement error in the program exposure control mode in response to said measuring means and said first, second and fourth data so that the calculated aperture value is restricted within the aperture value range defined between the first and second electric data, said calculating means including a plurality of exposure programs and means for adopting one of the programs in response to said third electric data, the first and second electric data being effective to restrict the calculated aperture value regardless of the selection of the program;

means, located in the camera body, for performing a calculation for the manual exposure control mode in response to said manual exposure time setting means and said manual aperture value setting means;

a shutter means located in the camera body;

first means, located in the camera body, for controlling said shutter means in response to the manually set or automatically calculated exposure time, and

second means, located in the camera body, for controlling said adjusting means in response to the manually set or automatically calculated aperture value.

11. The improvement according to claim **10**, further comprising means for retaining the manually set exposure time and the manually set aperture value against the selection between the manual and automatic exposure control modes.

[57] **ABSTRACT**

An objective of variable focal length includes a plurality of lens units of which the first, counting from front, is of negative power and the second is of positive power. At least the first and second lens units are moved with variation of the air separation therebetween to vary the focal length of the entire system. The objective is characterized in that at least one of the lens units is included with at least one refractive index distribution type lens arranged on the common optical axis of the other lenses.

OBJECTIVE OF VARIABLE FOCAL LENGTH

BACKGROUND OF THE INVENTION

1. Field of the Invention:

This invention relates to objectives of variable focal length, and more particularly to such an objective comprising a plurality of lens units of which the first and second counting from the front, i.e. objective side, are of negative and positive powers respectively, and are moved with variation of the amount of air separation therebetween to vary the focal length of the complete objective.

2. Description of the Prior Art:

In the objectives of variable focal length, besides the achievement of good correction of aberrations at a standard setting, it is generally required that the good correction of aberrations be maintained as stable as possible throughout entire range of variation of the focal length. To this end, all the movable lens units must be individually well corrected for spherical aberration, coma and astigmatism. So, each of such lens units is usually constructed with several lens elements.

Recently there have been an increasing demand for reducing the bulk and size of the varifocal objective and extending the range of the focal length. With respect to the former, in the type of varifocal objective comprising two or more lens units of which the first and second counting from the front are respectively negative and positive in the refractive power. The lens units are moved axially in differential relation to each other to vary the focal length of the complete objectives, so far as the paraxial region is concerned, either the power of each lens unit may be strengthened, or the interval between the principal points of the successive two of the lens units may be shortened. With respect to extending the range of variation of the focal length, so far as the paraxial region is concerned, either the power of each lens unit may be strengthened, or the total movement of the zoom lens unit may be elongated. For the paraxial region alone, a common means for achieving both a reduction in the size and an increase in the zoom ratio is found to strengthen the power of each zoom lens unit. For the intermediate and marginal zones, good stability of aberration correction is realized when the number of constituent lenses in each unit is increased in order to strengthen the power of the unit. Another method of strengthening the power of each unit is to increase the surface curvatures of each constituent lens. For this purpose, the minimum acceptable center thickness of the convex lens, or the minimum acceptable air separation of the concave lens surface must be increased. In either case, the overall thickness of each lens unit has to be increased, with the result that it becomes difficult to achieve a much-desired reduction of the physical length of the complete objective. Also, for a given value of the physical length, the longer the overall thickness of each lens unit, the shorter the total movement of the zoom lens unit. A much-desired increase in the zoom ratio becomes difficult to achieve.

In this connection, it should be pointed out that in the above-identified zoom lens unit, positive second lens unit often has the strongest power among all the lens units, thus contributing to a large proportion of the zoom ratio. If a reduction in size is attempted by further strengthening the power of the second lens unit, the necessary number of its constituent lenses increases. Concomitantly, its over all thickness tends to increase objectionably.

The thickness of last lens unit which increases due to the increase in the number of lenses also gives rise to a problem, i.e. if a flippable mirror or a beam splitter is positioned in a space between the rear vertex of the last lens unit and an image plane, a sufficiently large space cannot often be created. Such a vicious circle has placed a limitation on the reduction of the size and the increase of the range of variation of the focal length insofar as any usual homogenous medium lens system is adopted.

As a specific example, suppose a two-unit objective of variable focal length whose negative first and positive second units are moved with decreasing air separations therebetween as when zooming from the wide angle to the telephoto side is designed with an aim to reduce the total length of the entire system from the front vertex to the image plane. Such a design may be achieved by relying on the method of strengthening the power of the second lens unit in combination with shortening of the interval between the principal points of the first and second units. Then, increase of the power of the positive second unit calls for an increase in the necessary number of its constituent lenses to properly correct all aberrations therein itself. This involves an increase of the overall thickness of the second lens unit. Therefore, the principal point interval has to be increased. For this reason, this militates against a decrease in the total length of the entire system.

Such an increase of the overall thickness of the second lens unit has produced another problem. Since it is the last lens unit, for, as a flippable mirror or a prism occupies a space between the rear vertex of the second or last lens unit and the image plane, a somewhat long lens back is required. It is impossible to keep it at the minimum acceptable value.

Meanwhile, using the method of strengthening the power of each lens unit in shortening the total length of the complete objective of variable focal length makes correction of the Petzval sum difficult.

Taking an example of the two-unit objective whose first and second lens units counting from the front are negative and positive in power respectively. The focal length f of the entire system can be expressed by $f=f_1\times\beta_2$ where f_1 is the focal length of the negative first lens unit, and β_2 is the image magnification. Therefore, even for the same value of image magnification, whichever focal length of the positive second lens unit is shorter, the total length of the entire system can be shortened even more. To use this rule without sacrificing the preservation of the total zooming movements of the positive first and negative second lens units, the second lens unit has to be constructed in the telephoto form with such a power distribution that the principal point is brought farther ahead by increasing the tendency to the second lens unit to be of the telephoto type. So, an attempt to shorten the total length by this method results in a large negative value of the Petzval sum. This implies that the curvature of field is over-corrected.

Further, if the Petzval sum is corrected by lowering the refractive index of the convex lens, or by combining positive and negative lenses of strong power, the spherical aberration is increased very much and very large higher order aberrations are produced. Thus it becomes impossible to achieve good stability of aberration correction throughout the entire range of variation of the

focal length. It should be recognized that the reduction of the bulk and size of the objective of variable focal length and the good correction of the Petzval sum are contradictorily related to each other.

SUMMARY OF THE INVENTION

An object of the present invention is to eliminate the above-described drawbacks of the prior art, and to provide an objective of variable focal length which enables its bulk and size to be reduced with an increase in the range of variation of the focal length, while still permitting good stability of aberration correction to be achieved throughout the extended range of variation of the focal length.

Another object is to provide an objective of variable focal length which is amenable to easy assembling and adjusting techniques.

To achieve these objects, according to the present invention applied to the objective of variable focal length comprising a plurality of lens units of which the first counting from front, i.e. objective side, is of negative power and the second is of positive power, the first and second lens units being moved with varying air separations therebetween to vary the focal length of the entire system, at least one of the lens units is included with at least one refractive index distribution type lens.

The above-stated refractive index distribution type lens has a refractive index pattern along either the radius or the optical axis thereof (hereinafter referred to as "radial" or "axial" type, respectively). Both patterns of the radial and axial types can also take place in a single lens. Further, the radial type pattern has two directional aspects, one of which is to decrease the refractive index as the height from the optical axis increases, (hereinafter referred to as "positive gradient" power), and the other of which is to increase as the height increases (hereinafter referred to as "negative gradient" power).

As has been described above, the objective constituting the present invention has a feature that at least the second lens unit is made up by using at least one refractive index distribution type lens. Accordingly, it is possible possible to properly correct aberrations without involving any increase in the number of constituent lenses. Thus, a great reduction of the bulk and size and weight can be achieved. Further improved results can be attained when one or more of the lens units other than the second one is designed with the use of one or more of the refractive index distribution type lens. Again, the refractive index distribution type lens can take any form. So, when its surface curvature, focal length and refractive index gradient are controlled, the lens can embody a wide variety of capabilities. By selecting one or more of the lens units for employing such a lens and by arranging it in a desired position, a wide variety of forms of the lens system can be obtained.

BRIEF DESCRIPTION OF THE DRAWINGS

Odd-numbered FIGS. **1** to **11** are longitudinal section views of Examples 1 to 6 of specific objectives of the invention.

Even-numbered FIGS. **2** to **12** are graphic representations constituting the aberrations of the lenses of the present odd-numbered FIGS. **1** to **11** in three different focal length positions.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

FIGS. **1** and **2** illustrates an example of a specific objective constituting the present invention. In FIG. **1**, Ri(i=1, 2, 3, . . .) represents the i-th surface counting from front, Di(i=1, 2, 3, . . .) represents the axial thickness or air separation between the i-th and (i+1)th surfaces counting from front, and A and B represent the first and second lens units respectively, whose motions during zooming are roughly depicted by respective arrow-headed curves.

The aberration curves represent the spherical aberration, astigmatism and distortion when the focal length is f=100 mm, 138.9 mm, or 188.4 mm. The spherical aberration for spectral g-line or d-line is labelled g or d respectively, and S and M indicate the astigmatisms in the sagittal and meridional planes respectively.

The numerical data in accordance with which the objective of FIG. **1** can be constructed are listed in the following Tables 1-1 and 1-2, and the values of the coefficients of the terms of a refractive index distribution function for the used refractive index distribution type lens are listed in the following Table 1-3. In Table 1-1, f is the focal length, FNO is the F≠number, 2 w is the total image angle, Ri(i=1, 2, 3, . . .) is the radius of curvature of the i-th surface counting from front with the convex curvature toward the front being taken as positive, and the concave curvature as negative. Also, Di(i=1, 2, 3, . . .) is the axial thickness or air separation between the i-th and (i+1)th surfaces counting from front. Ni and Vi(i=1, 2, 3, . . .) are refractive index and Abbe number of the i-th lens counting from front respectively. Further, a refractive index distribution function for the radial type lens at the i-th place counting from front in terms of the height h from the optical axis can be expressed by the following formula:

$$Ni(h)=N_0+N_1h^2+N_2h^4+N_3h^6+N_4h^8+N_5h^{10}+\ldots \quad (1)$$

where N_O represents the value of refractive index on the axis, and N_1, N_2, N_3 . . . are the coefficients. The values for the g-line and d-line of the N_O and the coefficients are listed in Table 1-3. Table 1-2 shows the axial air separations between the lens units A and B during varying the focal length.

The objective of FIG. **1** has features which are described in detail below. This objective is constructed with, from front to rear, a negative first lens unit A and positive second lens unit B. As the focal length varies from the shortest or wide angle to the longest or telephoto side, the lens units A and B are moved axially while their air separation is shortened. The second lens unit B is constructed with, from front to rear, a positive radial gradient type lens defined by surfaces R7 and R8, and a negative radial gradient type lens defined by surfaces R9 and R10.

As the front lens R7, R8 in the positive second lens unit B has such a refractive index pattern that the refractive index becomes progressively lower as the distance in a perpendicular direction to the optical axis increases from the optical axis to the margin, the refractive index distribution coefficients N_1 and N_2 have negative values, or $N_1<0$, $N_2<0$. Such a refractive index distribution is used for correcting the spherical aberration of the positive lens R7, R8, since this lens, if of a homogeneous medium, would produce large residual

spherical aberration. That is, when the conditions or features $N_1<0$ and $N_2<0$ are satisfied, the refractive index pattern on the front or convex surface R7 of that positive lens can be made progressively lower from the optical axis to the marginal zone. Consequently that the spherical aberration which would otherwise be under-corrected as usual can be corrected toward the opposite direction. Because $N_2<0$, the third-order spherical aberration due to the positive gradient of refractive index in the medium of the lens is increased in a direction to be under-corrected. When this aberration is balanced with the aforesaid one of the front surface, good correction of spherical aberration and coma can be achieved.

Another advantage arising from $N_1<0$ is that because the medium of the lens gets a positive power $\phi(=-2NID)$, it shares the required power for the positive lens with its surface curvatures R7 and R8. This permits these curvatures to be weakened with a reduction of aberrations. Further, because the power of the positive or front lens can be strengthened, it is possible to increase the tendency of the second lens unit to be of the telephoto type.

With respect to the rear lens R9, R10 in the second lens unit B though of the convex form, because of its refractive index pattern, its refractive index becomes progressively higher with an increase in the height from the optical axis, and gets a negative power. When features $N_1<0$ and $N_2>0$ are satisfied, distortion in the wide angle side, and astigmatism in the wide angle and telephoto sides are well corrected. Further, the feature or $N_1>0$ implies that the negative power of the rear part of the second lens unit B is strengthened. This contributes to an increase in the tendency to the telephoto type. Another advantage is that as rays of light pass through the interior of the rear lens, over-corrected spherical aberration is produced particularly on the telephoto side, cancelling the residual under-corrected spherical aberration of the front lens R7, R8.

The use of such refractive index distribution type lenses in the objective of the invention produce additional advantages which are explained below.

Compared with the conventional second lens unit which usually requires five or more lenses provided that the conventional objective is of the same type as that of the objective of the invention, the positive second lens unit of the invention is constructed with only two lenses. Therefore, a great reduction of the weight and size has been achieved. Also, because the necessary number of lenses is greatly reduced, despite the fact that it is customary to assign very severe tolerances of the air separations and decentering to the second lens unit, the assembling and adjusting operations are facilitated. Also, the second lens unit B is used for correcting spherical aberrations in the telephoto positions, distortion in the wide angle positions, and astigmatism over the entire range of focal length.

The front and rear parts of the positive second lens unit B are both provided with the positive and negative gradient powers in the media thereof respectively. Consequently, the positive power of the front part of the positive second lens unit B and the negative power of the rear part can both be strengthened. Therefore, the tendency to the telephoto nature of the positive second lens unit B can be strengthened to bring the principal point farther ahead. Because the interval between the principal points of the negative first lens unit A and the positive second lens unit B can be shortened, and further the focal length of the positive second lens unit can be decreased, it made possible to achieve a great reduction of the total length of the entire system. Also, because the number of constituent lenses is so much reduced that the overall thickness of the second lens unit B can be held to a minimum, a sufficiently large lens back on the wide angle side can be preserved.

While the use of the method of strengthening the negative power of the rear part of the positive second lens unit to reduce the size of such an objective of variable focal length, as in the present invention, usually results in extreme over-correction of curvature of field, it is possible to avoid the fall of the curvature of field to over-correction by using the refractive index distribution type lens.

FIG. 3 illustrates another example of the objective of variable focal length according to the invention whose aberrations in the focal length positions of f=100 mm, 150 mm and 195 mm are shown in FIG. 4. This objective can be constructed in accordance with the numerical data given in Tables 2-1 to 2-3 where an equation for the refractive index distribution Ni(x) of the i-th lens which is of the axial type in terms of the axial distance, x, measured from the front vertex can be expressed by the following formula:

$$Ni(x)=N_0+N_1x+N_2x^2+N_3x^3+N_4x^4+\ldots \quad (2)$$

where N_0 is the refractive index at the front vertex, and N_1, N_2, N_3, . . . are refractive index distribution coefficients.

The objective of FIG. 3 comprises, from front to rear, a negative first lens unit A, a positive second lens unit B and positive third lens unit C. All three units being axially moved with the air separations between the units A and B and between the units B and C both being decreased as the focal length of the entire system is increased from the wide angle to the telephoto side.

The positive second lens unit B is included with a frontmost lens defined by surfaces R7 and R8 and a rearmost lens defined by surfaces R14 and R15. Both lenses are of the axial type and have such a pattern that the refractive index becomes progressively lower as the distance from the front to rear increases.

The frontmost lens R7, R8 has a positive power, and, because of its lowering refractive indices from the front surface to the rear surface, affects that spherical aberration which would otherwise usually result in large under-correction from the front surface of the unit B tends toward over-correction. Also, the astigmatism which would otherwise result in under-correction when in the wide angle and telephoto positions tends toward over-correction.

The rearmost lens R14. R15 has a positive power. Because of its lowering refractive indices from the front to the rear surface, it is able to correct the higher order spherical aberrations which have been too over-corrected by the positive frontmost lens R7, R8.

FIG. 5 illustrates a third specific example of the objective whose spherical aberrations for the spectral g- and d-lines, astigmatisms in the sagittal and meridonal planes S and M and distortion in the focal length positions of f=100 mm, 138.9 mm and 188.4 mm are shown in FIG. 6. The objective can be constructed in accordance with the numerical data given in Tables 3–1 to 3–3 for the radii of curvature, R, the axial thicknesses or air separations, D, and the refractive indices N and Abbe numbers V of the various lens elements. The subscripts are subscripts numbered consecutively from front to rear, and the plus and minus values of R indicate convex and concave surfaces relative to the front respectively. The refractive index distribution in the i-th lens counting from the front which is of the radial type can be expressed by the equation (1).

The objective of FIG. 5 comprises, from front to rear, a negative first lens unit A and a positive second lens unit B. Both lens units are axially moved with the air separation therebetween being decreased as the focal length of the entire system is varied from the shortest to the longest value. The front unit A consists of, from front to rear, a negative meniscus lens of forward convexity defined by surfaces R1 and R2 and a positive radial gradient type lens defined by surfaces R3 and R4. The rear unit B has its constituent lenses all made of homogeneous media.

The refractive index distribution type lens R3, R4 has such a pattern that the refractive index varies at a small rate in the paraxial region and drops steeply in the marginal zone. As the coefficient N_2 of the equation N(h) is $N_2<0$, it is able to correct barrel type distortion in the wide angle positions to a minimum.

Also in the telephoto positions, the spherical aberration produced from the second surface R2 of the frontmost or negative meniscus lens of the front unit A, as is largely over-corrected, is corrected to the opposite direction, when rays of light pass through the interior of the refractive index distribution type lens. Further, the coma in the telephoto positions is affected toward over-correction when the rays of light pass through the interior of that lens.

For this reason, the negative first lens unit which was heretofore constructed with three or four lenses can be constructed with only two lenses. A good stability of correction of the various aberration throughout the entire range is still achieved.

The use of the refractive index distribution type lens in the objective gives additional advantages which are explained below.

Because the negative first lens unit A, which is bulky and heavy as a rule, can be constructed with a greatly reduced number of constituent lenses, a great reduction in the weight and a great advance in compactness have been achieved. Moreover, this is accompanied with a possibility of shortening the total length of the entire system. Also, the effective diameter of the front unit necessary to the off-axis light pencil can be minimized. Further, concerning the aberration correction, barrel type distortion in the wide angle positions and spherical aberration and coma in the telephoto positions can be held to a minimum.

FIG. 7 illustrates a fourth specific example of the objective according to the invention whose aberrations in the focal length positions of f=100 mm, 171 mm and 287 mm are shown in FIG. 8. This objective can be constructed in accordance with the numerical data given in Tables 4–1 to 4–3, where the refractive index distribution is expressed by the equation (1).

The objective of FIG. 7 comprises, from front to rear, a negative first lens unit A, a positive second lens unit B, a negative third lens unit C and a positive fourth lens unit D. All of the lens units are axially moved with the air separations between the units A and B and between the units C and D being decreased, and the air separation between the units B and C being increased, as the focal length of the entire system is increased from the shortest to the longest value. The negative first lens unit A is provided with a positive radial gradient type meniscus lens defined by surfaces R1 and R2 at the frontmost position.

With the first lens unit of negative power, when the angular field is so widened as in the objective of the invention, the negative first lens unit produces large barrel type distortion in the wide angle positions. This has constituted an obstacle to aberration correction. In the objective of the invention, however, as the frontmost or negative meniscus lens of the negative first lens unit A, use is made of a positive radial gradient type lens having such a pattern that the refractive index in the marginal zone is smaller than that in the paraxial region. Accordingly, barrel type distortion produced from the first lens unit A in the wide angle positions is reduced.

Meanwhile, the second surface R2 of the negative meniscus lens of the negative first lens unit A usually produces large over-corrected spherical aberration. The impartment of such a refractive index pattern thereto reduces the tendency of the spherical aberration to be over-corrected, since the refractive index on the concave rear surface R2 of the negative meniscus lens becomes progressively smaller as the height from the optical axis increases.

The impartment of such a refractive index distribution also causes the rays of light in passing through the interior of the negative meniscus lens to produce spherical aberration and coma in the opposite direction to that in which they are produced from the second surface of the negative meniscus lens. Alternatively, it produces under-corrected spherical aberration and coma, thus producing an aberration correcting effect.

Therefore, it is possible to achieve an objective corrected for good stability of the various aberrations throughout the entire range of variation of the focal length.

The use of the refractive index distribution type lens in the objective provides additional advantages. The number of constituent lenses for the negative first lens unit of the objective of the type described above, which was heretofore usually four or more, is reduced to as few as three. This leads to a reduction of the weight and a decrease of the overall thickness of the negative first lens unit. Therefore, it is possible to shorten the total length of the entire system.

Also, barrel type distortion in the wide angle positions is held to a minimum, and the spherical aberration and coma in the telephoto positions can be properly corrected.

The above-described improved results can be attained particularly when the condition that $N_2<0$ where N_2 is the coefficient in the equation for the refractive index distribution N(h) is satisfied.

FIG. 9 illustrates a fifth specific example of the objective of variable focal length according to the invention whose aberrations in the focal length positions of f = 100 mm, 170.8 mm and 286 mm are shown in FIG. 10. This objective can be constructed in accordance with the numerical data given in Tables 5-1 to 5-3 where the refractive index distribution of the axial type lens is expressed by the equation (2).

The objective of FIG. 9 comprises, from front to rear, a negative first lens unit A, a positive second lens unit B, a negative third lens unit C and a positive fourth lens unit D. All of the lens units are axially moved with the air separations between the units A and B and between the units C and D being decreased, and the air separation between the units B and C being increased, as the focal length of the entire system is increased from the shortest to the longest value. The negative first lens unit A is provided with a positive radial gradient type lens defined by surfaces R1 and R2 at the frontmost position and an axial type lens having increasing refractive indices from the front surface R3 to the rear surface R4 and positioned on the image side of the radial type lens.

In the known wide angle objective having a configuration similar to that of the objective of the invention in that the first lens unit is of negative power, much barrel type distortion is produced in the wide angle positions. Thus, the negative first lens unit has been considered as an obstacle to improve aberration correction. According to the present invention, the frontmost or negative meniscus lens in the negative first lens unit A is imparted with such a refractive index distribution that the refractive index in the marginal zone is smaller than that in the paraxial zone. The frontmost lens use has a positive radial gradient type lens so that the barrel type distortion, produced from the negative first lens unit A in the wide angle positions, is minimized.

Meanwhile, the second surface R2 of the frontmost or negative meniscus lens in the first lens unit A produces spherical aberration in a direction to be largely over-corrected. The co-existance of the above-stated refractive index distribution reduces the tendency of spherical aberration to be over-corrected, because the refractive index in the concave surface R2 of the negative meniscus lens decreases with increases in the height from the optical axis.

The impartment of such a refractive index distribution to the negative meniscus lens also causes the rays of light passing in the interior thereof to produce spherical aberration and coma in the opposite direction to that in which the second surface R2 of the negative meniscus lens produces them, or under-corrected ones, thus producing a correcting effect. It should be recognized that the above-described improvement in aberration correction are attained particularly when the condition of $N_2 < 0$ is satisfied where N_2 is the coefficient of the equation (1) for the refractive index distribution N(h).

The other or rearmost lens, defined by surfaces R3 and R4 in the negative first lens unit A, has such a refractive index distribution that the refractive index becomes progressively higher as the distance from the front surface to the rear surface increases. This affects the spherical aberration which has been too under-corrected by the frontmost or negative meniscus lens toward the direction of being over-corrected.

Therefore, it is possible to achieve an objective of variable focal length corrected for good stability of aberrations over the extended range of variation of the focal length.

The advantages of the invention may be summarized as follows:

The number of constituent lenses for each of the lens units can be significantly reduced, enabling a great reduction of the weight and size to be achieved. The reduction of the number of constituent lenses of the positive second lens unit results in a reduction in its overall thickness. This leads to either or both of an increase of the total zooming movement of itself or any of the adjacent units and a reduction of the air separations between the second lens unit and any of the adjacent lens units. Therefore, it is very easy to achieve either or both of a great increase in the range of variation of the focal length and a great reduction of the total length of the entire system.

The use of at least one refractive index distribution type lens in either of the first and second lens units enables the interval between the principal points of the first and second lens units to be reduced. This leads to a decrease in the diameter of the first lens unit that admits of the off-axis light pencil. Therefore, the diameter of the outer lens barrel can be reduced. So, filters of smaller diameter become usable with the objective of the invention.

As for the aberrational problems, because each lens unit can be better corrected in itself than was heretofore possible, all the aberrations of the objective can be maintained more stable throughout the entire range of variation of the focal length. Because there is no necessity of using a compound-eye optical system, good image quality is preserved.

The reduction of the Petzval sum allows for an increase in the power of the positive second lens group. So, it becomes possible to shorten the physical length. Because the reduced Petzval sum is corrected by smaller surface curvatures or a gentler power arrangement than was heretofore required, the higher order aberrations can be reduced.

Ghosts which are very difficult to remove in the conventional objective can be significantly minimized due to the great reduction of the total number of lenses of the objective. From the same reason, as the light loss due to the surface reflection and internal absorption is reduced, the T-number can be made faster than was heretofore possible. The rapid reduction of the total number of lens surfaces implies that the cost of the multi-layer anti-reflection coatings is largely reduced. (The transmittance of the ordinary zoom lenses is not more than 90%, and, in the case of larger numbers of constituent lenses, it sometimes falls below 80%).

The assembling and adjusting operations are facilitated when the number of constituent lenses in each lens unit is reduced. In the past, it was impossible to build the zoom lens in ultra-small sized optical instruments such as sub-miniature cameras and gastrocameras, although there were urgent demands for it, since the total number of lenses of the complete zoom lens was very large, and the individual elements are very small in size. The use of the refractive index distribution type lens enables each lens unit to be constructed with only one or two lenses. So, the machining and assembling operations become far easier. Therely, it will be possible to install the zoom lens in the ultra-small sized optical instrument.

As has been described above, according to the present invention as applied to the two-unit objective of variable focal length whose first and second units are of negative and positive powers respectively, use is made of a refractive index distribution type lens made of a homogeneous medium in at least one of the two lens units. A great advance in the imaging performance, the reduction of the weight, the compactness, and further the zoom ratio have been achieved. This makes it possible to significantly reduce the complexity of structure of the operating mechanism for such a type of objective.

What is claimed is:

1. An objective of variable focal length comprising a plurality of lens units, of which the first lens unit, counting from an object side, has a negative refractive power and a second unit has a positive refractive power, at least said first and said second lens units being moved axially with their air separation being varied to vary the focal length of the entire system, whereby at least one of said lens units includes at least one refractive index distribution type lens varying in refractive index that is arranged on a common optical axis with said plurality of lens units, wherein said refractive index distribution type lens comprises a distribution of refractive indexes so that a change in aberrations due to a variation of the objective focal length is restricted.

2. An objective according to claim 1, wherein said refractive index distribution type lens is positioned in said first lens unit.

3. An objective according to claim 2, wherein said refractive index distribution type lens in said first lens unit has such a refractive index distribution that the refractive index becomes progressively lower as the height from the optical axis increases.

4. An objective according to claim 3, satisfying the following condition that, as the refractive index distribution in said refractive index distribution type lens is expressed by $N(h)=N_0+N_1h^2+N_2h^4+N_3h^6...$ where h is the height from the optical axis, N_0 is the refractive index on the optical axis, and N_1, N_2, N_3, . . . are the coefficients, $N_1<0$.

5. An objective according to claim 4, which satisfies the condition $N_2<0$.

6. An objective according to claim 5, wherein said refractive index distribution type lens is a negative lens having a concave surface on the image side.

7. An objective according to claim 6, wherein said negative lens is of a meniscus shape.

8. An objective according to claim 2, wherein said refractive index distribution type lens in said first lens unit has such a refractive index distribution that the refractive index becomes progressively higher as the axial distance from the front surface thereof increases.

9. An objective according to claim 1, wherein said refractive index distribution type lens is positioned in said second lens unit.

10. An objective according to claim 9, wherein said second lens unit includes a frontmost portion with a refractive index distribution type lens having a front convex surface in which the refractive index becomes progressively lower as the height from the optical axis increases.

11. An objective according to claim 10, wherein said refractive index distribution type lens has a refractive index that is variable in the optical axis direction.

12. An objective according to claim 10, satisfying the condition that as the refractive index distribution in said refractive index distribution type lens is expressed by $N(h)=N_0+N_1h^2+N_2h^4+N_3h^6+...$ where h is the height from the optical axis, N_0 is the refractive index in the paraxial region, and N_1, N_2, N_3, . . . are the coefficients, $N_1<0$ and $N_2<0$.

13. An objective according to claim 9, wherein said second lens unit includes a rearmost portion with a refractive index distribution type lens in which the refractive index becomes progressively higher as the height from the optical axis increases.

14. An objective according to claim 13, satisfying the condition that as the refractive index distribution in said refractive index distribution type lens is expressed by $N(h)=N_0+N_1h^2+N_2h^4+N_3h^6+...$ where h is the height from the optical axis, N_0 is the refractive index in the paraxial region, and N_1, N_2, N_3, . . . are the coefficients, and $N_1>0$.

15. An objective according to claim 14, which satisfies the condition $N_2>0$.

16. An objective according to claim 15, wherein said refractive index distribution type lens has a negative power.

17. An objective according to claim 1, further comprising a third lens unit which comprises another refractive index distribution type lens and has a negative refractive power.

18. An objective according to claim 1, further comprising a third lens unit which has a negative refractive power and a fourth lens unit which comprises another refractive index distribution type lens and has a positive refractive power.

[57] **ABSTRACT**

In a triplet type objective for a compact lens shutter camera with a diaphragm arranged behind the lens system, the first and the second lens elements are formed of plastic and the third lens element is formed of glass, so that it is advantageous in manufacturing cost and weight. Therefore, an F No. of the objective is small and aberrations, for example astigmatic difference, are corrected well.

TRIPLET TYPE OBJECTIVE WITH A DIAPHRAGM ARRANGED BEHIND THE LENS SYSTEM

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to an objective for compact lens-shutter cameras whose diaphragm is arranged behind the whole optical system, and more particularly to a compact wide angle objective with a simple construction for cameras for a spread use.

2. Description of the Prior Art

With a compact lens-shutter camera for cameras for a spread use, a wide angle objective with a diaphragm arranged behind the whole lens system is advantageous for accommodation in the camera, for compactization of the camera or the objective itself and for realization of precise focusing. As this kind of objective, triplet type objectives with F No. 4~2.8 and a total angular field coverage of 60°~64° have been proposed. With a wide angle triplet type objective, since a astigmatic difference tends to become large at a marginal angular field, it was conventional to construct this type of objective by using lens elements formed of glass with a high refractive index. For example, in Japanese patent application laid-open number Sho. 59-34510, all lens elements, one or two of which have an aspherical surface, are formed of glass with a high refractive index to construct an objective with a total angular field coverage of 64°, and F No. 3.5. In Japanese patent application laid-open number Sho. 57-2012, an objective with F No. 4 and a total angular field coverage of 64° has been realized by using glass with a high refractive index. But forming a lens element of glass of a high refractive index incurs an increase in the manufacturing cost.

On the other hand, in U.S. Pat. No. 3,784,287 or in Japanese patent application laid-open number Sho. 61-272710, a wide angle triplet type objective without using glass of a high refractive index have been proposed, but the objective in the former prior art is of F No. 5.6 and the objective in the latter prior art is of F No. 8.0 which are relatively small.

Further, in Japanese patent application laid-open number Sho. 62-183420, a wide angle triplet type objective with a diaphragm arranged behind the lens system comprising from the object side, a first positive lens formed of glass with a high refractive index, a second negative lens formed of plastic, a third positive lens formed of plastic. In the objective, the second and the third lenses are formed of plastic, so that manufacturing cost is low as well as the change in the back focus depending on the temperature is cancelled. And the first lens is formed of glass with a high refractive index, so that aberrations are corrected well. However, for securing sufficient marginal light rays, it is necessary to construct a diameter of the first lens so large that manufacturing cost tends to become high. Because, glass material, which is much expensive than plastic, is employed of the largest volume lens in the whole lens system.

SUMMARY OF THE INVENTION

An object of the present invention is to provide a triplet type wide angle objective with a compact size, a small F No. and light weight, whose manfuacturing cost is low, whose construction is advantageous in manufacturing of lens elements and whose aberrations are corrected well.

According to the present invention, the lens system comprises, from the object side, a first positive meniscus lens element having an object side surface convex to the object side, a second biconcave lens element, a third biconvex lens element and a diaphragm. The first and second lens elements are formed of plastic and the third lens element is formed of glass. Further the lens system fulfills the following conditions:

$$0.15<N_3-N_1<0.45$$

$$0.75<N_2/N_3<0.90$$

wherein, N_1 represents the refractive index of the first lens element, N_2 represents the refractive index of the second lens element, and N_3 represents the refractive index of the third lens element.

The features of the present invention, which are believed to be novel, are set forth with particularly in the appended claims. The present invention, both as to its organization and manner of operation, together with further objects and advantages thereof, may be best understood by reference to the following description, taken in conjunction with the accompanying drawing.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a cross sectional view of an objective according to the respective embodiments of the present invention.

FIGS. 2A to 2C represent the aberration curves of the embodiment 1 respectively;

FIGS. 3A to 3C represent the aberration curves of the embodiment 2 respectively;

FIGS. 4A to 4C represent the aberration curves of the embodiment 3 respectively;

FIGS. 5A to 5C represent the aberration curves of the embodiment 4 respectively;

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

The following description is provided to enable any person skilled in the optical and camera field to make and use the invention and sets forth the best modes contemplated by the inventors for carrying out our invention. Various modifications, however, will remain readily apparent to those skilled in the art, since the generic principles of the present invention have been defined herein specifically to provide a relatively economical and easily manufactured triplet type objective. The derivation of the formulas and the relation of the powers set forth herein can be accomplished with the assistance of a computer. The present invention represents the parameters of a compromise balance of acceptable aberrrations which can be relatively easily manufactured to provide a low cost lens system for utilization with a compact lens shutter camera.

In the drawings, FIG. 1 shows the position of the lens elements. Values of radii of curvature and axial distances for each lens element and air spaces in the respective embodiments are provided in the accompanying tables set forth herein, and the schematic cross sectional view of FIG. 1 follows the normal conventions of an object at the left-hand side of the drawing and the image plane at the right-hand side.

As shown in FIG. 1, the present invention provides a lens system comprising, from the object side, a first

positive meniscus lens element (L_1) having an object side surface convex to the object side surface, a second biconvex lens element (L_2), a third biconvex lens element (L_3), and a diaphragm (S). The first (L_1) and second (L_2) lens elements are formed of plastic and the third lens elements (L3) is formed of glass. Further the lens system fulfills the following conditions:

$$0.15<N_3-N_1<0.45 \quad (1)$$

$$0.75<N_2/N_3<0.90 \quad (2)$$

wherein, N_1 represents the refractive index of the first lens element (L_1), N_2 represents the refractive index of the second lens element (L_2), and N_3 represents the refractive index of the third lens element (L_3).

According to the present invention, the first positive lens element (L_1) and the second negative lens element (L_2) are made of plastic, so that the change in back focus caused by change of the temperature is cancelled. Although the first plastic lens element (L_1) has a low refractive index, the third lens element (L_3) formed of glass with a high refractive index prevents the petzval sum from becoming great. Further, because the radius of curvature of the third lens element (L_3) is larger than that of the first lens element (L_1) and the volume of the third lens element (L_3) is smaller than that of the first lens element (L_1), the weight of the lens system and the cost for manufacturing of the lens elements can decrease in comparison with a triplet type objective having a first lens element (L_1) formed of glass with a high refractive index.

Thus, the present invention is characterized in that the refractive index of the third lens element (L_3) is much greater than that of the first lens element (L_1) as represented by the condition (1). When the condition (1) is satisfied, image field of the objective can be kept substantially flat over angular field of 65° and the petzval sum can be kept substantially small. If the lower limit of the condition (1) is violated, the petzval sum cannot be kept small and the astigmatic difference at the great angular field becomes great. On the other hand, the upper limit of the condition (1) shows the highest limit of the refractive index of the glass which is normally available as the third lens element (L_3).

Condition (2) is for a ratio of the refractive index of the second lens element (L_2) to that of the third lens element (L_3). The refractive index of the second lens element (L_2) is about constant because the second lens element (L_2) is formed of plastic which is normally available for photographic lens. Therefore, if the upper limit of the condition (2) is violted, the refractive index of the third lens element (L_3) becomes so small that the third lens element (L_3) cannot be formed of glass with a high refractive index, and the petzval sum increases so much that it becomes difficult to correct the astigmatic difference and a field curvature well. On the other hand, the upper limit of the condition (2), as same as in the condition (1), shows the highest limit of the refractive index of glass which is normally available as the third lens element (L_3).

Furthermore, according to the present invention, it is desirable to fulfill the following conditions.

$$2.5<d_2/d_4<4.0 \quad (3)$$

$$0.55<|f_{12}|/f<0.8 \quad (4)$$

$$0.3<f_3/f<0.6 \quad (5)$$

wherein, d_2 represents the axial distance between the first lens element (L_1) and the second lens element (L_2), d_4 represents the axial distance between the second lens element (L_2) and the third lens element (L_3), f_{12} represents the compound focal length of the first (L_1) and the second (L_2) lens elements, f_3 represents the focal length of the third lens element (L_3), and f represents the focal length of the lens system.

Condition (3) is for correcting the field curvature well. If the upper limit of the condition (3) is violated, the petzval sum increases so much that it becomes difficult to correct the field curvature, and the diameter of the first lens element (L_1) must be constructed large for securing sufficient amount of marginal light rays. In contrast thereto, if the lower limit of the condition (3) is violated, a spherical aberration is in undercorrection state and it becomes difficult to correct a distortion, a astigmatism and a chromatic aberration, while the petzval sum decreases.

Condition (4) is desirable for compactization of the objective and for keeping a vignetting small. If the upper limit of the condition (4) is violated, the vignetting and the field curvature increase. In contrast thereto, if the lower limit of the condition (4) is violated, the total length of the lens system including the back focal distance increases so long that it is difficult to construct the lens system with compact in size, while the vignetting becomes small.

Condition (5) is desirable for decreasing the change of aberrations depending on the decentering of the third lens element (L_3) from the optical axis defined by the first (L_1) and second (L_2) lens elements. If the upper limit of condition (5) is violated, the vignetting at a large angular portion of the field increases and it becomes difficult to correct the field curvature well. On the other hand, if the lower limit of condition (5), the focal length of the third lens element (L_3) becomes so short that the change of aberrations depending on the decentering of the third lens element (L_2) increases.

Furthermore, for correcting aberrations more satisfactory, the lens system is recommended to fulfill the following condition instead of the condition (5).

$$0.32<f_3/f<0.5 \quad (6)$$

According to this invention, the first (L_1) and second (L_2) lens elements are formed of plastic, so that it becomes easier to employ an aspherical surface. Especially, when the aspherical surface is employed for at least one surface of the first lens element (L_1), the spherical aberration, the distortion, the field curvature and the coma which are not so satisfactory corrected in case of an object consisting of only spherical lens elements can be corrected almost completely.

The following tables 1 to 4 disclose, respectively design parameters of embodiments 1 to 4 of the present invention. In the embodiments r_1, r_2, r_3 . . . is respectively the radius of curvature from the object side, and the d_1, d_2, d_3 . . . is respectively the axial thickness including both air spaces and the actual thickness of a lens element. Nd_1, Nd_2, Nd_3 is respectively the refractive index of the first through third lens element and νd_1, νd_2, νd_3 is respectively the abbe number of the first (L_1) through third lens element (L_3). A surface with the mark * represents an aspherical surface, whose configuration is defined as follows:

$$X = \frac{Y^2}{ri + ri\sqrt{1 - \left(\frac{Y}{ri}\right)^2}} + AY^2 + BY^4 + CY^6 + DY^8 + EY^{10} + FY^{12} + \ldots$$

wherein, X represents the coordinate along the optical axix measured from an imaginary plane tangent to the aspherical surface perpendicularly to the optical axis, Y represents the coordinate perpendicular to the optical axis from the optical axis, ri represents a paraxial radius of curvature, and A, B, C, D, . . . is aspherical coefficient.

As can be readily appreciated, it is possible to deviate from the above embodiments of the present invention and, as will be readily understood by those skilled in the optical art, the invention is capable of many modifications and improvements within the scope and spirt thereof. Accordingly, it will be understood that the invention is not to be limited by these specific embodiments, but only by the scope and spirit of the appended claims.

What is claimed is:

1. A triplet type objective comprising,

(a) a lens system which includes from the object side;

a first positive meniscus lens element having an object side surface convex to the object side,

a second biconcave lens element,

a third biconvex lens element,

wherein, the first and the second lens elements are formed of plastic and the third lens element is formed of glass, and

(b) a diaphragm arranged behind the lens system,

(c) wherein the lens system fulfills the following conditions:

$$0.15<N_3-N_1<0.45$$

$$0.75<N_2/N_3<0.90$$

wherein:

N_1 represents the refractive index of the first lens element;

N_2 represents the refractive index of the second lens element;

N_3 represents the refractive power of the third lens element.

2. A triplet type objective as claimed claim 1, wherein the triplet type objective fulfills the following conditions:

$$2.5<d_2/d_4<4.0$$

$$0.55<|f_{12}|/f<0.8$$

$$0.3<f_3/f<0.6$$

wherein,

d_2 represents the axial distance between the first lens element and the second lens element;

d_4 represents the axial distance between the second lens element and the third lens element;

f_{12} represents the compound focal length of the first and the second lens elements;

f_3 represents the focal length of the third lens element;

f represents the focal length of the lens objective.

3. A triplet type objective as claimed claim 1, wherein one of the surfaces of the first lens element is an aspherical surface.

[57] **ABSTRACT**

A system and method for determining a rotational angle of an objective pattern which involves calculating the area A and linear moments M_x and M_y of the pattern from binary picture elements formed after optically sensing the pattern. The picture elements are stored in the memory in binary form. The center of gravity of the objective pattern is calculated on the basis of the area A and the linear moments M_x and M_y, and a circular or ring-like search region (a window) is formed about that center of gravity. Thereafter, significant picture information in the search region is extracted from the picture information stored in the memory (in either an inverted or non-inverted state). The rotational angle of the objective pattern is then determined either by using a moment of inertia method or a inter two-gravity centers method calculation. The selection between the moment of inertia method and the inter two-gravity centers method can be performed by means of pre-set switch state information.

SYSTEM FOR DETECTING ROTATIONAL ANGLE OF OBJECTIVE PATTERN

BACKGROUND OF THE INVENTION

The present invention relates generally to an apparatus in which an objective pattern is extracted by an image sensor, such as a television camera, then subjected to image processing to detect a rotational angle in order to inspect or recognize an objective pattern.

One conventional detection system utilizes a method, known as the moment of inertia method of calculation, in which an optically-sensed pattern is binary coded, and in which a main axis and a center of gravity of an equivalent ellipse are obtained from calculations using the linear moments, quadratic moments geometric moments and an area of the binary-coded pattern.

Thus, a rotational angle θ and a center of gravity P_G (P_{GX}, P_{GY}) are obtained through the following expressions (1) and (2):

$$\tan 2\theta = 2I_{xy}/(I_y - I_x) \quad (1)$$

$$P_{GX} = M_x/A,\ P_{GY} = M_y/A \quad (2)$$

where the various symbols are defined as follows:

M_x: the linear moment of the pattern with respect to the x-axis;

M_y: the linear moment of the pattern with respect to the y-axis;

I_x: the quadratic moment of the pattern with respect to the x-axis;

I_y: the quadratic moment of the pattern with respect to the y-axis;

I_{xy}: the synergistic moment of the pattern;

A: the area of the objective pattern; and

θ: the rotational angle.

Using this moment of inertia method of calculation, the rotational angle θ can be detected with relatively high accuracy for an elongated objective pattern, but not for an objective pattern which is more square or circular. In square or circular patterns, the quadratic moments I_x and I_y have similar values, and very small errors in quantization of the pattern are magnified when the denominator at the right hand side of the above-mentioned expression (1) approaches zero. Therefore, if rotation of an objective pattern is normalized by using a rotational angle obtained by the moment of inertia method described above, large errors could occur due to the introduction of errors based on shape-dependent calculations rendering any further pattern inspection and recognition of little practical use.

SUMMARY OF THE INVENTION

It is an object of the present invention to provide a system for detecting a rotational angle of an objective pattern in which accurate pattern detection can be achieved without shape-dependent errors.

Additional objects and advantages of the invention will be set forth in part in the description which follows, and in part will be obvious from the description, or may be learned by practice of the invention. The objects and advantages of the invention may be realized and attained by means of the instrumentalities and combinations particularly pointed out in the appended claims.

To achieve the objects and in accordance with the purpose of the invention, as embodied and broadly described herein, the method for detecting a rotational angle of an objective pattern comprises the steps of: (a) optically sensing an objective pattern by a picture sensor to form a sense signal; (b) binary coding the sense signal into picture elements; (c) calculating an area of the objective pattern and a plurality of linear moments of the objective pattern from the picture elements; (d) calculating a center of gravity of the objective pattern from the area and the linear moments; (e) storing the area, linear moments, center of gravity and the binary-coded picture elements into a memory; (f) calculating a displacement of the center of gravity corresponding to a difference between a center of gravity of a predetermined standard picture sample and the center of gravity of the objective pattern; (g) determining an appropriate search region from among the binary-coded picture elements and reading out data corresponding to the search region; (h) normalizing a position of the search region: and (i) calculating a rotational angle for the objective pattern based on predetermined mathematical formulae and utilizing the stored information.

The accompanying drawings, which are incorporated in and constitute a part of this specification, illustrate one embodiment of the invention and, together with the description, serve to explain the principles of the invention.

BRIEF DESCRIPTION OF THE DRAWINGS

FIGS. **1A**, **1B**, **2A**, **2B**, **3A**, **3B**, **4A** and **4B** are objective pattern diagrams illustrating principle of the present invention;

FIG. **5** is a block diagram illustrating a system for detecting a rotational angle of an objective pattern in accordance with a preferred embodiment of the present invention;

FIG. **6** is a flow chart illustrating the operation of the system of FIG. **5**;

FIG. **7** is a flow chart illustrating a switch setting operation; and

FIG. **8** is a timing diagram for explaining the operation of the embodiment of FIG. **5**.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENT

Reference will now be made in detail to the present preferred embodiment of the invention, an example of which is illustrated in the accompanying drawings in which like reference characters refer to corresponding elements.

First, referring to FIGS. **1A** through **4B**, a principle of the present invention called the inter two-gravity center method will be described. FIGS. **1A**, **2A**, **3A**, and **4A** each illustrate different objective patterns. Specifically, FIG. **1A** illustrates a case where black letters CH are written on a white circular pattern. FIG. **2A** illustrates a case where, for example, a hole HL is bored in a white circular pattern similar to the preceding one. FIG. **3A** illustrates a case where a notch BL is formed in a white circular pattern similar to FIG. **2A**. And FIG. **4A** illustrates a case where a protrusion PN is formed on a white circular pattern similar to FIG. **3A**. Each of these figures illustrates an example in which it is difficult to detect a rotational angle with high accuracy when using the moment of inertia method of calculation.
