FIG. **25** shows a main part of an image taking optical system in the fourteenth embodiment of the present invention. As in the thirteenth embodiment, because the adapter optical system **50** has the same optical axis as that of the relay lens system **52***c*, the relayed images **64***a* and **64***b* will be formed in substantially the same positions and will be taken by one image taking device **53**.

A lenticular lens **67** is arranged just before the light receiving surface of this image taking device **53** which is commonly used. When the right and left images are formed at intervals of one row or one line by the image taking device **53**, the two images will be separately taken. This embodiment has also an advantage in that only one image taking device **53** is required. The other effects are the same as in the thirteenth embodiment. By the way, the lens data of this embodiment are the same as in the thirteenth embodiment.

FIGS. **26**A and **26**B show an objective optical system in the fifteenth embodiment of the present invention. In this embodiment, the visual field direction is 30 degrees with the lengthwise direction of the endoscope (the optical axis direction of the relay lens). The reflecting prisms **68***a*, **68***b* and **69***a*, **69***b* forming the front groups **54***a* and **54***b* may be respectively two separate bodies or one integral body.

FIG. **27** shows an objective optical system in a modification of the fifteenth embodiment of the present invention. As in the fifteenth embodiment, a perspective objective optical system **70** is formed. In this modification, the visual field direction is 70 degrees with the lengthwise direction of the endoscope (the optical axis direction of the relay lens). The reflecting prisms **68***a*, **68***b* and **69***a*, **69***b* may be respectively two separate bodies or one integral body.

In the fifteenth embodiment and its modification, the visual field direction can be varied by varying the angles of the reflecting prisms **68***a*, **68***b* and **69***a*, **69***b*. Therefore, when the front group part is formed to be interchangeable, various visual field directions or visual field angles will be able to be obtained by interchanging only this front group. Needless to say, even when the entire objective optical system is formed to be interchangeable, the same effects will be obtained. The other effects are the same as in the tenth embodiment.

FIG. **28** shows an image taking optical system in the sixteenth embodiment of the present invention. As in the fifteenth embodiment, in this embodiment, the perspective objective optical system **70** is used. In this embodiment, the visual field direction is 45 degrees with the lengthwise direction of the endoscope (the optical axis direction of the relay lens). The reflecting prism **71** is integral on the right and left.

That is to say, in the illustrated tenth to fifteenth embodiments, the optical system divided into two parts of the front groups **54***a* and **54***b* is adopted. However, in this embodiment, a common reflecting prism **71** is used to form a front group **54** functioning the same as the two separated front groups **54***a* and **54***b*.

Negative lens systems **72***a* and **72***b*, such as negative power elements, and positive lens systems **73***a* and **73***b*, such as positive power elements forming the front group **54** on the left and right are formed in pairs as arranged eccentrically respectively on the left and right and are rotatable as illustrated. Therefore, the arranging direction of the two incident pupils of the objective optical system, that is, the direction of the parallax (the direction of d in FIG. **28**) can be varied and it is very effective in permitting stereo-observing of an object in many directions.

In this embodiment, with the rotation of the negative lens systems **72***a* and **72***b* and positive lens systems **73***a* and **73***b*, the incident pupil of the pupil image forming lens system **61** will also rotate. In the embodiment shown in FIG. **28**, the adapter optical system **50** shows an example in case the same formation as of the eleventh embodiment is adopted. The image forming lens systems **63***a* and **63***b* and the image taking devices **53***a* and **53***b* will synchronously rotate to prevent the beam from being intercepted.

Even in this embodiment, when the angle of the reflecting prism **71** is varied; the visual field direction will be able to be varied, when the combination of the focal distances of the negative lens and positive lens is varied, the visual field angle will be able to be varied; and when the optical axis distance between the negative lens and positive lens on the left and right is varied, the magnitude of the parallax will be able to be varied.

This embodiment can be applied to another adapter optical system. However, as mentioned above, with the rotation of the negative lens systems **72***a* and **72***b* and positive lens systems **73***a* and **73***b*, the projected pupil of the pupil image forming lens system **61** will also rotate. Therefore, it is necessary to rotate such parts having left and right separate optical axes as, for example, the mirror parts **62***a* and **62***b*, image forming lens systems **63***a* and **63***b*, image taking devices **53***a* and **53***b* and the like as synchronized in the tenth embodiment in FIG. **20**. The other effects are the same as of the tenth embodiment.

FIG. **29** shows the seventeenth embodiment of the present invention wherein the front group **54** including the negative lens systems **72***a* and **72***b* and positive lens systems **73***a* and **73***b* is arranged on the object side of the reflecting prism **71**.

In this embodiment, as the rotating parts in the front group **54** part can be concentrated in one place (in this case, on the object side of the reflecting prism **71**) as compared with the sixteenth embodiment, the formation is simple. Also, FIG. **29** shows an example wherein the adapter optical system **50** having the same formation as that of the thirteenth embodiment is used. The opening part of the shutter **66** synchronously rotates so that the beam may not be intercepted. At this time, other parts such as the image forming lens **63** and image taking device **53** may also rotate together with the shutter **66**.

FIG. **30** shows unit formations of the eighteenth embodiment of the present invention. In FIG. **30**A, the unit formation comprises the front group unit **81** having the front groups **54***a* and **54***b* built-in, the rear group—relay lens system—pupil image forming lens system unit **82** having the rear group **55**, relay lens systems **52***a*, **52***b* and **52***c* and pupil image forming lens system **61** built-in, the image forming lens system unit **83** having the image forming lens systems **63***a* and **63***b* built-in and the image taking device unit **84** having the image taking devices **53***a* and **53***b* built-in. By the way, the connecting part of the rear group—relay lens system—pupil image forming system unit **82** and the image forming lens system unit **83** corresponds to the border of the input section **25** and output section **24** shown in FIG. **5**.

FIG. **30**B shows a formation of the image forming lens system—image taking device unit **85** wherein, in FIG. **30**A, the image forming lens systems **63***a* and **63***b* and image taking devices **53***a* and **53***b* are made as one unit.

FIG. **30**C shows a formation in FIG. **30**A of the objective optical system unit **86** combining the front groups **54***a* and **54***b* in the front group unit **81** and the rear group **55** in the rear group—relay lens system—pupil image forming lens system unit **82**, the relay lens system—pupil image forming lens system unit **87** having the relay lens systems **52***a*, **52***b* and **52***c* and pupil image forming lens system **61** built-in and the image forming lens system—image taking device unit **85**, the same as in FIG. **30**B.

In FIG. **30**D, the objective optical system (that is, the front groups **54***a* and **54***b* and the rear group **55**), relay lens systems **52***a*, **52***b* and **52***c* and pupil image forming lens system **61** are formed of the objective optical system—relay lens system—pupil image forming system unit **88** and the image forming lens system—image taking device unit **85** are made as one unit.

In FIG. **30**E, the objective optical system and relay lens systems **52***a*, **52***b* and **52***c* are formed of the objective optical system—relay lens system unit **89** made one unit and the pupil image forming lens system **61**, image forming lens systems **63***a* and **63***b* and image taking devices **53***a* and **53***b* are formed of the pupil image forming lens system—image forming lens system—image taking device unit **90** are made as one unit.

In FIG. **30**F, the front group unit **81**, rear group **55** and relay lens systems **52***a*, **52***b* and **52***c* are formed of the rear group—relay lens system unit **91** and pupil image forming lens system—image forming lens system—image taking device unit **90** are made as one unit.

In FIG. **30**G, the relay lens systems **52***a*, **52***b* and **52***c* are formed of the relay lens system unit **92**, objective optical system unit **86** and pupil image forming lens system—image forming lens system—image taking device unit **90** are made as one unit. By the way, in FIGS. **30**B to **30**G, the lens system within each unit is shown with the reference numeral omitted.

Also, in FIGS. **30**A to **30**G, the ocular adapter **45'** shown in FIG. **16**D may be made connectable.

In FIG. **31**, the front group unit **81** is explained further. FIG. **31**A shows a front group unit **81** using a common front group **54**. In case it is fitted, a pupil dividing type stereoendoscope in the related art will be able to be formed.

FIG. **31**B shows the front group unit **81** of a visual field angle of 70 degrees. FIG. **31**C shows the front group unit **81** of a visual field angle of 40 degrees. When they are replaced, any desired visual field angle will be obtained.

FIGS. **31**D and **31**E show a front group perspective unit **81** of a visual field direction of 70 degrees. FIG. **31**E is a view as seen from the rear of FIG. **31**D. When the reflecting prism **71** is replaced, the front group perspective unit **81** of any visual field direction will be able to be formed.

FIG. **31**F shows the front group unit **81** in which the parallax is reduced and the optical axes of the front groups **54***a* and **54***b* are brought close to each other to make the distance d' smaller than the other optical axis distance d. In FIGS. **31**A to **31**F, if the beams from the front groups **54***a* and **54***b* are made substantially afocal beams, when the unit is displaced, a focus lag and image lag will be able to be controlled.

FIG. **32** shows a formation of the objective optical system unit.

FIG. **32**A shows an objective optical system unit **86** comprising the front group **54** and rear group **55** arranged to share the same optical axis. When it is used, the pupil dividing type stereoendoscope in the related art will be able to be formed. FIG. **32**B shows an objective optical system unit **86** having the front groups **54***a* and **54***b* of a visual field angle of 70 degrees. FIG. **32**C is of an objective optical system unit **86** having the front groups **54***a* and **54***b* of a visual field angle of 40 degrees. When these are replaced, any desired visual field angle will be obtained.

FIG. 32D is of a perspective objective optical system unit **86** of a visual field direction of 70 degrees. FIG. **32**E is a front view of FIG. **32**D. When the reflecting prism **71** is replaced, a perspective objective optical system unit of any visual field direction will be able to be formed. By the way, in FIG. **32**E, the light guide is omitted.

FIG. **32**F shows an objective optical system unit in which the parallax is reduced and the optical axes of the two front groups **54***a* and **54***b* are brought close to each other so that the optical axis distance d' may be smaller than d, for example, in FIG. **32**B and others.

FIG. **33** shows a formation of a unit including the rear group **55**, relay lens systems **52***a* and **52***b* and pupil image forming lens system **61**.

FIG. **33**A shows the rear group—relay lens system—pupil image forming lens system unit **82** including the rear group **55**, relay lens systems **52***a* and **52***b* and pupil image forming lens system **61**. FIG. **33**B shows the relay lens system—pupil image forming lens system unit **87** including the relay lens systems **52***a* and **52***b* and pupil image forming lens system **61**. FIG. **33**C shows the rear group—relay lens system unit **91** including the rear group **55** and relay lens systems **52***a* and **52***b*. FIG. **33** shows the relay lens system unit **92** comprising the relay lens systems **52***a* and **52***b*.

Any number of relaying times of the relay lens system can be used. As required, different lengths for the inserted section different can be selected.

The respective units in the eighteenth embodiment can be formed by adopting a part of the optical system of the tenth to seventeenth embodiment.

According to the eighteenth embodiment, the stereoendoscope of the formation adapted to the using object can be selected and used. The other effects are the same as the tenth to seventeenth embodiments.

The following nineteenth and twentieth embodiments are embodiments wherein formations (a) in the means and operations for solving the above mentioned problems are used. When a plurality of images taken in by an objective optical system and having a parallax between them are transmitted by a common image transmitting optical system, are taken and are selectively displayed by a displaying means, optimum stereo-images will be provided.

FIG. **34**A shows a formation of a stereoendoscope apparatus **101** provided with the nineteenth embodiment of the present invention and an operation made by using the stereoendoscope **102** of the nineteenth embodiment. FIG. **34**B shows an arrangement of an objective optical system **121** as seen from the distal end surface of the stereoendoscope **102**.

This stereoendoscope apparatus **101** comprises a stereoendoscope **102** having an image taking means for taking a plurality of images having a built-in parallax, a CCU **103** processing signals for this imaging means, a distributor **104** connected to this CCU **103** and distributing video signals, a color monitor **105** as plural displaying means displaying the video signals distributed by this distributor **104** and head mounted displays (abbreviated as HMD's) **106** and **107**.

In FIG. **34**A, a rigid inserted section **111** of the stereoendoscope **102** is inserted toward an affected part **114** from a hole **113** in an abdominal part **112** of a patient. Two operators **115** and **116** respectively fit HMD's to their head parts, observe the affected part **114** with stereo-inspection and treat the affected part **114** by using treating tools **117** and **118**. The treating tools **117** and **118** may be inserted through other holes or through channels in the stereoendoscope **102**.

Also, another observer **119** (an assistant, nurse or spectator) observes the same affected part with stereo-inspection by observing the color monitor **105** with shutter spectacles **120** fitted.

The stereoendoscope **102** comprises an objective optical system **121**, relay optical system **122**, adapter optical system **123** and image taking means **124** in the order mentioned from the object side.

At least three images having a parallax between them and formed by the objective optical system **121** are transmitted by one (or plural) relay optical system **122** and are spatially (or timely) separated and formed by respective image taking devices forming the image taking means **124**. The electrical signals of the respective images photoelectrically converted by the image taking means **124** are converted to video signals by the CCU **103**, are further divided into signals of any two images by the distributor **104** and are displayed by the color monitor **105** and HMD's **106** and **107** which are to be displaying means.

In this embodiment, when the various optical systems shown so far are used as combined with the objective optical system **121** and adapter optical system **123**, the stereo-image optimum to the respective operators and observers will be able to be effectively provided.

When a plurality of images are transmitted by one relay optical system built-in in one tubular inserted section **111**, only one hole **113** in the abdominal part **112** is required and the burden on the patient will be able to be reduced.

As shown, for example, in FIG. **34**B, the objective optical system **121** is formed of six objective lens systems **121***a* to **121***d* arranged in the positions separated by a fixed distance from the center axis at an angle of 60 degrees from the center axis of the inserted section. The six images by these objective lens systems **121***a* to **121***f* are taken, for example, by six image taking devices forming the image taking means **124** through the common relay optical system **122** and the adapter optical system **123** formed, for example, of three adapter lens systems.

According to this formation, by selecting the image, for example, by the objective lens systems **121***a* and **121***d*, a stereo-image having a large parallax can be obtained and, by selecting the image by the objective lens systems **121***b* and **121***e*, a stereo-inspection having a large parallax in the direction different by 60 degrees is possible. Further, by selecting the image by the objective lens systems **121***c* and **121***f*, a stereo-inspection having a large parallax in the direction different by 120 degrees is possible.

Further, by the combination in the above mentioned case, the parallax will become small. However, by selecting the image, for example, by the objective lens systems **121***a* and **121***c* or the objective lens systems **121***a* and **121***e*, an image having a stereo-feel in various directions can be obtained.

By the way, a remote display selecting means whereby the operator **115** using the displaying device can remotely select the two images distributed by the distributor **104** to the displaying device side of the HMD **106** or the like by a wireless remote controlling apparatus using infrared rays or ultrasonic waves may be provided.

An observing direction displaying means is provided whereby, in case the image by the objective lens systems (for example, **121***b* and **121***e*) in the parallax direction different from the parallax direction of a set of objective lens systems (for example, **121***a* and **121***d*) as a reference is selected, the parallax direction changing angle (in this case, 60 degrees) will be displayed within the displaying device so that the direction in which the operator **115** or the like is observing may be simply found.

By the way, in this embodiment, n (at least three or more) (in FIG. **34**, n=6) objective images are transmitted by one relay optical system **122** but may be transmitted by n-i relay optical systems (here, i=1 to n-1).

FIG. **35** shows a formation of the stereo-endoscope **131** of the twentieth embodiment of the present invention. FIG. **35A** shows a general formation of the stereoendoscope **131**. FIG. **35B** shows an elevation as seen from the distal end surface in FIG. **35A**. FIG. **35C** shows an arrangement of image taking devices as seen from the front surface side in FIG. **35A**. In this embodiment, too, several sets of stereo-images can be obtained.

Several front groups **133** (**133***a* to **133***f*) forming an objective optical system **132** arranged on the distal end side of the rigid inserted section **111** take in images having a parallax between them and an image **135** is formed in substantially superimposed positions by one common rear group **134**, is relayed several times by one common relay optical system and becomes a final image **137**.

This final image **137** is of several superimposed images. These images have their pupils spatially separated by a pupil image forming lens system **138** and, further, respective images **141** (**141***a* to **141***f*) are formed on CCD's **140** (**140***a* to **140***f*) by image forming lenses **139**.

In this embodiment, six images having a parallax between them can be obtained. When two of the images are selected and displayed, the images having various stereo-feels and parallaxes will be able to be stereo-inspected. Also, several persons can stereo-observe in separate directions.

FIGS. **36A** to **36F** show distal end side formations of the stereoendoscope of the twenty-first embodiment of the present invention. FIG. **36B** is an elevation of FIG. **36A**. FIG. **36C** shows an optical system as seen from the side of FIG. **36A**. FIG. **36D** is an elevation of FIG. **36C**. FIG. **36E** shows FIG. **36C** as bent. FIG. **36F** is an elevation of FIG. **36E**.

In this embodiment, the inserted section **152** can be bent on the distal end side.

A front group optical system **153**, a rear group **154***a* forming a relay optical system **154** and a relay lens system **154***b* are arranged from the distal end side within the inserted section **152**. The distal end section **155** of the inserted section covering the objective optical system **153** is formed of a tubular frame having a curvable hose structure. The proximal side from the relay optical system **154** is formed of a rigid tubular frame.

Mirrors **158** and **159** are arranged between concave lenses **156***a* and **156***b* as of a front group and convex lenses **157***a* and **157***b* forming the objective optical system **153** and are rotatable respectively around axes **161** and **162**.

When the mirrors **158** and **159** are rotated simultaneously with curving from the straight seen state in FIG. **36C**, the distal end section **155** will be curved to be bent as in FIGS. **36E** and **36F**. According to this embodiment, the observation can be made with the distal end section bent. The other effects are the same as in the first embodiment and others.

FIG. **37** shows a formation on the distal end side of the stereoendoscope of the twenty-second embodiment of the present invention. This embodiment is a combination of the twentieth embodiment wherein several sets of stereo-images can be obtained and the twenty-first embodiment having a bendable structure.

Usually, in an endoscope operation, the endoscope does not enter directly into the abdominal part but is inserted instead through a tragacanth **171**. The thinner the tragacanth **171**, the less the distress of the patient. On the other hand, in case several operators jointly operate, the observation can conveniently be made in the separate respective directions.

However, there is a limit to how much the parallax may be increased and the parallax can not be made greater than the outside diameter of the distal end section. This embodiment can cope with such circumstances and makes it possible to observe in separate directions.

In this embodiment, two bendable distal end sections **155** and **155'** are provided forward of the relay optical system **154** and objective optical systems **153** and **153'** of the same structure as in the twentieth embodiment in FIG. **36** are contained within the respective distal end sections **155** and **155'**. The same members as shown in FIG. **36** within the distal end section **155** shall bear the same reference numerals, the same members as shown in FIG. **36** within the other distal end section **155'** shall bear the same reference numerals fitted with ' and their explanation shall be omitted.

According to this embodiment, when the distal end section is inserted within the tragacanth **171**, it will be seen as straight as in FIG. **36C**. When the distal end section comes out of the tragacanth **171**, it will be bent as in FIG. **37A** and several observers will be able to observe in separate directions through one thin relay optical system **154**.

By the way, for example, in the first embodiment, each of the objective optical systems **21***a* and **21***b* may be formed of an anamorphic optical system wherein the image forming magnification in the horizontal direction can be made smaller than the image forming magnification in the vertical direction (intersecting at right angles with this horizontal direction).

In the case of this formation, particularly, in case a common image taking device **23** is adopted, the two right and left images will be able to be prevented from being superimposed and the right and left image taking ranges in the image taking device **23** will be able to be substantially expanded.

In the function of transmitting images by the relay optical system **22**, because the right and left images can be intercepted less than in the case of no anamorphic optical system, that much, the objective optical systems **21***a* and **21***b* will be able to be arranged as having increased separation from each other (with the optical axis distance d larger) and a picture image having a higher stereo-feel will be able to be obtained.

In this case, in the CCU **4**, the signal of extending the picture image in the horizontal direction or compressing the picture image in the vertical direction may be processed.

By the way, the relay optical system **22** may be also formed of an anamorphic optical system. Even in the other embodiments, the objective optical system, relay optical system and adapter optical system may be formed of anamorphic optical systems.

By the way, in the lens data of the respective embodiments, in case the same lenses are paired in the objective optical system, adapter optical system and the like, only the lens data of one of the pair will be shown. In the respective embodiments, the relay lens optical system formed of a homogeneous bar-like lens is shown. However, even in case a refractive index distributing type lens is formed of such non-homogeneous rod as of a Shelphock (trade name) and is used for the relay optical system (image transmitting optical system), the present invention will be effective.

By the way, the embodiment wherein a plurality of images having a parallax are formed in spatially separated positions

by the objective optical system and the embodiment wherein a plurality of images having a parallax are formed in spatially substantially coinciding positions have been explained above. However, the case of their intermediate functions, that is, the case where a plurality of images having a parallax are formed in spatially at least partly superimposed positions and the case that a plurality of images having a parallax are formed in spatially at least partly separated positions belong to the present invention. Also, the case of applying an image by an objective optical system to the case that the image by the objective optical system is transmitted by such image transmitting optical system as the relay optical system belongs to the present invention.

As explained above, as the stereoendoscope in the fist to twenty-second embodiments is provided with an objective optical system having a plurality of incident pupils formed in different positions and forming a plurality of images having a parallax between them having passed through these plural incident pupils and a common image transmitting optical system transmitting the plural images having a parallax between them, the parallax will be able to be made large by the optical system, a sufficient stereo-feel will be obtained, the parts of the light path transmitting a plurality of images will be able to be made common by making the image transmitting optical system common, the number of the parts will be able to be reduced and the dispersion of plural images by production errors will be able to be extremely prevented.

When a stereoendoscope is formed by providing a plurality of objective optical systems arranged in parallel, separating plural images having a parallax and forming images and a common image transmitting optical system transmitting the plurality of images, the parallax will be able to be made large by the optical system, a sufficient stereo-feel will be obtained, the parts of the light path transmitting the plurality of images will be able to be made common by making the image transmitting optical system common, the number of the parts will be able to be reduced and the dispersion of plural images by production errors will be able to be extremely prevented. Further, as the images transmitted by the image transmitting optical system are spatially separated, the stereo-inspection will be made possible by the image taking means and ocular optical system without using an image separating means.

Also, when a stereoendoscope is formed by providing several front group optical systems, common rear group optical systems forming objective optical systems forming a plurality of images having a parallax in spatially substantially coinciding positions and a common image transmitting optical system transmitting the plurality of images, the parallax will be able to be made large by the optical system, a sufficient stereo-feel will be obtained, the parts of the light path transmitting the plurality of images will be able to be made common by making the image transmitting optical system common, the number of the parts will be able to be reduced and the dispersion of the plurality of images by production errors will be able to be extremely prevented. When a common rear group optical system is used in the objective optical system part, many parts will be able to be used in common and a plurality of picture images less influenced by production errors and high in quality will be obtained.

Further, there is a stereo-inspectable endoscope in U.S. Pat. No. 5,191,203 shown in FIG. **38**A wherein an objective optical system **500** is formed of collimator lenses **501** and a pair of left and right image forming lenses **502***a* and **502***b* arranged in the order mentioned from the object side.

In the objective optical system of the stereoendoscope of this related art, there are the following three problems:

(1) When the picture angle is to be made large, the inward angle will not be able to be made large and the stereo-feel will reduce.

As in FIG. **38**B, in case the picture angle is to be made large, it will be necessary that the power arrangement of the collimator lenses **501** will be negative and positive in the order from the object side. When the power of the negative lens **503** on the object side is made large, the picture angle will be able to be made large. However, in this case, the focal distance fc of the collimator lenses **501** will become larger than the object distance s and the inward angle a will become small by the following formula:

$$\alpha=2\cdot\arctan\left(d/2\,fc\right)$$

wherein d represents an optical axis distance between the two image forming lenses **502***a* and **502***b*.

(2) A relative error between the left and right images is likely to occur.

The relative error between the right and left images is produced mostly in the parts of the left and right separate bodies by a surface shape error, surface distance error, eccentricity error or the like between right and left independent lens systems. In the prior example, the parts of the left and right separate bodies (the parts having left and right separate optical axes) correspond to the image forming lenses **502***a* and **502***b* which are so many that an error is likely to occur. When a relative lag (focusing, eccentricity or the like) is produced between the left and right images, the left and right images will become difficult to resolve, resulting in fatigue.

(3) It is difficult to adjust the eccentricity error of the left and right images.

In order to adjust the eccentricity error of the left and right images, the lens or CCD of the left and right separate body parts must be adjusted. However, in the prior example, either the lens or the CCD is in a position through the other part (in this case, the collimator lens **501**) from the distal end section of the endoscope and is difficult to adjust.

The twenty-third to twenty-fifth embodiments provide a stereoendoscope wherein the picture angle and stereo-feel (inward angle) can be set to be optimum, the error between the left and right images is small and is easily adjustable, resulting in less fatigue, which shall be explained below.

In the stereoendoscope of these embodiments, there are an elongate inserted section, an objective optical system arranged within the distal end of the inserted section and an image taking means arranged within the inserted section for taking object images formed by the objective optical system. The objective optical system is formed of two negative lenses and one coaxial positive lens arranged in parallel with each other in the order mentioned from the object side. The inward angle is determined by the optical axis distance between the two negative lenses, therefore the picture angle and stereo-feel (inward angle) can be set to be optimum, the error between the left and right images is small and is easy to adjust and the fatigue feel can be reduced. in the stereoendoscope having an elongate inserted section,

In the twenty-third embodiment, the objective optical system is applied to a so-called electronic scope having a CCD in the distal end part of the inserted section of the endoscope.

As shown in FIG. **39**, a stereoendoscope apparatus **201** comprises a stereoendoscope **202** of the twenty-third embodiment having an image taking optical system for

stereo-inspection built-in, a light source apparatus **203** feeding an illuminating light to an illuminating light transmitting means transmitting the illuminating light and provided in this stereoendoscope **202**, a camera controlling unit (abbreviated as CCU hereinafter) processing signals for an image taking means built-in in this stereoendoscope **202**, a scan converter **205** converting to a video signal the signal put out of this CCU **204**, a color monitor **206** displaying the video signal put out of this scan converter **205** and shutter spectacles **207** having a shutter function of stereo-perceiving the picture image displayed by this color monitor **206**.

The stereoendoscope **202** has an elongate inserted section **208** to be inserted into a body cavity or the like and a gripped section **209** to be gripped by the operator and formed to be thick at the proximal end of this inserted section. This inserted section **208** is formed of a cylindrical metallic hose high in the flexibility and a soft jacket tube made of a metallic mesh and resin or the like. The distal end section **216** of the inserted section **208** is formed of a cylindrical rigid jacket tube made of such metal as stainless steel. An objective optical system **218** and two image taking devices **220***a* and **220***b* (for example, CCD's) are enclosed in the distal end section **216**. By the way, the entire inserted section may be formed of a rigid jacket tube, just as in the distal end section.

This stereoendoscope has a light guide **215** as an illuminating light transmitting means transmitting the illuminating light fed from the light source apparatus **203** and an illuminating optical system (not illustrated) for emitting the transmitted illuminating light through an illuminating window just as in the ordinary endoscope. Two observed images having a parallax are obtained so that the object illuminated by this illuminating optical system may be stereo-inspected and has an observing optical system comprising the optical system **218** and two image taking devices **220***a* and **220***b*.

By the way, this embodiment includes an example wherein two images having a parallax are formed by the image taking devices **220***a* and **220***b* having a photoelectrically converting function as an observing optical system and is therefore also called an image taking optical system.

The gripped section **209** is provided with a light guide mouthpiece **210** to which a light guide cable **211** is removably connected at one end. A light guide connector **212** at the other end of the light guide cable **211** is removably connected to the light source apparatus **203**.

A lamp **213** generating a white illuminating light and a lens **214** condensing this white light are arranged within the light source apparatus **203**. The illuminating light condensed by this lens **214** is radiated on the end surface of the light guide connector **212**, is transmitted by the light guide within the light guide cable **211**, is transmitted from the light guide mouthpiece **210** to the light guide **215** side within the stereoendoscope **202** and is fed.

The light guide **215** as an illuminating light transmitting means is bent within the gripped section **209** and is inserted through the inserted section **208**. This light guide **215** transmits the fed illuminating light and emits the illuminating light forward from the distal end surface fixed to the distal end section **216** of the inserted section **216**.

An object (indicated by the arrow in FIG. **39**) **217** illuminated by this illuminating light has optical images (**219***a* and **219***b* in FIG. **39**) having a parallax between them formed in image forming positions by the objective optical system **218** fitted to an observing window arranged adjacently to the illuminating window within the distal end section. These images **219***a* and **219***b* are formed on the photoelectric converting surfaces (image taking surfaces) of the image taking devices **220***a* and **220***b* arranged the same within the distal end of the inserted section.

As shown in FIG. **40**, the objective optical system **218** is formed of left and right separate negative lenses **221***a* and **221***b* and an axially symmetrical positive lens group **222** arranged in parallel with each other in the order mentioned from the object side. The light passing through a diaphragm opening **223***b* of the light from the object forms an image on the image taking device **220***a* and the light having passed through a diaphragm opening **223***a* forms an image on the image taking device **220***b*. By the way, a cover glass **240** made of parallel plane plates is arranged on the object side of the negative lenses **221***a* and **221***b*.

Here, the lens data of the objective optical system **218** of this embodiment are shown in Table 10.

In FIG. **39**, the image taking devices **220***a* and **220***b* have, for example, square image taking surfaces. The vertical or horizontal direction of this image taking surface coincides with the horizontal direction in which the two diaphragm openings **223***a* and **223***b* are separated and arranged.

The image taking devices **220***a* and **220***b* are extended out and are connected with the CCU **204** by the signal cable **224**. The image taking signal photoelectrically converted by the image taking devices **220***a* and **220***b* is processed in the CCU **204**. The image signal processed in this CCU **4** is further put into a scan converter **205** and is converted to a video signal. The video signal is put out in a color monitor **206** in which the picture images having a parallax between each other and separately formed through the two diaphragm openings **223***a* and **223***b* are alternately displayed and the operator can observe and stereo-inspect the picture images with the shutter spectacles.

FIG. **41** shows a power arrangement of the objective optical system **218** in this embodiment. The inward angle a determining the magnitude of the stereo-feel is as follows from the optical axis distance d between the two negative lenses **221***a* and **221***b* and the object distance s:

$$\tan(\alpha/2)=d/(2s).$$

That is to say, as shown in FIG. **41**, the inward angle of the objective optical system in this embodiment is determined by the optical axis distance d between the two negative lenses and does not depend on the picture angle. Further, as the left and right separate parts are only the negative lenses **221***a* and **221***b*, no relative error will be likely to be produced. Therefore, there can be obtained the following results:

(1) As the inward angle is determined by the optical axis distance between the two negative lenses and the inward angle and picture angle can be independently set, the picture angle will be able to made large with the inward angle kept large.

(2) As the main cause of the relative error between the left and right images is only the negative lens, the relative error between the left and right images will be little.

(3) As the left and right separate parts for adjusting the error between the left and right images are on the distal end side of the endoscope, they will be easy to adjust.

FIG. **42** shows a frame structure of the distal end section **216** of the stereoendoscope **202** in this embodiment. The frame structure comprises an inner tube **225** holding lenses and a CCD and an outer tube **226** enclosing the inner tube **225**, an illuminating light guide and forceps channel not illustrated.

In the objective optical system of the prior example in FIG. **38A**, as the left and right separate bodies for adjusting the eccentricity of the left and right images are in the

positions through the collimator lens from the distal end within the inner tube, when they are to be adjusted, adjusting grooves, screws and adjusting spaces will have to be prepared in the inner tube and the inner tube will not be able to be made the inner tube **25** of such simple structure as in FIG. **42** and will be large in the outside diameter. on the other hand, in this embodiment, as the two negative lenses **221***a* and **221***b* which are the left and right separate parts to be adjusted are outside the distal end of the inner tube **225**, the positions of the negative lenses **221***a* and **221***b* will be able to be simply adjusted without requiring a special structure for the inner tube **225**. The negative lenses **221***a* and **221***b* are adjusted in the position and are then bonded and fixed and the inner tube **225** is inserted into the outer tube **226** to complete the stereoendoscope.

The twenty-fourth embodiment shall be explained in the following with reference to FIG. **43**. As the twenty-fourth embodiment is substantially the same as the twenty-third embodiment, only the different formations shall be explained.

In the twenty-fourth embodiment, the objective optical system of the stereoendoscope according to the present invention is applied to a so-called rigid endoscope wherein an image is transmitted to the proximal side by an objective optical system **218** and a transmitting optical system **227** arranged in an inserted section consisting of a cylindrical rigid jacket tube and is taken.

As shown in FIG. **43**, images **219***a* and **219***b* formed by the objective optical system **218** are relayed by relay lenses **227***a*, **227***b* and **227***c* which are of a transmitting optical system **227** and are then formed on CCD's **229***a* and **229***b* by an image taking lens **228**. All the lenses other than the negative lenses **221***a* and **221***b* at the distal end are coaxial. The images, that is, pupils of the diaphragm openings **223***a* and **223***b* are transmitted respectively to positions **250**, **251**, **252** and **253**. The other formations, operations and effects are the same as in the twenty-third embodiment.

Here, the lens data of the objective optical system **218** and transmitting optical system **227** in this embodiment are shown in Table 11.

The image taking lens **228** in this embodiment is one coaxial lens system but the two pupils are separated in the position **253**. Therefore, as the image forming lens of the image taking lens shown in the following, image forming lenses arranged in parallel with each other may be used after the pupil **253** to form images.

The twenty-fifth embodiment shall be explained in the following with reference to FIGS. **44** and **45**. As this embodiment is substantially the same as the twenty-fourth embodiment, only the different formations shall be explained.

The twenty-fifth embodiment is an embodiment as applied to a rigid endoscope just as in the twenty-fourth embodiment.

In this embodiment, as shown in FIG. **44**, the basic formation of the objective optical system **218** is the same as in the twenty-fourth embodiment. However, the image **219***a* formed of the light passing through the diaphragm opening **223***b* of the light from the object and the image **219***b* formed of the light passing through the diaphragm opening **223***a* are partially superimposed.

The images **219***a* and **219***b* formed by the objective optical system **218** are relayed by the relay lenses **227***a* and **227***b* as shown in FIG. **45**. The images are then formed to be infinite by the pupil image forming lens **230** and are formed respectively on the CCD's **229***a* and **229***b* by a pair of left and right image forming lenses **231***a* and **231***b*. The images (pupils) of the diaphragm openings **223***a* and **223***b* are transmitted respectively to the positions **254**, **255** and **256**. As the two pupils have been separated in the position **256**, the two partially superimposed images **233***a* and **233***b* relayed by the relay lenses **227***a* and **227***b* are formed separately by the image forming lenses **231***a* and **231***b*. The other formations, operations and effects are the same as in the twenty-fourth embodiment.

Here, the lens data of the objective optical system **218** and transmitting optical system **227** of this embodiment are shown in Table 12.

In the 25th embodiment, the left and right separate parts are present not only in the distal end section (the negative lenses **221***a* and **221***b*) but also within the image taking lens **232** (the image forming lenses **231***a* and **231***b*). Therefore, when the negative lenses are not adjusted but the image forming lenses are adjusted, the eccentricity error between the left and right images will be able to be adjusted.

However, in case the stereoendoscope **202** is made removable between the input section (until the transmitting optical system **227** or until the pupil image forming lens) and the output section (after the pupil image forming lens **230** or after the image forming lenses **231***a* and **231***b*), it will be necessary for the input section and output section to be independently adjusted. Therefore, even during such adjustment of the input section, the objective optical system of the present invention is very effective.

A plural visual field direction type endoscope after the 26th embodiment shall be explained in the following.

The endoscope apparatus **310** shown in FIG. **46** has an inserted section **302**, an endoscope **311** in which the visual field direction is changeable in the 26th embodiment, a camera **304**, monitor **305** and light source apparatus **307**.

An objective optical system having a plurality of visual field directions and a light guide illuminating the respective visual field directions are incorporated in the distal end section **301** of the inserted section **302** of the endoscope **311**. The inserted section **302** is provided with a relay lens system which is an image and pupil transmitting optical system following the objective optical system. An ocular optical system is arranged in the proximal section **303** of the endoscope **311**. The camera **304** can be fitted in the rear of the ocular optical system. Here, the proximal section **303** of the endoscope **311** and the camera **304** are formed to be integral or removable. The object having had the image taken by the camera **304** is displayed to be observable by the observer as an endoscope picture image finally in the monitor **305**.

The illuminating light from the light source apparatus **307** passes through the light guide cable **306** and illuminates the respective visual field directions through the proximal section **303**, inserted section **302** and distal end section **301**.

The details of the optical system of the endoscope **311** shall be explained as follows:

On the optical systems of the endoscope of the 26th embodiment, a pupil division is utilized in the objective optical system and an ocular optical system is formed.

The pupil dividing system is fundamentally formed of an optical system having one optical axis but, in order to make a plural visual field direction type, a lens group corresponding to a plurality of visual field directions is arranged in front of the optical system. The plural visual field direction type optical system having adopted this pupil dividing system is formed of a front side lens group formed the same in a plurality of visual field directions and arranged in the respective plurality of visual field directions, a prism for forming images in the plurality of visual field directions in

the rear step of the front side lens group corresponding to the plurality of visual field directions, a brightness diaphragm having a plurality of openings arranged near pupils, thereby forming a plurality of pupils and a rear side lens group forming one image of superimposed beams in the plurality of visual field directions in the order mentioned from the object side.

The inherent one beam of the optical system is divided near the pupil by the brightness diaphragm **321** having two openings and is shown in FIG. **37B**. The beam passing through one opening of the brightness diaphragm **321** is seen straight-on as it is and the beam passing through the other opening of the brightness diaphragm **321** is perspectively seen in the visual field direction by the prism. Here, the two images in the visual field direction are formed to be superimposed on the image surface.

The formation of the optical system relating to this embodiment shall be explained concretely with reference to FIG. **47A**. The optical system shown in FIG. **47A** comprises an objective optical system **322**, a set of relay lens system **323** as a transmitting optical system and an ocular optical system **324**.

The objective optical system **322** has a front side lens group **329***a* comprising two objective lenses **325** and **326** arranged in the positions nearest to the object and directed respectively in the straight seen direction and side seen direction, a first prism **327** making the beam from the two objective lenses **325** and **326** incident on different surfaces, a second prism **328** making the beam from the first prism **327** incident on the same surface and a brightness diaphragm **321** for dividing the pupil into a plurality of pupils in response to the visual field direction and has a rear side lens group **329***b* for converging the beam from the pupils and forming the object image arranged in the rear of this front side lens group **329***a*. In the drawing, the one-point chain lines represent the optical axes of the respective visual field directions.

The image in the direction as seen straight-on in this optical system is formed as follows. The rays having passed through the objective lens **326** pass through the surface **331** of the first prism **327** to the joint surface **332**. The joint surface **332** on the first prism side **327** is black-painted so as to pass no others than the rays effective to prevent detrimental flares and is made a flare diaphragm. Because the first and second prisms **327** and **328** are made of the same glass material, their refractive indices are equal and the rays pass through the surface **332** without being refracted. Then an image I1 having the lower side of the brightness diaphragm **321** as a pupil surface and having the optical axis of this rear side lens group **329***b* as a center axis by the rear side lens group **329***b* is formed.

On the other hand, the image in the perspectively seen direction is formed as follows. The rays passing through the perspectively seeing objective lens **325** pass through the surface **333** of the first prism **327** to the joint surface **332**. At this time, the rays forming the image in the perspectively seen direction proceed straight through the joint surface without being refracted the same as the straight-on seen rays.

The joint surface **332** on the first prism side **327** is made a flare diaphragm passing no others than the rays effective to prevent detrimental flares. As the optical axis in the straight-on seen direction and the optical axis in the perspectively seen direction intersect with each other on the joint surface, the same flare diaphragm will effectively function on the rays in both directions. The straight proceeding rays in the perspectively seen direction are reflected by the mirror-processed surface **334** and go again to the surface **332** on the second prism **328** side.

The surface **332** on the second prism **328** side is mirror-processed in the range of not intercepting the straight-on seen rays and perspectively seen rays separated by the pupil division and in the range of covering the reflected perspectively seen rays reflected by the surface **334**. Therefore, the rays in the perspectively seen direction reflected by the surface **334** without being perceived pass on the upper side of the brightness diaphragm **321** and are made the image II having the optical axis of the rear side lens group **329***b* as a center axis by this rear side lens group **329**, just as the straight-on seen rays and the image is formed.

The images I1 in the plurality of visual field directions made by the objective optical system **322** and the pupil P1 are transmitted in the ocular optical system direction by the relay lens system **323**. In the drawing, the reference numeral P2 represents a plurality of pupils corresponding to the respective visual field directions transmitted by the relay lens. An image I2 is formed between the relay lens system **323** and ocular optical system **324**. A plurality of pupils P3 corresponding to the respective visual field directions are obtained through the ocular optical system **324**.

When the observer moves the position of his pupil to the position of the pupil transmitted in the visual field direction he wants to observe, he will be able to select the visual field direction.

In this embodiment, the objective optical system is originally designed as a coaxial optical system but not as an eccentric optical system and is formed to be bent with a prism for a pupil in a different visual field direction. That is to say, the optical axis of the objective lens **326** is on the extended line of the optical axis of the rear side lens group **329***b* through the joint surface **332** and the optical axis of the objective lens **325** is on the extended line of the optical axis of the rear side lens group **329***b* reflected on the joint surface **332** and further reflected on the reflecting surface **334**. Therefore, between the optical system comprising two negative lenses and a prism and the optical system in the rear of it, even if the beam is not afocal, two images superimposed before the relay system will be able to be formed.

In this embodiment, as the pupil division is utilized and originally one optical system is used, with a formation of few lenses, a high picture quality will be obtained, if the means for determining plural pupils is in a position conjugate with the pupil position of the objective optical system, it may be the position of the pupil P2 of the relay system **323** or any other part and, as the objective system and transmitting optical system have no visual field direction switching apparatus, the structure will be simple and the ease of assembly will be high.

An example of designing an actual objective optical system is shown in FIG. **48** and its numerical value data are mentioned in Table 13. By the way, in the formation shown in FIG. **48**, the part shown as the rear side lens group **329***b* in FIG. **47A** is formed of a lens **329"** jointed to a prism and three jointed lenses **329'**.

In this embodiment, because the formed image is one, the following effects will be able to be obtained.

That is to say, as the objective optical system of the plural visual field direction type endoscope has a plurality of visual field directions, a plurality of pupils corresponding at 1 to 1 to the visual field directions and one image, the one image is a superimposition of images in a plurality of visual field directions, the optical axis of the plurality of visual field directions coincides with the optical axis of the transmitting system in the position of the image and, on the way of the transmission in the transmitting optical system after the image, one image and a plurality of pupils will be transmitted without being intercepted.

Therefore, in this embodiment, after the transmitting optical system, the visual field direction can be selected and no movable part is required in the objective optical system and transmitting optical system for selecting the visual field direction. Further, in this embodiment, because the objective optical system and the like have no visual field direction switching apparatus, the structure will be simple and the ease of assembly will be high. Also, because no polarization is used, there will be no deterioration of the image in the peripheral part by the rotation in the polarizing direction.

These effects will be the same even in case the pupil dividing means is in the transmitting optical system or image forming optical system.

The 27th embodiment shall be explained in the following with reference to FIGS. **49** to **54**.

In the endoscope of this embodiment, an eccentric optical system is utilized for the objective optical system, an image forming optical system and solid state image taking device are used instead of the ocular optical system in the 26th embodiment and no optical visual field direction selecting means is provided.

FIG. **49**A shows a formation of an optical system arranged within the endoscope of this embodiment.

The optical system of this embodiment comprises in the order mentioned from the distal end side an objective optical system **341**, relay lens system **342**, pupil image forming lens **343**, such reflecting members **344***a* and **344***b* as a pupil separating optical member **344***c* and mirror and two solid state image taking devices **346***a* and **346***b* as an image taking means. By the way, though only one relay lens system is shown, it is natural that a plurality of relay lens systems may be used as required. The image forming lenses **345***a* and **345***b* form the image forming optical system.

In the objective optical system **341**, a front optical system **347** comprising substantially afocal lens groups **347***a* and **347***b* independent of each other and having two straight-on seen and perspectively seen visual field directions and pupils P11 corresponding to these visual field directions is arranged in the front group and a rear side lens system **348** having a size capable of transmitting the beams from the plurality of pupils P11 to the image without being intercepted and forming one superimposed image of the beams in the plurality of visual field directions is arranged in the rear group.

The relay lens system **342** forms the images of the pupils P11 as pupils P12, forms the image I11 as an image I12 and transmits them to a pupil image forming lens **343**. The pupil image forming lens **343** transmits the pupils transmitted from the relay lens system **342** to the side of a pupil separating optical member **344***c* having a plurality of reflecting surfaces. This pupil separating optical member **344***c* receives a plurality of pupils P13 and separates and delivers them in respectively different directions, that is, to the reflecting members **344***a* and **344***b*.

The reflecting members **344***a* and **344***b* reflect the beams passing through the separated respective pupils, that is, in the illustration, the two pupils corresponding to the optical system in the straight-on seen direction and the optical system in the perspectively seen direction respectively toward the lens systems **345***a* and **345***b*. The lens systems **345***a* and **345***b* form images corresponding to the respective pupils in the solid state image taking devices **346***a* and **346***b*.

In this formation, first the rays in the respective visual field directions pass through two substantially afocal lens groups **347***a* and **347***b* forming the front optical system **347**, then the optical axes in the respective visual field directions are bent by the rear side lens system **348** and the image III is formed on the optical axis of the rear side lens system **348**.

In this embodiment, substantially the same basic formation which realizes the perspective view made by the prisms **327** and **328** in the 26th embodiment is used. Here, the perspective view prism may be a 300 prism shown in the publications of Japanese Patent Applications Laid Open Nos.140313/1985, 91333/1975 and 108013/1990 or a 700 prism or 1100 prism shown in the publication of Japanese Patent Application Laid Open No.87403/1984.

Also, the objective optical system **341** may be the front optical system **347***c* including the same prisms as the prisms **327** and **328** of the above mentioned embodiment as in FIG. **50**, that is, may be a straight-on seeing and perspectively seeing optical system in common. Or the objective optical system **341** may realize a perspective view by utilizing refraction with a wedge prism **349** placed near the pupil P11 as in FIG. **51**. In this formation, the lens group to be used respectively in the straight seen direction and the perspectively seen direction may be substantially the same lens group differing only in length, and the perspectively seeing lens group may be inclined to the straight-on seeing lens group and the wedge prism **349** may be arranged in the rear of it.

Otherwise, as shown in FIG. **54**, the objective optical system **341** may have three or more visual field directions if in a range that the image and pupil are not intercepted by the relay lens system arranged in the rear. In the illustrated example are shown the most distal end side lenses **350**, **351** and **352** forming respective lens groups respectively of 0 degrees (straight-on seen), 30 degrees (perspectively seen) and 70 degrees (perspectively seen).

As shown in FIG. **49**A, the beam from the objective optical system **341** forms an image I12 in the rear of the relay lens system just as in the 26th embodiment by the relay lens system **342**. Of the rays in the respective visual field directions forming the image I12 made in the rear of the relay lens system **342**, the beams of the two pupils differing in the visual field direction are respectively separated by the pupil separating optical member **344***c* arranged in the rear of the pupil image forming lens **343**.

This pupil separating optical member **344***c* is, for example, a prism arranged near the pupil P13 transmitted by the relay lens system **342** and formed as an image by the pupil image forming lens **343**. The separated beams in the respective visual field directions are reflected respectively by the reflecting members **344***a* and **344***b* and are formed as images respectively on the image taking devices **346***a* and **346***b* through the lens systems **345***a* and **345***b*.

In this embodiment, by the pupil image forming lens **343** forming images of pupils, the optical axes in the respective visual field directions are made substantially parallel with the optical axis of the relay lens system **342** and the object point is formed as an image to infinity. By the way, the image may be formed so as not to be superimposed on one solid state image taking device.

According to this embodiment, images differing in the visual field direction can be independently taken by a plurality of solid state image taking devices and the number of visual fields and the visual field direction can be easily selected by the objective optical system. Without an optical visual field direction switching means, images in all the visual field directions are taken in. As in the illustrated example, in the formation using a plurality of solid state image taking devices, the outputs of the respective image taking devices are selected by switching the switch and the signals are processed as determined and can be displayed.

In the formation utilizing one solid state image taking device, the respective images different in the visual field

direction may be selected by a signal processing means connected to the later step. The picture image in only one visual field direction can be displayed in a monitor.

That is to say, in this embodiment, without moving the optical system or without optically switching the visual field direction, the visual field direction can be changed. Also, depending on the way of processing the signal, a plurality of images in the visual field direction can be simultaneously displayed in one or a plurality of monitors.

An example of designing an objective optical system is shown in FIG. **52**. Also, an example of designing an objective optical system and relay lens system as combined is shown in FIG. **53**. In the drawings, the reference numeral **354** represents an objective optical system and the reference numeral **355** represents a relay lens system. The lens data are mentioned in Table 14.

By the way, just as in the 26th embodiment, the diaphragm determining the pupil may be in the objective optical system, may be in the pupil position in the conjugate relay lens system or may be in the pupil position near the pupil dividing optical member.

In FIG. **49B** is shown a modification of the 27th embodiment. In this modification, a pupil image P13 is formed of dispersed beams or converged beams by the pupil image forming lens **356** provided instead of the pupil image forming lens **343**. A focal beams are then formed by the lens **357** making the beams parallel and the beams are further formed as images by the image taking devices **346***a* and **346***b* through the image forming lenses **345***a* and **345***b*. In this modification, a reflexing prism as a pupil dividing optical member is unnecessary. The diaphragm may be arranged above the pupil position P13 in the drawing, in the relay lens system or in the pupil position in the objective optical system. The other same formations and operations as in the 27th embodiment shall bear the same reference numerals and shall not be explained here.

The 28th embodiment of the present invention shall be explained in the following with reference to FIGS. **55** to **58B**.

In the formation of the 28th embodiment, an image forming optical system and a solid state image taking device are provided the same as in the 27th embodiment and further an optical visual field direction switching means is arranged.

The objective optical system in this embodiment may be the pupil dividing system in the 26th embodiment or may be formed of the substantially afocal plurality of optical systems and rear optical systems in the 27th embodiment. This embodiment is different from the above mentioned respective embodiments in the formation of the optical system and the like arranged in the rear of the relay lens system arranged in the rear of the objective optical system.

As shown in FIG. **55**, the optical system in this embodiment comprises a lens system **361** for making the light which was once formed as an image by a relay lens system in the rear of the relay lens system (not illustrated) and then became dispersed beams in the respective visual field directions parallel with the optical axis of the relay lens, a pupil switching apparatus **362** as a selecting means switching the beams in the respective visual field directions made parallel in response to the respective pupils and arranged near the pupils to be formed as images through the lens system **361** and an image forming lens system **363** forming images of the rays selected by the pupil switching device **362** on the solid-state image taking device **364**.

The rays in the respective visual field directions forming the image I21 formed in the rear of the relay lens system are made parallel with the optical axis of the relay lens system by the lens system **361**. By the switching apparatus **362** near the pupil position, the rays passing through the other images than in the visual field direction the observer wants to observe are intercepted. The intercepting means as a selecting means may be a mechanically moved shielding plate or may be a liquid crystal shutter switch to be on/off.

The selecting means may be such image rotator **365** as in FIGS. **56A** and **56B** to be moved to switch the visual field direction. The reference numeral **366** represents an image forming lens system forming an image of the rays obtained by the image rotator **365** on the solid state image taking device. By the way, FIGS. **56A** and **56B** show that the visual field direction is switched by moving the image rotator **365**.

Also, as shown in FIG. **57**, the selecting means may be moved to the position of the visual field direction desired to be observed integrally with the image forming lens system **365** and solid state image taking device **364** to switch the visual field direction. Only the image in the selected visual field direction is formed on the solid state image forming device **364**.

The effect of this embodiment is that the visual field direction can be changed in a small space.

By the way, in case the pupil and image made by the objective optical system are transmitted by the relay lens system and the pupil dividing means is arranged after the relay lens system, the brightness diaphragm **321** can be omitted.

The formations of the 27th and 28th embodiments have an image taking means and may be applied to an outside fitted camera connectable to the ocular optical system of the 26th embodiment. In this formation, the lens system **343** or **361** is replaced with the ocular optical system **324**.

The optical system after the transmitting optical system combining utilizing the pupil division in the objective optical system and utilizing the eccentric optical system can be selected either to have the ocular optical system and optical visual field direction switching means or to have none.

In the case of either utilizing the pupil division in the objective optical system of the present invention or utilizing the eccentric optical system, when the means of intercepting the rays other than in the required visual field direction are provided near the pupils in the respective visual field directions, even if the transmitting optical system is replaced with the solid state image taking device or image guide, the visual field direction variable endoscope will be able to be realized.

In the formation shown in FIG. **58A**, a pupil switching apparatus **368** is provided near the pupil formed in the light path of the objective optical system **370** consisting of the front side lens group which is the same as the front side lens group **329***a* of the 26th embodiment and the rear side lens system **348** and a solid state image taking device **369** is arranged. The pupil switching apparatus **368** may be a liquid crystal shutter or the like.

Also, in the formation shown in FIG. **58B**, an eccentric optical system **371** including the same optical system as the front optical system **347***c* shown in FIG. **50** is utilized.

FIG. **59A** is a formation view of an optical system in the plural visual field direction type endoscope in the 29th embodiment. FIG. **59B** is a formation view of an objective optical system made partially common.

The objective optical system in the 29th embodiment is formed of a plurality of lens groups provided for respective visual fields instead of the objective optical system **322** so that a plurality of images may be formed by these lens groups. The other formations and operations which are the same as in the 26th embodiment shall bear the same reference numerals and shall not be explained here.

The objective optical system **373** shown in FIG. **59**A is formed of a plurality of (two in the illustrated example) independent lens groups. The relay lens system **323** and ocular optical system **324** are arranged in the rear of the objective optical system **373**. By the way, the relay lens system **323** and ocular optical system may be replaced with an image forming optical system and solid state image taking device.

The objective optical system **373** may be formed of an independent optical system as in FIG. **59**A and may have a part, that is, the prism on the distal end side made common as in the objective optical system **373'** shown in FIG. **59**B.

The plurality of images I31 and I32 formed by the objective optical system are transmitted rearward by the relay lens system **323** as a transmitting optical system. In the formation having the ocular optical system **324**, as in FIG. **59**A, the observer can simultaneously see the respective visual field directions with the eye placed in the pupil position **374**.

On the other hand, in the formation of the image forming optical system and solid state image taking device, the plurality of images made in the rear of the relay lens system **323** are formed on one solid state image taking device by the image forming lens. The effect by this formation can be technically comparatively easily realized by any optical system after the objective optical system and transmitting optical system.

By the way, in this embodiment, images may be formed on a plurality of solid state image taking devices with the image forming magnification made large and the solid state image taking devices placed in the positions corresponding to the plurality of images.

The 30th embodiment shall be explained with reference to FIG. **60**A. As shown in FIG. **60**A, in the optical system of this embodiment, an image is formed on the solid state image taking device **370** through the lens system **343** which is arranged in the rear of the relay lens system **342** and whereby the light once formed as an image by the relay lens system **342** and then made dispersed beams in the respective visual field directions is made parallel with the optical axes of the relay lens system **342** and optical systems arranged along two optical axes in the rear of this lens system **343**.

Multiple relay systems by the lens systems **371** and **372** are arranged along one optical axis of the two optical axes and an image is formed on the solid state image taking device **370** by the lens system **372**.

Also, multiple relay systems are arranged on the other optical axis. That is to say, the prism **373** for bending the optical axis is arranged near the pupil formed through the lens system **374** and on the rear side of this prism **373** are arranged the lens system **374**, prism **375**, lens system **376**, prism **377**, lens system **378** and mirror **379**. The beam is reflected by this mirror **379** arranged at the point P of intersection of this optical system and the other optical axis and forms an image on the solid state image taking device **370** through the lens system **372**.

This mirror **379** is rotatable as illustrated. The visual field direction can be selected by switching to either of the state A indicated by the solid line and the state B indicated by the dotted line. The other formations are the same components as are explained in FIG. **49**A.

In the inserted section of the rigid endoscope to which this embodiment is applied, the distance between the two optical axes cannot help being so small as to be several millimeters due to the restriction of the outside diameter. As the image is formed on one solid state image taking device **370** after the lens system **343**, in case one optical system is used the same as in the relay lens system **342**, the beam will diagonally project into the solid state image taking device **370** and a color shading will be generated. In order to prevent this phenomenon, in this embodiment, one of the two optical axes is bent by the prisms **373**, **375** and **377** on the rear side of the lens system **343** as in FIG. **60**A so that the beams having passed respectively through the two optical axes may project vertically onto the image taking surface of the solid state image taking device **370** and the generation of the color shading may be controlled.

FIG. **60**B shows a formation of a modification of FIG. **60**A. The optical system in FIG. **60**A is formed of expanded lens systems **374'**, **376'** and **378'** expanding respectively the lens systems **374**, **376** and **378** so that the image may be observed in a larger picture surface size with one of the optical systems having two visual field directions. When the formation is separated into the inserted section **380** and the camera adapter section **381** rotatably fitted to this inserted section **380** and the camera adapter section **381** is rotatably formed, the picture sizes in the respective visual field directions will be able to be selectively made large.

FIG. **61**A shows the 31st embodiment. In this embodiment, objective optical systems **391** and **391'** to be a pair on the respective optical axes separated by a distance D are provided on the distal end side of the inserted section **390** and the respective images by the optical objective systems **391** and **391'** are transmitted to the rear side respectively by the relay optical systems **392** and **392'**.

The image transmitted by the relay optical system **392** is formed on the solid state image taking device **370** by the multiple relay optical systems comprising the lens systems **371** and **372** the same as in FIG. **60**A.

Also, the image transmitted by the relay optical system **392'** is formed on the solid state image taking device **370** through the same relay systems as in FIG. **60**A, that is, the multiple relay systems by the prism **373**, lens system-**374**, prism **375**, lens system **376**, prism **377**, lens system **378**, mirror **379** and lens system **372**.

The same as in the embodiment in FIG. **60**A, as a means of switching the two optical systems, a mirror **379** is provided at the point P at which the two optical axes intersect with each other. The visual field direction can be selected by this mirror **379**.

In the modification shown in FIG. **61**B, the lens systems **374**, **376** and **378** forming the relay systems in FIG. **61**A are formed respectively of the expanded lens systems **374'**, **376'** and **378'** so that one optical system, that is, the objective optical system **391'** and relay optical system **392'** of the two optical systems arranged within the inserted section **390** may be made thinner, the outside diameter of the inserted section may be made smaller and the insertability may be improved.

Also, when the formation is separated into the inserted section **390** and the camera adapter section **393** rotatably fitted to the rear end of this inserted section and the camera adapter section **393** is rotatably formed, the picture size will be able to be selectively varied.

By the way, the present invention is not limited to these embodiments and modifications and any embodiment or modification formed by combining parts of them belongs to the present invention.

What is claimed is:

1. A stereoendoscope, comprising:

an elongate inserted section having a distal end;

an illuminating light projecting means for projecting an illuminating light from the distal end of said inserted section;

an objective optical system arranged on the distal end of said inserted section for forming the light from the object illuminated by said illuminating light as a plurality of images having a parallax between them through a plurality of incident pupils; and

one image transmitting optical system comprising one relay lens optical system contained at least partially within said inserted section for transmitting said plurality of images having a parallax between them by said objective optical system,

wherein said objective optical system is formed of two negative lens units arranged in parallel with each other and one positive lens group, said two negative lens units being arranged to be substantially symmetrically concentric about an optical axis of said one positive lens group and said image transmitting optical system, said two negative lens units being arranged nearer the object side of said distal end of said inserted section than said one positive lens group.

2. A stereoendoscope, comprising:

an elongate inserted section having a distal end;

an illuminating light projecting means for projecting an illuminating light from the distal end of said inserted section;

an objective optical system arranged on the distal end of said inserted section for forming a plurality of images having a parallax between them such that they are substantially superimposed on one another of the object illuminated by said illuminating light; and

one image transmitting optical system comprising one relay lens optical system for transmitting said plurality of images;

wherein said objective optical system comprises a plurality of front lens groups and one rear lens group positioned proximally of said plurality of front lens groups.

3. A stereoendoscope according to claim 2, comprising:

a pupil dividing and image forming means for separating and forming said plurality of images having a parallax between them formed such that they are substantially superimposed on each other on a final image surface by said image transmitting optical system; and

at least one image taking means for taking the images formed by said pupil dividing and image forming means.

4. A stereoendoscope according to claim 3,

wherein said plurality of front lens groups are formed of a negative power element and a positive power element, said negative power element being arranged nearer the object side of said distal end of said inserted section than is said positive power element.

5. A stereoendoscope according to claim 3 having an adapter optical system for separating and reforming the plurality of images having a parallax between them and made such that they are substantially superimposed on one another on a final image surface of said image transmitting optical system.

6. A stereoendoscope according to claim 3, wherein said plurality of images are simultaneously spatially separated by said pupil dividing and image forming means.

7. A stereoendoscope according to claim 3, wherein said plurality of images are alternatively formed in a time-sequential manner by said pupil dividing and image forming means.

8. A stereoendoscope according to claim 2,

wherein the space between said plurality of front lens groups and said rear lens group is afocal.

9. A stereoendoscope, comprising:

an elongate inserted section having a distal end;

an illuminating light projecting means for projecting an illuminating light from the distal end of said inserted section;

an objective optical system wherein a plurality of optical systems are arranged in parallel on the distal end of said inserted section and a plurality of images having a parallax between them are formed of the object illuminated by said illuminating light;

an image transmitting optical system comprising one relay lens optical system for transmitting the plurality of images formed by said objective optical system; and

an image taking means for taking at least two images of the plurality of images transmitted by said image transmitting optical system,

wherein said objective optical system comprises a plurality of front lens group optical systems which are arranged in parallel, and a rear lens group optical system,

wherein said plurality of front lens group optical systems is arranged to be substantially symmetrically concentric about the optical axis of said rear lens group optical system and said image transmitting optical system.

said objective optical system forming images of the beams from said plurality of front lens group optical systems in substantially superimposed positions,

said image transmitting optical system transmitting a substantially superimposed plurality of images having a parallax between them formed by said objective optical system.

10. A stereoendoscope according to claim **9**, wherein positions of pupils transmitted by said image transmitting optical system are separated from each other.

11. A stereoendoscope according to claims **9**, wherein a beam projected from said plurality of front lens group optical systems is a substantially afocal beam.

12. A stereoendoscope according to claim **9**, wherein said plurality of front lens group optical systems are arranged more on the object side than said rear group optical system and are separated more from said rear group optical system than from a front side focus position of said rear group optical system.

13. A stereoendoscope comprising:

an elongate inserted section having a distal end;

an illuminating light projecting means for projecting an illuminating light from the distal end of said inserted section;

an objective optical system arranged with the distal end of said inserted section; and

an image taking means arranged within said inserted section for taking the object image formed by said objective optical system,

said objective optical system having two negative lens units arranged in parallel with each other and one positive lens group opposed to said two negative lens units,

said two negative lens units being arranged symmetrically concentric about the central axis of said positive lens group,

said two negative lens units being arranged nearer the object side of said distal end of said inserted section than is said positive lens group.

[57] **ABSTRACT**

An apparatus is described for aligning an actuator lens of an optical disk drive or the like within a baseplate assembly. The apparatus comprises a frame, a cradle assembly mounted to the frame with at least one degree of freedom of motion, a tower assembly mounted to the frame, a lever assembly rotatably mounted to the frame, and a gripper assembly mounted to the lever assembly. The cradle assembly includes a baseplate alignment assembly comprising a source of radiant energy for projecting a beam of radiant energy, means for determining the tilt alignment of the beam with respect to the tower assembly, and a plurality of tilt actuators for aligning the tilt of the beam with respect to the tower assembly. The baseplate alignment may further comprise means for determining the lateral alignment of the beam with respect to the tower assembly and a plurality of lateral actuators for aligning the beam laterally with respect to the tower assembly. The tower assembly comprises a video camera having a camera lens, a tower magnifying lens, and a monitor for displaying a representation of a beam of radiant energy passing through the tower magnifying lens and into the video camera. The gripper assembly comprises an objective lens assembly, an objective lens mounted to the objective lens assembly, an objective lens alignment assembly for aligning the objective lens with respect to the tower assembly and the cradle assembly, and an actuator lens tilt assembly for aligning the actuator lens with respect to the tower assembly and the cradle assembly.

METHOD AND APPARATUS FOR ALIGNING AN OBJECTIVE LENS

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to manufacturing of optical systems, and, in particular, to the manipulation and alignment of an objective lens during manufacture of an optical system.

2. Description of the Related Art

In the manufacture of prior optical systems, specific alignment of the objective lens with respect to a storage medium was not critical. In those systems, a spindle which holds the storage medium is aligned with respect to guide rails. A carriage rides along the guide rails, and the objective lens is placed within the carriage. Because the information storage densities used in such optical systems were sufficiently low, and because manufacturing tolerances of the spindle, rails, and objective lens were sufficiently high, specific alignment of the objective lens was not necessary. The objective lens was placed, then tested for alignment within tolerable limits.

Another example of a prior art optical system does perform active alignment of the objective lens. However, the objective lens is fixedly mounted to an actuator, and the objective lens/actuator combination is aligned with respect to a carriage assembly. Once aligned with respect to the carriage assembly, the actuator is mounted to the carriage assembly, which is aligned with respect to the storage medium. This prior art optical system requires that the actuator be alignable with respect to the carriage assembly. Additionally, the actuator/carriage assembly combination is quite large relative to such assemblies in other optical systems.

SUMMARY OF THE INVENTION

As information storage densities increase, the alignment between the objective lens and the storage medium becomes more critical. As a result, either stricter manufacturing tolerances or improved alignment of the objective lens is necessary. Because stricter manufacturing tolerances increase manufacturing cost significantly, improved alignment of the objective lens allows higher information storage densities at an economically feasible cost.

An apparatus is described which aligns such an objective lens. The apparatus comprises a frame, a cradle assembly mounted to the frame with at least one degree of freedom of motion, a tower assembly mounted to the frame, a lever assembly rotatably mounted to the frame, and a gripper assembly mounted to the lever assembly. The cradle assembly includes a baseplate alignment assembly comprising a source of radiant energy for projecting a beam of radiant energy, means for determining the tilt alignment of the beam with respect to the tower assembly, and a plurality of tilt actuators for aligning the tilt of the beam with respect to the tower assembly. The baseplate alignment assembly may further comprise means for determining the lateral alignment of the beam with respect to the tower assembly and a plurality of lateral actuators for aligning the beam laterally with respect to the tower assembly. The tower assembly comprises a video camera having a camera lens, a tower magnifying lens, and a monitor for displaying a representation of a beam of radiant energy passing through the tower magnifying lens and into the video camera.

The gripper assembly comprises an objective lens assembly, a gripper objective lens mounted to the objective lens assembly, an objective lens alignment assembly for aligning the gripper objective lens with respect to the tower assembly and the cradle assembly, and an actuator lens tilt assembly for aligning the objective lens with respect to the tower assembly and the cradle assembly. The objective lens assembly further comprises a housing having an opening at one end for receiving an objective lens and a bellows structure on its surface to allow bending of the housing, a gripper objective lens, a non-opaque substrate mounted within the housing, and a pneumatic tube attached to the housing for creating a pressure differential between the interior and the exterior of the housing sufficient to hold the actuator lens against the opening. The objective lens alignment assembly further comprises an assembly support, a first lateral alignment support slidably mounted to the assembly support, a first lateral actuator for positioning the first lateral alignment support, a second lateral alignment support slidably mounted to the first lateral alignment support, a second lateral actuator for positioning the second lateral alignment support, a support frame having a frame base and a frame extension, mounted to the second lateral actuator, a support leaf spring mounted to the support frame and biasing the housing against the frame extension, and a focus actuator for positioning the frame extension with respect to the frame base. The actuator lens tilt assembly further comprises a flexure support ring; two flexure support plates; four flexure plates mounted at equal intervals around the flexure support ring, two of which are mounted to the housing and two of which are mounted to the flexure support plates; a first lever disposed against a flexure plate; a first tilt actuator mounted against the first lever for imparting motion on the first lever which is translated into rotational motion by the flexure support ring, the flexure support plates, and the flexure plates; a second lever disposed against a flexure plate; and a second tilt actuator mounted against the second lever for imparting motion on the second lever which is translated into rotational motion by the flexure support ring, the flexure support plates, and the flexure plates.

A method for aligning an actuator lens is described comprising the steps of moving a baseplate assembly with respect to the tower assembly, moving the objective lens assembly with respect to the tower assembly, and moving the actuator lens with respect to the tower assembly. The step of moving the baseplate assembly further comprises moving the baseplate assembly laterally with respect to the tower assembly and rotating the baseplate assembly with respect to the tower assembly. The step of moving the actuator lens further comprises moving the actuator lens laterally with respect to the tower assembly and rotating the actuator lens with respect to the tower assembly. Such a method may be used with the above-described apparatus.

For a better understanding of these and other objects of the present invention, reference is made to the detailed description of the invention which is to be read in conjunction with the following drawings, wherein:

BRIEF DESCRIPTION OF THE DRAWING

FIG. 1 is a generalized side view of one embodiment of the invention, showing the gripper assembly in a closed position.

FIG. 2 is a generalized side view of one embodiment of the invention, showing the gripper assembly in an open position.

FIG. 3 is a cross-sectional view of the tower assembly, including an embodiment of the analysis assembly.

FIG. 4 is a cross-section view of the vacuum chuck and the microscope objective lens assembly.

FIG. 5 is a view of the microscope objective lens alignment assembly.

FIG. 6 is a side view of the actuator lens tilt assembly.

FIG. 7 is a front view of the actuator lens tilt assembly.

FIG. 8 is a view of an alignment actuator.

FIG. 9 is a top view of one embodiment of the cradle assembly.

FIG. 10 is a cross-sectional view of one embodiment of the cradle assembly, taken along line 10—10 of FIG. 9.

FIG. 11 is a cross-sectional view of one embodiment of a vacuum clamp in the open position, taken along line 11—11 of FIG. 9.

FIG. 12 is a cross-sectional view of one embodiment of a vacuum clamp in the closed position, taken along line 11—11 of FIG. 9.

FIG. 13 is a top view of a baseplate assembly.

DESCRIPTION OF THE PREFERRED EMBODIMENT

Referring to exemplary FIGS. 1 and 2, according to one aspect of the invention, the apparatus comprises a tower assembly 1, a gripper assembly 2, and a cradle assembly 3. The tower assembly 1 is fixedly mounted to a frame 4. The tower assembly 1 defines a tower axis. The gripper assembly 2 is fixedly mounted to a lever assembly 5, which is rotatably mounted to the frame 4. The cradle assembly 3 is mounted to the frame 4 with at least one degree of freedom of motion. A line (not shown) between the tower assembly 1 and the cradle assembly 3 is referred to as an assembly axis. In the closed position, as shown in FIG. 1, the gripper assembly 2 is between the tower assembly 1 and the cradle assembly 3 along the assembly axis. In the open position, as shown in FIG. 2, the gripper assembly 2 is not along the assembly axis.

Referring to exemplary FIG. 3, a cross-section of the tower assembly 1 is shown in more detail. The tower assembly 1 comprises a tower magnifying lens 6 and a video camera 7 having a camera lens 8. The optical axes of the camera lens 8 of the video camera 7 and the tower magnifying lens 6 are the same, and are referred to collectively as the tower optical axis. The output from the video camera 7 is connected to an analysis assembly 9. The analysis assembly 9 may be any assembly suitable for analyzing the characteristics of a radiant beam of energy. In the embodiment shown in exemplary FIG. 3, the analysis assembly 9 comprises a processor 10 and a monitor 11.

Referring to exemplary FIGS. 4, 5, 6 and 7, the gripper assembly 2 comprises a vacuum chuck 12, a microscope objective lens assembly 13, a microscope objective lens alignment assembly 14, and an actuator lens tilt assembly 15. FIG. 4 shows a cross-sectional view of one embodiment of the vacuum chuck 12 and the microscope objective lens assembly 13. FIG. 5 shows a view of one embodiment of the microscope objective lens alignment assembly 14. FIGS. 6 and 7 show two views of the actuator lens tilt assembly 15.

Referring to exemplary FIG. 4, the vacuum chuck 12 comprises a housing 16, a bellows structure 17, and an actuator lens receiving opening 18. A pneumatic tube (not shown) is connected to the housing 16. In operation, an actuator lens (not shown) is placed within the actuator lens receiving opening 18 such that the actuator lens receiving opening 18 is completely covered. The actuator lens may be an objective lens. Air is then evacuated from the housing 16 through the pneumatic tube (not shown) to create a pressure differential between the interior and the exterior of the housing 16. This pressure differential operates to hold the actuator lens against the actuator lens receiving opening 18 when the gripper assembly 2 moves. The housing 16 contains the bellows structure 17 to allow the housing 16 to bend while maintaining a pressure differential.

The microscope objective lens assembly 13 comprises a microscope objective lens 19 and a substrate 20. In operation, a beam of radiant energy will enter the housing 16 through the actuator lens receiving opening 18 and, if present, through the actuator lens. The beam will pass through the substrate 20 and through the microscope objective lens 19. The beam then passes through the housing 16 and into the tower assembly 1, where it passes through the tower magnifying lens 6 and is received by the video camera 7. Together, the microscope objective lens 19 and the tower magnifying lens 6 magnify the beam and focus the beam in the video camera 7. The tower magnifying lens 6 may be a tube lens. The substrate 20 simulates the optical properties of an information-bearing disk, and the effects of those properties on the beam. The substrate 20 is mounted such that, when the gripper assembly 2 is in the closed position, the substrate 20 is orthogonal to the tower optical axis.

Referring to exemplary FIG. 5, the microscope objective lens alignment assembly 14 comprises an X-axis lateral alignment actuator 21, a Y-axis lateral alignment actuator 22, and a focus actuator 23. Referring to exemplary FIG. 5, there is shown a reference coordinate system 24. This reference coordinate system 24 is chosen for purposes of explanation only, and it will be obvious to one skilled in the art that any convenient coordinate system could be chosen without departing from the spirit and scope of the present invention.

In the embodiment particularly shown in FIG. 5, a microscope support frame 25 having a frame extension 28 supports the housing 16 by a support leaf spring 26. The support leaf spring 26 biases the housing 16 against a cylindrical bearing 27 located between the housing 16 and the frame extension 28. The focus actuator 23 is mounted to the frame extension 28, and maintains a distance between the frame extension 28 and the microscope support frame 25 along the Z-axis, as indicated by the reference coordinate system 24. Motion of the housing 16 along the Z-axis adjusts the focus of the microscope objective lens 19 in combination with the tower magnifying lens 6.

The microscope support frame 25 is mounted on a Y-axis lateral alignment support 29 such that the microscope support frame 25 may slide relative to the Y-axis lateral alignment support 29 along the Y-axis, as indicated by the reference coordinate system 24. The Y-axis lateral alignment actuator 22 is mounted to the microscope support frame 25, and will actuate the relative sliding motion along the Y-axis.

The Y-axis lateral alignment support 29 is mounted on an X-axis lateral alignment support 30 such that the Y-axis lateral alignment support 29 may slide relative to the X-axis lateral alignment support 30 along the X-axis, as indicated by the reference coordinate system 24. The X-axis lateral alignment actuator 21 is mounted to the Y-axis lateral alignment support 29, and will actuate the relative sliding motion along the X-axis.

The X-axis lateral alignment support 30 is mounted to a lateral alignment assembly support 31. The lateral alignment assembly support 31 is mounted to the lever assembly 5. It will be apparent to one skilled in the art that the mountings between the microscope support frame 25, the Y-axis lateral alignment support 29, the X-axis lateral alignment support 30, and the lateral alignment assembly support 31 may be rearranged from the above description without departing from the spirit and scope of the present invention.

Referring to exemplary FIGS. **6** and **7**, there are shown two views of the actuator lens tilt assembly **15**. FIG. **6** represents a left side view of the actuator lens tilt assembly **15** according to one aspect of the invention. FIG. **7** represents a front view of the same actuator lens tilt assembly **15**. The actuator lens tilt assembly **15** comprises an X-axis tilt actuator **32**, a Y-axis tilt actuator **33**, and a flexure assembly **34**. The X-axis tilt actuator **32** is mounted to the lever assembly **5** and against an X-axis lever **35**. The X-axis lever **35**, at the end nearest the X-axis tilt actuator **32**, is biased against the lever assembly **5**, and at the other end is mounted to the flexure assembly **34**. The Y-axis tilt actuator **33** is mounted to the lever assembly **5** and against a Y-axis lever **36**. The Y-axis lever **36**, at the end nearest the Y-axis tilt actuator **33**, is biased against the lever assembly **5**, and at the other end is mounted to the flexure assembly **34**.

The flexure assembly **34** comprises a plurality of flexure plates **71**, **72**, **73**, **74**, a flexure support ring **38**, and a plurality of flexure support plates **39**. Flexure plate **71** is mounted at one end to the flexure support ring **38**, and mounted at its other end to the X-axis lever **35** and the housing **16**. Flexure plate **73** is mounted opposite flexure plate **71** to the flexure support ring **38** and to the housing **16**. Flexure plate **74** is mounted at one end to the Y-axis lever **36** and the flexure support ring **38**, and mounted at its other end to a flexure support plate **39**. Flexure plate **74** is mounted at a 90 degree interval from both flexure plate **71** and flexure plate **73**. Flexure plate **72** is mounted opposite flexure plate **74** to the flexure support ring **38** and to a flexure support plate **39**. The flexure support plates **39** are mounted to the lever assembly **5**.

Flexure plates **71**, **72**, **73**, **74** each lie in a separate plane. The planes in which flexure plates **71** and **73** lie intersect along a line through an intersection point **40**. The planes in which flexure plates **72** and **74** lie intersection along a line through the intersection point **40**. The lines may be orthogonal to each other.

The operation of the actuator lens tilt assembly **15** will be described with respect to a downward motion imparted on each of the tilt actuators, the X-axis tilt actuator **32** and the Y-axis tilt actuator **33**.

A downward motion of the X-axis tilt actuator **32** imparts a downward motion on the X-axis lever **35**. This downward force produces a counterclockwise rotational force on flexure plate **71** about the point where flexure plate **71** is mounted to the flexure support ring **38**. The downward force also translates into a counterclockwise rotational force on flexure plate **73** about the point where flexure plate **73** is mounted to the flexure support ring **38**. These two rotational forces cause rotation about the intersection of the two planes in which the flexure plates **71**, **73** lie. This intersection occurs at intersection point **40**.

A downward motion of the Y-axis tilt actuator **33** imparts a downward force on the Y-axis lever **36**. This downward force produces a clockwise rotational force on flexure plate **74** about the point where flexure plate **74** is mounted to the flexure support plate **39**. Because of the rigidity of the flexure support ring **38**, this rotational force translates into a clockwise rotational force on flexure plate **72** about the point where flexure plate **72** is mounted to the flexure support plate **39**. These two rotational forces cause rotation about the intersection of the two planes in which the flexure plates **72** and **74** lie. This intersection occurs at intersection point **40**.

Referring to exemplary FIG. **8**, there is shown one embodiment of an alignment actuator **41**. The alignment actuator **41** may be a tilt actuator or a lateral alignment actuator, as described above. The alignment actuator **41** contains a handle **42** and a threaded body **43**. The threaded body **43** is threadably mounted through a fixed surface **44** and against a movable surface **45**. The movable surface **45** is biased toward the fixed surface **44** by a spring **46** or other suitable biasing means. The mounting of the movable surface **45** determines whether the force by the alignment actuator **41** or the biasing by the spring **46** produces a lateral or rotational force. The alignment actuator **41** may include what is commonly referred to as a micrometer stage.

Referring to exemplary FIG. **9**, there is shown a top view of the cradle assembly **3**. Referring to exemplary FIG. **10**, there is shown a cross-sectional view of the cradle assembly **3**, taken along line **10—10** of FIG. **9**. The cradle assembly **3** comprises a cradle **47** having a surface **48** and a side **49**, a plurality of vacuum clamps **50**, and a baseplate alignment assembly (not shown). The cradle includes side walls **52** and end walls **53** for securing a baseplate assembly (not shown) in the cradle **47**. In the embodiment particularly shown in exemplary FIGS. **9** and **10**, the baseplate alignment assembly (not shown) comprises a source of radiant energy **54**, a Y-axis source lateral actuator **55**, a Z-axis source lateral actuator **56**, an X-axis cradle assembly tilt actuator **57**, a Y-axis cradle assembly tilt actuator **58**, a mirror **59**, and an alignment analyzer **60**. In another embodiment, the baseplate alignment assembly (not shown) comprises a source of radiant energy **54**, an X-axis cradle assembly tilt actuator **57**, a Y-axis cradle assembly tilt actuator **58**, a mirror **59**, and an alignment analyzer **60**. In both embodiments, the mirror **59** is aligned below a hole **61** in the surface **48** of the cradle **47**. Additionally, the source of radiant energy **54** and the alignment analyzer **60** may be combined in an auto-collimator or an auto-collimator/telescope.

Referring to exemplary FIG. **11**, a cross-sectional view of a vacuum clamp **50** is shown in the open position. Exemplary FIG. **12** shows a cross-sectional view of a vacuum clamp **50** in the closed position. The surface **48** of the cradle **47** extends laterally beyond the side **49** of the cradle **47**. The vacuum clamp **50**, having a U-shaped cross-section, is placed over the extension **51** of the cradle **47**, with one leg of the U on each side of the extension **51**. A pivot pin **62** is placed through each leg of the U-shape and through the extension of the cradle **47**. In the open position, a baseplate assembly can be placed on the cradle **47**. Once in place, a pneumatic tube (not shown) biases the vacuum clamp **50** to the closed position, securing the baseplate against movement.

In operation, as shown in exemplary FIG. **13**, a baseplate assembly **63** is provided. The baseplate assembly **63** contains a spindle **64** and a spindle motor **65** for rotating an information-bearing disk, and a spindle servo (not shown) for controlling the speed of the spindle motor **65**. The baseplate assembly **63** further contains an optics module assembly **66**. The baseplate assembly **63** also contains a carriage motor (not shown) and a carriage assembly **67** for directing a beam of radiant energy from the optics module assembly **66** toward a position on the information-bearing disk, and a carriage control servo (not shown) for controlling the position of the carriage assembly. At this point, the carriage assembly **67** does not contain an actuator lens for focussing the beam of radiant energy on the information-bearing disk. The carriage assembly **67** may be held in place relative to the spindle **64** by a carriage stop (not shown).

The baseplate assembly **63** is placed on the surface **48** of the cradle **47** and secured with the vacuum clamps **50**. A test disk of glass or other suitable material (not shown) is placed on the spindle of the baseplate assembly **63**. The gripper assembly **2** is then lowered into the closed position.

The source of radiant energy **54** radiates two cradle alignment beams of radiant energy toward the mirror **59**. The first cradle alignment beam is reflected from the mirror **59**, then passes through the hole **61** in the cradle **47** and through the baseplate assembly **63**. The first cradle alignment beam reflects off the test disk and is received by the alignment analyzer **60**. The second cradle alignment beam is reflected from the mirror **59**, then passes through the hole **61** in the cradle **47** and through the baseplate assembly **63**. The second cradle alignment beam reflects off the substrate **20** and is received by the alignment analyzer **60**. By analyzing the relative positions of the first and second cradle alignment beams, the alignment analyzer **60** determines the tilt of the test disk with respect to the substrate **20**. It will be obvious that the mirror **59** may comprise two parallel mirrors, each reflecting one of the cradle alignment beams.

Tilt between the test disk and the substrate **20** is corrected in the following manner. The X-axis cradle assembly tilt actuator **57** tilts the cradle assembly **3** about the X-axis. The Y-axis cradle assembly tilt actuator **58** tilts the cradle assembly **3** about the Y-axis. Acting together, the cradle assembly tilt actuators **57**, **58** tilt the cradle assembly **3**, including the test disk, with respect to the substrate **20**. Because the substrate **20** is orthogonal to the tower optical axis, this action tilts the cradle assembly **3** with respect to the tower optical axis. Each of the actuators **57**, **58** may be an alignment actuator **41** as shown in exemplary FIG. **8**.

In one embodiment, lateral alignment of the cradle assembly **3** with respect to the tower optical axis is done mechanically, and is not tested or measured. In another embodiment, if the cradle alignment beam is not received by the alignment analyzer **60**, or is off-center when received by the alignment analyzer **60**, the position of the source of radiant energy **54** can be moved using the Y-axis source lateral actuator **55** and the Z-axis source lateral actuator **56**. As shown best in FIG. **9**, the mirror **59** is situated such that a change in the position of the source of radiant energy **54** along the Y-axis is translated into a change in the position of the cradle alignment beam along the Y-axis as it is received by the alignment analyzer **60**. The Y-axis source lateral actuator **55** effects this change in position. Similarly, a change in the position of the source of radiant energy **54** along the Z-axis is translated into a change in the position of the cradle alignment beam along the X-axis as it is received by the alignment analyzer **60**. The Z-axis source lateral actuator **56** effects this change in position. Each of the actuators **55**, **56** may be an alignment actuator **41** as shown in exemplary FIG. **8**.

In the embodiment particularly described below, all references to a coordinate system are made in accordance with reference coordinate system **24** shown in exemplary FIG. **5**.

Once aligned, the source of radiant energy **54** is turned off and the test disk is removed. If not previously aligned, the carriage assembly of the baseplate assembly **63** is moved in approximate alignment with the assembly axis, and an actuator lens (not shown) is placed within the carriage assembly of the baseplate assembly **63** and is allowed to assume a natural rest position. The lever assembly **5** is lowered to the closed position.

A pressure differential is then created between the vacuum chuck **12** and the atmosphere. This pressure differential operates to hold the actuator lens against the vacuum chuck **12**, while maintaining the orientation of the actuator lens. Additionally, the optical center of the actuator lens is maintained at the intersection point **40**. This optical center may also be substantially at the center of mass of the actuator lens.

An adjustable power supply is attached to the radiant energy source within the optics module assembly **66**. The radiant energy source projects a lens alignment beam of radiant energy into the carriage assembly. Within the carriage assembly, the lens alignment beam passes through a pentaprism (not shown) and through the actuator lens. The lens alignment beam then passes through the substrate **20**, through the microscope objective lens **19**, and into the tower assembly **1**, where the lens alignment beam passes through the tower magnifying lens **6** and is received by the video camera **7**. The analysis assembly **9** then displays and analyzes the spot profile of the lens alignment beam.

If the lens alignment beam is not received by the video camera **7** and passed to the analysis assembly **9**, the X-axis lateral alignment actuator **21** and the Y-axis lateral alignment actuator **22** are used to move the microscope objective lens **19** laterally with respect to the tower assembly **1**. The X-axis lateral alignment actuator **21** and the Y-axis lateral alignment actuator **22** may be alignment actuators **41** as shown in exemplary FIG. **8**.

If the lens alignment beam is not focussed properly in the video camera **7** and analysis assembly **9**, the focus actuator **23** is used to move the microscope objective lens **19** toward or away from the tower assembly **1** until the lens alignment beam is in proper focus within the video camera **7** and analysis assembly **9**. The focus actuator **23** may be an alignment actuator **41** as shown in exemplary FIG. **8**.

Once focussed properly, the analysis assembly **9** analyzes the profile of the beam for coma and astigmatism, as the cradle alignment beam was previously analyzed. If these optical aberrations occur, the actuator lens tilt assembly **15** operates to minimize these aberrations by aligning the actuator lens. As described above, the X-axis tilt actuator **32** rotates the actuator lens about the X-axis. Likewise, the Y-axis tilt actuator **33** rotates the actuator lens about the Y-axis. Together, the actuator lens tilt assembly **15** can rotate the actuator lens in any direction with respect to the lens alignment beam, while maintaining the optical center or the center of mass of the actuator lens at the intersection point **40**.

Once the misalignment is corrected to within an acceptable tolerance, the gripper assembly **2**, including the vacuum chuck **12** and the actuator lens, is raised to the open position. A fastening agent is placed on the pedestals of the carriage assembly, and the gripper assembly **2** is again lowered to the closed position. The actuator lens is secured by the fastening agent to the carriage assembly, without changing the orientation of the actuator lens established by the actuator lens tilt assembly **15**. The fastening agent may be a selectably-curable adhesive, such as ultraviolet radiation-curable adhesive.

Once the fastening agent has cured, the actuator lens is tested for alignment. As above, a lens alignment beam is radiated through the actuator lens, the substrate **20**, the microscope objective lens **19**, the tower magnifying lens **6**, and into the video camera **7**. The analysis assembly **9** then analyzes the spot profile of the lens alignment beam. Each of the alignments described above may need to be adjusted for this testing process. Depending on its configuration, the vacuum chuck **12** may need to be retracted or removed to avoid contacting and damaging the carriage assembly.

In another embodiment of the invention, the cradle assembly **3** may comprise a plurality of cradles **47**, a plurality of vacuum clamps **50**, and a baseplate alignment assembly (not shown). The cradles **47** may be movable with respect to the tower assembly **1**, and there may be either one baseplate

alignment assembly (not shown) for each cradle **47**, or a single baseplate alignment assembly (not shown) which aligns only the cradle **47** presently in position with respect to the tower assembly **1**. Further, there may be a single source of radiant energy **54** and set of actuators **55**, **56**, **57**, **58** regardless of the number of cradles **47**, with one mirror **59** associated with each cradle **47**.

According to this embodiment, there may be a second tower assembly **1** identical to the first tower assembly **1** described above. In addition, there may be a second gripper assembly **2** associated with the second tower assembly **1** as described above. The second gripper assembly **2** will not contain a vacuum chuck **12**.

In operation, the first tower assembly **1** and first gripper assembly **2** operate as described in the previous embodiment. After fastening the actuator lens to the carriage assembly with the fastening agent, the cradle **47** containing the baseplate assembly **63** is moved beneath the second tower assembly **1** and second gripper assembly **2**. Again, a lens alignment beam of radiant energy is projected by the optics module assembly **66** through the same path in the second tower assembly **1** and second gripper assembly **2** as described with respect to the first tower assembly **1** and first gripper assembly **2**. The analysis assembly **9** associated with the second tower assembly I analyzes the spot profile of the lens alignment beam after the actuator lens is fastened to the baseplate assembly **63**. It will be obvious to one skilled in the art that, by allowing the vacuum chuck **12** to be removable or retractable, the first tower assembly **1** and first gripper assembly **2** may function as the second tower assembly **1** and second gripper assembly **2**, respectively.

While this invention has been explained with reference to the structure disclosed herein, it is not confined to the details set forth and this application is intended to cover any modifications and changes as may come within the scope of the following claims:

What is claimed is:

1. An apparatus for aligning an actuator lens defining an actuator optical axis and an actuator optical center within a baseplate using a beam of radiant energy, comprising:

a frame;

a cradle assembly for holding the baseplate, said cradle assembly mounted to said frame with at least one degree of freedom of motion;

a tower assembly defining a tower axis and mounted to said frame, said cradle assembly and said tower assembly defining an assembly axis, for receiving the beam of radiant energy along said tower axis;

a lever assembly positioned in a closed position, rotatably mounted to said frame; and

a gripper assembly mounted to said lever assembly, comprising:

an objective lens defining an objective optical axis;

an objective lens assembly mounted to said objective lens, for selectively holding the actuator lens stationary relative to said objective lens;

an objective lens alignment assembly for aligning said objective lens with said tower assembly and said cradle assembly by aligning said objective optical axis laterally with respect to said assembly axis when said lever assembly is in the closed position; and

an actuator lens tilt assembly for aligning the actuator lens with said tower assembly and said cradle assembly by rotating said actuator optical axis about an axis orthogonal to said assembly axis when said lever assembly is in the closed position;

whereby when said lever assembly is in said closed position said gripper assembly, said tower assembly, said cradle assembly, said baseplate, and said actuator lens tilt assembly are positioned with respect to each other such that the beam of radiant energy can be used to align the actuator lens with said baseplate by adjusting the relative position or alignment of one or more of said objective lens assembly, said cradle assembly, and said actuator lens with respect to said tower assembly.

2. An apparatus for holding an actuator lens defining an optical center stationary with respect to an objective lens, comprising:

a housing having at least two ends and an opening at a first end for receiving an actuator lens, and having a flexible bellows structure for allowing realignment of said end of said housing with respect to a second end of said housing;

an objective lens mounted to the interior of said housing between said bellows structure and said opening, said objective lens defining an optical axis which passes through said opening;

a non-opaque substrate mounted within said housing such that said optical axis passes through said substrate; and

a pneumatic tube attached to said housing, for creating a pressure differential between the interior and the exterior of said housing sufficient to hold said actuator lens covering said opening stationary relative to said housing.

3. An apparatus for manipulating an object, comprising:

an assembly support;

a first lateral alignment support slidably mounted to said assembly support to allow sliding motion of said first lateral alignment support relative to said assembly support along a first axis;

a second lateral alignment support slidably mounted to said first lateral alignment support, to allow sliding motion of said second lateral alignment support relative to said first lateral alignment support along a second axis orthogonal to said first axis;

a support frame including a frame base and a frame extension, said support frame being mounted to said second lateral alignment support, and said frame base and said frame extension being separated by a distance along a third axis orthogonal to said first axis and said second axis;

a support leaf spring fixed to said support frame, for biasing an object toward said frame extension along said third axis;

a first lateral actuator for positioning said first lateral alignment support relative to said assembly support along said first axis;

a second lateral actuator for positioning said second lateral alignment support relative to said first lateral alignment support along said second axis; and

a third lateral actuator mounted to said frame extension and against said frame base for altering the distance between said frame extension and said frame base along said third axis.

4. An apparatus for manipulating a lens, comprising:

an assembly support;

a first lateral alignment support slidably mounted to said assembly support to allow sliding motion of said first lateral alignment support relative to said assembly support along a first axis;

a second lateral alignment support slidably mounted to said first lateral alignment support, to allow sliding motion of said second lateral alignment support relative to said first lateral alignment support along a second axis orthogonal to said first axis;

a support frame including a frame base and a frame extension, said support frame being mounted to said second lateral alignment support, and said frame base and said frame extension being separated by a distance along a third axis orthogonal to said first axis and said second axis;

a support leaf spring fixed to said support frame, for biasing a lens defining an optical axis toward said frame extension along said optical axis, said optical axis being parallel to said third axis;

a first lateral actuator for positioning said first lateral alignment support relative to said assembly support along said first axis;

a second lateral actuator for positioning said second lateral alignment support relative to said first lateral alignment support along said second axis; and

a focus actuator mounted to said frame extension and against said frame base for altering the distance between said frame extension and said frame base along said third axis.

5. An apparatus as defined in claim **1**, wherein said objective lens alignment assembly comprises:

an assembly support mounted to said lever assembly;

a first lateral alignment support slidably mounted to said assembly support to allow sliding motion of said first lateral alignment support relative to said assembly support along a first axis;

a second lateral alignment support slidably mounted to said first lateral alignment support, to allow sliding motion of said second lateral alignment support relative to said first lateral alignment support along a second axis orthogonal to said first axis;

a support frame including a frame base and a frame extension, said support frame being mounted to said second lateral alignment support, and said frame base and said frame extension being separated by a distance along a third axis orthogonal to said first axis and said second axis;

a support leaf spring fixed to said support frame, for biasing said objective lens toward said frame extension along said objective optical axis, said objective optical axis being parallel to said third axis;

a first lateral actuator for positioning said first lateral alignment support relative to said assembly support along said first axis;

a second lateral actuator for positioning said second lateral alignment support relative to said first lateral alignment support along said second axis; and

a focus actuator mounted to said frame extension and against said frame base for altering the distance between said frame extension and said frame base along said third axis.

6. An apparatus as defined in claim **2**, wherein said objective lens alignment assembly comprises:

an assembly support mounted to said lever assembly;

a first lateral alignment support slidably mounted to said assembly support to allow sliding motion of said first lateral alignment support relative to said assembly support along a first axis;

a second lateral alignment support slidably mounted to said first lateral alignment support, to allow sliding motion of said second lateral alignment support relative to said first lateral alignment support along a second axis orthogonal to said first axis;

a support frame including a frame base and a frame extension, said support frame being mounted to said second lateral alignment support, and said frame base and said frame extension being separated by a distance along a third axis orthogonal to said first axis and said second axis;

a support leaf spring fixed to said support frame, for biasing said objective lens toward said frame extension along said objective optical axis, said objective optical axis being parallel to said third axis;

a first lateral actuator for positioning said first lateral alignment support relative to said assembly support along said first axis;

a second lateral actuator for positioning said second lateral alignment support relative to said first lateral alignment support along said second axis; and

a focus actuator mounted to said frame extension and against said frame base for altering the distance between said frame extension and said frame base along said third axis.

7. An apparatus for manipulating an object, comprising:

a flexure support ring;

a first flexure plate mounted at one end to said flexure support ring, said first flexure plate defining a first plane;

a second flexure plate mounted at one end to the opposite end of said flexure support ring from said first flexure plate, said second flexure plate defining a second plane, said second flexure plate positioned relative to said first flexure plate such that said first and second planes intersect, the intersection of said first plane and said second plane defining a first line;

a support frame;

a first flexure support plate mounted at one end to the end of said first flexure plate remote from said flexure support ring, and mounted at the other end to said support frame;

a second flexure support plate mounted at one end to the end of said second flexure plate remote from said flexure support ring, and mounted at the other end to said support frame;

a first lever having a first end and a second end, said first end disposed against the juncture of said first flexure plate and said flexure support ring;

a first tilt actuator mounted on said support frame and against said second end of said first lever, for moving said first lever laterally toward or away from said first flexure plate and said flexure support ring;

a third flexure plate mounted at one end to said flexure support ring and mounted at the other end to an object, said third flexure plate defining a third plane;

a fourth flexure plate mounted at one end to said flexure support ring and mounted at the other end to said object, said fourth flexure plate defining a fourth plane, said fourth flexure plate positioned relative to said third flexure plate such that said third and fourth planes intersect, the intersection of said third plane and said fourth plane defining a second line orthogonal to said first line, the intersection of said first line and said second line defining a rotation point;

a second lever having a first end and a second end, said first end disposed against the intersection of said third flexure plate and said object; and

a second tilt actuator mounted on said support frame and against said second end of said second lever, for moving said second lever laterally toward or away from said third flexure plate;

whereby said first tilt actuator imparts a first movement on said first lever toward or away from said first flexure support plate, thereby causing rotation of said first flexure support plate, said second flexure support plate, said flexure support ring, and said object about said first axis, and said second tilt actuator imparts a second movement on said second lever toward or away from said third flexure support plate, thereby causing rotation of said third flexure support plate, said fourth flexure support plate, said flexure support ring, and said object about said second axis.

8. An apparatus as defined in claim **7**, wherein said rotation point is located at the center of mass of said object.

9. An apparatus as defined in claim **1**, wherein said actuator lens tilt assembly comprises:

a flexure support ring;

a first flexure plate mounted at one end to said flexure support ring, said first flexure plate defining a first plane;

a second flexure plate mounted at one end to the opposite end of said flexure support ring from said first flexure plate, said second flexure plate defining a second plane, said second flexure plate positioned relative to said first flexure plate such that said first and second planes intersect, the intersection of said first plane and said second plane defining a first line;

a first flexure support plate mounted at one end to the end of said first flexure plate remote from said flexure support ring, and mounted at the other end to said lever assembly;

a second flexure support plate mounted at one end to the end of said second flexure plate remote from said flexure support ring, and mounted at the other end to said lever assembly;

a first lever having a first end and a second end, said first end disposed against the juncture of said first flexure plate and said flexure support ring;

a first tilt actuator mounted on said lever assembly and against said second end of said first lever, for moving said first lever laterally toward or away from said first flexure plate and said flexure support ring;

a third flexure plate mounted at one end to said flexure support ring and mounted at the other end to said actuator lens, said third flexure plate defining a third plane;

a fourth flexure plate mounted at one end to said flexure support ring and mounted at the other end to said actuator lens, said fourth flexure plate defining a fourth plane, said fourth flexure plate positioned relative to said third flexure plate such that said third and fourth planes intersect, the intersection of said third plane and said fourth plane defining a second line orthogonal to said first line, the intersection of said first line and said second line defining a rotation point, said rotation point located at said actuator optical center;

a second lever having a first end and a second end, said first end disposed against the intersection of said third flexure plate and said actuator lens; and

a second tilt actuator mounted on said lever assembly and against said second end of said second lever, for moving said second lever laterally toward or away from said third flexure plate;

whereby said first tilt actuator imparts a first movement on said first lever toward or away from said first flexure support plate, thereby causing rotation of said first flexure support plate, said second flexure support plate, said flexure support ring, and said actuator lens about said first axis, and said second tilt actuator imparts a second movement on said second lever toward or away from said third flexure support plate, thereby causing rotation of said third flexure support plate, said fourth flexure support plate, said flexure support ring, and said actuator lens about said second axis.

10. An apparatus as defined in claim **2**, wherein said actuator lens tilt assembly comprises:

a flexure support ring;

a first flexure plate mounted at one end to said flexure support ring, said first flexure plate defining a first plane;

a second flexure plate mounted at one end to the opposite end of said flexure support ring from said first flexure plate, said second flexure plate defining a second plane, said second flexure plate positioned relative to said first flexure plate such that said first and second planes intersect, the intersection of said first plane and said second plane defining a first line;

a first flexure support plate mounted at one end to the end of said first flexure plate remote from said flexure support ring, and mounted at the other end to said lever assembly;

a second flexure support plate mounted at one end to the end of said second flexure plate remote from said flexure support ring, and mounted at the other end to said lever assembly;

a first lever having a first end and a second end, said first end disposed against the juncture of said first flexure plate and said flexure support ring;

a first tilt actuator mounted on said lever assembly and against said second end of said first lever, for moving said first lever laterally toward or away from said first flexure plate and said flexure support ring;

a third flexure plate mounted at one end to said flexure support ring and mounted at the other end to said actuator lens, said third flexure plate defining a third plane;

a fourth flexure plate mounted at one end to said flexure support ring and mounted at the other end to said actuator lens, said fourth flexure plate defining a fourth plane, said fourth flexure plate positioned relative to said third flexure plate such that said third and fourth planes intersect, the intersection of said third plane and said fourth plane defining a second line orthogonal to said first line, the intersection of said first line and said second line defining a rotation point, said rotation point located at said actuator optical center;

a second lever having a first end and a second end, said first end disposed against the intersection of said third flexure plate and said actuator lens; and

a second tilt actuator mounted on said lever assembly and against said second end of said second lever, for moving said second lever laterally toward or away from said third flexure plate;

whereby said first tilt actuator imparts a first movement on said first lever toward or away from said first flexure support plate, thereby causing rotation of said first flexure support plate, said second flexure support plate, said flexure support

ring, and said actuator lens about said first axis, and said second tilt actuator imparts a second movement on said second lever toward or away from said third flexure support plate, thereby causing rotation of said third flexure support plate, said fourth flexure support plate, said flexure support ring, and said actuator lens about said second axis.

11. An apparatus as defined in claim 5, wherein said actuator lens tilt assembly comprises:

a flexure support ring;

a first flexure plate mounted at one end to said flexure support ring, said first flexure plate defining a first plane;

a second flexure plate mounted at one end to the opposite end of said flexure support ring from said first flexure plate, said second flexure plate defining a second plane, said second flexure plate positioned relative to said first flexure plate such that said first and second planes intersect, the intersection of said first plane and said second plane defining a first line;

a first flexure support plate mounted at one end to the end of said first flexure plate remote from said flexure support ring, and mounted at the other end to said lever assembly;

a second flexure support plate mounted at one end to the end of said second flexure plate remote from said flexure support ring, and mounted at the other end to said lever assembly;

a first lever having a first end and a second end, said first end disposed against the juncture of said first flexure plate and said flexure support ring;

a first tilt actuator mounted on said lever assembly and against said second end of said first lever, for moving said first lever laterally toward or away from said first flexure plate and said flexure support ring;

a third flexure plate mounted at one end to said flexure support ring and mounted at the other end to said actuator lens, said third flexure plate defining a third plane;

a fourth flexure plate mounted at one end to said flexure support ring and mounted at the other end to said actuator lens, said fourth flexure plate defining a fourth plane, said fourth flexure plate positioned relative to said third flexure plate such that said third and fourth planes intersect, the intersection of said third plane and said fourth plane defining a second line orthogonal to said first line, the intersection of said first line and said second line defining a rotation point, said rotation point located at said actuator optical center;

a second lever having a first end and a second end, said first end disposed against the intersection of said third flexure plate and said actuator lens; and

a second tilt actuator mounted on said lever assembly and against said second end of said second lever, for moving said second lever laterally toward or away from said third flexure plate;

whereby said first tilt actuator imparts a first movement on said first lever toward or away from said first flexure support plate, thereby causing rotation of said first flexure support plate, said second flexure support plate, said flexure support ring, and said actuator lens about said first axis, and said second tilt actuator imparts a second movement on said second lever toward or away from said third flexure support plate, thereby causing rotation of said third flexure support plate, said fourth flexure support plate, said flexure support ring, and said actuator lens about said second axis.

12. An apparatus as defined in claim 6, wherein said actuator lens tilt assembly comprises:

a flexure support ring;

a first flexure plate mounted at one end to said flexure support ring, said first flexure plate defining a first plane;

a second flexure plate mounted at one end to the opposite end of said flexure support ring from said first flexure plate, said second flexure plate defining a second plane, said second flexure plate positioned relative to said first flexure plate such that said first and second planes intersect, the intersection of said first plane and said second plane defining a first line;

a first flexure support plate mounted at one end to the end of said first flexure plate remote from said flexure support ring, and mounted at the other end to said lever assembly;

a second flexure support plate mounted at one end to the end of said second flexure plate remote from said flexure support ring, and mounted at the other end to said lever assembly;

a first lever having a first end and a second end, said first end disposed against the juncture of said first flexure plate and said flexure support ring;

a first tilt actuator mounted on said lever assembly and against said second end of said first lever, for moving said first lever laterally toward or away from said first flexure plate and said flexure support ring;

a third flexure plate mounted at one end to said flexure support ring and mounted at the other end to said actuator lens, said third flexure plate defining a third plane;

a fourth flexure plate mounted at one end to said flexure support ring and mounted at the other end to said actuator lens, said fourth flexure plate defining a fourth plane, said fourth flexure plate positioned relative to said third flexure plate such that said third and fourth planes intersect, the intersection of said third plane and said fourth plane defining a second line orthogonal to said first line, the intersection of said first line and said second line defining a rotation point, said rotation point located at said actuator optical center;

a second lever having a first end and a second end, said first end disposed against the intersection of said third flexure plate and said actuator lens; and

a second tilt actuator mounted on said lever assembly and against said second end of said second lever, for moving said second lever laterally toward or away from said third flexure plate;

whereby said first tilt actuator imparts a first movement on said first lever toward or away from said first flexure support plate, thereby causing rotation of said first flexure support plate, said second flexure support plate, said flexure support ring, and said actuator lens about said first axis, and said second tilt actuator imparts a second movement on said second lever toward or away from said third flexure support plate, thereby causing rotation of said third flexure support plate, said fourth flexure support plate, said flexure support ring, and said actuator lens about said second axis.

13. An apparatus for aligning a baseplate assembly, comprising:

a lens defining an optical axis;

a source of radiant energy for projecting a radiant energy beam into said lens along a beam axis;

means for determining the tilt alignment of said beam axis with respect to said optical axis;

a first tilt actuator for rotating said beam axis about a first repositioning axis orthogonal to said optical axis; and

a second tilt actuator for rotating said beam axis about a second repositioning axis orthogonal to said optical axis and said first repositioning axis.

14. An apparatus as defined in claim **13**, further comprising a mirror disposed along said beam axis for redirecting said radiant energy beam into said lens in response to motion by one or more of said actuators.

15. An apparatus as defined in claim **1**, further comprising:

a source of radiant energy for projecting said beam of radiant energy into said tower assembly along a beam axis;

means for determining the tilt alignment of said beam axis with respect to said tower axis;

a first tilt actuator for rotating said beam axis about a first repositioning axis orthogonal to said tower axis; and

a second tilt actuator for rotating said beam axis about a second repositioning axis orthogonal to said tower axis and said first repositioning axis.

16. An apparatus as defined in claim **6**, further comprising:

a source of radiant energy for projecting said beam of radiant energy into said tower assembly along a beam axis;

means for determining the tilt alignment of said beam axis with respect to said tower axis;

a first tilt actuator for rotating said beam axis about a first repositioning axis orthogonal to said tower axis; and

a second tilt actuator for rotating said beam axis about a second repositioning axis orthogonal to said tower axis and said first repositioning axis.

17. An apparatus as defined in claim **12**, further comprising:

a source of radiant energy for projecting said beam of radiant energy into said tower assembly along a beam axis;

means for determining the tilt alignment of said beam axis with respect to said tower axis;

a first tilt actuator for rotating said beam axis about a first repositioning axis orthogonal to said tower axis; and

a second tilt actuator for rotating said beam axis about a second repositioning axis orthogonal to said tower axis and said first repositioning axis.

18. An apparatus for aligning a baseplate assembly, as defined in claim **13**, further comprising:

means for determining the lateral alignment of said beam axis with respect to said optical axis;

a first lateral actuator for repositioning said beam axis laterally with respect to said optical axis along said first repositioning axis; and

a second lateral actuator for repositioning said beam axis laterally with respect to said optical axis along said second repositioning axis.

19. An apparatus as defined in claim **18**, further comprising a mirror disposed along said beam axis for redirecting said radiant energy beam into said lens in response to motion by one or more of said actuators.

20. An apparatus as defined in claim **1**, further comprising:

a source of radiant energy for projecting said beam of radiant energy into said tower assembly along a beam axis;

means for determining the lateral alignment and tilt alignment of said beam axis with respect to said tower axis;

a first lateral actuator for repositioning said beam axis laterally with respect to said tower axis along a first repositioning axis orthogonal to said tower axis;

a second lateral actuator for repositioning said beam axis laterally with respect to said tower axis along a second repositioning axis orthogonal to said tower axis and said first repositioning axis;

a first tilt actuator for rotating said beam axis about said first repositioning axis; and

a second tilt actuator for rotating said beam axis about said second repositioning axis.

21. An apparatus as defined in claim **6**, further comprising:

a source of radiant energy for projecting said beam of radiant energy into said tower assembly along a beam axis;

means for determining the lateral alignment and tilt alignment of said beam axis with respect to said tower axis;

a first lateral repositioning actuator for repositioning said beam axis laterally with respect to said tower axis along a first repositioning axis orthogonal to said tower axis;

a second lateral repositioning actuator for repositioning said beam axis laterally with respect to said tower axis along a second repositioning axis orthogonal to said tower axis and said first repositioning axis;

a first tilt actuator for rotating said beam axis about said first repositioning axis; and

a second tilt actuator for rotating said beam axis about said second repositioning axis.

22. An apparatus as defined in claim **12**, further comprising:

a source of radiant energy for projecting said beam of radiant energy into said tower assembly along a beam axis;

means for determining the lateral alignment and tilt alignment of said beam axis with respect to said tower axis;

a first lateral repositioning actuator for repositioning said beam axis laterally with respect to said tower axis along a first repositioning axis orthogonal to said tower axis;

a second lateral repositioning actuator for repositioning said beam axis laterally with respect to said tower axis along a second repositioning axis orthogonal to said tower axis and said first repositioning axis;

a first tilt repositioning actuator for rotating said beam axis about said first repositioning axis; and

a second tilt repositioning actuator for rotating said beam axis about said second repositioning axis.

23. An apparatus as defined in claim **17**, wherein said tower assembly comprises:

a video camera having a camera lens defining a camera optical axis, said camera optical axis being parallel to said tower axis;

a tower magnifying lens defining a tower lens optical axis, said tower lens optical axis being parallel to said tower axis, for cooperating with said objective lens to focus said beam of radiant energy on said camera lens; and

a monitor for displaying a representation of said beam of radiant energy.

24. An apparatus as defined in claim **17**, further comprising:

a second cradle assembly for holding a second baseplate, said second cradle assembly mounted to said frame with at least one degree of freedom of motion;

a second source of radiant energy for projecting a second beam of radiant energy; and

a second tower assembly mounted to said frame, said second tower assembly defining a second tower axis, for receiving said second beam of radiant energy along said second tower axis and analyzing the spot profile of said second beam of radiant energy, said second cradle assembly and said second tower assembly defining a second assembly axis.

25. A method of aligning an actuator lens with respect to a baseplate assembly, comprising the steps of:

moving a first time said baseplate assembly with respect to a tower assembly, said baseplate assembly defining a baseplate optical axis, said tower assembly defining a tower optical axis, whereby said first moving step aligns said baseplate optical axis and said tower optical axis;

moving a second time an objective lens assembly with respect to said tower assembly, said objective lens assembly defining an objective lens optical axis, whereby said second moving step aligns said objective lens optical axis and said tower optical axis; and

moving a third time said actuator lens with respect to said tower assembly, said actuator lens defining an actuator lens optical axis,

whereby said third moving step aligns said actuator lens optical axis and said tower optical axis.

26. A method of aligning a lens, as defined in claim **25**, wherein said first moving step comprises:

moving said baseplate assembly with respect to said tower assembly laterally such that said baseplate optical axis and said tower optical axis intersect at a first intersection; and

rotating a first time said baseplate assembly with respect to said tower assembly about a first rotational axis through said first intersection and orthogonal to said baseplate optical axis and said tower optical axis.

27. A method of aligning a lens, as defined in claim **25**, wherein said third moving step comprises:

moving said actuator lens with respect to said tower assembly laterally such that said actuator lens optical axis and said tower optical axis intersect at a second intersection; and

rotating a second time said actuator lens with respect to said tower assembly about a second rotational axis through said second intersection and orthogonal to said actuator lens optical axis and said tower optical axis.

28. A method of aligning a lens, as defined in claim **26**, wherein said third moving step comprises:

moving said actuator lens with respect to said tower assembly laterally such that said actuator lens optical axis and said tower optical axis intersect at a second intersection; and

rotating a second time said actuator lens with respect to said tower assembly about a second rotational axis through said second intersection and orthogonal to said actuator lens optical axis and said tower optical axis.

29. A method of aligning a lens, as defined in claim **26**, wherein said first rotating step comprises:

rotating said baseplate assembly with respect to said tower assembly about a first reference axis through said first intersection and coplanar with said first rotational axis; and

rotating said baseplate assembly with respect to said tower assembly about a second reference axis through said first intersection and coplanar with said first rotational axis and orthogonal to said first reference axis;

whereby said baseplate assembly is rotated about said first rotational axis.

30. A method of aligning a lens, as defined in claim **27**, wherein said second rotating step comprises:

rotating said actuator lens with respect to said tower assembly about a third reference axis through said second intersection and coplanar with said first rotational axis; and

rotating said actuator lens with respect to said tower assembly about a fourth reference axis through said second intersection and coplanar with said second rotational axis and orthogonal to said third reference axis;

whereby said actuator lens is rotated about said second rotational axis.

31. A method of aligning a lens, as defined in claim **28**, wherein:

said first rotating step comprises:

rotating said baseplate assembly with respect to said tower assembly about a first reference axis through said first intersection and coplanar with said first rotational axis; and

rotating said baseplate assembly with respect to said tower assembly about a second reference axis through said first intersection and coplanar with said first rotational axis and orthogonal to said first reference axis;

whereby said baseplate assembly is rotated about said first rotational axis; and

said second rotating step comprises:

rotating said actuator lens with respect to said tower assembly about a third reference axis through said second intersection and coplanar with said first rotational axis; and

rotating said actuator lens with respect to said tower assembly about a fourth reference axis through said second intersection and coplanar with said second rotational axis and orthogonal to said third reference axis;

whereby said actuator lens is rotated about said second rotational axis.

[57] **ABSTRACT**

An apochromatic wide-angle objective has an improved correction of transverse chromatic aberration while at the same providing a high correction of other errors. These corrections are obtained utilizing long-crown and short-flint glasses.

APOCHROMATIC WIDE-ANGLE OBJECTIVE

FIELD OF THE INVENTION

The invention relates to an apochromatic wide-angle objective wherein: the majority of the lenses have considerable anomalous partial dispersion, the majority of the converging lenses behind the system diaphragm are of the long-crown type and the majority of the convex lenses are of the short-flint type.

BACKGROUND OF THE INVENTION

An objective of this kind was presented at the "Photokina 1992" in Cologne under the designation Carl Zeiss Distagon 2.8/21 mm No. 104926 configured as a wide-angle objective for miniature cameras, such as 24×36 mm^2 cameras. In this objective, most lenses forward of the diaphragm having positive refractive power are made of glasses having anomalous partial dispersion and are of the short-flint type. Most lenses having a negative refractive power are made of the long-crown type. After the diaphragm, the association of the sign of the refractive power is inverted with respect to the glass type. In this way, the correction of the transverse chromatic aberration for three wavelengths and three image heights was made possible by continuous reduction from lens to lens.

However, in the above, it is not possible to simultaneously optimally correct the oblique spherical aberration which would require a different refractive power distribution over the lenses.

The full image quality is obtained with this objective, as with other commercially available wide-angle objectives, only after stopping down approximately two stop numbers with respect to the nominal full opening.

SUMMARY OF THE INVENTION

It is an object of the invention to provide an apochromatically corrected wide-angle objective wherein the transverse chromatic aberration and the oblique spherical aberration are corrected to a great extent. The highest image quality should already be available when the aperture is completely open, that is, the objective is set to its smallest stop number. An embodiment defining an apochromatic perspective compensating wide-angle objective is also provided.

A front lens made of glass having anomalous partial dispersion is introduced which is so configured that it generates a transverse chromatic aberration which is in addition to that which occurs for normal glass. It was surprisingly found that introducing a front lens made of this glass made it possible, together with further lenses made of such glass types, to obtain the correction of the transverse chromatic aberration and simultaneously realize a progression of the refractive powers which permits a correction of the oblique spherical aberration. Overall, a correction is possible in this manner which results in a complete image quality up to the full opening (minimum stop number). In this way, the exposure latitude available to a photographer is significantly expanded.

The apochromatic wide-angle objective of the invention is for viewing an object. The objective includes: a plurality of lenses defining an optical axis and more than half of the lenses having anomalous partial dispersion; the plurality of lenses being subdivided into first and second groups of lenses; a system diaphragm mounted on the axis between the first and second groups; the first group of lenses having a front lens facing toward the object; the front lens being a converging lens made of a long-crown type of glass; the second group of lenses including a plurality of converging lenses and a plurality of diverging lenses; and, more than half of the converging lenses of the second group being made of a long-crown type of glass and more than half of the diverging lenses of the second group being made of a short-flint type of glass.

According to another feature of the invention, a forward group, which deliberately increases the transverse chromatic aberration, and a center group, which reduces this aberration, are provided forward of the system diaphragm.

According to another feature of the invention, preferred tolerances are provided when other than long-crown or short-flint glasses are used which cannot always be avoided.

Preferably, the front lens significantly increases the transverse chromatic aberration. The front lens is preferably a meniscus having a convex front surface because the objective is then especially compact.

In an advantageous embodiment, a composite lens made of two lenses of glass is provided forward of the system diaphragm. The dispersion functions of these lenses in the spectral range used are distinguished from each other only by a constant, that is, the lenses have different refractive indices but the same Abbe number and the same anomalous partial dispersions.

In this way, a surface is made available which is without influence with respect to the chromatic errors and which can be used for correcting the remaining imaging errors.

While the front lens increases the transverse chromatic aberration, this aberration is well corrected by the entire objective in a preferred embodiment for three wavelengths over all field angles. Likewise, it is a special advantage of the invention that the oblique spherical aberration of the sagittal imaging is well corrected.

The objective is preferably configured as a retrofocus objective and especially as an interchangeable lens and is especially suited as a shift objective. The embodiment according to the invention leads to a good correction even for the problems caused by the backfocus distance which is necessarily large.

A lens made of long-crown glass Hoya ATF 2 is used or a lens made of the glass known as Hoya ADC 1. The glass Hoya ATF 2 is a long-crown glass which is known for its athermal characteristic and is used only in special objectives where this characteristic is needed. The Hoya ADC 1 glass is likewise of the long-crown type and is especially suited for the front lens. Glasses of other manufacturers having practically the same optical characteristics are likewise suitable.

The designations "long crown" and "short flint" identify optical glasses with respect to their partial dispersion. In a primary dispersion/partial dispersion diagram v, P the Abbe normal is determined by the glass pair K7, F2 (Schott). Most conventionally available optical glasses are close to this normal straight line.

Glasses of the long-crown type have a significantly lower partial dispersion. Glasses of the short-flint type have a significantly higher partial dispersion than the glasses which lie on the Abbe normal straight line, that is, they have an anomalous partial dispersion.

There are, however, various definitions of primary dispersion (v) and partial dispersion (P) in use which refer to different spectral lines. In this context, reference can be

made to the text of H. Naumann et al entitled "Bauelemente der Optik" published by Carl Hanser Verlag, Munich, 1983, pages 52 and 55. Here, it is stated that at least one type of glass having anomalous partial dispersion must be used for apochromatization.

Here, an apochromatization for the following lines is delineated:

g: blue mercury line at 435.84 nm;

d: yellow helium line at 587.56 nm; and,

C: red hydrogen line at 657.27 nm

and achromatized for g, d.

The primary dispersion is defined as:

$$\nu = \frac{n_d - 1}{n_g - n_d}$$

This equation is therefore only characterized by the indices of refraction at two lines.

The partial dispersion is defined as:

$$P = \frac{n_d - n_C}{n_g - n_d}$$

Thus, an extrapolation of the refractive index is carried out toward the third line C.

The Abbe normal straight line for K2, F7 has, with this definition, the form

$$P_n = A \cdot \nu + B$$

and the deviation therefrom as a relative partial dispersion is given as:

$$\Delta P = P - A \cdot \nu - B \text{ with}$$

$$A = 0.9007 \cdot 10^{-4} \text{ and } B = 0.2025.$$

A uniform distribution of commercially available glass types about the normal straight line results over the entire range of the primary dispersion values compared to the normal straight lines defined above and with the primary dispersion ν and partial dispersion P defined above. The distinction fixed thereby of long-crown, normal and short-flint glasses corresponds well to the requirement to select a glass for pregiven primary dispersion which has a relatively pronounced partial dispersion amongst the glasses available.

According to another feature of the invention, the selection of the glasses in accordance with the definition given above is especially advantageous.

An especially advantageous embodiment of the objective of the invention can be scaled for other focal lengths by the scale of the focal length ratio.

BRIEF DESCRIPTION OF THE DRAWINGS

The invention will now be described with reference to the drawings wherein:

FIG. **1** is a lens section view taken through an Apo-Distagon 3.5/25 mm objective according to the invention;

FIG. **2** is a schematic representation of a shift interchangeable objective mounted on a camera;

FIG. **3** is a diagram of a modulation transmission function for the objective of FIG. **1**;

FIG. **4** is a diagram of the total transverse aberration in a sagittal section for the objective of FIG. **1**;

FIG. **5** is a diagram of the total transverse aberration in the meridional section for the objective of FIG. **1**;

FIG. **6** is a diagram of the sagittal coma of the objective of FIG. **1**; and,

FIG. **7** is a diagram showing the progression of the transverse chromatic aberration and longitudinal chromatic aberration over the lenses of the objective of FIG. **1**.

DESCRIPTION OF THE PREFERRED EMBODIMENTS OF THE INVENTION

The main rays for minimum and maximum image angle are shown in the lens section of FIG. **1**. Table 1 presents the following: the radii of the surfaces **1** to **39**, the thicknesses and the glass types as well as further essential data of the objective. Surface **39** is the image plane. The cement used has the refractive index 1.57 at a wavelength of 587.6 nm.

Also presented in Table 1 are: the refractive index for the d-line (n_d), the primary dispersion (ν) and the relative partial dispersion (ΔP) in accordance with the definitions presented above. Also delineated in Table 1 are the long-crown character L or the short-flint character K of the glasses.

The planar-parallel element after surface **13** is made of normal glass and functions as an exchangeable filter. Of the 17 lenses, a total of 14 lenses have a considerable anomalous partial dispersion.

Behind the system diaphragm **24** in the base group **103**, all lenses of a positive refractive power (**25**, **29**, **35**, **37**) have a long-crown characteristic and the lenses (**27**, **33**) of negative refractive power have a short-flint characteristic as in the above-mentioned Carl Zeiss Distagon 2.8/21 mm.

The first lens **1** of the objective is a convex meniscus of positive refractive power and is on the object end of the objective. This first lens **1** has a pronounced long-crown character in contrast to the rule applied in the above-mentioned known objective. The first lens **1** is made of Hoya ADC 1, which is a glass seldom used, or a like substitute and is made with the following parameters: n_d=1.620;ν=50 and ΔP=–0.0033.

In this way, and in accordance with the invention, a transverse chromatic aberration is generated which must subsequently be corrected. This transverse chromatic aberration is greater than for a theoretical glass having the same refractive index and primary dispersion but with a vanishing relative partial dispersion. It is, however, possible in this manner to reduce the angle and elevation of the light rays in the region of lenses having surfaces (**1**, **3**, **5**, **7**) very rapidly whereby the oblique spherical aberration of the sagittal imaging is effectively reduced.

In the entire forward group **101**, the same relationship of refractive power and character of the anomalous partial dispersion is maintained as in the base group **103**. Only for the third lens having the surfaces (**5**, **6**) with a very high refractive index (n_d=1.92) and low primary dispersion (ν=15.9), only long-crown glasses which are inconsistent with the system are available so that this system deviation must be accepted.

The center group **102** is built up in an opposite manner and comprises the lenses having surfaces (**17**, **18**; **20**, **21**; **21**, **22**). Here, the lenses with surfaces (**21**, **22**) have a positive refactive power and are made of short-flint glasses and those lenses having surfaces (**17**, **18**) have a negative refractive power and are made of long-crown glasses.

The following glasses: Ohara LAH **75** (lenses having surfaces **3**, **4**; **31**, **32**); Ohara BPH 45 lenses having surfaces (**27**, **28**) and Ohara BAH 30 lenses having surfaces (**15**, **16**) all having an amount of relative partial dispersion ΔP below 2×10^{-3} can be considered as normal glasses. It is, however,

significant that the partial dispersion ΔP thereof (even when small) are in the proper direction.

The composite lens having surfaces (**20**, **22**) comprises two glasses (Hoya TAFD 30, Ohara BPH 35) with different refractive index (n) but with practically the same primary dispersion (v) and with practically the same relative partial dispersion (ΔP). The dispersion functions of both are distinguished therefore only by a constant Δn. The cement interface at surfaces (**21**, **22**) has therefore no effect with respect to spectral correction and can separately act on other errors. Overall, the composite lens having surfaces (**20**, **22**) has a positive refractive power and a short-flint character.

The system deviation of the first lens having surfaces (**20**, **21**) of the composite element lenses having surfaces (**20**, **22**) as short flint results from this special function.

The glass selection for an apochromatic wide-angle objective according to the invention then takes place as delineated below.

In the front group **101**, the transverse chromatic aberration for the red spectral range is deliberately magnified already by the first lens having surfaces (**1**, **2**). The objective here is to greatly increase the error in the external field. A demagnification of the transverse chromatic aberration would here lead to the condition that a large undercorrection in the field center (zone) would occur or that an overcorrection would occur at the edge. The rule therefore states for the forward group:

lenses of positive refractive power are made of long-crown glass; and,

lenses of negative refractive power are made of short-flint glass.

The refractive index and primary dispersion are, however, pregiven by the primary requirements of the achromatic correction. For this reason, the situation can occur that for the lenses having surfaces (**5**, **6**), no suitable glass is available in the marketplace and nonconforming glass must be utilized, for example, a lens having surfaces (**5**, **6**) of negative refractive power made of long-crown glass.

In the center group **102**, the objective is the reduction of transverse chromatic aberration in the entire field and, for this purpose, the rule is the opposite as for the first group **101** and is as follows:

lenses of positive refractive power are made of short-flint glass; and,

lenses of negative refractive power are made of long-crown glass.

It is necessary that one lens having surfaces (**20**, **21**) not adhere to the rule in the context of the special configuration of the composite element lenses having surfaces (**20**, **21**, **22**) already described.

In the base group **103**, and after the system diaphragm **24**, it is the objective to completely eliminate the remaining transverse chromatic aberration in the red spectral range, that is, for the C-line.

The rule here is as follows:

lenses of positive refractive power are made of long-crown glass; and,

lenses of negative refractive power are made of short-flint glass.

The glasses of higher anomalous partial dispersion ΔP are preferably provided in the center of the base group **103** and this is realized by lenses having surfaces (**29**, **30**) which drastically reduce the transverse chromatic aberration over all image heights (see FIG. **7**). The rule is maintained in the embodiment shown. Since the remaining image errors must also be corrected, a smaller transverse chromatic aberration remains in the center of the field (zone).

FIG. **7** shows the transverse chromatic aberration for lines (C, d) plotted as a function of the lenses of the objective for various ray elevations (y). In this, the above color correction can be clearly seen. For comparison, the longitudinal chromatic aberration is also shown. The chromatic aberration is shown in the image plane **39** for simulation computations. In these equations, all lenses are made of glass (which is not really available) having the same refractive index and primary dispersion as presented in the table for the embodiment, but with vanishing relative partial dispersion (ΔP=0).

For focusing the objective, the backfocus distance (spacing **38**, **39**) is changed, that is, the entire objective is displaced and, at the same time, the front group **101** is shifted with respect to the following center and base groups (**102**, **103**) as a "floating element". The air spacings (**18** to **20**) and (**38**, **39**) are changed at the same time.

FIG. **2** shows the objective **100** of the invention mounted on a camera **200**. The objective includes lens groups (**101**, **102**, **103**) and the frame **110** and is attached with an adapter **120** to adapter **220** of the camera **200**. The adapter is shown schematically as screw thread. Since the backfocus distance S of the objective **100** (the spacing of the last lens apex of the base group **103** to the image plane **210** in the camera **200**) is greater than the spacing of the adapters (**120**, **220**) to the image plane **210**, the objective **100** of the invention can be equipped with a shift device (**111**, **121**) to prevent tumbling lines (perspective-compensating wide-angle objective).

The excellent overall quality of the wide-angle objective of Table 1 which is obtained is shown in FIG. **3** wherein the modulation transmission T is shown as a function of the image height (u) for 10, 20 and 40 lines per mm (LPM) sagittally (solid lines) and tangentially (shown dotted) and to the right for the maximum aperture K=3.65, to the left for K=5.6, therefore stopped down by two stop numbers, for white light comprising ten wavelengths from 404.7 nm to 656.3 nm and distance to object is infinity.

The exceptionally stable trace of the modulation transmission T up to large image heights is especially very useful for the embodiment (see FIG. **2**) in the form of a shift objective.

FIG. **4** shows a diagram of the total transverse aberration (DZS) in the sagittal section for the same objective for six different image heights (y') or image angles (W) as a function of the tangent of the aperture angle tan DW' for the three spectral lines (d shown as a solid line, g shown as a broken line of long segments and C as a broken line of short segments). The line of the adjusting plane is shown diagonally.

FIG. **5** shows the same but for the meridional section (DYM, total meridional transverse aberration) and FIG. **6** shows the sagittal aberration (DYS) for the same parameters.

All of these errors are well corrected up to large aperture angles and image heights.

It is understood that the foregoing description is that of the preferred embodiments of the invention and that various changes and modifications may be made thereto without departing from the spirit and scope of the invention as defined in the appended claims.

What is claimed is:

1. An apochromatic wide-angle objective for viewing an object, the objective comprising:

a plurality of lenses defining an optical axis and more than half of said lenses having anomalous partial dispersion;

said plurality of lenses being subdivided into forward, center and base groups of lenses;

a system diaphragm mounted on said axis between said center group and said base group;

said base group including a first plurality of converging lenses and a second plurality of diverging lenses;

more than half of said converging lenses of said base group being made of a long-crown type glass and more than half of said diverging lenses of said base group being made of short-flint type glass;

said forward group having a third plurality of lenses having a positive refractive power and a fourth plurality of lenses having a negative refractive power;

more than half of the lenses of said third plurality of lenses including a front lens being made of long-crown type of glass and more than half of the lenses of said fourth plurality of lenses being made of short-flint type glass;

said center group having a fifth plurality of lenses having a positive refractive index and a sixth plurality of lenses having a negative refractive index; and,

more than half of lenses of said fifth plurality of glasses being made of short-flint type glass and more than half of the lenses of said sixth plurality being made of long-crown type glass.

2. The apochromatic wide-angle objective of claim 1, wherein said forward and center groups comprise up to seven lenses; and, at most two of said lenses of said forward and center groups are missing the rules given in claim 1 for more than half of each of the first to sixth pluralities of lenses.

3. The apochromatic wide-angle objective of claim 1, wherein said forward and center groups comprise more than seven lenses; and, at most three of said lenses of said forward and center groups are missing the rules given in claim 1 for more than half of each of the first to sixth pluralities of lenses.

4. The apochromatic wide-angle objective of claim 1, said forward group of lenses having a front lens facing toward the object; said front lens being made of a long-crown type of glass and generating a transverse chromatic aberration which is greater than for a conventional glass otherwise having the same characteristics.

5. The apochromatic wide-angle objective of claim 1, said front lens being a meniscus having a convex front surface.

6. The apochromatic wide-angle objective of claim 1, said center group including a composite lens having two component lenses made of glasses having dispersion functions $(n, (\lambda))$ which differ only by a constant in the spectral range used.

7. The apochromatic wide-angle objective of claim 1, wherein said transverse chromatic aberration is corrected for three wavelengths (g, d, C) over all field angles.

8. The apochromatic wide-angle objective of claim 7, wherein said transverse chromatic aberration is corrected with an error less than ±5 micrometers.

9. The apochromatic wide-angle objective of claim 7, wherein the oblique spherical aberration of sagittal imaging is well corrected.

10. The apochromatic wide-angle objective of claim 1, wherein said objective is configured as a retrofocus objective.

11. The apochromatic wide-angle objective of claim 10, wherein said objective is an exchangeable objective adapted for mounting on a camera; said objective and said camera conjointly defining a device for connecting said objective to said camera; said camera having an image plane and said objective having a last lens facing toward said image plane; and, said last lens having an apex which does not extend beyond said device.

12. The apochromatic wide-angle objective of claim 10, wherein said objective is configured as a shift objective.

13. The apochromatic wide-angle objective of claim 1, wherein at least one of said lenses has characteristics of a glass Hoya ATF2.

14. The apochromatic wide-angle objective of claim 1, wherein at least one of said lenses has characteristics of a glass Hoya ADC1.

15. The apochromatic wide-angle objective of claim 1, comprising a focal length of 25 mm; a numerical aperture of 0.14; an image end back focal distance of 48 mm; and, for all image angles up to 51° in the spectral range of the lines g to C, a total transverse aberration (DZS) in the sagittal section of less than 30 μm for all tangents of the aperture angle (tanDW') less than 0.1; a total transverse aberration DYM) in the meridional section less than 30 μm for all tangents of the aperture angle (tanDW') less than 0.5; and, a sagittal coma (DYS) less than 30 μm for all tangents of the aperture angle (tanDW') less than 0.1.

16. The apochromatic wide-angle objective of claim 1, wherein up to fully opened diaphragm K=3.65 for white light in the spectral range of the lines g to C, the modulation transfer (T) sagittally and tangentially for 10 lines per mm up to an image height (YB) of 20 mm is greater than 90%, up to an image height (YB) of 30 mm is still greater than 80%, and for 40 lines per mm up to an image height (YB) of 20 mm is greater than 60%, and for an image height (YB) of 30 mm is still greater than 50%.

17. The apochromatic wide-angle objective of claim 1, wherein: the refractive index for the wavelength 435.84 nm is n_g; the refractive index for the wavelength 587.56 nm is n_d; the refractive index for the wavelength 657.27 nm is n_C; with the definition of the primary dispersion being given by:

$$\nu = \frac{n_d - 1}{n_g - n_d}$$

with the definition of the partial dispersion being given by

$$P = \frac{n_d - n_C}{n_g - n_d}$$

and the Abbe normal for the glasses (K2, F7) being given by:

$$P_n = A\,\nu + B$$

wherein:

A=0.9007·10^{-4} and B=0.2025 and the deviation from the normal

$$\Delta P = P - P_n = P - A\nu - B$$

wherein:

ΔP is negative for all long crown glass;

ΔP is positive for all short flint glass;

all glasses used having an amount ΔP greater than 8·10^{-4}; and, at least half the glasses an amount ΔP greater than 2.5·10^{-3}.

18. An objective comprising the following characteristics:

focal length 25 mm

largest diaphragm 3.65

[57] **ABSTRACT**

A wide angle objective system is described for, inter alia CCD cameras, which system is compact, inexpensive and satisfactorily corrected. It comprises a front meniscus lens (L_1), a thick convex-concave central lens element (L_2) and a biconvex lens element (L_3), the two last-mentioned elements preferably being cemented together, the pupil (P) being present at the area of the exit surface (4) of the second lens element and the first and the third element (L_1,L_3) being made of, for example PMMA and the second element (L_2) being made of, for example PC.

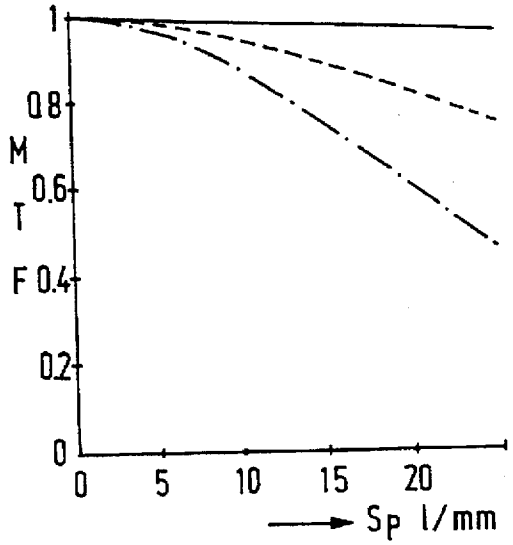

FIG.2a

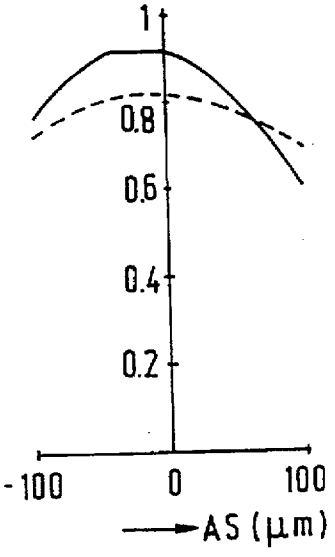

FIG.2b

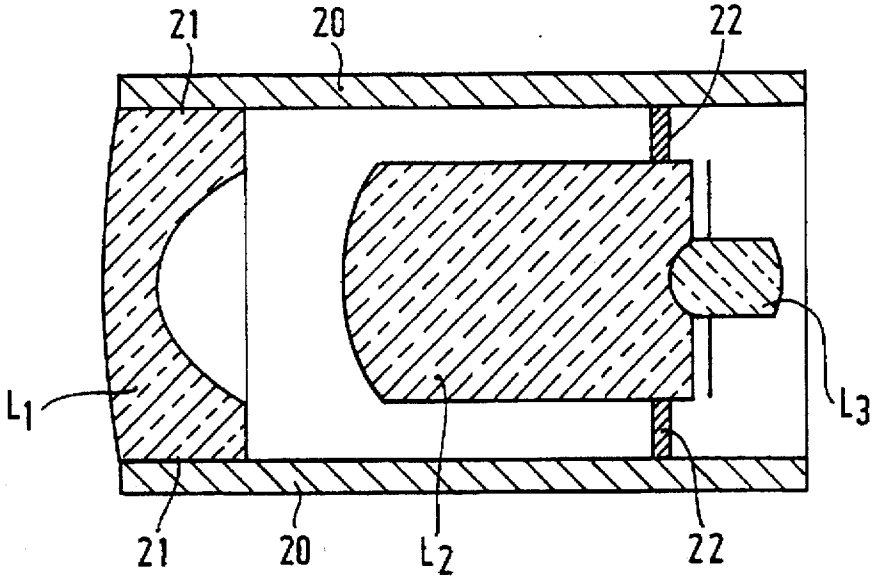

FIG.3

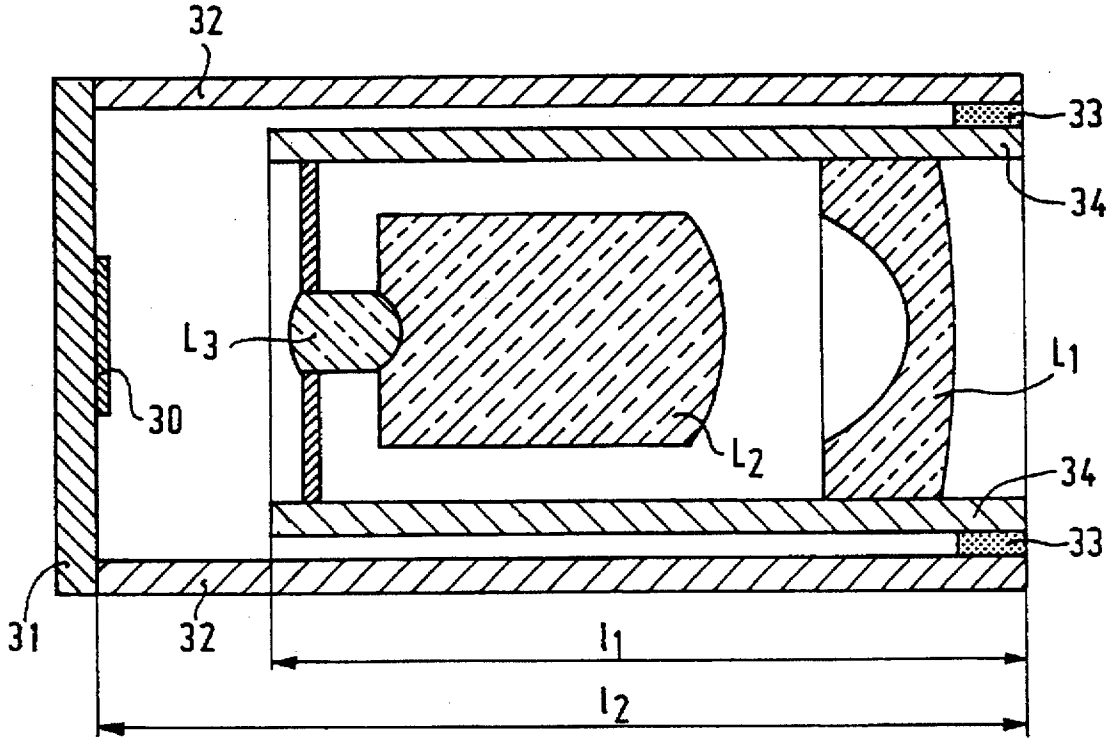

FIG.4

WIDE ANGLE OBJECTIVE SYSTEM

The invention relates to an objective system having a large angular aperture for demagnified imaging a scene in an image plane, which system, viewed from the object side, successively comprises:

- a first lens element having a first and a second convex refractive surface,
- a second lens element having a third, convex refractive surface and a fourth refractive surface,
- a third lens element having a fifth refractive surface and a sixth refractive surface.

The invention also relates to an image pick-up device provided with such an objective system.

BACKGROUND OF THE INVENTION

Such an objective system having, however, an extremely large angular aperture ranging between 125° and 150°, which can be used in a CCD camera, is described in U.S. Pat. No. 5,251,073. This system is of the retrofocus type, which is also referred to as inverse telephoto type, which means that it has a relatively large front focal length at the image side. The known objective system has an F number of F/2.0 and comprises at least four and preferably six glass lens elements. In the known system, the entrance pupil between the first and the second lens element is located in air.

The objective system of the present invention is intended for mass application and for combination with, for example an electronic image sensor, or CCD sensor, having a photosensitive surface diagonal of, for example 4 mm. If the objective system is inexpensive enough, such a combination may be used in a monitoring camera, in a videophone or in a camera which is associated with a personal computer working station coupled to other such stations, so that visual data can be transmitted together with the actual data from one station to other stations. These data can be obtained by scanning a document, also referred to as bitmapping. For said applications, the objective system should have a field of view of the order of 2×35° or more, a focal length of, for example 3 mm dependent on the surface of the image sensor for a CCD image sensor having a diagonal of 2 mm and an F number of, for example F/2.5 so as to pick up scenes of sufficient quality, even at low light levels. Such an objective system cannot be made in accordance with the design described in U.S. Pat. No. 5,251,073 because it would then be too expensive. Moreover, this system has a resolving power which is too small and exhibits too much spherical aberration and astigmatism, the latter effect being particularly troublesome in said bitmapping application.

SUMMARY OF THE INVENTION

It is an object of the present invention to provide an objective system for, inter alia said application, which system is inexpensive and compact, has a satisfactory colour correction and little astigmatism and distortion, and a satisfactory resolving power. This objective system is characterized in that the sixth refractive surface is concave, in that the pupil of the lens system is present at the area of, or very proximate to the fourth refractive surface, and in that the first and the third lens element are manufactured from the same first material having a first refractive index, and the second lens element is manufactured from a second material having a second refractive index which is different from the first refractive index.

At the area of the fourth surface the angles of incidence of the imaging beam, which angles are determined by the first and second lens elements, are considerably reduced as compared with those of the beam incident on the first lens surface. Since the transition of the second lens element having the second refractive index to the third lens element having the first refractive index is present at the location of the pupil, which transition has a correcting effect for the longitudinal colour error, this error is satisfactorily corrected for all angles of incidence of the imaging beam. Such an effective correction is not realised in the objective system in accordance with U.S. Pat. No. 5,251,073, in which the pupil is not present at the location of, or very proximate to a correction element. The longitudinal colour error is understood to mean that the position of the image plane is dependent on the colour, or wavelength, of the beam or the beam components.

By making use of a thick second lens element having the second refractive index, the transversal colour error of the first lens element having the first refractive index is corrected. The transversal colour error is understood to mean the colour, or wavelength-dependent magnification of the objective system.

The first and third lens elements may be separated from each other by a narrow air gap. An embodiment of the objective system, which is preferred from a manufacturing-technical point of view and as regards stability, is, however, characterized in that the fourth and the fifth refractive surface have the same curvature and are cemented together.

Use is made of a cementing material whose refractive index is in the range between a value which is slightly larger than the smallest of said first and second refractive indices and a value which is slightly larger than the largest of said refractive indices.

This embodiment is preferably further characterized in that it satisfies the conditions

$$0.20 \leqq \frac{K_+}{K_{tot}} \leqq 0.60$$

in which K_+ is the positive focal power of the assembly of the second and the third lens element and K_{tot} is the total focal power of the lens system.

An inexpensive embodiment of the objective system having a satisfactory quality is characterized in that the lens elements are entirely manufactured of a synthetic material.

Since all lens elements consist of a transparent synthetic material, the objective system is inexpensive, while it still has the imaging quality desired for said applications. Moreover, lens elements made of such synthetic materials can easily be provided with aspherical surfaces by making use of aspherically profiled moulds for manufacturing the lens elements.

It is to be noted that an objective system for use in a CCD camera and consisting of synthetic material elements is known per se from the abstract of Japanese Patent Application 4-107407. However, this system comprises only two lens elements, a negative meniscus lens and a biconvex lens, in which the meniscus lens does not have an aspherical surface. The abstract neither states that the materials of the lens elements are different. The quality of this objective system cannot match that of the objective system according to the present invention, not only in the field but also on the axis.

A preferred embodiment of the objective system using synthetic material elements is characterized in that the first and the third lens element are manufactured of polymethyl methacrylate and the second lens element is manufactured of polycarbonate. Practice has proved that these materials

having a refractive index of 1.49 and 1.58, respectively, are materials having a good optical quality.

In this embodiment the fourth and the fifth lens surface are convex, as viewed from the object side.

The objective system is preferably further characterized in that the fourth lens surface is aspherical.

An aspherical lens surface is understood to mean a surface whose fundamental shape is spherical but whose real shape deviates to a slight extent so as to correct for the spherical aberrations of the fundamental shape of the lens. Since the aspherical surface is present at the location of, or proximate to the pupil of the lens system, it can satisfactorily correct for all angles of incidence of the imaging beam. Since the fourth surface also ensures the correction of the longitudinal colour error, this surface thus has a double correction function in the relevant lens system.

If the objective system is further characterized in that at least one of the first and the second lens surface is aspherical, this system is satisfactorily free from distortion.

By giving also the sixth refractive surface an aspherical shape, an objective system is obtained which has a large F number of the order of F/2.5 with sufficiently small spherical aberrations.

The invention also relates to an image pick-up device provided with an objective system and an opto-electronic image sensor for converting images formed by the objective system into an electronic image signal. This image pick-up device is characterized in that the objective system is a system as described hereinbefore.

If this image pick-up device is further characterized in that the image sensor is a CCD sensor, this device can be implemented in a compact and inexpensive way.

The synthetic materials, abbreviated to PMMA and PC, have a greater temperature sensitivity than glass. To minimize the effect of this temperature sensitivity and those of the holder accommodating the lens elements on the supplied image signal, the image pick-up device may be further characterized in that the sensor is provided with a fitting for accomodating a lens holder in which the lens elements of the objective system are secured and in that the thermal coefficient of expansion of said fitting is larger than that of the lens holder.

BRIEF DESCRIPTION OF THE DRAWING FIGURES

These and other aspects of the invention will be apparent from and elucidated with reference to the embodiments described hereinafter.

In the drawings

FIG. **1** shows an embodiment of the objective system according to the invention,

FIGS. **2***a* and **2***b* show the modulation transfer curve and an aberration curve of this system,

FIG. **3** shows this system accommodated in a holder, and

FIG. **4** shows an image pick-up device provided with such an objective system.

DESCRIPTION OF THE INVENTION

The objective system shown in a cross-section in FIG. **1** comprises a first lens element L_1, a second lens element L_2 and a third lens element L_3. The scene to be imaged is at the left-hand side in FIG. **1** and the image plane **10** is at the right-hand side. The first lens element has the shape of a meniscus lens having a slightly curved exit surface **2**. This element ensures that a beam portion b_0 entering along the optical axis **00'** becomes divergent and that a peripheral beam portion b_1 entering at a relatively large angle α is deflected in such a way that it will extend more parallel to the optical axis and becomes divergent. The lens element L_2 has an entrance surface **3** with such a radius of curvature that it has a collimating effect so that all beam portions can be combined on the exit surface **4** which has a smaller diameter and a smaller radius of curvature than the entrance surface **3**. The surface portions **5** at both sides of the exit surface **4** of the lens element L_2 may be plane. The exit surface **4** itself has a diverging effect which is overcompensated by the third lens element so that the beam portions b_0 and b_1 are focused at the points a and b of the image plane **10**. All beam portions incident under the optical axis **00'** at angles between 0° and α° are focused at points located between the points a and b. The peripheral beam portion incident above the optical axis at an angle $-\alpha$ is focused at a point c in the image plane which is symmetrical with respect to the point b. The beam portions which are incident above the optical axis at angles between 0° and $-\alpha$° are focused at points between said point c and point a. The third lens element has an entrance surface **6** and an opposite curved exit surface **7**. The surface **4** of element L_2 is preferably cemented against surface **6** of element L_3. However, these surfaces may also be separated by a narrow air gap.

In FIG. **1**, the references H_1 and H_2 denote the main planes of the objective system, F_2 denotes the image focal point and p denotes the exit pupil. For the sake of completeness, a glass plate **11** is also shown which may be located in front of a sensor and which should be taken into account in designing the objective system.

The refractive indices of the lens element materials, the curvatures of these elements and the distances between these surfaces are preferably chosen to be such that it holds for the focal powers that:

$$0.20 \leqq \frac{K_+}{K_{tot}} \leqq 0.60$$

in which K_+ is the positive power of the assembly of element L_2 and element L_3, and K_{tot} is the total power of the objective system.

To be able to keep the price of the objective system as low as possible, the lens elements are preferably manufactured of a synthetic material. The first and the third lens element L_1 and L_3 are manufactured of the same transparent synthetic material, preferably polymethyl methacrylate (PMMA) having a refractive index n_1=1.49, while the second lens element is manufactured of a different synthetic material having a different refractive index, for example polycarbonate (PC) having a refractive index n_2=1.58. With this choice of synthetic materials, surface **4** is concave and surface **6** is convex, as is shown in FIG. **1**. With a different choice of synthetic materials, may become convex and surface **6** may become concave. Instead of PMMA, another similar polymer may be used and instead of PC, for example styrene or the material CA-**39**. The second lens element is a thick element, i.e. its length 1 is considerably larger than the diameter m of its first lens surface **3**. With this element of, for example PC the transversal colour error of the negative front element L_1 of, for example PMMA can be corrected. Moreover, the longitudinal colour error is corrected at the transition between the refractive surface **4** of the lens element L_2 and the refractive surface **6** of the lens element L_3, hence at an internal refractive surface.

This internal refractive surface is present in or proximate to the pupil of the objective system, hence at a position

where the axes of the different beam portions extend at small angles to the optical axis **00'** of the system, so that this correction for these beam portions is equally satisfactory.

The surface **4** is preferably aspherical so that at the location of the pupil it is also possible to correct for the aspherical aberration, which correction is again substantially identical for all beam portions. The surface **4** then has a dual correcting effect. An aspherical surface may be characterized by

$$Z = \Sigma A_{2i} \cdot Y^{2i}$$

in which Y is the distance between a point on the aspherical surface and the optical axis of the lens element, Z is the distance between the projection on the optical axis of this point and the point of intersection of the optical axis with the aspherical surface and A_{2i} are the aspherical coefficients.

By giving the surface **2** or surface **1** an aspherical shape, the distortion of the objective system can be maintained sufficiently small. By giving also the surface **7** an aspherical shape, the spherical aberration of the system can even be better corrected so that the system is sufficiently free from spherical aberration, also for the relatively large F number: $F_{2.5}$.

For an embodiment of the objective system in accordance with FIG. **1**, having three aspherical surfaces in which the lens elements L_1 and L_3 are made of PMMA and the lens element L_2 is made of PC, the following values, computed from the object side, apply for the axial surface curvatures C_1, the axial distances d between these surfaces and the refractive indices n:

		c (mm^{-1})	d(mm)	n
	1	0.03078		
L_1			1.5	1.49
	2	0.33483		
			5.346	1
	3	0.17400		
L_2			10.055	1.58
	4/6	0.49336		
L_3			3.2118	1.49
	7	−0.46157		

while the aspherical coefficients A_{2i} of the surfaces **2**, **4** and **7** are equal to:

1. $A_2=0.167446.10^0$
   $A_4=0.410699.10^{-2}$
   $A_6=-0.361459.10^{-3}$
   $A_8=0.332931.10^{-4}$
   $A_{10}=-0.942326.10^{-6}$
4. $A_2=0.246681.10^0$
   $A_4=0.163018.10^0$
   $A_6=-0283456.10^{-1}$
   $A_8=0.332336.10^{-1}$
7. $A_2=-0.230787.10^0$
   $A_4=-0.904503.10^{-2}$
   $A_6=0.433596.10^{-2}$
   $A_8=-0.444410.10^{-2}$
   $A_{10}=-0.841075.10^{-3}$

If a glass plate **11** having a thickness of 0.19 mm and a refractive index of 1.51 is arranged between the lens surface **7** and the image plane **10**, the image field is located at a distance of 5.3132 mm from this lens surface.

This objective system has a focal length of 3 mm, an image diagonal of 4.02 mm, an F number $F_{2.5}$, a field of view of 2×38° and a resolving power of more than 50% for a structure of 40 lines/mm. The system is satisfactorily corrected for colour in a wavelength band between 500 and 900 nm.

FIG. **4** shows diagrammatically an embodiment of an image pick-up device according to the invention which comprises the above-described objective system and an image sensor **30**, preferably in the form of a CCD sensor as its basic elements.

The objective system has a total power of $K_{tot}=0.333$ mm^{-1}, the power of the lens element L_1 K being 0.16 mm^{-1} and the power of the assembly of the lens elements L_2, L_3: K_+ being 0.13 mm^{-1}.

FIG. **2***a* shows the modulation transfer function (MTF) of this embodiment of the objective system as a function of the spatial frequency SP (expressed in lines per mm) while FIG. **2***b* shows the MTF as a function of the distance AS to the optical axis for a spatial frequency of 12.5 lines per mm. It appears that the astigmatism is only small and that the MTF is 50% for a spatial frequency of **40** lines per mm.

In practice, the separate lens elements are accommodated in a common holder **20**, as is shown in FIG. **3**.

The synthetic materials preferably used for the lens elements L_1, L_2 and L_3 have a larger thermal coefficient of expansion than glass. Moreover, their refractive index is temperature-dependent. Consequently, the optical behavior of the objective system might change when the ambient temperature varies so that the scene would be imaged out of focus on the image sensor. To prevent this, a material having such a thermal coefficient of expansion may be chosen for the lens holder **20** that the equivalent coefficient of expansion of the objective system causing the change of optical behaviour of this system as a function of the temperature and being determined by:

- the coefficients of expansion of the materials of the lens elements,
- the refractive indices of these materials and their variations with temperature, and
- the dimensions of the lens elements is equal to the coefficient of expansion of the holder material which is present between the fixations **21**, **22** on the holder of the two outer elements of the objective system.

This provides a compensation for temperature variations in the objective system itself. For the principle and further elaboration of this temperature compensation, reference is made to U.S. Pat. No. 4,855,987 in which a temperature-compensated radiation source unit and an optical scanning unit are described.

FIG. **4** shows diagrammatically an embodiment of an image pick-up device according to the invention, which comprises the above-described objective system and an image sensor **30**, preferably in the form of a CCD sensor as its basic elements. This sensor is arranged on a holder **31**. To be able to correct for temperature variations, a bush **32** may be secured to the holder **31** as an alternative to the compensation described with reference to FIG. **3**. This bush is connected at the points **33** to an inner bush **34** within which the lens system L_1, L_2, L_3 is arranged. The thermal coefficient of expansion α_1 of the bush **32** is larger than that, α_2, of the bush **33**. If the length of the bush **32** is l_1 and that of the bush **34** is l_2, an offset ΔZ of the objective system with respect to the sensor **30** will occur at a temperature variation of ΔT, which offset is given by

$$\Delta z=(l_{1\alpha 1}-l_{2\alpha 2})\Delta T$$

This offset can correct the offset of the focal point of the objective system occurring as a result of the temperature variation ΔT.

I claim:

1. An objective system having a large angular aperture for demagnified imaging a scene in an image plane, which system, viewed from the object side, successively comprises:

a first lens element having a first convex surface and a second concave surface,

a second lens element having a third convex surface and a fourth refractive surface,

a third lens element having a fifth refractive surface and a sixth convex surface,

a pupil of the lens system being positioned proximate the fourth refractive surface, and wherein the first and the third lens element are manufactured from a first material having a first refractive index, and the second lens element is manufactured from a second material having a second refractive index different from the first refractive index.

2. An objective system as claimed in claim 1, wherein the fourth and the fifth refractive surface have the same curvature and are cemented together.

3. An objective system as claimed in claim 2, satisfying the conditions

$$0.20 \leqq \frac{K_+}{K_{tot}} \leqq 0.60$$

in which K_+ is the positive focal power of the assembly of the second and third lens element and K_{tot} is the total focal power of the lens system.

4. An objective as claimed in claim 3, wherein the lens elements are entirely manufactured of a synthetic material.

5. An objective system as claimed in claim 4, wherein the first and the third lens elements are manufactured of polymethyl methacrylate and the second lens element is manufactured of polycarbonate.

6. An objective system as claimed in claim 5, wherein the fourth lens surface is aspherical.

7. An objective system as claimed in claim 6, wherein at least one of the first and the second lens surface is aspherical.

8. An objective system as claimed in claim 7, wherein the sixth lens surface is aspherical.

9. An objective system as claimed in claim 1, and including a holder for accommodating the lens elements, the lens holder being manufactured of a material having a thermal coefficient of expansion so that the equivalent coefficient of expansion of the lens system causes a change of optical behavior of said lens system as a function of the temperature and being determined by:

the coefficients of expansion of the materials of the lens elements,

the refractive indices of said materials and their variations with temperature, and

the dimensions of the lens elements is equal to the coefficient of expansion of the holder material which is present between the fixations on the holder of the two outer lens elements.

10. An image pickup device provided with an objective system as claimed in claim 1 and an opto-electronic image sensor for converting images of a scene formed by the objective system into an electronic image signal.

11. An image pick-up device as claimed in claim 10, wherein the image sensor is a CCD sensor.

12. An image pick-up device as claimed in claim 10, wherein the sensor is provided with a fitting for accommodating a lens holder in which the lens elements of the objective system are secured and in that the thermal coefficient of expansion of said fitting is larger than that of the lens holder.

13. An objective as claimed in claim 1, wherein the lens elements are entirely manufactured of a synthetic material.

14. An objective system as claimed in claim 13, wherein the first and the third lens elements are manufactured of polymethyl methacrylate and the second lens element is manufactured of polycarbonate.

15. An objective system as claimed in claim 1, wherein the fourth lens surface is aspherical.

16. An objective system as claimed in claim 15, wherein at least one of the first and the second lens surface is aspherical.

17. An objective system as claimed in claim 16, wherein the sixth lens surface is aspherical.

18. An objective system as claimed in claim 1, wherein the pupil is located intermediate the fourth and the sixth refractive surfaces.

[57] **ABSTRACT**

A double sided telecentic measurement objective for contactless length measurement in two-dimensional and three-dimensional space. The objective has an image-side optical system consisting of three elements equivalent to those of an object-side optical system but in the reverse order, including a cemented positively refracting lens element turned toward the object of image respectively, a collecting lens spaced by an air gap from the cemented lens, and a dispersive meniscus spaced by an air gap from the collecting lens. The widths of the air gaps between the collecting lenses and the meniscus are substantially greater than the widths of air gaps between the cemented lens elements and the collecting lenses.

FIG. 2

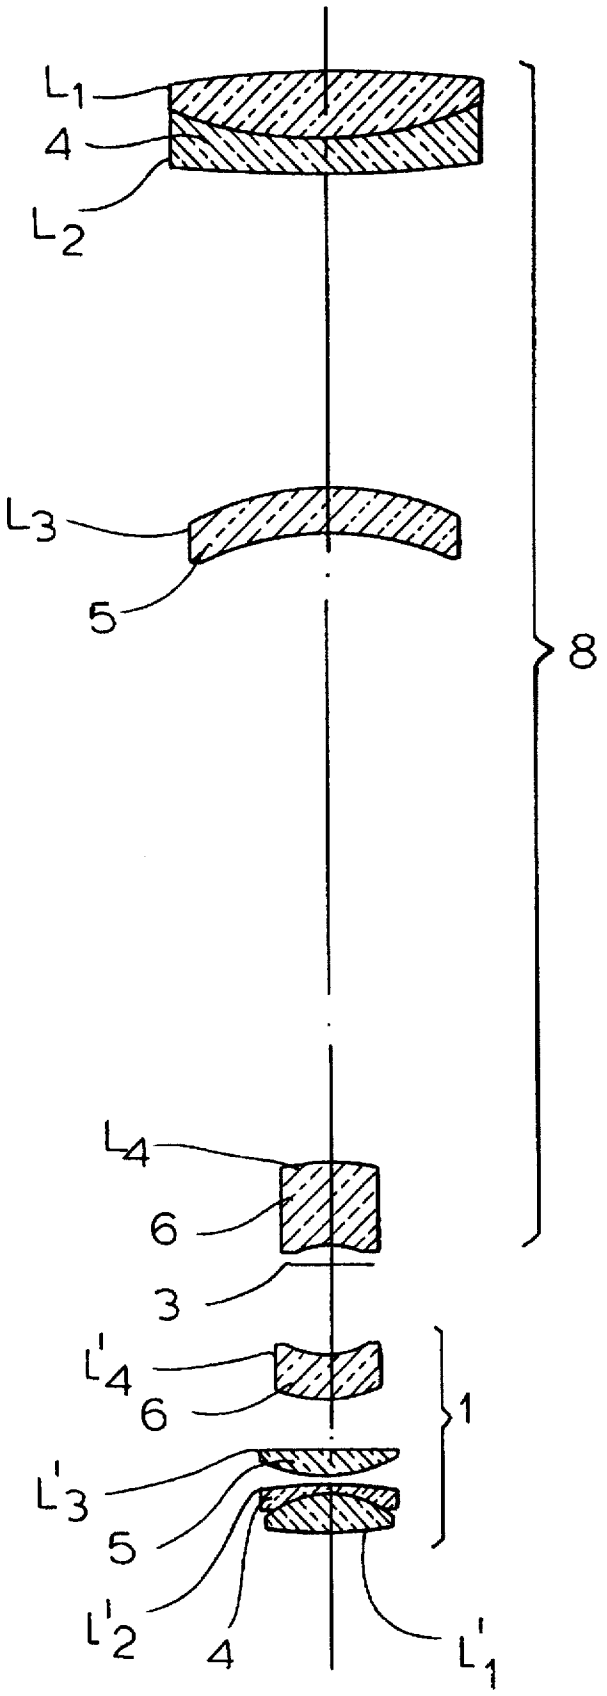

FIG.3

DOUBLE-SIDED TELECENTRIC MEASUREMENT OBJECTIVE

FIELD OF THE INVENTION

My present invention relates to a double-sided telecentric measuring objective for contactless length measurements in two-dimensional and three-dimensional space.

BACKGROUND OF THE INVENTION

For the contactless measurement of objectives in automatic product lines, video cameras are increasingly of interest as pick-ups for measurement systems. A measuring camera, for example, is described in U.S. Pat. No. 5,453,785.

The measurement principle utilizes the central projection of object points in an image plane. The image is then digitalized and the digitized image is interpreted in an image-processing computer and stretches between contour features of the object in the image are measured. A precondition for this type of measurement approach, of course, is a sufficiently precisely defined set of chamber constants and position of the main points photogram-metric. These parameters define the so-called internal orientation of the measurement camera (see the aforementioned patent).

The measurement precision in video measurement techniques is directly dependent upon the precision and stability of the parameters of the internal orientation. These parameters give the correlation between the measured image size and the geometry of the object. They may be determined by a camera calibration procedure.

When a measuring system is intended not only for a single kind of measurement and the position of the article to be measured cannot be maintained with a high level of precision, camera calibration must be frequent and is expensive and time-consuming since it must be carried out with each change in the article to be measured or each change in the position of the article.

It is known to avoid such camera calibration or at last to reduce the frequency of such calibration by providing telecentric objectives. The use of a telecentric objective makes the image size independent from the object distance and does not require as meticulous adjustment of the measuring unit. By providing telecentric objectives in automatic production lines, the effective quality control can be substantially simplified. Nevertheless, even with such optical systems, the measurement system must be calibrated and in particular, the dependency of the reduction scale or ratio of the image to the object size must be determined for the selected image plane position.

It has already been proposed to completely eliminate the need for camera calibration by providing double-sided telecentric optical systems. Such objectives are comprised of two distinct optical systems or partial systems aligned along a common optical axis which have the same general constructions and between which an iris diaphragm is disposed. The lens elements of the second optical system are disposed in an opposite or reverse order from the sequence of the lens elements of the first optical system. Such telecentric measuring objectives are afocal and have a fixed image ratio or reduction which is independent not only of the object position but also of the image position.

One such afocal and telecentric objective is described in SU Patent 935 099. Because of the construction of this objective, pupil aberration exists, i.e. in spite of the afocal construction, not all of the major rays are telecentric. The pupil aberration results in a change of distortion upon shifting of the object plane or image plane. This objective is, therefore, unsuitable for measurement purposes. In GB Patent 1,423,597, afocal systems for transcription of markings is described. This system does not permit correction of pupil aberration and of coma. It is also unsuitable as a measurement objective.

EP 0 299 473 A2 describes a system which, as a consequence of its construction, allows only small variation of the object plane or image plane. The optical system of this patent also is not highly suitable for measurement purposes since control of the sharpness is not possible and a scale of reproduction which deviates significantly from −1 cannot be achieved with high image quality. This objective is also costly to produce and with significant variations of the object plane positions, cause a considerable loss of imaging quality.

OBJECTS OF THE INVENTION

It is, therefore, the principal object of the present invention to provide a double-sided measurement objective for contactless measurement systems which makes superfluous internal calibration of the camera, is of simple construction and can ensure high image quality even for a substantial range in variation of the object plane position.

Another object of this invention is to provide a telecentric objective for the purposes described whereby drawbacks of the earlier systems described can be avoided.

Still another object of the invention is to provide a telecentric objective for a measurement camera which is of simple and economical construction.

SUMMARY OF THE INVENTION

These objects and others which will become apparent hereinafter in a telecentric lens system of the double-sided type having the object-side optical part system and the image-side optical systems as described, each with three lens elements of which a cemented lens element is turned toward the object side or the image side of the respective system, a collecting lens is spaced by an air gap from the cemented lens element and a dispersive meniscus lens is spaced by an air gap from the collecting lens, the image-side optical system thus having lenses equivalent to those of the object-side system but in the reverse order.

According to the invention, the cemented positively refracting lens element has a dispersive cemented surface and is made up of a convergent lens and a divergent lens cemented thereto.

According to the invention, moreover, the two optical systems are so arranged that the back focal point of the first optical system coincides with the front focal point of the second optical system along the optical axis. The image scale (or magnification or reduction ratio) of the total system is equal to the ratio of the focal lengths of the optical part-systems.

It has been found to be important to the invention that the third element of each optical system is a dispersive meniscus whose convex side is turned toward the object.

With a construction of this type, a wide range of variation is possible in the selection of the location of the object and image planes.

Even in the event that the object or image plane positions are not selected to be optimum, the image can remain free from coma so that a high measurement precision is assured within the total band width of the possible object/image relationship.

An optical system according to the invention has, if applied to scaled down imaging, and allows an image size aperture of at least 0.14. It is corrected for an image circle diameter of 0.2·f'2 where f'2 is the focal length of the image-side optical system.

A variation of the object plane position in the range of

$$\pm 3\ \text{mm} \cdot \left(\frac{f1}{f2}\right)^2$$

is possible without loss of image quality. In this relationship f'1 is the focal length of the object-side optical system.

By appropriate selection of the optical systems which are applicable, objectives with various focal lengths for the image-side or the object-side optical systems can be provided and the measurement objective can be of the double sided telecentric type for different magnification ratios.

BRIEF DESCRIPTION OF THE DRAWING

The above and other objects, features, and advantages will become more readily apparent from the following description, reference being made to the accompanying drawing in which:

FIG. **1** is a diagram of a measurement objective for a magnification or reproduction ratio of −1 according to the invention;

FIG. **2** is a diagram of a measurement objective for a magnification or reproduction ratio of −0.5 according to the invention; and

FIG. **3** is a diagram of a measurement objective for a magnification or reproduction ratio of −0.25 according to the invention.

SPECIFIC DESCRIPTION

FIG. **1** shows a double-sided telecentric objective for use in a measurement camera, e.g. of the type described in U.S. Pat. No. 5,453,785, which comprises an image-side optical system **1** and an object-side optical system **2** for the measurement of an object **10** and reproduction thereof in an image plane **11**. The two optical systems are arrayed along a common optical axis **12** and, in the embodiment of FIG. **1** which is entirely symmetrical, midway between the optical systems, an iris diaphragm **3** is provided. The objective of FIG. **1** has a magnification ratio of −1 and an image size aperture of 0.14.

Each optical system **1**, **2** is comprised of a cemented element **4** turned toward the object to be measured and the image plane, respectively, with a positive refractivity and a dispersive cemented surface (the surfaces with radii r_2 and r_2', respectively. The intermediate lens element of both the object-side and the image-side systems **2**, **1**, are collecting lenses **5** of a highly respective crown glass. Lying directly opposite the Iris diaphragm **3** are respective dispersive meniscuses **6** whose convex side is turned toward the object and the image respectively. For a two sided telecentic measurement objective with a magnification ratio −1 with a symmetrical configuration of the lenses, the object-image distance may be 284 and a range of object positions between **71** and **77** from the objective can be sustained without a detrimental effect upon the image quality when the image-side optical system has for its four lenses L_1' to L_4', the radii r_1' to r_7' and thicknesses of the lenses and air gaps d_1' to d_6', refractive indices and Abbé numbers as given in the following table:

Lens	Radius	Thickness	n_e	ν_e
	$r_1' = 130.882$			
L_1'		$d_1' = 9.60$	1.4891	70.2
	$r_2' = -22.140$			
L_2'		$d_2' = 2.00$	1.6072	37.8
	$r_3' = -127.464$			
		$d_3' = 3.10$		
	$r_4' = 40.965$			
L_3'		$d_4' = 5.70$	1.6413	55.1
	$r_5' = -597.046$			
		$d_5' = 13.50$		
	$r_6' = 28.247$			
L_4'		$d_6' = 11.39$	1.5848	40.6
	$r_7' = 15.845$			

focal length: 57

distance to back focal point: 23.20 all thicknesses, radii, distances and lengths being in the same distance units.

In the symmetrical lens system of FIG. **1**, the lenses L_1 through L_4 for radii r_4 to r_7 and thicknesses d_1 to d_6, refraction indices and Abbé numbers correspond to the numerical valves of the foregoing table as well.

Throughout this application, r refers to the radius of curvature of the respective lens surfaces, n_e to the refractive index and ν_e to the Abbé number for the wavelength e=546 nm of the glass from which the lenses are constituted and d represents distances between the respective lens surfaces as measured along the optical axis.

In FIG. **2**, there is shown an embodiment of a double sided telecentric measuring objective with a magnification ratio of −0.5 and an image-side aperture of 0.14. The position of the object plane can vary within a distance range of 185 to 209 without detriment to the image quality. The object/image distance can then vary between **467** and **485** all thicknesses, radii, distances and lengths being in the same distance units. In this case, for the same construction of the image-side optical system as in FIG. **1**, the numerical data of the object-side optical system can correspond to the following table:

Lens	Radius	Thickness	n_e	ν_e
	$r_1 = 163.039$			
L_1		$d_1 = 12.00$	1.4891	70.2
	$r_2 = -42.468$			
L_2		$d_2 = 4.00$	1.6072	37.8
	$r_3 = -219.485$			
		$d_3 = 14.72$		
	$r_4 = 53.840$			
L_3		$d_4 = 11.40$	1.6413	55.1
	$r_5 = -96.899$			
		$d_5 = 42.58$		
	$r_6 = 38.188$			
L_4		$d_6 = 22.78$	1.5848	40.6
	$r_7 = 20.358$			

focal length: 114

distance to back focal point: 28.07 all thicknesses, radii, distances and lengths being in the same distance units.

In the third embodiment illustrated in FIG. **3**, for a measuring objective with a magnification ratio of −0.25 and an image-side aperture of 0.14, the position of the object plane can vary at a distance of **246** through **342** from the objective without detriment to imaging quality. The object/image distance then varies between **505** and **595**. While the image side optical system **1** corresponds to that given in connection with FIG. **1**, the object side optical system **8** corresponds to the following numerical data:

Lens	Radius	Thickness	n_e	υ_e
L_1	r_1 = 243,547	d_1 = 17.00	1.4996	66.7
	r_2 = −88.326			
L_2		d_2 = 8.60	1.6072	37.8
	r_3 = −342.441			
		d_3 = 82.40		
	r_4 = 72.157			
L_3		d_4 = 12.00	1.6413	55.1
	r_5 = −78.537			
		d_5 = 163.70		
	r_6 = 47.746			
L_4		d_6 = 22.80	1.5848	40.6
	r_7 = 29.641			

focal length: 228

distance to back focal point: 4.75 all thicknesses, radii, distances and lengths being in the same distance units.

I claim:

1. A double-sided telecentric measurement objective for contactless length measurement in two-dimensional and three-dimensional space, said objective comprising:

two optical systems, each comprising three lenses aligned along an optical axis and constituted of an object-side optical system and an image-side optical system,

said object-side optical system having in succession from a side turned toward an object:

a cemented positively refracting lens element and a dispersive cemented surface formed by a convergent lens L_1 with radii of curvature r_1 and r_2 and a thickness d_1 and a divergent lens L_2 with radii of curvature r_2 and r_3 and a thickness d_2,

a collecting lens L_3 spaced by an air gap of a thickness d_3 from said cemented lens element and having radii of curvature r_4 and r_5 and a thickness d_4 of a highly refractive crown glass, and

a dispersive meniscus lens L_4 spaced by an air gap of thickness d_5 from said collecting lens and having radii of curvature of r_6 and r_7 and a thickness d_6;

and an image-side optical system having in succession from a side turned away from said object:

a cemented positively refracting lens element and a dispersive cemented surface formed by a convergent lens L_1' with radii of curvature r_1' and r_2' and a thickness d_1' and a divergent lens L_2' with radii of curvature r_2' and r_3' and a thickness d_2',

a collecting lens L_3' spaced by an air gap of a thickness d_3' from said cemented lens element and having radii of curvature r_4' and r_5' and a thickness d_4' of a highly refractive crown glass, and

a dispersive meniscus lens L_4' spaced by an air gap of thickness d_5' from said collecting lens and having radii of curvature of r_6' and r_7' and a thickness d_6' with a convex side turned away from said object;

widths of air gaps between the respective collecting lenses and the respective meniscuses being substantially greater than widths of air gaps between the cemented lens elements and the respective collecting lenses;

a back focal point of said object-side optical system coinciding with a front focal point of said image-side optical system so that a reproduction scale of the objective is equal to a ratio of front and back focal lengths of said optical systems, said image-side optical system having substantially the following numerical parameters wherein n_e and ν_e are respectively the refractive indices and Abbé numbers of the respective lenses:

Lens	Radius	Thickness	n_e	υ_e
L_1'	r_1' = 130.882	d_1' = 9.60	1.4891	70.2
	r_2' = −22.140			
L_2'		d_2' = 2.00	1.6072	37.8
	r_3' = −127.464			
		d_3' = 3.10		
	r_4' = 40.965			
L_3'		d_4' = 5.70	1.6413	55.1
	r_5' = −597.046			
		d_5' = 13.50		
	r_6' = 28.247			
L_4'		d_6' = 11.39	1.5848	40.6
	r_7' = 15.845			

focal length: 57

distance to back focal point: 23.20.

2. The objective defined in claim 1 wherein the lenses L_1 through L_4 have radii of curvature r_1 through r_7 and thicknesses d_1' through d_6, refractive indices and Abbé numbers corresponding to those of the lenses L_1' to L_4' for the radii r_1' through r_7' and thicknesses d_1' through d_6', and the respective refractive indices and Abbé numbers.

3. The objective defined in claim 1 wherein the object-side optical system has the following numerical parameter:

Lens	Radius	Thickness	n_e	υ_e
L_1	r_1 = 163.039	d_1 = 12.00	1.4891	70.2
	r_2 = −42.468			
L_2		d_2 = 4.00	1.6072	37.8
	r_3 = −219.485			
		d_3 = 14.72		
	r_4 = 53.840			
L_3		d_4 = 11.40	1.6413	55.1
	r_5 = −96.899			
		d_5 = 42.58		
	r_6 = 38.188			
L_4		d_6 = 22.78	1.5848	40.6
	r_7 = 20.358			

focal length: 114

distance to back focal point: 28.07.

4. The objective defined in claim 1 wherein said object-side optical system has the following numerical parameter:

Lens	Radius	Thickness	n_e	υ_e
L_1	r_1 = 243,547	d_1 = 17.00	1.4996	66.7
	r_2 = −88.326			
L_2		d_2 = 8.60	1.6072	37.8
	r_3 = −342.441			
		d_3 = 82.40		
	r_4 = 72.157			
L_3		d_4 = 12.00	1.6413	55.1
	r_5 = −78.537			
		d_5 = 163.70		
	r_6 = 47.746			
L_4		d_6 = 22.80	1.5848	40.6
	r_7 = 29.641			

focal length: 228

distance to back focal point: 4.75.

[57] **ABSTRACT**

The present invention relates to image-formation on any selected kind of objective body. The characterizing features reside in such that, based upon fed image data, required images are formed on an image-transferable sheet acting for image carry-over service and in reliance on sublimation image transfer technique, and then, by the use of said sheet with said images thus formed thereon, the formed images thereon are transferringly applied on the objective body. By adopting the above measures, the objective body can be formed sharply and clearly with any desired images, irrespective of kind and configuration thereof, with such superior results of highly improved unity and solidability between the formed images and the objective body to be decorated with.

IMAGE FORMATION ON OBJECTIVE BODIES

This is a Division of application Ser. No. 08/395,850 filed Feb. 28, 1995, now pending, which in turn is a continuation of application Ser. No. 08/034,186 filed Mar. 18, 1993, now U.S. Pat. No. 5,451,560, which in turn is a continuation of application Ser. No. 07/467,415 filed Jan. 19, 1990, now abandoned, which in turn is a division of application Ser. No. 07/138,384 filed Dec. 8, 1987, now U.S. Pat. No. 4,923,848.

TECHNICAL FIELD

This invention relates to methods and apparatus for the formation of images as prints on objective bodies through transfer of images preformed by the sublimation transfer technique, and more specifically it relates to such systems as adapted for the formation of images on any selected objective body, such as cards, clothes, papers, and transparent sheets, although these are not limitative to the present invention.

BACKGROUND ART

Reliance is made generally upon the normal printing technique for formation of images on objective bodies. For the execution of the printing technique, provision and use of printing plates (forms or blocks) are requisite. No matter how simple the image-printing is, the plate-making is a very time-consuming and laborious procedure. This is much more so in the printing of various and complexed image combinations, such as those of graphic or portrait images combined with characters, letters or barcodes, as an example, representing extremely complicated and troublesome work.

Further, in the normal printing operation, various operating conditions, including ink selection and the like, must be carefully considered, depending upon the kind and nature of the printing object, thus the best selection thereof is highly delicate and not as simple as expected.

The present invention is proposed upon careful consideration of the foregoing facts, and an object of the invention is to provide a unique process for the formation of sharp and clear images regardless of the kind and nature of the object to be printed upon, and usable and effective materials and apparatuses for carrying out this unique process.

The method of thermal image transfer (sublimation image transfer) on clothes or fabrics with the use of thermal transfer dyestuffs has been practiced for a long time. In this conventional process, a dyestuff picture layer carrying thermal transfer dyestuff is formed on a substrate sheet which is then subjected to heat in an overlapped state on a cloth or fabric, the dyestuff thereby being transferred thermally onto the latter for forming the desired images thereon. By utilizing this technique, and with recent development of the image forming technology concerning fine thermal printers and the like, various fine image forming processes have been proposed to provide fine images which are comparable to photographic images and are transferred onto plastic films from thermal transfer sheets carrying thermal transfer dyestuffs.

According to these recently proposed processes, various images of cameras, or TVs, graphic images of personal computers and the like can be reproduced easily in the form of hard copies on the surface of a transferred material such as a paper or the like sheet carrying thereon a fixedly attached layer of polyester resin, as an example. These

images thus reproduced represent an amply high level comparable to those obtained by photography or fine printing arts.

The thermal transfer process so far set forth has an advantage in that it can form any image in a convenient manner yet entails a problem in that it is limited to image-transferred products preferably of polyester and the like materials which must be dyed with thermal transfer dyes. On the other hand, the image-transferred products must be limited to specifically selected shapes, preferably film, sheet or the like configuration, and thus, such materials as wood, metal, glass or ceramics cannot be formed with images in this way. Further, even if the material is plastics such as polyester or the like, and when the image-forming surface is curved or undulated, or physical body other than sheet, even if it represents a plane surface, it is almost impossible to reproduce images precisely thereon, which naturally constitutes a grave problem in the art.

With recent development and enlargement of utilizing fields of various card-style products, such as cash-cards, telephone-cards, prepayment cards; and ID-cards, there are increasing demands for providing these cards with images, symbols and codes, so as to give various other functional and/or decorative effects. Most of these cards are of planar form, but they are frequently not pliable and/or have uneven rough portions due to provision of characters and symbols, resulting in great difficulty in the scheduled image formation relying upon the thermal image transfer process.

There is therefore an urgent demand among those skilled in the art for the provision of a unique technique capable of forming sharp and clear images of desired patterns on the surface of an objective body of any preferred kind of material and having any shape and configuration and surface condition of any kind, and indeed, for combining and unifying image- and decoration effects.

DISCLOSURE OF THE INVENTION

The present invention is basically based on such a principle that a first image transfer pattern is formed on an image transfer material, preferably an image transfer sheet, and in the form of dyestuff images through the sublimation image transfer process executed by first image transfer means, depending upon given image data, preferably including those of letters, characters, symbols, line images, graduated graphic representations, and then the first transfer pattern is transferred to second transfer means for retransferring the images onto an objective body So as to provide a final product.

Based upon the image data fed from various image data input means and at the first image-transfer means, a thermal head is actuated to execute printing operation through a dyestuff film (thermal image-transfer sheet) on an image-transfer material (or more specifically on an image-transferable material which means an image-transferable sheet,. This image-printing is carried out according to the sublimation or sublimative image transfer technique. Thus, in this case, the dyestuff on the dyestuff film is transferred or shifted under the influence of heat energy from the thermal head onto the image-transfer material through sublimation, thus providing the first image-transferred means. Since this first image-transferred means has been thus formed with the images by the sublimated dyestuff, they are, then, transferred onto the second image-transferable means which will be brought into tight contact with the object to be decorated and subjected to heat and pressure for execution of further image-transfer operation to provide the final desired product.

In the present invention, the image-transfer material (image-transferable sheet) is, as above referred to, formed with images by the sublimative image transfer technique for providing first image-transfer means which has highly sharp and clear images as the operation and results of the characterizing feature of the sublimation image-transfer technique. Therefore, because of the transfer of such sharp and clear images onto the object, it becomes possible to form the images thereon, and indeed, practically irrespective of the kind and nature of the object. In this way, thus, fine image-formation is assured onto practically any objective substance.

And further, by execution of control of the thermal energy applied during- the sublimative image-transfer step, the resulting color effect is superior and the image quality is good.

The images sublimatingly applied and formed in the foregoing way are subjected to a further transfer, and onto a substrate product, for providing a final decorative product as desired. In this final product, it should be noted that the underlying layer underneath the images during the sublimative image-transfer stage appears now at the top, acting thus as a kind of protecting layer upon up-and-down positional conversion during execution of the second and final image-transfer stage, resulting in realization of various and numerous effects. As an example, attainment of substantial reduction of contamination, improvement of light resistance, weather resistance and chemical resistance; substantial reduction of color fading; provision of glazing effect; easier and simpler introduction of granular and/or undulated image appearance.

The inventive process is carried into effect basically in such a manner that an image-reception layer provided on one surface of an image-transferable sheet is subjected to an image-forming step with the use of dyestuff capable of depositing therein depending upon the fed image data, so as to form the required images, and then, the image-reception layer of the image-transferable sheet, having been image-fixed and thus now image-carrying, is stuck onto the surface of the object to be decorated upon.

As for the image-transferable sheet adapted for use in the image-transfer during execution of the inventive process, it consists basically of a sheet-like substrate and a reception layer attached, however, in a separable manner, onto one surface thereof. As a modification of the inventive process from the basic mode set forth above, the sheet-like substrate is caused to remain, even after completion of the image-transfer step, as may be occasionally required. In this modified case, it is unnecessary to make the image-reception layer of the image-transfer sheet separable.

Under occasion, the inventive process may be brought into effect in such a way that the image-reception layer of the image-transfer sheet is transferred upon execution of the image-forming step, and indeed, once onto an intermediate image-transfer substrate which is then retransferred, together with the once transferred image-reception layer, onto the surface of an object to be decorated on; and thus, in a retransferring manner.

BRIEF DESCRIPTION OF THE DRAWINGS

In the accompanying drawings:

FIG. 1A is a block diagram, showing a preferred embodiment of the apparatus according to the present invention;

FIG. 1B is a schematic view illustrating at (a), (b) and (c), several image-transfer steps for the execution of a process according to the invention;

FIG. 1C is a schematic view of an image-transfer step, using a platen roll;

FIG. 1D is a plan view of part of a multi-color dyestuff film adapted for use in an image-forming step;

FIG. 1E is a schematic view for the illustration of several image-transfer steps;

FIG. 2 is a flow chart of successive operation steps with use of a data-processor, shown in FIG. 1, functioning as an operating center;

FIG. 3A is a schematic block diagram, showing a data-processor for the printer;

FIG. 3B is a block diagram of a sublimative image-transferring printer adopted in the present invention, as a preferred embodiment thereof;

FIG. 4 is a schematic block diagram, showing a color correction unit shown in FIG. 3A, and several related parts cooperating therewith;

FIG. 5 is a schematic block diagram of a comparator and several related parts cooperating therewith;

FIG. 6 is a circuit block diagram of an image-transfer head shown in FIG. 1B;

FIG. 7 is a graph showing operational characteristics of a color tone or -gradation corrector unit shown in FIG. 3A;

FIG. 8 is a table for the illustration, as an example, of picture- or image-elements, as expressed in binary signals;

FIG. 9 is a table showing a conversion operation, as an example, of a parallel/series converter shown in FIG. 3A;

FIG. 10 is a flow chart, illustrating the operation of the sublimative image transfer printer;

FIG. 11 is a plan view of a final decorative product prepared according to the inventive technique;

FIG. 12 is a sectional view of the product card shown in FIG. 11, and taken along a section line A—A shown therein;

FIGS. 13 through 31 are a series of sectional views, respectively illustrating several structural examples of image-transferable sheets, suitable for use in the invention; and

FIGS. 32 (*a*), (*b*), and (*c*) are sectional views, indicating final transfer steps.

BEST MODES FOR CARRYING OUT THE INVENTION

Referring now to FIG. 1A and FIG. 1B, (a), (b) and (c), a basic scheme of the inventive image data processing and image formation will be illustrated. First, in FIG. 1A, numeral **101** represents an image input means which is adapted for forming image data based upon optical and the like inputs delivered from a TV-camera, line sensor or the like. Other than those above enlisted only by way of example, video; CD; TV; scanner; personal computer, captain system, capable of providing R.G.B.—and picture image and the like signals may also be utilized in a similar way. The image signal data delivered from the image input means are fed through a data processor **104** to a memory **105** for being stored therein. These stored data can be taken out from the memory and fed through data processor **104** to display means **102** for being displayed thereat.

To the data processer **104**, a mouth/tablet digitizer and/or the like position data processer **103** is electrically connected for introducing position data concerning displayed images appearing at the display **102**. In addition, key board and the like character data input means **106** and font generator **109** are provided for introducing character data. Still further, a barcode generator **110** is provided for introducing barcode

when necessary. By the use of these means and units, various additional processing modes can be executed.

The thus processed data are subjected to conversion at a data converter **107** into proper data adapted for operating a sublimation transfer printer and fed forward through a driver **108** to the thermal head.

In this case, by controlling the current duration period to the thermal element of the thermal head, the transfer quantity from the dyestuff film (thermal transfer sheet) is controlled depending upon the thermal energy of the element for realization of the desired gradation degree of concentration on the transfer sheet. There are two different modes of such control of current duration period as follows:

(a) A method for controlling the pulse length corresponding to the picture element in the impressed data to the thermal element of the thermal head or, more specifically, a series data introduced as input to the shift register shown in FIG. **6** and to be described more specifically hereinafter.

(b) A method for controlling the number of pulses of the pulse series corresponding to the picture elements of the data impressed upon the thermal element in the thermal head (in this case, the pulse length being constant).

The degree of gradation of the transfer image can be controlled in the above mentioned way by the regulation of the current-conducting period depending upon the desired gradation degree. On the other hand, the image concentration can be controlled by adjusting the pulse length or the number of pulses contained in the pulse series in correspondence to the picture elements contained in the data as introduced in the shift register and depending upon the driving mode of the thermal head. Further in this case, if the number of gradation of introduced image data is larger than that which can be expressed by the printer unit, a proper conversion operation can be performed by the known strobe control method. As an example, in such case, the conversion of gradation number 256 to 64 may be executed by a ROM, and the thus reduced gradation number can be used as output.

Next, referring to FIG. 1B at (a) and (b), reference numeral **121** represents a thermal head which receives signals from the driver **108** shown in FIG. 1A. This thermal head **121** is arranged in opposition to platen roll **122**, forming the printing position therebetween. The dyestuff film (thermal transfer sheet) is fed from a delivery roll **123** to a winding roll **124** through this printing position, these structural and functional features being commonly employed in both the arrangements shown in FIG. 1B at (a) and (b).

In the case of FIG. **1B**, (a), the mechanism is so arranged that card or sheet style transfer sheets are printed with dyestuff images.

On the other hand, in the case of FIG. **1B**, (b), the mechanism is so arranged that cards are continuously produced with the use of a film style transfer sheet and a dyestuff film in combination.

Now turning back to FIG. 1B, (a), a number of transfer sheets (cards, sheets or the like) have been stacked and stored within a storage casing **125** and are being thrust upward from below by a spring so that the uppermost sheet is kept in pressure contact with a take-out roll **126**. With the rotation of the roll **126**, the sheets are successively delivered from the casing **125** by conveyer belts **127**, **128** onto a platen roll **122**. Each one of the sheets is fixed on the peripheral surface of the platen roll, now positionally indexed, by means of a gripper or the like mechanical attaching and separating means, static attracting means, or electromagnetic attaching means. Then, the roll **122** is so rotated that the transfer sheet is positioned at the ready-for-printing-position.

Next, the thermal head **121** is brought into pressure contact with the transfer sheet through the intermediary of the dyestuff film, and then the thermal head **121** is energized with electric current while the dyestuff film and platen roll **122** are moved in synchronism for the execution of image transfer (first image transfer).

Upon execution of the image transfer, the platen roll **122** is rotated, the gripper is released and the take-out roll **129** is rotated and brought into pressure contact for taking out the image transfer sheet onto a tray **130**.

The thus taken-out sheet is brought into overlapped state with a new image transfer sheet, not shown, and then, both the sheets are fusingly united together by pressure application of a heated roll, not shown, for execution of a second transfer step job. The whole operation has thus been completed. Before the fusion process, the sheets may be subjected to punching, trimming and/or the like processing, if necessary.

By execution of the foregoing operational steps, a monocolor printing operation has been completed. However, in the case of multicolor printing, use is made of tricolored or quadruple colored dyestuff film and the corresponding printing operations must be repeated. In this case, upon completion of a single monocolor printing procedure, the platen roll is rotated without contact of the take-out roll **129**, until it arrives again at the printing-initiation position, and so on.

In the following, a tricolor printing job will be illustrated with reference to FIG. 1B, (b), and with use of three different series color zones, of cyan, magenta and yellow.

First, a platen roll **122** is positionally indexed, and an image transfer sheet taken out from the roll **131** and a dyestuff film taken out from the roll **123** are brought into pressure contact in an overlapped state. Then a thermal head **121** is pressed against the platen roll **122** through the intermediary of the overlapped sheets. At this stage, the platen roll **122** is rotated counterclockwise while synchronism is kept between the platen roll **122** and the dyestuff film, and the thermal head **121** is kept electrically energized. In this way, the first color printing is executed.

Further, the dyestuff film is fed to the second color zone position, and then, the platen roll **122**, the dyestuff film and the image transfer sheet are fed forward clockwise around the center roll **122**. Thus a second color printing step is executed.

Further, the print-serviced two color sections of the film is fed back counter clockwise around the center of the platen roll **122** for the execution of a third color printing step. Then, each card sheet is taken out from the stack **200** under the action of take-out rolls or the like, not shown, towards and between a pair of thermal transfer rolls **132**, **133**, brought into overlapping state with the image transfer sheet positionally indexed and already subjected to image transfer steps as was described above, and finally subjected to a picture printing operation by pressurizing application of the thermal image transfer rolls **132**, **133** from both sides of each taken-out card, and so on.

The color-printing step with the use of the thermal head is carried into effect in the following manner, as an example.

(First color printing)

Platen roll, image transfer sheet and dyestuff film perform the printing while they are moved in the counterclockwise direction.

(Second color printing)

Platen roll and image transfer sheet are moved in the clockwise direction while the dyestuff film is moved at the same speed and in the counterclockwise direction for performing the color printing under consideration.

(Third color printing)

Platen roll, image transfer sheet and dyestuff film are moved in the counterclockwise direction for execution of the color printing under consideration.

In the modified arrangement shown in FIG. **1B**, (c), thermal image transfer rolls **132**, **133** have been replaced by a flat press type image transfer head having up-and-down movable flat printer elements **132'**, **133'**.

It should be noted that in the course of the foregoing first and second image transfer steps, image reversal phenomenon is necessarily brought about upon execution of each image transfer step. In other words and more specifically, when two successive image transfer steps in the foregoing sense are executed, reverse images which have once appeared will return to the original normal images. Therefore, when the printed-out products are to be provided upon execution of the first image transfer step, it is necessary to provide reversed image data in the signal processing system. For this purpose, it is only necessary to reverse the addressing order at the data introduction or readout stage into or from the memory.

In the modified arrangement shown in FIG. **1C**, the foregoing platen roll means has been replaced by a metal block **141** lined with a rubber plate **142** in an overlapped manner. The image transfer sheet and dyestuff film are fed out from respective rolls **131** and **123**. With the use of this modified arrangement, the dyestuff surface layer of the dyestuff film can be brought into tight contact with the image-receiving surface layer of the image transfer sheet, and thermal energy will be transferred evenly form the thermal head **121** to the dyestuff film.

In this case, the image transfer sheet is delivered from the roll **131**, and the desired zone or region of the sheet is set underneath the rubber plate **142** (step **1**).

At the same time, the dyestuff film shown in FIG. **1D** on an enlarged scale is delivered from the roll **123** and a selected one of the different color regions is set underneath the rubber plate **142** (step **2**).

Next, the thermal head **121** is brought into the rear surface of the dyestuff film which is the opposite surface to the dyestuff-coated front layer, and the head **121** is driven while it is being translated in the direction shown by an arrow A, images thereby being formed at the specifically allocated zone(s) or region(s) of the image transfer sheet (step **3**).

Further, the thermal-head **121** and rolls **416** and **418** are shifted downwards as shown by arrows B, so as to form an idle gap between the image transfer sheet and the dyestuff film for allowing the latter to shift towards the next following color region (step **4**).

Further, the thermal head **121** and rolls **416** and **418** are returned to their original positions, whereupon the third and further succeeding steps are repeatedly executed until a certain predesired number of color printings are completed.

As shown in FIG. **1D**, the dyestuff film is colored to have several different color regions denoted by Y (yellow), M (magenta), C (cyan) and Bk (black). However, the arrangement order is not limited to that shown: Y; M; C and Bk. In addition, as occasionally required, the Bk-region may be dispensed with. Further, as the color elements to be adopted in the Y, M, C-system may not be limited to the three primary colors provided by the subtractive color mixture. On occasion, a characterizing color which means such a color as preadjusted to provide an objective specifically selected one may be used to form the images concerned. As a further modification, the arrangement shown in FIG. **1C** may be so modified that the traveling direction of the image transfer sheet is selected to be perpendicular to that of the dyestuff film.

FIG. **2** is an operation flow chart for showing schematically operational modes taking the data processor **104** adopted in the embodiment shown in FIG. **1** as the centrum of description. The operational contents several working parts downstream of the data converter **107** will be set forth separately hereinbelow. Now referring to FIG. **2**, in combination with FIG. **1** and at the step of **S101**, image pickup operation is carried out by means of the image pickup means **101**. For execution of this step, it may be better to pick up the face of a person per se which is to be represented on the card, or alternatively, a photograph, portrait or imagery product thereof will do. Depending upon the nature of the object, a TV camera, line sensor or the like instrument may naturally be selectively utilized.

The data taken by the image pickup means **101** are stored through the data processor **104** at a memory **105** (**S102**). By the use of these stored data, image or images is/are displayed at the display **102** (**S103**). Since this display image is not yet subjected to any processing, it is generally unsuitable for representing on the card. However, under certain circumstances, it may be represented thereon as it is.

Then, the operator observed the displayed image or images on the display unit **102** and adjudges whether additional processing is necessary or not (**S104**). If it is not necessary, he will manipulate the key board **106** to make a certain operation, resulting in the termination of processing at the data processing unit **104**, data being fed out therefrom to the succeeding data converter **107**.

On the contrary, when additional processing is necessary, the operator-observes carefully the displayed image or images on the unit **102** and adjudges whether the picture image data, or character data or barcode data should be processed. If the picture image data should be processed, such an operation is made for selecting the proper mass of trimming or layout within the menu range of position-data input means **103**. By the execution of this operation, functions and operations at steps **S105** and **S106** can be executed at one stroke. If trimming is taken as an example, the next step is executed in such a way that position data are fed from the position input means **103** to the data-processer **104** with the use of a carsor. When a tablet digitizer is used as the position data input means, the carsor image displayed in an overlapped manner on the displayed picture image appearing at the display unit **102** by carsor manipulation is positionally specified beforehand in registration with the specified position on the card, for determining the trimming range. Then the operation is carried out in such a way that the picture image data outside the specified trimming range are canceled. By completing these operations, data processing operations relating to step **107** are executed, and, then, the mass for completion of the menu range is selected out. By these measures, steps progress through **S109** to **S102**, and data storing is executed, and further, display representation is brought about through step **S103**. If there is no need for additional processing, an operation termination manipulation is carried out as before at key board **106**, and further operations will be made through data converter **107**.

As for the layout, the operation is carried out with the position data input means **103**, similarly as in the foregoing trimming operation. More specifically, layout is selected out in the menu range of position data input means **103**, and the

overall configuration of the card and the display position of picture image are shown at display unit **102**. Then, image inclination correcting operation and the like are carried out so as to realize correspondence thereof with the displayed positional information, the processing operations relating to step **S108** thereby being brought about. After completion of these operations, the mass for the ending in the menu range is selected.

In this way, when selection is made from the menu range by reliance on the position data input means **103**, trimming or layout operation can be brought about. At this stage, when manual operation is carried out at the key board **106**, introduction of character data is executed (**S110**). As the character data in this sense, in the case of ID card, as an example, the name and/or birthday, month and year of the owner may be used. The data introduced from the key board **106** in accordance with the output character style from the font generator **109** are shown at the display unit **102** in the specified positions on the displaying surface and respectively arranged in accordance with display items. The operator acknowledges these items and detailed displays of the represented images. When he acknowledges them as being true, he will operate the key board **106** for showing the operation ending (**S111**).

Upon ending the operations as described above, the data are stored in memory **105** (**S102**) and represented at the display **102**. The operator will acknowledge again this fact, and upon the execution of this, the operations are terminated.

As for the barcode introduction, the data are subjected to inputing at steps **S112** and **S113**, as in a manner similar to the character data introduction as set forth above. The barcodes and the like data may be introduced separately through printing or other mechanical method.

In FIG. **3A**, a data processing circuitry usable in the sublimation image transfer printing method is shown only schematically. As shown, the circuitry **107** comprises a picture element density converter **3**; a color corrector **4**; a gradation corrector **10**; a memory **11**; a switch **12**; a buffer **13** and parallel/series converter **14**. The picture element density converter **3** is connected to a picture image input unit **100**.

The unit **100** serves for generation of three primary color data of R.G.B.- or Y.M.C.-mode from original picture images and is connected through the picture element density converter **3** to the color corrector **4**. The converter **3** converts the picture element density of the image data fed from the unit **100** to the desired one, by subtracting or supplementing, as the case may be, image data for each color element. It should be mentioned that for attaining high quality hard copies, conversion of the picture element density to at least 10 lines/mm or so is preferable.

Color corrector **4** consists preferably of a color decoder, level adjuster or color converter, and serves to correct three primary color data converted to those of a predetermined density of picture elements in consideration of characteristics of the image transfer ink in the image transfer sheet and in addition to provide black color data.

The data processing circuitry **107** is connected through a driver **108** to the sublimation image transfer printer.

In FIG. **4**, an example of the color corrector **4** is shown schematically in structure. As shown, it comprises adders **6Y**; **6M** and **6C**, a black color data calculator **7**, and primary and secondary color correction circuits **8** and **9**. Primary color correction circuit **8** serves for making correction of turbidity of the image transfer ink, while secondary color correction circuit **9** provides a capability of arbitrary and selective correction control relative to specifically selected color hue.

The gradation corrector **10** is so arranged as to make correction of the gradation of the data for each color Y, M, C or K (representing black color) fed from the foregoing color corrector **4** when necessary. For this purpose, the corrector **10** includes a gradation circuit (not shown) and the like, whereby a certain mode of highlight stressing or shadow stressing is introduced and realized.

The memory **11** functions to preserve temporarily the data of each color delivered from the gradation corrector **10**, a selection switch **12** being provided at the output side of the memory for selective writing-in of the data of each color to the buffer **13**. The buffer **13** is capable of writing-in the data of one line of the image transfer head **16** and kept in connection with the parallel/series converter **14** adapted for converting parallel data into series data. Additionally, in the simplified machine, black color data series is dispensed with in some instances.

In FIG. **5**, a schematic construction of the parallel/series converter **14** is shown. As shown, parallel data delivered from the buffer **13** are fed to an input side of a comparator **22**, while outputs from a counter **23** are fed to another input side of the comparator **22** which delivers the converted series data to the driver **15** for driving a thermal head **121**.

If necessary, however, the comparator **22** may be replaced by a converter table, not shown, utilizing a parallel/series converting ROM.

In FIG. **6**, a detailed circuit scheme of the thermal head **121** is shown. As shown, series data delivered from the comparator **22** are fed into a shift register SR and thence, after being subjected to latching at a latch circuit LT, fed to thermal elements HE through NAND gates NA which are fed at respective one side inlets with strobe signals.

Next, referring to FIG. **3A**, the operation of the data processing circuitry **107** will be described more specifically.

First, when three primary color image data are fed from the picture image inlet circuit **100** to the picture element density converter **3**, the latter converts these three primary color data to those which represent a predetermined picture element density and then are fed to the color correction unit **4**. In this case, it is assumed that the unit **4** is fed with three primary color data expressed in respective concentration signals, which are of yellow: **Y0**; of magenta: **M0** and of cyan: **C0**, respectively, in the present example.

These data: **Y0**; **M0** and **C0** are, as shown in FIG. **4**, fed through respective adders **6Y**; **6M** and **6C** to the black color data calculator **7**, to provide a K-output as expressed mathematically by the following formula:

$$K=\min(Y, M, C)$$

wherein, "min" represents a function which provides a possible minimum value.

These data: **Y0**, **M0** and **C0** are fed from the converter **3** to the primary color correction circuit **8** to provide primarily corrected data **Y1**, **M1** and **C1** which are thence fed to the secondary color correction circuit **9** to provide, through calculation, secondarily corrected data: **Y2**, **M2** and **C2**, respectively. These are then fed to respective adders **6Y**, **6M** and **6C**, which add them to respective data **Y0**, **M0** and **C0**, to provide respectively added output data Y, M, and C to be fed to the gradation correcter circuit **10**, respectively, after being utilized for calculation of the K-output signal value.

The primary color correction circuit **8** serves to calculate primarily corrected data: **Y1**, **M1** and **C1** which are necessarily utilized for correct-out of transfer ink turbit. In this case, the original data: **Y0**, **M0** and **C0** are subjected to matrix calculation to provide the primarily corrected data **Y1**, **M1** and **C1**, as folows:

$$Y1=k_{11}\cdot C0-k_{12}\cdot M0+k_{13}\cdot Y0$$

$$M1=k_{21}\cdot C0+k_{22}\cdot M0-k_{23}\cdot Y0$$

$$C1=k_{31}\cdot C0+k_{32}\cdot M0-k_{33}\cdot Y0$$

where, k_{ij} represents weight coefficients:

i=1–3; and

j=1–3.

The secondary color correction circuit **9** serves to calculate secondary color correction data **Y2**, **M2** and **C2** from primary color correction data **Y1**, **M1** and **C1** by modifying the latter to make certain thereto by performing matrix calculations so as to provide a capability for making an arbitral and selective color control at a certain specifically selected-out color hue, in the following manner:

$$Y2=Y1+l_{11}\cdot\Delta B+l_{12}\cdot\Delta C+l_{13}\cdot\Delta G+l_{14}\cdot\Delta Y+l_{15}\cdot\Delta R+l_{16}\cdot\Delta M$$

$$M2=M1+l_{21}\cdot\Delta B+l_{22}\cdot\Delta C+l_{23}\cdot\Delta G+l_{24}\cdot\Delta Y+l_{25}\cdot\Delta R+l_{26}\cdot\Delta M, \text{ and}$$

$$C2=C1+l_{31}\cdot\Delta B+l_{32}\cdot\Delta C+l_{33}\cdot\Delta G+l_{34}\cdot\Delta Y+l_{35}\cdot\Delta R+l_{36}\cdot\Delta M$$

wherein, l_{ij} represents weight coefficients:

i=1–3;

j=1–6;

ΔB, ΔC, ΔG, ΔY, ΔR, ΔM:

characterizing color data.

Thus, when these-secondary correction data **Y2**, **M2** and **C2** are added to the corresponding original data **Y0**, **M0** and **C0** by means of respective adders **6Y**, **6M** and **6C** and under proper selection of weight coefficients k_{ij} for primary color correction circuit **8**, any color discrepancy of the ideal color of the ink appearing on the printed picture images under the action of the sublimation transfer printer can be arbitrarily ammended. In this case, when the weight coefficients l_{ij} for the secondary correction circuit **9** are selected out properly, the color tone of the printing picture images can be modified to an arbitrary degree.

Further, as for the black color data K, correction data K2 can be calculated by the following formula. With use of these correction data K2, which are added to the original black color data K, the desired correction can be executed in a similar manner.

$$K2=K+m1\cdot\Delta B+m2\cdot\Delta C+m3\cdot\Delta G+m4\cdot\Delta Y+m5\cdot\Delta R+m6\cdot\Delta M$$

wherein, Mi represents weight coefficients:

i=1–6.

In this way, output data: Y, M, C and K delivered from the color correction circuit **4** are introduced into the gradation corrector **10** as inputs thereof, and each constituent of these data can be subjected to correction as desired.

FIG. **7** shows several characteristic curves illustrating corrections by means of the gradation corrector **10**. More specifically, **f0** represents a standard characteristic curve; **f1** a highlight-stressing operation curve; **f2** a shadow-stressing operation curve; **f3** a highlight-and-shadow stressing operation curve; and **f4** a medium tone stressing operation curve.

As indicated in FIG. **7**, by presetting, as necessary, the tone-reproducing characteristics, which determine the relationship between that concentration of color data and that of the prints printed by means of a sublimation image transferring printer, a color tone similar to that possessed by the original image can be reproduced. More specifically, when no correction is adopted, the curve **f0** is used, while in the case of correction, any selected one of these curves **f1** to **f4** may be utilized depending upon the part of gradation to be stressed. Further, it should be noted that the tone reproducing characteristic curves are not exclusively limited to those which have been specifically shown and described above. As an example, the control of gradation correction by color tone reproducing characteristic mentioned above is executed by a gradation circuit, not shown, and the setting of the color tone reproducing characteristic is brought about by manipulation of any selected one of the control knobs, not shown, which are provided separately for "highlight"; "medium tone" and "shadow".

Y.M.C.K.-data subjected to correction by the gradation corrector **10** are once stored in the memory unit **11**. The thus stored data may be read out from the memory for each color by manipulation of the selection switch **12** and, after provisional storing, per one line of transfer head **16**, at the buffer **13**, introduced into the parallel/series converter **14** for conversion thereby into corresponding series data.

Another example of the data processing circuit for the sublimation transfer printer is shown only schematically in FIG. **3B**. As shown, the processing circuit in **107'** comprises a level regulator **503**; a color converter **504**; an A/D converter **505** and a parallel/series converter **14**.

As the image data introduced into the processing circuit **107'**, those which have been subjected to conversion into R.G.B.-signals in the color decoder **502** from composite video signals delivered from a T.V. camera, VTR or the like are used. On the other hand, R.G.B.-signals delivered from a personal computer, captain system or the like means are introduced as input into the level adjuster **503**.

As the color correction method with the use of the foregoing arrangements, it is possible, more specifically, to adjust the hue saturation and/or brightness in the color decoder **502**, or to adjust the signal level of each color light of R.G.B.-system in the level regulator **503**.

As an example, the color conversion from R.G.B.- to Y.M.C.-system can be executed in the color converter **504**. The simplest possible method in this color conversion is to procure the opposite color to each of the normal colors.

The thus produced color signals of Y.M.C.-system is subjected to A/D conversion and then fed successively through the parallel/series converter **14** and the driver **108** to the thermal head, not shown, to carry out printing in the sublimation transfer principle.

Additionally, in normal cases, with the use of the foregoing system composition, input image data must be of static mode. However, by provision of memory means in front of the color decoder or at an intermediate position between the A/D converter and parallel/series converter, animating images can be processed.

The series data converted in the foregoing manner in the data converter **107** or **107'** are fed to the shift register SR shown in FIG. **6** by n-image elements and then, upon being subjected to latching in the latch circuit LT are further delivered to NAND gate NA as its inputs. When a strobe signal ST is fed as input to the NAND gate NA, the foregoing n-image element data is fed to the thermal element HE.

FIG. **8** is a schematic diagram, showing signals for respective image elements. The gradation has been so selected that the first image element is at the highest gradation level, while the n-th image element corresponds to the lowest gradation level, and that the second to (n–1)th image elements vary linearly in gradation levels, so as to provide representatively a better understandable example of the invention.

Next, the operation of the parallel/series converter **14** will be described.

First, as shown in FIG. **5**, image elements data A, consisting of parallel data, more specifically, comprising paral-

lel eight bit data A0–A7, are fed to one-side inputs of comparator 22, while another side inputs thereof are fed with outputs B, comprising eight bit increment outputs B0–B7, of counter 23. The counter 23 counts clock signals in increments, the outputs B0–B7 being successively varied.

The comparator 22 performs comparison between the two inputs A and B, so as to deliver successively outputs of binary "1" until the increment output B is brought into coincidence with image elements data A, or more specifically, under the condition of A>B and A=B, while, thereafter, binary "0"-outputs are delivered therefrom. More specifically, comparator 22 will continue to deliver binary "1" until an increment value which corresponds to the weight of concentration of image element data A is given thereto. As an example, if the image element data A has a concentration of gradation 128 of a total 256, output "1" will be repeated to deliver 128 times first and then, output "0" will follow after again 128 times, so as to provide in total a specific series data peculiarly in this case.

These series data are taken out from the comparator 22 in the form of A>B- and A≥B-outputs and of A=B-outputs through an attributed OR-gate 24, and in the present example, the gradation consists of 256 steps or increments. However, in practice, the gradation may represent a smaller number of steps. As an example, if the incrementing bit is B1 instead of hitherto employed B0, the gradation will have 128 steps; and if B2 employed, it will have only 64 steps. In this way, the gradation setting may be varied in a simple manner.

When in the foregoing way, the output B from the counter 23 is stepwise incremented, such series data consisting of a first series of "1" will be delivered until the relationship between the image elements data A and the output B from counter 23 becomes A=B, and of a second series of "0" issued thereafter, as shown in FIG. 8.

In FIG. 9, a conversion mode at the parallel/series converter 14, which, however, is different from that shown in FIG. 8, as an example, is shown again in the form of a matrix. As-shown, when the image data are of 8-bit parallel kind, as an example, the gradation data are ranged from 0 to 255, providing, therefore, binary series data from "00 . . . 00" to "11 . . . 11".

In this way, the data, per line in the transfer head 16, kept preserved in the buffer 13 are fed to the parallel/series converter 14 for providing as outputs therefrom into corresponding series data which are then delivered through the driver 15 to the transfer head 16 and thus recorded on a print paper P supported on the transfer drum 17.

FIG. 10 represents a flow chart illustrating the operation of the sublimate printer as employed in the present invention.

At the first step S1, print papers are set in position and the printing ribbon is also set in position ready for performing the required procedure.

At the second step S2, printing operation is initiated, and line printings are executed, line by line, accompanying necessary intermittent line shifts, with relation to any selected one of four colors: C (cyan); M (magenta); Y (yellow) and K (black) being carried out. Refer to S3 and S4. When line printings with the selected-out single color have been completed (S5), the image transfer sheet is replaced by another color sheet (S6) and so on. In this way, line printings are completed in all four colors. In this case, it is naturally most preferable to use a long extended single transfer sheet on which four color ink regions are repeatedly printed in a certain predetermined pattern. The image reception paper is initiated to make print from a certain prescribed position for each of these colors (S8). When all of the printing steps have been completed with the four colors, the paper is discharged from position (S9) and the printing operation is terminated to be repeated.

In FIG. 11, a card style sample of the final products according to this invention is shown in front view at 200. FIG. 12 is a sectional view thereof. Numeral 201 represents the substrate material of the card; 202 a display layer; 203 a surface protecting layer; and 204 a display image as an example. Depending upon the kind of usage and when necessary, the protecting layer 203 may be dispensed with. It should be noted that the display image 204 on the display layer 202 is represented by a sublimative dyestuff, as a characterizing feature of the present invention.

As the main and substantial material of the image transfer sheet, various plain papers, convertea papers, plastic resin sheets or the like may be used per se or in combination. When a plastic resin sheet which can be colored directly with a sublimative dye or dyes is used, these image transfer substrates (articles or objects) as at 201 can be united each with the display layer 202. Each of these substrate materials, when it is of the card style, may have generally such dimensions: thickness of 0.68 to 0.80 mm and size: 11 to 8×8 to 5 cm.

As the material of the display layer 202, various known materials which may be colored with sublimative dyestuffs, such as polyethylene, polypropylene, polyester, ABS, AS, polyvinylchloride, polyvinyl/vinyl acetate copolymer, polystyrene, polyacrylate, polyester, polyamide, polyurethane and the like plastic material, may be advantageously utilized. As will be more specifically described hereinafter, this material layer can be united with the substrate material layer 201. In the case of such unified structure with substrate layer 201, the thickness and size dimensions may be substantially as the same as before. However, when normal and/or converted papers or metals, which are practically impossible to color with sublimative dyestuffs, are used as the substrate layer 201, various methods can be utilized for desired coloring. As an example, a solution including at least any selected one of plastic resin materials capable of coloring with sublimative dyestuffs may be coated on the substrate surface, or alternatively used in the form of a film which is laminated thereon. This kind of film preferably has a thickness of about 3 to 50 μm or so. One of main characterizing features represented in and by the final products 200 is that the appearing display image or images as at 204 is/are formed at least partially or wholly with a sublimative dyestuff or dyestuffs. Additionally, the process for formation of such images can be executed in the conventional art.

As an example, the processing method may be executed conventionally as follows.

As an example, a sublimative image transferable sheet, such as a paper sheet, plastic resin film or sheet capable of acting as the carrier is coated on its surface with any suitable binder resin carrier carrying a sublimative a dyestuff or dyestuffs under heat, is overlapped on the display layer 202 and then subjected to heat from behind the heat-transferable sheet, preferably in the pattern mode, so as to transfer the dyestuff or dyestuffs into the display layer 202. It is proper to select the molecular weight of 250 or larger of the dyestuff, for improving the fastness thereof. However, a molecular weight higher than 370 is more favorable. In the case of provision of the surface protecting layer, there is practically no limitation to the selectability of the dyestuff molecular weight.

The sublimative image transfer may be executed directly on the surface of substrate 201 provided with the display

layer **202**. Or alternatively, a carrying, image transferable sheet is prepared separately and, after formation of the image **204** thereon, may be stuck onto or laminated on the substrate **201**.

Image-Carrying and Image-Transferable Sheet

In the following, structure, material, usage and application purpose of the image-transferable sheet to be employed in the present invention will be described in detail:

FIG. **13** illustrates Only basically and in schematic sectional view the image-transferable sheet adopted in the present invention, while FIGS. **14** through **19** and **22** through **24** illustrate preferable embodiments thereof.

The basic structure of the image transferable sheet **310** is characterized in that, as shown in FIG. **13**, a sheet-like substrate **301** is provided at its one surface with an image-reception layer **302** capable of peel-off from the substrate. By adopting such a structural configuration of the image-transferable sheet, the image-reception layer **302** can be formed with the required image or images with the use of an image transferable sheet having thermally shiftable dyestuff, and then, the image-formed, image-reception layer **302** is peeled off from substrate **301** and attached firmly, preferably as by sticking, on the surface of any selected object or article with use of any suitable means. In this way, various conventional drawbacks inherent in the comparative conventional technique can be basically overcome.

More specifically, as the material of the aforementioned image-reception layer **302**, limitation must be imposed to those which can be colored with thermally shiftable or transferable dyestuff. However, upon Eormation of necessary images and upon peel-off from the sheet-like substrate **301**, the image-reception layer **302** may be attached fixedly onto the surface of glass-made, metal-made or wooden-made products or plastic-resin made ones which are very difficult to color with thermally shiftable and transferable dyestuffs, indeed, by reliance on conventional sticking techniques as properly adopted in consideration of the specific nature and kind of the material of decorative products to be ornamented. Further, the image-formed and peeled-off, image-reception layer **302** from the sheet substrate **301**, is highly thin and thus sufficiently pliable so that it may be applied even onto any uneven and complicated surface of a product to be decorated or ornamented, having undulations, convexities, concavities, recesses and projections. Therefore, a maximum possible better fitness of the image-reception layer to be ornamented is attained and guaranteed by the present invention. Thus, practically no limitation in the attaching use thereof may be encountered. Further, in sharp contrast to conventional sealing seals and the like, the very thin image-reception layer bearing necessary images can be applied easily to the product per se in a very uniform manner, thus providing no raised and thickened feeling, and giving rise to no foreign feeling upon attachment.

FIG. **14** shows a further example of the image transferable sheet **310**. In this case, there is provided a parting agent layer **303** on the surface of image-reception layer **302**. Between the latter and the sheet substrate **301**, there is provided a parting agent layer **303'**. If necessary, however, any one of the two layers **303**; **303'** may be dispensed with.

The first parting agent layer **303** is provided for prevention of thermal fusion between the image-reception layer **302** and an image transferable sheet, not shown, as may occur during image transfer and formation on the first layer **302** through transfer of thermally transferable dyestuff from the said transferable sheet to the first layer. If there is no risk of such thermal fusion of the above nature, or when the image-transferable sheet has been already provided with such a parting agent layer, the present provision thereof may be unnecessary. As for another parting agent layer **303'**, it is for the purpose of making the latter peel-off operation, to be executed after image-forming step, easier. When the sheet-like substrate **301** is made of polyester or the like material which has, as it is, sufficient separability from image-reception layer **302**, provision of parting agent layer may naturally be dispensed with.

FIG. **15** illustrates a still further example of image transferable sheet **310**,. In this case, between the image-reception **302** and the sheet-like substrate **301**, an intermediate layer **304** and/or parting agent layer **303'** is/are provided. The laminating order is optional and thus not binding. The intermediate layer **304** will serve to assist the image formation to be rather firm and beautiful, the image formation being carried out by transferring the thermally shifting and transferring dyestuff from the image transferable sheet to the image-reception layer **302**. For this purpose, the intermediate layer **304** may take, for example, the form of a cushioning layer or heat insulating layer. When a cushioning layer is provided as the intermediate layer **304**, the cohesion between the image transferable sheet and the image reception layer **302** is greatly improved and the thermal shift and transfer of the dyestuff during image formation with the use of a thermal head is evenly executed, the image formation thereby being carried out amply in correspondence with the supplied image signals. Further, when a heat insulating layer consisting of a highly heat-insulative material is used as the intermediate layer **304**, ineffective release of the heat applied during shift and transfer of the dyestuff from the image transferable sheet to the image-reception layer **302** can be reduced to a minimum possible, the effective thermal efficiency thereby being correspondingly improved and ample image formation being accelerated. If necessary, however, these cushioning layer and heat-insulating layer can be prepared independently and arranged concurrently in any arranging order.

Additionally, when the intermediate layer **304** is arranged at a higher level than the parting agent layer **303'**, the intermediate layer **304** will be conjointedly peeled off in the case of peel-off of the image-reception layer **302**. On the contrary, when the intermediate layer **304** is arranged at a lower level than the parting agent layer **303'**, the intermediate layer will remain on the sheet-like substrate **301** after execution of the separation of image-reception layer **302**. In this case, therefore, the intermediate layer **304** may be made preferably and at least substantially transparent, when the peeled-off image-reception layer **302** is stuck on a decorative product, while directing the surface of parting agent layer **303** towards the latter.

In the modifications shown in FIGS. **16**, **17**, and. **18**, modified from the foregoing embodiment shown in FIG. **15**, a further protecting layer **305** is provided between the image-reception layer **302** and the sheet-like substrate **301**. This protecting layer **305** serves to prevent deterioration of the formed images in the image-reception layer **302** when the latter is stuck on the decorating product while directing the surface (more specifically the image-formed surface) towards the product. For example, this protecting layer **305** is prepared from a superior material which exhibits at least one of desirous properties such as antiwearing, light-fast, weather proofing and anti-chemical qualities. With the use of the protecting layer **305** having these superior qualities, the images can represent improved fastness in the above various aspects, even after execution of the foregoing sticking procedure.

In the modification shown in FIG. **16**, the protecting layer **305** is arranged between the intermediate layer **304** and the parting agent layer **303'**.

In the further modification shown in FIG. **17**, the protecting layer **305** is arranged between the image-reception layer **302** and the parting agent layer **303'**.

In still another modification shown in FIG. **18**, the intermediate layer **304** takes the role of the protecting layer **305**.

In each of these modifications, the protecting layer **305** is arranged in neighboring relationship with the partition agent layer **303'**, whereby the image-formed and remotely arranged, image-reception layer **302**, kept in its up-and-down reversed state, is capable of adhering securely to the decorative product, so as to be positioned as an uppermost layer, as may be required. In a still further modification shown in FIG. **19**, derived from that shown in FIG. **14**, a sticking layer **306** is further provided between the image-reception layer **302** and the partition agent layer **303**. It should be noted, however, that such a sticking layer as at **306** may be provided in any one of other foregoing examples and modifications, if necessary, in neighboring relationship with the parting agent layer **303'**.

The provision of such a sticking layer as at **306** is highly valuable when the image-f6rmed and peeled-off, image-reception layer is adhering without position reversal onto the decorative product. With this arrangement mode, the protecting layer **305** shown in FIGS. **16**, **17**, and **18** may be dispensed with. If, however, the protecting layer **305** is composed of a material in the form of a sheet-like substrate, the part to be peeled off is thereby strengthed, the peel-off procedure thus being greatly facilitated.

By previous provision of the sticking layer **306**, the image-formed and peeled-off, image-reception sheet **302** can be caused to adhere as it is onto the decorative product without use of a separate sticking agent. As the sticking layer **306**, an ordinary sticking agent which is active at room temperature can be used. Or alternatively, a heat-sensible or light-sensitive sticking agent may be used, if necessary.

In the foregoing, the main structure of the image transferable sheet employed in the present invention has been described in detail. However, other structural modes than those set forth hereinbefore which occur easily to those skilled in the art may be employable in the invention, and thus. they may be included within the scope of the invention without departing from the appended claims.

It should be further noted that, in the present invention, the sheet-like substrate may be provided on its one surface with an image-transferable layer capable of peeling off through the intermediary of only one weakly sticking layer.

FIG. **22** shows only schematically in a sectional view a preferred embodiment of such an image-transferable sheet, denoted with same reference numeral **310**.

As shown in FIG. **22**, the image-transferable sheet **310** represents a basic structural characteristic such that any suitable sheet-like substrate **301** is provided on one of the surfaces with an image-reception layer **302** through an only weakly sticking intermediate layer **402**, the layer **302** thus being easily peeled-off when desired. By providing the image-transferable sheet with such a structural characteristic as set forth above, desired positive or negative images are formed by transferring thermally shiftable and transferable dyestuff from the image heat transferable sheet to the image-reception layer **302**, and the thus image-formed layer is peeled off from the sheet-like substrate **381** and then attached onto any suitably selected product with the use of proper means or attached per se thereon without the peeling-off operation, the substrate then being peeled off, whereby an image-formed final product can be obtained.

In the foregoing example, it should be noted that the image reception sheet **302** per se has only a thin thickness and thus represents only poor feedability during the sheet-feeding period within the printer at the time of image formation, insufficient cushioning effect and only insufficient thermal efficiency during the printing operation, and further, it is very difficult to treat in advance of as well as after execution of the image formation. Therefore, the coexistence of the image-reception layer **302** and the sheet-like substrate **301** is absolutely necessary. In addition, it is a requisite requirement that the image reception layer **302** be easily peeled off from the sheet-like substrate **301** upon execution of the image-forming operation, and thus, the layer **302** and the sheet **301** should not be stuck too strongly together. In order to satisfy this requirement, provision is made of weakly stuck layer **402** therebetween. Thus, it should be noted that the term "weakly stuck" employed in this specification and appended claims may be defined as "to be separable by finger's end and the like means from each other without entailing destruction or breakage of the parts originally stuck together". It is worthwhile to say, in considering the relative relationship between the image-reception layer **302** and the sheet-like substrate **301**, there is no necessity to provide the weakly-stuck layer **402** if the aforementioned peeling-off is very easy to bring about.

FIG. **23** illustrates still another modification of the image-transferable sheet **310** denoted by the same reference numeral **310** only for simplicity and convenience, wherein a further parting agent layer **303** is provided on the surface of image-reception layer **302**.

This layer **302** is provided for occasional thermal sticking between the thermal image transferable sheet, not shown, and the image reception layer **302** in the progress of thermal shift and transfer of the dyestuff from the sheet to the layer **302**. This provision of the parting agent layer **303** may be dispensed with if there is no risk of occurrence of such disadvantageous sticking attachment or the sheet under consideration has already been fitted with such a parting agent layer.

A modification shown in FIG. **24** from that shown in FIG. **23** has such a modified structure that a protecting layer **305** is provided between the image-reception layer **302** and the weakly stuck layer **305**. This layer **305** serves to prevent otherwise occurring deterioration of the images at the image-reception layer **302** which has been formed with preferably reversed images and subjected to peeling-off, together with protecting layer **305**, preferably a plastic sheet layer, from the sheet-like substrate **301** and finally stuck onto the decorative product, while directing the image-formed surface of the image-reception layer towards the product. The protecting layer **305** is made of a material having various excellent physical properties, such as anti-wearing-, light-fastness and antichemical characteristics. Provision of such a protecting layer improves various fastness performances of the formed images after sticking attachment of the image-reception layer **302**.

When necessary, a separate parting agent layer, not shown, may be provided between the protecting layer **305** and the weakly stuck layer **402** for providing easy peel-off capability between these two layers **305** and **402**, as being applicable to the example shown in FIG. **24**. If the surface of the protecting layer **305** should have sufficient peel-off capability, it is natural to provide such an intermediate parting agent layer as above.

Further, in the case of the image-transferable sheet **310**, it is naturally easy to separate from each other through a peel-off operation, upon the formation of necessary images thereon and before practical use thereof as the image-transfer sheet, and a cut-out slit as at **407** in the sheet-like substrate **301** may be provided for attaining such an easy separation as stated above at a portion of the sheet **310** in proximity to one end thereof. Upon the provision of such a cut-out slit as at **407**, the thus formed flap-like portion can be easily folded out by the operator's finger-tip, thereby affording convenience in a peel-off operation.

The usable materials and composing methods of the foregoing image transferable sheets will now be described.

As a material usable for the sheet-like substrate may be any one or any combination of the following categories:

(1) synthetic paper (polyolefin-series; polystyrene series and the like);

(2) fine quality paper; art paper; coated paper; cast-coated paper, wall paper; back-up paper; backing paper; resin-, emulsion- or synthetic rubber-imprignated paper; resin-admixed paper; paper board; cellulose fiber paper;

(3) polyolefin-, polyvinyl chloride-, polyethylene terephthalate; polystyrene; polymethacrylate; polycarbonate and the like plastic film or sheet.

Use of the synthetic paper belonging to the foregoing category (1) is highly suitable for the purpose of the present invention since the surface thereof generally represents a microvoid layer which provides a low heat conductivity and thus a high heat-insulating peformance. A laminated material representing any combination of the foregoing categories (1), (2) and (3) can be used in the present invention. A representative and recommendable example of such a laminate is that of cellulose fiber paper and synthetic paper or that of cellulose fiber paper and plastic resin film or sheet. Among others, use of the first mentioned kind of laminate will provide an advantage in that the thermal instability such as thermal elongation or shrinkage possessed by the synthetic paper component is compensated for by the cellulose fiber paper, whereby a high thermal sensibility is demonstrated during the printing step due to low thermal conductivity of the synthetic paper component. Further, in the case of the present paper combination, however, a further modified combination of a three-layer laminate: synthetic paper-cellulose fiber paper-synthetic paper may be more advantageously employed for making the frequently appearing lesser by providing a well-balanced structure between both the surfaces of the final laminate.

As the synthetic paper mentioned above, any suitable one usable as a synthetic paper substrate used as a component of the image-transferable sheet layer may be used. As a recommendable example thereof, having a fine porous fine paper structure layer, the synthetic paper called "YUPO", manufactured and sold by Oji Yuka Goseishi Kabushiki Kaisha, Tokyo, may be mentioned. This paper layer having a fine pore structure may be prepared in such a way that a suitable plastic resin material containing a filler of finely divided state is subjected to a mechanical elongation step. When the image-transferable sheet composed of the synthetic paper sheet containing finely divided air as above mentioned is formed with images through a thermal image transfer setp, the concentration of the thus formed images is surprisingly high and no fluctuation of image configuration and concentration is encountered, thanks to the heat insulation effect provided by the very existence of fine air pores, in addition to the improved thermal energy efficiency. Especially, due to the advantageous cushioning effect provided by the air-filled fine pores, the image-receiving layer is supposed to be rather advantageously affected during the image formation step. As an alternative measure, the paper-like layer containing the above-mentioned fine air pores may be, if desired, provided directly with the core material consisting of the cellulose fiber paper or the like.

It is further possible to use plastic film in addition to the cellulose fiber paper in the laminate described above. Still further, a laminate of said cellulose fiber paper and plastic film composed together can be used.

As the method for co-sticking of synthetic paper and cellulose fiber paper, use of a known adhesive agent is naturally adopted, as an example. Or alternatively, the extrusion-laminating, heat-adhesion, or the like process may be relied upon, as the case may be. On the other hand, as the sticking-process between the synthetic paper and the plastic film, the lamination process to be carried out simultaneously with the formation of the film may be adopted. Calendering or the like method may be utilized for the same purpose. Selection of any suitable one of the several foregoing sticking processes depends upon the kind of material or the like condition of the partner member to be stuck together with the synthetic paper. As for the adhesive agent mentioned above, emulsion adhesive such as ethylene-vinyl acetate copolymer, polyvinyl acetate or the like, aqueous solution type adhesive polyester containing carboxyl radicals; or the like may be mentioned. On the other hand, as the laminating use adhesive, organic solvent solution type one such as polyurethane-, acrylic- or the like, may be mentioned.

The material for the image-reception layer must be suitable for reception of heat-transfer dyestuff, such as sublimative disperse dye from the image transfer sheet and holding and maintaining the thus formed images thereon. From the view point of image-holding and blocking prevention, use of such synthetic resin as having glass transition temperature higher than 40° C. may be advantageous. For example, the synthetic resins set forth in the following items (a) through (e) may be used separately or in combination.

(a) Ester bond-bearing resins:

Polyester resin; polyacrylic ester resin; polycarbonate resin; polyvinyl acetate resin; styrene acrylate resin; vinyltoluene acrylate resin and the like.

(b) Urethane bond-bearing resins:

Polyurethane resin and the like.

(c) Amide-bond carrying resins:

Polyamide resins (nylons).

(d) Urea-bond carrying resins:

Urea resins and the like.

(e) Other high polar-bond carrying substances:

Polycaprolactorc resin; polystyrene resin; polyvinylchloride resin; polyacrylonitrile resin and the like.

The image-reception layer may be prepared from a resin mixture of saturated polyester and vinylchloride-vinyl acetate copolymer. As the saturated polyester, such commercialized products: "Vylon 200"; "Vylon 290"; "Vylon 600"; "Vylon 103" and the like, manufactured and sold by Toyoboseki K.K., Osaka, Japan; "KA-1038C" (manufactured and sold by Arakawa Kagaku K.K., Osaka, Japan; "TP 220"; "TP 235", manufactured and sold by Nippon Gosei K.K., Osaka, Japan; may be advantageously used. The vinyl chloride-vinyl acetate copolymer may have preferably 85–97 wt. % of vinyl chloride component, the polymerization degree being between about 200 and 880. The vinyl chloride-vinyl acetate copolymer may further contain a vinyl alcohol

component, maleic acid component within the purpose of the invention in addition to the main components. According to our experiments, it has been found that these modified copolymers should have rather superior compatibility with polyester resin. The image-reception layer may be, if necessary, composed of polystyrene resin, for example, in this case, styrene monomer, preferably styrene, α-methyl styrene, and vinyl toluene may be used separately or in the form of copolymer or saying in general sense polystyrene resin. Further, such styrene copolymer resin may be used as specifically recommendable material in the above sense, comprising said styrene monomer(s) with other monomer, preferably for example, acrylic acid ester, methacrylic acid ester, acrylonitrile, methacrylonitrile and the acrylic or methacrylic monomer, or further styrene copolymer resin comprising maleic acid anhydride.

It should be noted, however, that among others, polyester series resin is especially superior for the purpose of the present invention.

In any of the foregoing embodiments, however, white pigment is preferably admixed with the material of the image-reception layer for improving the whiteness thereof and further accentuating the sharpness and fineness of the images when transferred thereto and to provide a manually writing-on performance. As the white pigment for this purpose, the following materials may be used separately or in any combination: titanium oxide; zinc oxide; china clay calcium carbonate; finely divided silica and the like.

For further improving the whiteness fluorescent whiteness-increasing agent or -bleaching agent may be added to. Further, for improving the light fastness of transferred images, ultraviolet absorption agent and/or photostabilizing agent may be added to, preferably in a quantity of 0.05 to 10 and 0.5 to 3 weight parts per 100 weight parts of the material resin composing the image-reception layer.

The image-transferable sheet used in the present invention is preferably constituted for improving the separability from the image-transfer sheet in such a way that the surface of the image-reception layer is formed with a partition agent layer, or instead, such agent is admixed to the image-reception layer. As for the partition agent to be used for this purpose, polyethylene wax; Amido Wax, Teflon Powder or the like solid wax; surface active agents such as fluorine-contained agent or phosphoric acid ester series surfactant; silicone oil or the like may be selectively used. Among others, silicone oil may be advantageously utilized.

The silicone oil may be used in oily state, but a hardenable type thereof may be rather advantageous. As the hardenable silicone oil, reaction-hardening one, photo-hardening one, catalytically hardening or the like one may be used selectively according to necessity. However, use of the reaction-hardenable one is most highly recommendable. Silicone oil of this type may be obtained, as example, by reacting amino-modified silicone oil with epoxy-modified silicone oil to obtain a reaction-hardened product. As for the amino-modified silicone oil, "KF-394", "KF-857", "KF-858"; and "X-22-3680"; "X-22-3801C" (manufactured and sold by Shinetsu Kagaku Kogyo K.K., (Tokyo, Japan)) and equivalents thereof may be used. As for the epoxy-modified silicone oil, "KF-100T"; "KF-101"; "KF-60-164"; and "KF-103" (manufactured by Shinetsu, above mentioned) and equivalents thereof may be used. Further, as the catalytically hardenable and photohardenable silicone oils in the above sense, "KS-705F"; "KS-770" of the catalytic hardenable or hardened silicone oils, manufactured by Shinetsu; and "KS-720" and "KS-774" of the photo-hardenable or hardened silicone oils (manufactured equally by Shinetsu) and equivalents thereof may be used. The adding quantity of each of these hardenable or hardened silicone oils may advantageously range from 0.5 to 30 wt. % depending on the material of the resin composing the image-reception layer.

At least a part of the image-reception layer is coated with a solution or dispersion of any of the foregoing partition agents in a suitable solvent and dried and further treated, a suitable parting layer being provided thereon. A-particularly suitable partition agent for the formation of this kind of partition layer is the aforementioned reaction type hardenable one obtainable by reacton of an amine-modified silicone oil with an epoxy-modified one. The thickness of the partition layer is 0.01–5μ, preferably 0.05–2μ.

It should be noted that when silicone oil is admixed during formation of the image-reception layer, the silicone oil will bleed out after coating and the parting agent layer can be formed by the hardening even after such bleeding. In order to improve the parting ability between the image transferable layer and sheet-like substrate, it is possible to provide a parting layer consisting of a heat-hardenable resin, preferably of the melamine series, and having better affinity for the image transferable layer compositions. For the same purpose as above, however, without special provision of the parting layer, a protecting layer consisting of polymethyl methacrylate resin or cellulose acetate propionate can be provided.

For the formation of the image transferable layer, a solution or dispersion of a material composition suitable for the purpose is applied on the sheet-like substrate through conventional coating or printing. As an alternative way, a separate film or sheet for the image transferable layer **302** is formed preparatorily on a provisional carrier sheet or film and then, as a succeeding step, subjected to an image-transfer onto the substrate.

The intermediate layer is made of either a cushioning or a porous material. In some cases, the intermediate layer may additionally function as the adhesive layer.

The cushioning layer is mainly composed of such a resin which has a value of 100%-modulus as defined at JIS-K-6031 (Japanese Industrial Standard) of less than 100 kg/cm^2. If this value should exceed the above prescribed value, the rigidity will become much higher than that recommended for the intermediate layer. When the layer is formed with such disadvantageous material resin, sufficient adhesion between the heat image-transfer sheet and the image-reception layer cannot be maintained during the printing step. The lower limit of the prescribed 100%-modulus is of the order of 0.5 kg/cm^2 in actual practice.

Preferable kinds of resin to be used for the above purpose, may be enlisted as follows:

polyurethane resin; polyester resin; polybutadine resin; polyacrylic acid ester resin; epoxy resin; polyamide resin; rosin-modified phenol resin; terpene phenol resin; ethylene/vinylacetate copolymer resin; and the like.

These resins can be used independently or in combination of two or more kinds. Since these resins are rather viscous and tend to give rise to manufacturing troubles inorganic additives may be admixed, such as, for example, silica; alumina; clay; calcium carbonate; amide series substance such as amide stearate; and/or the like.

The cushioning layer is preferably formed with the use of one or more of the above specified resins, occasionally with the addition of suitable additive(s); solvent or diluent, prepared into a coating agent or printing ink which is then applied on, according to a known coating or printing process and then subjected to drying to provide a coating. The

thickness of the coating should be between 0.5–50 μm, preferably 2–20 μm or so. With a thickness less than 0.5 μm, the coating will not be able to compensate for the surface irregularities on the substrate, thus being ineffective for the desired purpose. On the other hand, when the thickness exceeds the above specified maximum value or more specifically 50 μm, the overall thickness of the image-transferable layer becomes much too large, so that handling troubles may be encountered during wind-up and overlapping procedures, without attaining further effect as desired. In addition, in this case, a loss of production economy will be inevitably introduced.

The thus obtainable improvement of intimate adhesion between the heat-image transfer sheet and the thermally image-transferable sheet by the provision of the above intermediate layer may be conceivably attributed to the lower rigidity of the intermediate layer per se, whereby it is liably to be deformed under the influence of the printing pressure, and further to the generally relatively low glass transition temperature and softening temperature of the aforementioned kinds of resin resulting in further lowering of rigidity and tendency to deform than at room temperatures upon reception of heat energy during the image printing step.

The porous layer may be formed generally in the following four ways: 1) through 4).

1) Emulsion of polyurethane or the like resin, methylmethacrylate-butadiene series synthetic rubber latex is foamed by mechanical agitation, coated, and dried on the sheet substrate into a layer.

2) The synthetic resin emulsion or synthetic rubber latex is admixed with a foaming agent and the liquid mixture is coated and dried on the substrate into a layer.

3) Vinyl chloride-plastisol, polyurethane or the like synthetic resin or styrene-butadiene series or the like synthetic rubber is added with a foaming agent and the liquid mixture is coated on the substrate and subjected to heating to provide a foamed layer formed thereon.

4) A thermoplastic resin or synthetic rubber is dissolved in an organic solvent to provide a solution, and a non-solvent (including that containing aqueous main component), and the latter solution are mixed together to provide a liquid mixture, said nonsolvent being less volatile than the organic solvent and having a considerable mutual solubility with the solvent, and showing, however, non-solubility with the thermoplastic resin or synthetic rubber. The thus prepared liquid mixture is then coated on the sheet-like substrate and dried, to provide a porous membrane upon micro-coagulation of the constituents. The resulting microporous layer can be utilized for the above purpose.

It should be noted that the layers produced by any of the foregoing three processes 1) to 3) have rather large foams contained therein, and thus when the foaming solution for the image-transferable layer is applied thereon and dried, the latter may exhibit excessively coarse surface conditions. Therefore., in order to obtain an optimumly image-transferable smooth surface capable of providing transferred images of high uniformity, provision of the micro-porous layer prepared by the process as set forth in the foregoing item 4) is highly recommendable.

As the thermoplastic resin suitable for the formation of the above porous layer, saturated polyester; polyurethane; vinylchloride-vinylacetate copolymer; cellulose acet0propionate and the like can be used. Further, as the synthetic rubber usable for the same purpose, those of styrene-butadiene series, isoprene series, urethane and the like series may be used. Still further, as the organic solvent and non-solvent liquid used for the formation of the microporous layer, various known substances may be used. Generally speaking, however, methyl ethyl ketone; alcohol and the like are representatively used. On the other hand, as the non-solvent, water is mostly used.

The thickness of the porous layer usable in the present invention is preferably greater than 3 μm, especially preferably in the range of 5 to 20 μm. With the use of a porous layer having a thickness of less than 3 μm, the desired cushioning and heat-insulating effects cannot be attained.

As was referred to hereinbefore in the description stage for the formation of the image-transferable layer, the intermediate layer may act simultaneously as the sticking layer in some cases.

This kind of intermediate layer(s) may be provided on one or both of the surfaces of the thermally image-transferable sheet.

In practice, however, an electrostatic charge may accumulate in the material of the thermally image-transferable sheet during its processing step or during running through the printer. As a countermeasure, a proper antistatic agent may be applied on one surface of the image-transferable-layer or on the bottom surface of the thermally image-transferable sheet or it can be included in the material of the image-transferable layer. As the antistatic agent in this sense, a surfactant such as a cation-exchange agent (for example, a quaternary ammonium salt, polyamide derivatives and the like) may be advantageously used. Further, an anion exchange type surfactant, such as alkyl sulfonate may be used. Otherwise, amphoteric ion type surfactants or even, non-ionic surfactants may be used for the same purpose.

On the other hand, the antistatic agents may be coated on the surface of image-reception layer by gravure-coating, bar-coating or the like process or alternatively, these agents may be kneaded with the material resin and then subjected to transfer towards the surface during the coating formation and drying step for preparing and providing the image-transferable layer. As the antistatic agents to be admixed with the image-transferable layer material resin, cation-type acrylic polymers may be employed.

The protecting layer is peeled off together with the image-transferred layer, from the sheet-like substrate, and then stuck, in inverted reversed state, onto any desired decorative object, the protecting layer thereby being positioned at the uppermost position, for improving the anti-wearing-light-proofing and anti-chemical performances of the image-bearing layer. As the material adapted for the formation of the protecting layer, for example, alkyd resin; phenol-modified alkyd resin; aminoalkyd resin; phenol resin; urea resin, melamine resin; silicone resin, thermoserring acryl resin, thermosetting polyurethane resin and the like thermosetting resin or normal temperature setting resin; further, ultraviolet hardenable resin; electron ray hardenable and the like activating energy flux hardenable resins or thermoplastic resins such as polyester-; polyurethane-; polyvinyl acetate resin; vinyl chloride-vinyl acetate copolymer resin; polyolefin resin, acryl resin and the like, can be used.

Preparation and use of a protecting layer comprising one or more of the above-mentioned resins are made in such a way that the material resin is dissolved in a properly selected solvent according to the necessity, so as to provide a coating liquid or ink, as the case may be, which is provided between the parting layer and the image transferable layer. The thickness thereof is generally 0.5 to 20 μm. It is also possible to form the protecting layer with the use of a resin film which consists of polyester-; acryl-; acrylpolyol-; polyvinyl chloride-; olefin resin or the like resin. It is further possible

advantageously to admix an ultraviolet ray absorbing agent and/or photostabilizer to the material of the protecting layer.

The protecting layers prepared and formed in the foregoing way are thus not made integral with the sheet-like substrate or parting layer and, therefore, the peel-off operation of the sheet-like substrate upon execution of the image transfer is very simple and easy.

It is further recommendable, if necessary, to provide a slip-promoting layer on the bottom surface of the sheet-like substrate, which surface is naturally the one opposite to the image-transferable layer side, so as to properly adjust the friction between the image-transferable sheet and feed roll paper or carrier belt acting during passage through the printer and to improve the running performance of the thermally image-transferable sheet in the printer.

The slip-promoting layer can be formed by adding an organic powder such as polyethylene wax fluorine resin powder or an inorganic powder such as talc, according to necessity, to a resin such as polymethyl methacrylate resin; vinyl chloride-vinylacetate copolymer; vinyl chloride copolymer; cellulose acetate butyrate; cellulose acetate propionate; styrene-acryl series or the like resin and kneading the resulting mixture to prepare a composition, applying this composition as a coating on the sheet substrate either directly or after application of a suitable primer treatment, and drying the coating thus applied. A suitable quantity of the slip-promoting layer is 0.5 to 5 g/m^2 after drying.

In the embodiments-shown in FIGS. **22**, **23**, and **24**, as the adhesive agent to be used in the slightly weak or weak adhesive layer, it should be noted that those conventionally used adhesives for adhesive tapes and seals can all be used. Preferred examples are polyisoprene rubber; polyisobutyl rubber; styrene butadiene rubber; butadiene acrylonitrile rubber and the like rubber-series resins; (meth)acrylic acid ester-series resins; polyvinyl ether-series resins; polyvinyl acetate-series resins; vinylchloride-acetate copolymer series resins; polystyrene-series resins; polyester-series resins; polyamide-series resins; polychlorinated olefin-series resins; and polyvinyl butyrol-series resins. To the suitably selected adherent may be added a proper quantity of a stickness improver, such as rosin; dammar; polymerized rosin; partially hydrogenated rosin; ester rosin; polyterpene-series resins, terpene-modified substances; petroleum-originated resins; cyclopentadiene series resins; phenol resins; styrene resins; xylene resins; and coumarone-indene resin. Further, when necessary, to the mixture may be added a softening agent, filler; antiaging substance or the like conventional agent(s). As the material for the formation of slightly or weak-adherent layer said above, emulsion type adhesive, preferably of acryl acid ester series can be used. As for the parting function after a long time of preservation, emulsion type adhesives are highly recommendable. These adhesive agents are easily procurable from market.

When necessary, these adhesives are added with proper organic solvent(s) for the adjustment of the viscosity, and then applied by roll coating, die-coating, knife coating, gravure coating or the like conventional technique on the surface of the sheet-like substrate, image-reception layer or protecting layer, so as to provide an adhesive agent layer. The thus formed adhesive layer is preferably of a thickness of 1–50 μm, although this is not limitative.

Formation of Images

In the following, the decorating process according to this invention will be set forth in detail. Utilization of the image-transferable sheet according to this invention constitutes an important main feature thereof.

In FIGS. **20** and **21**, basic practising processes will be described first.

The embodiment shown in FIG. **20** is a result of the use of the transferable sheet shown in FIG. **13**. First, a known transfer sheet **320** is applied onto the image-transferable sheet **310** in an overlapped manner such that the dye-carrying layer **321** is kept in opposition to the image-reception layer **302** of image-transfer sheet **320**, and heat energy is applied, as schematically shown by a plurality of arrows, in accordance with image signals fed at a thermal head, not. shown, from the side of image-transferable sheet **310**, or preferably, from the side of the image-transfer sheet **320**, thereby forming the desired images as at **307** in the image-reception layer **302**. Next, the image-reception layer **302** formed therein with the desired images **307** is peeled off from sheet-like substrate **301** and stuck onto the decorative product **306**. Or alternatively, both the sheets **302**; **301** are stuck onto the product **306** without preparatory peeling-off. In the latter case, the peel-off step may be executed after execution of the stickingly attaching step. In the above former case, and in such a case where an adhesive agent layer **306** has preparatorily provided between image-reception layer **302** and sheet-like substrate **301** as was set forth hereinbefore, the sticking attachment is carried into effect in such a way that the adhesive layer **306** iS kept in opposing contact with the product **330**, and then the sticking operation is brought about by application of heat and pressure or light and pressure, depending upon the nature and structure of the layer **306**. In this way, the decoration according to the present invention is completed as a preferred one mode thereof.

On the other hand, if there is no preparatory provision of the adhesive layer, either the surface of product **330** or of the peeled-off image reception layer **302**, may be coated with the adhesive agent, and the latter layer **302** per se or otherwise in the up-and-down reversed state may be stickingly attached onto the product **330** (refer to FIG. **21**).

Since the image-reception layer **302** is composed generally of such thermoplastic resin material as is liable to be colored with thermally transferable dyestuff, it can be thermally and fusingly attached to plastic resin-made formlings, clothes or metals even with provision of an adhesive layer, if necessary.

In this case, the image-bearing layer **302**, the image thereof having been formed in the aforementioned way, is stuck on, through the intermediary of the adhesive agent layer **306** as shown in FIG. **25**, while retaining the sheet-like substrate **301** on the surface of the image-reception layer **302**.

A modification of the last-mentioned mode is shown in FIG. **26**. In this case, sheet-like substrate **301** is formed on the surface of the product **330** and the image-reception layer **302** is formed as the outermost layer. Further, in this case, sheet-like substrate **301** and product **330** may be stuck together, and, through the intermediary of a suitable adhesive layer, sticking layer or heat-sealable sheet or the like.

As for the transparent film usable as the said sheet-like substrate, it must be transparent to such a degree as not to conceal the images formed in the image-reception layer, and, in addition, it must have superior surface properties such as, for instance, antiwearing characteristics. As an example, polyolefine; polyvinyl chloride; polyethylene terephthalate; polystyrene; polymethacrylate; polycarbonate and the like plastic resin-made films may be used upon variously surface conditioning. If these transparent films should be too thick, the images will be raised, and the unitary feelings may be

lost when these are stuck on respective products to be decorated. Therefore, the film thickness is preferably of the order of 0.5 to 50 μm.

In the case of a further embodiment of the present invention, the image reception layer of image transferable sheet which has been, however, formed with necessary images is subjected to image transfer treatment onto an intermediate image transferable substrate, the latter is then subjected to an image-retransfer with the images, and the thus retransferred images are again transferred onto the surface of the product to be decorated. In the following, this image transfer mode will be set forth in detail.

Embodiments shown in FIGS. **27**, **28** and **29** represent such a process for execution of image transfer operation as by the intermediary of intermediate image transfer sheet **510**. First, as shown in FIG. **27**, a thermally image-transfer sheet **320** having a thermal transferable dyestuff layer **321** is overlapped to image-transfer sheet **510** which is, at this stage, not formed with images **307** and thus consists of a thermal image-transferable sheet, in such a way that the dyestuff layer **321** or more specifically the parting layer **322** is in opposition to the image-reception layer **302** of the foregoing sheet **510**. In such a case, however, that heat energy is supplied in accordance with image-forming signals delivered from the thermal head, not shown, and, indeed, preferably from the side of the sheet **320** as hinted by a plurality of double-line arrows for thermal formation of desired images (positive images) as at **307** in the image-reception layer **302**, it is highly recommendable to provide an adhesive layer **402** between the layer **302** and sheet-like substrate **301**.

Then, with the use of the image transfer sheet **510** formed with positive images **307**, the images of layer **302** are transferred, as shown in FIG. **28**, to a separate intermediate substrate **501**, which is, however, fitted with a protecting film layer **305**, thus, the transfer being carried out, in fact, onto the latter, and indeed, with the correspondingly inverted images, attached with same reference numeral only for convenience, from the foregoing layer **302**. In this case, it is preferable to subject the adhesive layer **402** of the image-transfer sheet **510** to the image-transfer operation, together with the image-reception layer **302**. Further, as for the intermediate image-transfer substrate **501**, it is recommendable to provide the protecting film layer **305** through the intermediary of a weak-adhesive layer **402'** as shown. The thus provided intermediate image-transfer sheet **610** represents generally the image-transferable sheet.

FIG. **29** illustrates the step for transfer of the image-reception layer **302** now carrying positive images **307** onto the object **330** to be decorated and under utilization of the previously described intermediate image-transfer sheet **610**.

More specifically, the intermediate image-transfer sheet **610** is overlapped onto the said object **330** in such a way that the adhesive layer **402** of the former in opposition to the surface of the object **330** and pressurized together. Then, the intermediate transfer substrate **501** together with the weak-adhesive layer **402'** is peeled off from the remainder of the thus-pressurized assembly, the now image-carrying layer **302** formed with positive images **307** covered with protecting the film layer **305** thereby remaining in the transferred state on the product **330**. In the case of no provision of the protecting film layer **305** on the intermediate image-transferable sheet **610**, the layer **302** remains in an exposed state. Therefore, an overcoat layer, if necessary, can be provided on the now image-carrying layer **302**.

The previously set forth process carried out by the use of said intermediate image-transferable sheet can be executed by means of the apparatus which is shown schematically in FIG. **1E**.

In this apparatus, more specifically, there is provided a carrier system comprising a series of rolls **411**, **412**, **413** and **414** for conveying the intermediate transfer substrate (sheet), arranged in addition to the apparatus shown in FIG. **1B**. More specifically, the substrate is drawn out from feed roll **414**, conveyed through successive rolls **413**; **412** and retransferred onto one of the products **200**. Other operations are same as set forth hereinbefore with reference to FIG. **1B**. Further, in the case of FIG. **1E**, the final product may take the form of a roll-like substrate which is subjected to an image transfer operation through the intermediate substrate, by transferring its image-carrying, image-transferable layer, for later being punched out properly. Alternatively, under occasion, it may be subjected to half-cut operations downstream of roll **122**.

As was set forth herein above, the preferable method for the formation of desired images on the image-transferable sheet is carried out by use of a heat image-transfer sheet comprising a sheet-like substrate having a layer including a thermally transferable dye (evaporative dye). The heat image-transfer sheet which can be utilized in this method is known per se. And almost every kind of these known sheets can be useful in the practice of the present invention. It should be noted that by employing the foregoing image-transfer method, mono-color or full-color images can be easily formed as occasion may desire.

It should be further noted that details of such heat image-transferable sheet can be easily understood with reference to our U.S. patent application Ser. No. 833,039. As for the heat image-transferable sheet usable in the present invention, the coating layer of the sheet (coating film) may include a parting agent. By adopting this measure, the image-reception layer of the image-transferable sheet or the surface thereof, to be subjected to sublimative image-transfer, must not have a separate parting agent layer, the adhesive ability between the image-reception and the surface of object to be decorated can be still further improved upon execution of the sublimative image-transfer and image-formation at the image-reception layer and adherent attachment thereof to the object. As the parting agent to be included in the coating layer of the thermally image-transferable sheet (coating film), silicone oil; silicone resin; phosphoric ester or the like surfactant; and/or chelate- and the like agents, may be selectively utilized. These agents, upon mixed, will ooze out from inside to the outer surface of the coating layer, resulting in providing a better parting quality. However, it is preferable to properly select the kind and nature of the parting agent to be used for this purpose, being such that the agent cannot transfer to the image-reception layer of the image-transferable sheet during the sublimating image-transfer stage. The adding quantity of the parting agent may preferably be 3–25 wt. parts based upon the total amount of resin and coating composing the coating layer taken as 100 wt. %.

In practice, any kind of conventionally known heat transfer sheets is overlapped on the thermally image-transfer sheet employed in the present invention, and then necessary heat energy of 5–100 mJ/mm^2 is applied by use of a conventionally known heat transfer unit, for instance, "Video-printer: VY-100" manufactured and sold by Hitachi Seisakusho, Tokyo, or its equivalent machine, for the formation of necessary images on the image-reception layer of the image-transfer sheet as set forth hereinbefore.

Peel-off operation for removal of the image-reception layer formed with necessary images in the above manner may be carried into effect in a very easy manner, so as to provide it in a thin film carrying the images thereon. In case where the thus-peeled off film carrying the images is pro-

vided beforehand with an adhesive layer, composed of a suitable adhesive agent as was referred to, at the opposite surface to the image-carrying one, the peeled-off film can be, as it is, stuck on the object to be decorated. It is natural that this adhesive attachment procedure can be performed only partially and locally on selected part of the whole surface of the object, or totally thereon, as the case may be. On the contrary, if the peel-off film is provided beforehand with no adhesive layer, the film can be subjected occasionally to a heat fusion onto the surface of the object, if the physical properties or material kind thereof is suitable for such kind of thermal fusion. Or alternatively, a properly selected adhesive agent can be preparatorily applied onto the surface of the film or object, and then, the stick-on job can be executed.

If the image-reception layer is provided preparatorily with a parting layer thereon, as was referred to, the latter layer can be removed off partially or wholly, by grinding or rubbing operation after execution of the sublimating image-transfer job, for avoiding otherwise occurrence of ill effect by the very presence of parting layer in the adhesive attachment of the image-carrying layer film onto the decorative object.

In case of that where the image-transferable sheet is provided with a protecting layer and the latter is composed of a plastic resin film, this film may preferably be cut into pieces or subjected to punch-cuttings.

FIG. **32** illustrates successive die-cutting steps in sectional views, serving for the above purpose. In this case, as shown in FIG. **32** at (a), only image-reception layer **305** of the image-transferable sheet **310**, which has been image-formed through the way of the foregoing image-transfer step, are die-cut by operation of a cutter **801**. Next, as shown in FIG. **32** at (b), a pair of hot stamps **132'**; **133'** are used to execute a pressurizing job under heat from opposite sides, thereby the decorative product **330** being processed into a final product provided tightly with an image-reception layer and a protecting layer, as shown in FIG. **32** at (c).

Further, when occasion desires, the image-carrying film is reversed up-and-down in position after execution of the peel-off job, and, the film is stuck onto the product to be decorated in such a state that the image-carrying surface of the film is kept in direct opposition to the product's decorating surface. In this case, however, it would be rather preferable that in advance of preparatory peel-off of the image-reception layer, the image-carrying transferable sheet is stuck onto the surface of the product to be decorated, and indeed, preferably with use of an adhesive agent, in such a way that the image-carrying layer is kept in direct opposition to the product surface and finally, the sheet-like substrate is peeled off, so as to leave the image-carrying surface on the product's surface.

As in the foregoing, when the images are once reversed and then stuck onto the object to be decorated, the forming images are preferable to reverse in mode (mirror-like relationship) the original to those of reversed mode.

It is further possible that the transfer or sticking-on of the image-carrying layer is carried out through the intermediary of a separate fusing sheet.

In FIG. **30**, use of such fusing sheet **701** for reimage-transfer operation of image-carrying layer **2** already formed with necessary images **307**, however, of reversed mode, and onto the surface of a product.

More specifically, the image-transferable sheet **310** is overlapped onto the product **330** to be decorated in such a way that the image-reception layer **302** carrying the necessary images **307** is kept in opposition to the surface of the product, and indeed, through the intermediary of a fusing seat **701** and then these three components are pressurized together. Further, sheet-like substrate **301**, together with parting layer **303'**, is peeled off, thereby the image-reception layer **302**, now having positive images **307** formed thereon, and protecting the latter, being transferred onto the product **330**. It will be seen in this case, that there is no need for this transfer job, to provide in advance on adhesive layer on the surface of image-reception layer **302** and/or on the surface of the product **330**, and further that a direct heat fusion onto the surface of the product **330** which may be composed of plastic resin, textile fabric, metal or the like common material, however, through the intermediary of a heat-fusible or heat-sealable sheet.

In case where the protecting layer **305** is of plastic resin, similar composing technique as mentioned above may be employed by substituting a weak-sticking layer **402'** for parting layer **303'**.

As the heat-fusible or heat-sealable sheet as at **701** employable in the present invention, it may be composed of one or other material capable of adhering under heat, pressure or both, especially suitable one of those which become soft to be adhesive upon heating. These heat adhering materials in the form of sheets will be, upon softening, charge the pores, meshes or stitches of the product material composed preferably of textiles, woven or non-woven; knits, rough-surface papers or meshed materials, thereby the surface of the product becoming highly smooth for well receiving the image-reception layer **302** for desired image-retransfer with trouble, which effect is superior in the art.

On the contrary, when such heat-fusible or heat adhesive sheet materials which may be called "heat bond sheets" as at **701** are not utilized, it is highly difficult to realize the image-retransfer operation onto certain kind of objects such as rough-surfaced or rough-meshed fabric or the like. Even if the retransfer job could be executed, the obtained images may be blurred and the adhesive may be insufficient, on account of the very thin thickness of the image-reception layer **302**, thus giving rise to technical and commercial troubles.

As for the heat fusible sheet **701** to be used in the foregoing manner, ethylene/vinyl acetate copolymer, nylon copolymer; epoxy/phenol copolymer; epoxy/vinyl copolymer; acrylic resin; polyester resin; or polyolefin resin and the like thermoplastic resins (heat sensible adhesive agents) which are formed into sheets or films may be used. These materials must be softened at 100°–250° C. or so to represent viscous adhesive characteristics. These materials are, when used, capable of being stuck to both the image-transferred product **330** and the image-carrying layer **302**.

These heat bond sheets **701** have generally thickness of 1–200 μm. When the surface of the product **330** to be decorated is relatively smooth, the sheet selected out may be of relatively thin thickness, while, on the contrary, when the surface of the decorative product **330** is relatively rough, as in the case of textile fabrics, unwoven fabrics, meshed fabrics or the like, use of thicker heat bond sheets is rather recommendable.

As set forth above, the use of heat bond sheets is highly recommendable in the decorative image-transfer onto rough surface products, such as those of rough fabrics, woven or non-woven, knitted clothes, meshed one or the like, thereby a better quality image-transfer being executed, in spite of the meshed or highly undulating surface conditions of the objects to be decorated.

Further in the present invention, during the adhering attachment of the image-reception layer already formed with

necessary images onto the object or product, an additional processing step is preferably introduced for prevention of occasional interference in the foregoing adhering attachment step, by rubbing-off or grinding-off part or whole of the parting layer, provided on the surface of the now image-carrying layer, upon completion of the sublimating image-transfer step.

Still further, in such a case that the image-transferable sheet is fitted with a protecting layer which is composed of a plastic resin film, the latter must in advance be subjected to punching or the like cutting step for cutting the film into desirously sized pieces.

FIG. **32** represents such a die-cut (half-cut) process in sectional schema. In this case, at first, as shown at (a) of FIG. **32**, the image-reception layer **302** of an image-transferable sheet **310**, now formed with necessary images through a sublimative image-transfer step, and the protecting layer **305**, are subjected to a die-cutting process by means of a cutter **801** to shape a desired shape. And then, as shown at (b) in FIG. **32**, the cut-out piece is subjected to a pressurizing step under heat by means of a pair of hot stamps **132'**; **133'** to provide a final decorative object, as shown at (c) in FIG. **32**, which is composed of a product **330** to be decorated, however, now attached integrally and jointly with image-carrying layer **302** and protecting layer **305**.

Applied Products

The products applicable with the inventive process for decorating purposes are not limited to occasionally employed kind, shape and nature of the materials. Preferred examples of the usable product may be: cartons; vessels or packages; bags; cassette cases; cassette halves; floppy cases; paper packages and envelopes; stock certificates; personal and bank cheques; bills; bonds; certificates; notifications; car tickets; travel tickets; betting tickets; tax stamps; postage stamps; entrance tickets, money-exchangeable papers and documents; cashcards, credit cards, orange cards, telephone cards; member's cards; greeting cards; postcards, name cards; driver's certificates; IC-cards; optical cards and the like various cards; accounting cards and documents-envelopes; tags; OHP-sheets; slide films; bookmark slips; calendars; posters; pamphlets; menus; passports; POP-goods and articles; coasters; displays; nameplates; keyboards; cosmetics; personal ornaments (watches; cigarette lighters); stationaries; construction materials; radio-receiving sets; T.V.-sets; speakers; table calculators; automotive gauge boards; emblems; keys; clothes; wearing commodities; footwears; appliances; OA-instruments; sample books; tickets in general; albums; computer graphic and/or medicare graphic image printouts; and the like, where the material kinds, sizes and configurations are regardless for purposes of the invention.

The aforementioned goods and instruments may have printed or the like other images in advance of execution of the process of the invention. Or conversely, the goods and instruments can be formed with necessary images in accordance with the present process, and then, additional images may be formed in conventional printing or the like process.

As an example, when the invention is applied to a card style intermediate product, it is possible to combine image-forming means of the present invention with conventional recording means. As the latter, magnetic recording by use of a magnetic material layer; optical recording by use of an optical recording layer; preferably composed of a membrane having low melting point metal; application of hologram; embossing formation of characters and numerals; application of personal face photograph; engraved formation of personal face or the like; human signatures; recorded information with use of IC-memory; mechanical printing; formation of bar codes; formation of characters and patterns by use of printer, typewriter or pen plotter may be used independently or in any combination.

In the following, the present invention will be more fully described by way of preferred embodiments. In these embodiments, parts or % will be given by weight, not otherwise specifically referred to.

As the image transfer film (dye film) used for sublimating transfer onto the image-transferable sheets, a polyester film, 6 μm thick, subjected to a heat-resisting treatment on one surface thereof only, and bearing color ink composition areas of yellow, magenta and cyan, respectively, was used. The coating rate of the color ink composition was 1.0 g/m^2 when measuring at the dry state.

These color ink compositions were as follows.

Yellow Ink Composition

polyvinyl butyral resin ("Eslek-BX-1", manufactured and sold by Sekisui Kagaku K.K., Tokyo)	4.80 parts
dispersion dye ("PTY-52, Disperse Yellow-141", manufactured and sold by Mitsubishi Kasei Kogyo Co., Ltd., Tokyo)	5.50 parts;
methyl ethyl ketone	55.00 parts;
toluene	34.70 parts;
(parting agent	1.03 parts)

Magenta Ink Composition

polyvinyl butyral resin (same as above in the case of yellow color ink)	3.92 parts;
dispersion dye ("MS Red G, disperse red 60", manufactured and sold by Mitsui Toatsu K.K.)	2.60 parts;
dispersion dye ("Macrolex Red Violet R, Disperse Violet 26", manufactured and sold by Beyer A.G., West Germany)	1.40 parts;
methyl ethyl ketone	43.34 parts;
toluene	43.34 parts;
(parting agent	0.40 part)

Cyan color Ink Composition

polyvinyl butyral resin (same as in said yellow color ink composition)	3.92 parts;
dispersion dye ("Kayaset Blue-714, solvent blue-63", manufactured and sold by Nippon Kayaku K.K., Tokyo)	5.50 parts;
methyl ethyl ketone	68.18 parts;
(parting agent	0.94 parts)

Each of the foregoing color ink compositions was prepared wihh and without addition of parting agent.

As the parting agent occasionally used in each of the foregoing color ink compositions, any of the following specific agents may be employed:

(a) silicone alkyd-parting agent, "KR-5206", manufactured and sold by Shinetsu Kagaku Kogyo K.K., Tokyo;

(b) graft polymer of. silicone and acryl, "GS-30", manufactured and sold by Toa Gosei Kagaku K.K.;

(c) silicone graft polymer, "US-3000", manufactured and sold by the above company;

(d) phosphoric acid ester, natrium salt, "RE-410", manufactured and sold by Toho Kagaku Kogyo K.K.;

(e) natural phosphoric acid ester, "Lecytin", manufactured and sold by Ajinomoto Co., Ltd., Tokyo;

(f) silicone oil, "KF 412", manufactured and sold by Shinetsu Kagaku Kogyo K.K., Tokyo;

(g) aluminum chelate agent, "ALM", manufactured and sold by Ajinomoto; and

(h) titanium chelate agent, "TTS", manufactured and sold by Nippon Soda K.K., Tokyo.

EXAMPLE A-1

As the substrate, a laminate of a synthetic paper, "Yupo FPG 150 μm thick" manufactured and sold by Oji Yuka Co., Ltd., Tokyo, and a polyester film, 6 μm thick, was prepared and coated on the polyester film side surface by a wire bar with a mixture of pull-separating varnish, "Hakurinisu 45" manufactured and sold by Showa Ink Co., Ltd., Tokyo, with an ultra-violet absorbing agent, or more specifically, 2.5-bis (5'-tert-butylbenzoxazolyl (2))-thiofin, 0.5% based on the resin content of the varnish, and dried up to provide a protecting layer of 1 g/m^2, when weighed upon drying.

Then, on the surface of the foregoing protecting layer, an ink composition adapted for the formation of an image-reception layer was coatingly applied and dried up. The applied quantity amounted to 7 g/m^2 when measured upon drying.

Ink composition for the Formation of Image-Reception Layer

polyester resin (manufactured and sold by Toyobo K.K.)	100 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu Kagaku Kogyo K.K., Tokyo)	5 parts;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu Kagaku Kogyo)	5 parts;
solvent (methyl ethyl ketone/toluene/ cyclohexanon 4/2/2)	900 parts.

The ink composition was coated, dried up and cured one day under normal temperature. Then, the layer was kept at 100° C. for 30 minutes under heat, for letting the silicone to bleed up to the surface, to provide an image-transferable layer formed on its surface with a hardened silicone layer.

On the thus-provided image-reception layer, a sublimating image-transfer film was overlapped which is composed of cyan color sublimative dye (molecular weight being higher than 250) carried by a proper binder resin and thermal energy is fed thereon from a thermal head adapted for receiving electric signals representing cyan color components. obtained by a color analysis of a portrait photograph, as an example, for providing portrait images corresponding thereto. Then, two successive sublimative image-transfer jobs were executed with use of respective sublimating image-transfer films carrying sublimative magenta and yellow color dyes, each molecular weight being higher than 250, and substantially in the manner set forth above. In this way, after all, an overall combined display image composed of a full color portrait, in combination with several characters and graphics, was provided.

The image-reception layer of the sheet, now carrying these display images, was overlapped on the card substrate composed of a polyester resin sheet, 100 μm thick, which had been primed to white-opaque state, and pressurized together at 160° C. by means of heated pressure rolls. Then, the polyester film was peeled off at the interface with the protecting layer, thereby providing a final product card transferred with image-reception layer now carrying the desired image display.

It was found that the overall surface of the product card was generally smooth and showing no raised feeling of the thus-formed and displaying images. Even upon an accelerated testing of the product card for three months held in an atmosphere of 40° C., the images showed no blurtings as well as no interlayer separation. Further, according to an accelerated light-proof test carried out as prescribed in JIS-Standard with use of a carbon arc lamp, the results showed to be classified to JIS-4 or -5 corresponding to an acceptable superior performance. Additionally, a surface scratch test and the like showed also superior durability.

EXAMPLE A-2

The foregoing image-transferable sheet, now image-carrying, as processed in Example A-1, is then subjected to a peel-off operation for separating the image-carrying layer from the sheet. Then, an adhesive agent of polyester series was coated on the exposed surface of the peeled-off film, and stuck under pressure on a curved surface part of a telephone set. The images could follow up to the stuck curvature into a unitary solid mass, and indeed, without inviting any stuck-on feeling, contrary to the case when a sticky loose-leaf stamp should have been stuck on. In this way, miracle viewing feelings as obtainable with direct-printing operation only, were created and maintained.

EXAMPLE A-3

A white polyester film, baked on one surface thereof with melamine coating, "E 20", 100 μm thick, manufactured and sold by Toray Co., Ltd. Tokyo, is formed on the opposite surface with a slipping layer, same as in the following Example C-2, through application of polyurethane primer. And an identification mark was provided thereon through the way of regular printing technique. On the melamine resin-baked surface of the white polyester resin film, a layer of peeling varnish (of polymethyl methacrylate-series), manufactured and sold by Showa Inku. Co., Ltd., Tokyo) was applied in dry quantity of 2 g/m^2 and dried up to provide a definite layer.

On the thus-formed protecting layer, the following image-reception layer-forming composition was coated and dried up, so as to form an image-heat transferable sheet. The coated composition was in quantity of 6 g/m^2 by dry weight.

Image-Reception Layer-Forming Composition

polyester resin ("Vylon 600", Tg: 47° C., manufactured and sold by Toyobo, Osaka)	80 parts;
polyester resin ("Vylon 290", Tg: 77° C., manufactured and sold by Toyobo)	20 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu Kagaku Kogyo)	7 parts;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu Kagaku Kogyo)	7 parts;
solvent (methyl ethyl ketone/toluene = 1/1)	800 parts.

On the image-reception layer of the foregoing heat image-transferable sheet, reversed images composed of full color portrait images together with characters and graphics by use of a thermal head, as in the same way with Example A-1, were formed.

Next, the image-reception layer, however, now carrying the reversed images formed in the foregoing manner was brought into contacting and overlapping State with the image displayable surface on a card style substrate made of white color polyester resin, 125 μm thick, preparatorily primer treated as before, and pressurized together under the action of thermal rolls, and the white polyester film, 100 μm, was peeled off between the protecting layer and the melamine-baked layer, thus providing a final card-style product transferred with the image-reception layer now carrying the necessary images.

The surface of the final card style product represented a smooth and slippery, without fear of interlayer separation and with superior light resistant power.

EXAMPLE A-4

A white foam polyester resin film, "Merinex", 125 μm thick, manufactured and sold by ICI, was provided with an identification mark on one surface thereof, with regular printing technique.

Then, on the opposite surface of the white foam polyester resin film to the foregoing surface formed with the identification mark, a coating of a polyurethane-series primer was applied and dried up. Further, the following protecting layer-forming composition was applied in dry quantity of 3 g/m^2 and dried up to form a protecting layer.

Protecting Layer-Forming Composition

acrylic polyole ("Acrit 6416MA", manufactured and sold by Taisei Kako K.K.)	41 parts;
toluene	36 parts;
methyl ethyl ketone	27 parts;
diisocyanate ("Colonate", manufactured and sold by Nippon Polyurethane K.K.)	6 parts.

On the above protecting layer, the following composition was applied in dry quantity of 3 g/m^2 and dried up, to provide an intermediate layer.

Intermediate Layer-Forming Composition

polyester resin ("Vylon 290", manufactured and sold by Toyo Boseki (Toyobo) K.K., Osaka)	15 parts;
toluene/methyl ethyl ketone = 1/1	85 parts.

On the thus-formed intermediate layer, an image-reception layer which is substantially same with that in the foregoing Example A-3 was provided, so as to form an image-transferable sheet. Then, as same in the foregoing Example A-3, correspondingly inverted images were formed on the image-reception layer and further then, subjected to transfer onto the card substrate by use of thermal rollers. In this way, a final product card, having an image transferable, yet now image-formed layer, was provided.

This card showed favorable results of light-resisting test. Further, it showed a better scratch test result than the foregoing card obtained in Example A-3.

EXAMPLE A-5

Substrate

A white polyester film, "E-20", 100 μm thick, manufactured and sold by Toray Co., Ltd., Tokyo, was used.

Intermediate Layer-Forming Composition

Polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki K.K., Osaka)	15 parts;
toluene/methyl ethyl ketone = 1/1 (dry weight: 5 g/m^2)	85 parts.

Protecting Layer-Forming Composition

"Hakuri-Nisu" (acrylic resin varnish, manufactured and sold by Showa Ink K.K.) (dry weight)	2 g/m^2

Image-Reception Layer-Forming Composition

polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki K.K., Osaka)	10 parts;
polyester resin ("Vylon 200", supplied by Toyo Boseki K.K.)	5 parts;
toluene/methyl ethyl ketone = 1/1	85 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu Kagaku Kogyo)	1 part;
epoxy-modified silicone ("X-22-343", supplied by Shinetsu Kagaku Kogyo)	1 part.
(coated quantity (dry) 5 g/m^2)	

With use of the foregoing composition and processed in similar way as in Example A-3, to provide a final card product, having an image-reception layer transferred with necessary images.

EXAMPLE A-6

Substrate

White polyester resin film, "E-20", 100 μm thick, manufactured and sold by Toray was coated with polyurethane-series primer and dried up.

Parting Layer-Forming Composition

melamine resin ("Meran 45", manufactured and sold by Hitachi Kasei)	100 parts;
hardener (para-toluenesulfonic acid)	20 parts;
(coating quantity (dry), 2 g/m^2)	

Protecting Layer-Forming Composition

vinylchloride-vinylacetate ("Vinylite VYHH", manufactured and sold by Union Carbide Corp.)	15 parts;
methyl ethyl ketone = 2/1	85 parts;
(coating quantity (dry): 2 g/m^2)	

Intermediate Layer-Forming Composition

polyurethane resin ("Takelac T-3350", manufactured and sold by Takeda Pharmaceutical Company, Osaka, of 23% - concentration)	50 parts;
isopropyl alcohol	15 parts;
toluene	25 parts;
methyl ethyl ketone	10 parts.
(coating quantity (dry) 5 g/m^2)	

Image-Reception Layer Composition

polystyrene resin ("Picolastic D125" (Tg = 53° C., manufactured and sold by Hercules	15 parts;
toluene/methyl ethyl ketone = 1/1	85 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu Kagaku)	1 part;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu Kagaku)	1 part.
(coating quantity (dry): 6 g/m^2)	

The foregoing composition was prepared and used as in the same manner with Example A-3, to provide a card with the image-reception layer subjected to image-transfer as desired.

EXAMPLE B-1

As the substrate, a polyester resin film, 6 μm thick, was used and a polyester resin-series primer was coated on one surface thereof and dried up. Further, the following ink composition was applied and dried up. The coating quantity of the composition was set to about 7 g/m^2.

Image-Reception Layer-Forming Composition

polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki K.K.)	100 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu Kagaku)	5 parts;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu Kagaku)	5 parts;
solvent (methyl ethyl ketone/toluene/ cyclohexanone = 4/2/2)	900 parts.

The ink composition was coated, dried up and left standing for a full day, and then subjected to heat treatment at 100° C. for 30 minutes, so as to bleed the silicone towards the film surface for providing thereon an acceptable image-reception layer composing the active surface.

Then, a sublimative image-transferable film, composed of a resin binder evenly mixed with a proper amount of sublimative cyanic dye, the molecular weight being higher than 250, was overlapped on the above image-reception layer and applied with heat energy by means of a thermal head supplied with electric signals corresponding to cyanic color components of a portrait full color photograph as determined by regular color analysis, thus providing cyanic color component images.

Next, as for magenta and yellow color components, similar respective processings were executed and finally, full color display portrait images could be formed.

Then, the exposed surface of image-reception layer of the thus-display image-formed film was overlapped on a card substrate composed of a white opaque, hard vinyl chloride resin sheet, 100 μm thick and pretreated with a conventional primer, and then this assembly was subjected to heat and pressure by means of a pair of heated rolls. In this way, a card product stuck with an image-transferable and now carrying layer was provided.

The surface of this card was generally smooth and slippy, the thus-formed images thereon providing no raised feelings. In an accelerated test of these formed images in hot atmosphere of 40° C. for a continuous period of three months, there were no appreciable image blurring and interlayer separation. Upon execution of a light exposure test in accordance with prescribed conditions in JIS with use of an arc lamp, the results were classified to JIS-4 to 5 Classes which means as acceptable and better image quality. Scratch test results were also superior.

EXAMPLE B-3

A sticking layer, 1 μm thick, was formed with a polyamide resin sticking agent on the image-carrying surface of the image-transferable sheet, image-formed in the manner as described in foregoing Example B-1, and the thus provided sheet was stuck on the curved surface of a glass tumbler. These images express practically no stuck-on feelings, rather providing such a touch and viewing feeling as if they had been formed by the regular and direct printing technique.

EXAMPLE C-1

With use of the image-transferable sheet prepared in the foregoing Example A-1, images were formed substantially in accordance with procedures mentioned therein, however, with exception of the formation of reversed images, and then, the image-carrying layer was, without execution of the foregoing peel-off operation, stuck on a portion of curved outer surface of a glass tumbler, whereupon the sheet-like substrate was peeled off, together with the weak-sticking layer. The thus-applied images represent almost no sticking-

on grip and viewing feeling, as if they should have been applied through regular and direct-printing technique.

EXAMPLE C-2

On the surface of a transparent polyester film, 12 μm thick, employed as a protecting film, the following image-reception layer forming composition was applied to form a coated layer (in quantity of 6 g/m^2 when measuring upon drying), dried up and left as it was for full one day. Then, it was held at 100° C. for 30 minutes, to form an image-reception layer. On the surface thereof, a parting surface layer was found to exist, which was composed of a combined hardened product of amino-modified silicone resin and epoxy-modified silicone resin.

Image-Reception Layer-Forming Composition

polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki)	100 parts;
amino-modified silicone resin ("KF-393", manufactured and sold by Shinetsu)	7 parts;
epoxy-modified silicone resin ("X-22-343", manufactured and sold by Shinetsu)	5 parts;
solvent (methyl ethyl ketone/toluene = 1/1)	800 parts.

As the substrate, on the other hand, white polyester resin film, "E-20", 75 μm, manufactured and sold by Toray, was used and coated on one surface thereof with a polyurethane-series primer and dried up. Then, the following composition (in the dried quantity of 1 g/m^2) and dried up, so as to provide a smooth and stick layer.

Smooth Layer-Forming Composition

polymethyl methacrylate resin ("Dianal BR-85", manufactured and sold by Mitsubishi Rayon Co., Ltd., Tokyo)	12 parts;
polyethylene wax ("MF8F", manufactured and sold by Dulacon Co.)	0.5 part;
toluene/methyl ethyl ketone = 1/1	85 parts.

On the opposite surface of the-white-polyester resin sheet to the smoothed surface there, a primer coating of polyurethane-series is applied and dried up, and further coated thereon with the following composition, in quantity of 3 g/m^2, so as to provide a weak-sticky layer.

Weak-Sticky Layer-Forming Composition

weak-sticky adhering agent ("Esdyme AE-206", manufactured and sold by Sekisui Kagaku Kogyo K.K., Tokyo)	50 parts;
water	50 parts.

The weak-sticky adhering layer is brought into contact with the protecting film consisting of a polyester film, 12 μm thick, at the opposite surface to the image-reception layer, and then subjected to heat and pressure, to provide an image-transferable sheet. Upon bringing the image-reception layer of the image-transferable sheet and the dyestuff layer of the heat-image transfer sheet into contact with each other, heat energy was applied from a thermal head, as in the similar manner mentioned in the foregoing Example A-1, and thus heat image-transfer job was executed, so as to provide reversed mode images for expressing a full color portrait as well as characters and graphics.

Next, the image-reception layer formed with the reversed images thereon was overlapped onto the image-displayable surface of a card style substrate, 100 μm thick, made of a white color polyester resin material preparatorily applied with a primer layer by coating a composition, consisting of "Vylon 200", 100 μm thick, manufactured and sold by Toyo Boseki K.K., and then subjected together to heat and pressure by means of at least a heated roll at 160° C. Then, the white polyester film, 75 μm thick, and the weak-sticky adhesive layer were peeled off in unison, for providing a final decorative product card having the image-reception layer transferred with images and carrying dislay images.

This card had a highly smooth surface and was not liable to invite any interlayer separation and showed superior light fastness.

In place of white color polyester-made card substrate preparatorily formed with a primer layer, such a modification was prepared and experimented that the white polyester sheet was formed on its rear surface with a magnetic layer, while, on its front surface there is formed with a write-on layer which consists of proper filler and resin as conventionally, so as to provide a telephone card. This processed telephone card had the write-on layer provided with display images formed by image-transfer.

EXAMPLE C-3

On the surface of a transparent polyester film, 9 μm thick, used as the protecting layer, an intermediate layer was provided by coating. The coated amount was 5 g/m^2 as measured upon being dried up.

Intermediate Layer-Forming Composition

polyurethane resin ("Takelack T-3350", solid content 23%, manufactured and sold by Takeda Pharmaceutical Co., Ltd., Osaka)	50 parts;
isopropyl alcohol	15 parts;
toluene	25 parts;
methyl ethyl ketone	10 parts.

Onto the intermediate layer, the following composition was applied for the formation of an image-reception layer. The coated quantity was 5 g/m^2 as measured upon being dried up.

Image-Reception Layer-Forming Composition

polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki)	10 parts;
polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki)	5 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	1 part;

-continued

epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	1 part;
solvent (methyl ethyl ketone/toluene = 1/1)	85 parts.

On the other hand, a white color polyester film, which was similar to that employed in the foregoing Example C-2 was formed with a slidingly smooth layer, as well as a weak-sticking adhesive layer, the latter being brought into intimate contact with a transparent polyester film, 9 μm thick, at the opposite surface to the image-reception layer and then, subjected to heat and pressure, for providing a heat image-transferable sheet. As further processed in the similar manner in the foregoing Example C-2, full-color photographic images (reversed images) were thus formed on the image-reception surface. In this way, a final product card, having its image-reception layer transferringly formed with display images.

EXAMPLE C-4

Substrate

White color polyester sheet, "E-20", 100 μm thick, manufactured and sold by Toray was formed thereon with a polyurethane-series primer coating. Then, a weak-sticking layer was applied thereon with use of the following composition.

Weak-Sticking Layer-Forming Composition

weak-sticking agent ("Esdyne AE-206", manufactured and sold by Sekisui Kagaku Kogyo K.K., Tokyo)	50 parts;
water	50 parts.

Protecting Layer-Forming Composition

polyester resin ("Vylon-200", manufactured and sold by Toyo Boseki)	15 parts;
diisocyanate ("Colonate L", manufactured and sold by Nippon Polyurethane Co., Ltd.)	1 part;
toluene/methyl ethyl ketone = 1/1	84 parts.

Image-Reception Layer-Forming Composition

polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki K.K.)	10 parts;
vinyl chloride-vinyl acetate copolymer resin ("Vinylite VAGH" (Tg = 79° C.), manufactured and sold by Union Carbide Corp)	5 parts;
toluene/methyl ethyl ketone = 1/1	85 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	1 part;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	1 part.

With use of the above composition and processed substantially same as in the foregoing Example C-2, a final card product was obtained.

EXAMPLE D-1

An image-transferable sheet was prepared as in the foregoing Example A-1 and thermally image-transferred with reversed mode images of a full color portrait photograph, to provide an intermediate image-transfer medium. The latter is overlapped by its image-reception layer onto the surface of a sheet of rough-textured cotton cloth, however, through the intermediary of an acrylic acid ester-vinyl acetate copolymer sheet, 100 μm thick. Then, the assembly was subjected to heat and pressure. Then, the substrate sheet and weak-sticky adhesive layer, together, were peeled off. The thus transfeted images have sufficient surface smoothness, showing superior surface conditions.

Without use of the bond-attaching sheet in the above process and when similar image-transfer job as above was performed, the resulted images followed the surface undulations appearing disadvantageously on the material product of the rough fabrics and thus were highly uneven, and further, on account of insufficient adhering performance acting between the image-receiving layer and the woven fabrics serving as product material, easy and frequent separations took place therebetween.

EXAMPLE D-2

In the similar way as was disclosed in the foregoing Example D-1, an intermediate image-transfer medium carrying reversed images was prepared and overlapped on a polymethacrylate board preparatorily subjected to surface-toughening operation through a conventional sandblasting step, and through the intermediary of a bond-adhering sheet pressurized together under heat, as was employed in Example D-1. Then, the sheet-like substrate was peeled off, together with the weak adhesive layer. The thus-provided images were highly smooth and even in spite of the highly rough and undulating conditions at the surface to be image-transferred. In addition, the image-carrying surface showed superior results in various resisting tests.

Without use of the foregoing bond-sticking layer, the similarly transferred images showed considerable undulations and distortions. Further, on account of insufficient adhering performance, easy and frequent peel-offs of applied images were feared.

EXAMPLE D-3

On the surface of a polyester resin film, 25 μm thick, the following composition adapted for the formation of bond-sticking layer was coated and dried up, in dried quantity of 5 g/m^2, to provide a film formed thereon a bond sticking sheet.

Bond-Sticking Sheet-Forming Composition

polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki)	15 parts;
methyl ethyl ketone/toluene = 1/1	84 parts.

The bond-sticking sheet surface, together the polyester resin film proper, was brought into contact with the image-representing surface of a white color polyester made-card substrate, 25 μm thick, and then, subjected to heat and pressure by means of at least a heat roll kept at 200° C, arranged to supply heat energy from the side of the polyester resin surface, thereby heat bonding the bond-sticking sheet onto the card surface, whereupon the polyester resin film being forcedly peeled off.

Further then, as in the similar way as adopted in foregoing Examples C-2; A-3; A-4 and C-3, use is made of the image-reception layers representing reversed images thereon, the respective image-reception layers were whereupon brought into contact with the card's bond-sticking surface of the card and subjected to heat and pressure by use of at least a heat roll kept at 200° C. Then, the white color polyester resin substrate was peeled off, together with the weak-sticky adhering layer. In this way, a final product card displaying the portrait photograph was obtained.

EXAMPLE D-4

Substrate

A white color polyester resin sheet, "E-20", 100 μm thick, manufactured and sold by Toray Co. Ltd., was coated with a polyurethane-series primer. On the surface of the thus precoated sheet, the following composition was coated to form a weak-sticking adhesive layer.

Weak-Sticking Adhesive Component

weak-sticking adhesive agent, ("Esdyne AE-206", manufactured and sold by Sekisui Kagaku)	50 parts.

Image-Reception Layer-Forming Composition

polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki)	7.5 parts;
polyester resin ("Vylon 290", manufactured and sold by Toyo Boseki)	7.5 parts;
toluene/methyl ketone = 1/1	85 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	1 part;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	1 part.

The foregoing compositions were prepared. On the other hand, a polyester resin film, 25 μm thick, was coated on one surface thereof with a 15%-solution of polyester resin, "Vylon 200", manufactured and sold by Toyo Boseki, in toluene/methyl ethyl ketone=1/1 and dried up. The coating quantity was adjusted to 5 g/m^2 when measuring in dried state. In this way, a bond-sticking sheet was provided.

Then, the coated surface of the thus prepared bond-sticking sheet was brought into contact with the image display surface of a card style substrate of white color hard vinyl chloride or the like resin material preparatorily subjected to a primer coating treatment in overlapping state and then, the whole assembly was subjected to heat and pressure with use of at least a heated roll to 130° C., thus the bond-sticking layer being stuck on the card surface. Under this condition, the polyester resin film, 25 μm thick, was peeled off.

Then, the image-reception layer, now carrying thereon reversed images, was brought into contact with the bond-sticking sheet and the resulted whole was subjected to heat and pressure by use of at least a heated roll and the white color polyester resin substrate, together with the weak-sticking adhesive layer, was peeled off. In this way, the card, now displaying the portrait images, was provided.

EXAMPLE D-5

Substrate

Same as in the foregoing Example D-4.

Weak-Sticking Adhesive Layer

Same as in the foregoing Example D-4.

Protecting Layer-Forming Composition

polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki)	15 parts;
diisocyanate ("Colonate L", manufactured and sold by Nippon Polyurethane)	1 part;
toluene/methyl ethyl ketone = 1/1	84 parts.

Image-Reception Layer-Forming Composition

polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki)	10 parts;
toluene/methyl ethyl ketone = 1/1	85 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	1 part;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	1 part.

With use of the foregoing materials and compositions, the processings were carried out as in the foregoing Example D-4, to provide a final product card displaying portrait images as was desired.

EXAMPLE D-6

Substrate

Same as in the foregoing Example D-4.

Weak-Sticking Adhesive-Layer

Same as in the foregoing Example D-4.

Image-Reception Layer Forming Composition

polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki)	10 parts;
vinyl chloride-vinyl acetate copolymer resin ("Vinylite VAGH", manufactured and sold by Union Carbide Corp.)	5 parts;
toluene/methyl ethyl ketone = 1/1	85 parts.

The foregoing materials and compositions were prepared and processed in the similar way as in the foregoing Example D-4, to provide a final product card, displaying the desired portrait images as were desired.

EXAMPLE E-1

On a polyethylene terephthalate film, 9 μm thick, a solution of saturated polyester resin, "Vylon 600", manufactured and sold by Toyo Boseki, in toluene/methyl ethyl ketone=1/1, was coated by reliance of the known reverse roll-coating process, and dried up. The coated quantity was 7 g/m^2 when measuring in dry condition. In this way, a weak-sticking adhesive layer could be formed.

On the weak-sticking adhesive layer, the following composition, 3 g/m^2 (dry), was coated by means of an oblique-lined gravure roll for solid and full printing use and in the reverse roll-coating process, and then dried up, to provide an image-reception layer.

Image-Reception Layer-Forming Composition

polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki)	70 parts;
polyester resin, ("Vylon 290", manufactured and sold by Toyo Boseki)	30 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	5 parts;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	5 parts;
methyl ethyl ketone (wt. ratio 1/1)	700 parts.

On the opposite surface to the image-reception layer of the thus-prepared image-transferable sheet, a synthetic paper substrate, "Yupo FPG 110", 110 μm thick, manufactured and sold by Oji Yuka K.K., coated with "Vylon 600" as the adhesive agent in quantity of 10 g/m^2 (dry) was stuck intimately together.

On the other hand, a polyethylene terephthalate film substrate, 6 μm thick, preparatorily provided on one surface thereof with a heat-resisting layer was used and the following composition was applied on the opposite surface of the substrate with use of a wire bar and dried up, in the quantity of 1 g/m^2 (dry), so as to provide a dyestuff layer. In this way, a heat image-transferable sheet was prepared and provided.

Dyestuff Layer-Forming Composition

dispersion dye ("Kayaseo Blue-136", manufactured and sold by Nippon Kayaku K.K.)	4 parts;
ethylhydroxyethyl cellulose	6 parts;
methylethylketone/toluene (wt. ratio: 1/1)	90 parts.

The dyestuff layer of the foregoing heat image-transfer sheet was brought into contact with the image-reception layer of the image-transferable sheet in overlapping manner, then, heat energy was applied from a thermal head from the side of heat-resisting layer of the heat image-transfer sheet, thereby dyestuff being transferred to the image-reception layer of image-transferable sheet, and indeed, for the formation of positive images.

Then, the image-transferable sheet, now carrying the required positive images was stuck together under heat and pressure at 140° C. for 5 seconds on the intermediate image-transfer substrate prepared in the following manner, in mutually opposed manner. Then, the synthetic paper "Yupo" was peeled off at the intersurface between the polyester resin film and the "Vylon 600" layer. In thus way, the inventive image-transfer sheet (intermediate image-transfer medium) carrying the corresponding reverse images was provided.

Method for the Preparation of Intermediate Image-Transfer Substrate

A sheet of fine quality or stick paper, unit weight: 82 g/m^2 was applied with a coating, about 20 μm thick, of polyethylene resin through conventional extrusion coating process. Thereon, further, a catalyst-added toluene solution of a parting agent silicone, "KS-707", manufactured and sold by Shinetsu was applied and dried up in quantity of about 2 g/m^2 (dry), for the purpose of curing. Thereon, still further, the following coating liquid composition was applied by means of a conventional coating bar and dried up, to provide an intermediate image transfer substrate. The thus coated and dried resin quantity was measured to 7 g/m^2.

Coating Liquid Composition

polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki)	100 parts;
methyl ethyl ketone/toluene (mixing ratio by weight: 1/1)	700 parts.

A sheet of coated paper, pretreated for pore-filling, was coated, in the similar manner as above, with the foregoing liquid composition, to provide an image-transferable medium. On and with the presently coated surface, the image carrying surface of the foregoing intermediate image-transfer medium is brought into opposing contact and stuck together under heat and pressure at 140° C. for 7 seconds. Finally, the laminate of fine-quality paper and polyethylene was peeled off, to provide a final decorative product now displaying the positive images as required.

It will thus be seen that by adopting the above processing steps, the positive images formed under the action of the thermal head are transferred, through the intermediary of intermediate image transfer medium, onto the final object to be decorated, and indeed, in the form of positive mode. It

will be further seen that, since the dyestuff is well distributed within the image-reception layer, the transferred positive images are highly sharp and fresh, in addition to much profundities.

Since a resin layer was overlappingly applied on the thus-formed images, weather fastness, frictional durability and light-fastness of the finally formed images could be highly and amazingly improved. When suitable ultraviolet absorbing agent, antioxydant, quenching agent and/or radical scavenger is added to, further improvement of the light-fastness can be attained.

EXAMPLE E-2

The substrate of image-transferable medium adopted in the foregoing Example E-1 was replaced by a hard polyvinyl chloride card, 100 μm thick, and other processing modes were same as in Example E-1. In this way, a high quality, positive-image transferred, decorative final product was successfully provided. When the image include human portrait photograph, the final product was highly useful for ID-card.

EXAMPLE E-3

The substrate of image-transferable medium adopted in the foregoing Example E-1 was replaced by a transparent polyester film, and other processing modes were same as employed therein. In this way, a transparent film formed with the wanted positive images of better quality as before was obtained. This film was highly useful in OHP-services.

EXAMPLE E-4

A sheet of high quality paper, unit weight: 104 g/m^2, was coated with a layer of polypropylene resin, thickness: about 20 μm, through the way of conventional extrusion coating technique, then the coating was further coated with a silicone solution for use in parting service and hardenable under electron rays and dried up. The quantity of the coating silicone was about 1 g/m^{2}upon drying. In this way, an electron-hardened, provisional substrate was provided. On this substrate, the following, image-reception layer-forming composition was applied as a layer by use of a coating bar, and then dried up, for providing an image-reception layer. The coated resin quantity in the above last step amounted about 5 g/m^2.

Image-Reception Layer-Forming Composition

polystyrene ("Picolastic D 150" (Tg = 69° C.), manufactured and sold by Rika-Hercules Co., Ltd.	100 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	7 parts;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	7 parts.

Further processing was carried out as was set forth in the foregoing Example E-2, for providing a final product card, carrying thereon the wanted positive images of same superior quality, as was in Example E-2.

EXAMPLE E-5

On the image transferable medium used in the foregoing Example E-4, however, in the present Example, a thermoplastic resin, adhesive, polyolefine-series film, "Adwin 500", manufactured and sold by Showa Denko K.K., Tokyo, was applied as a layer. Other materials were used and processed as set forth therein. In this way, a decorative final product formed with necessary positive was obtained with superior results.

INDUSTRIAL AVAILABILITIES

As will be well understood from the foregoing detailed description of the invention, it is possible according to the present inventive system, to form highly easily and evenly the desired images sharply and attractingly on any product and object to be decorated or graphically ornamented, substantially irrespective of material kind and configuration thereof, and indeed, with a surprising unitary touch and feeling with the substrate. Therefore, the invention can be utilized broadly and conveniently in such various industrial fields, where unitary formation of various images, characters, symbols, numerals and graphics, on and to the articles, objects and substrate products to a sufficiently miracle and attracting degree.

We claim:

1. An image-transferable sheet for image-transfer onto the surface of an objective body, comprising a substrate sheet, an image-reception layer separably provided on one surface of said substrate, and a parting agent layer provided on the surface of said image-reception layer.

2. The image-transferable sheet of claim **1**, further comprising at least one of a parting agent layer, an intermediate layer and a protecting layer, provided between said image-reception layer and said substrate sheet.

3. The image-transferable sheet of claim **1**, further comprising an adhesively sticking layer provided between said image-reception layer and said substrate sheet.

4. The image-transferable sheet of claim **1**, further comprising a parting agent layer provided between said image-reception layer and said substrate sheet and an adhesively sticking layer provided on said parting agent layer which is in contact with said image-reception layer.

5. The image-transferable sheet of claim **1**, wherein said image-reception layer is composed of a material on or in which at least a thermally transferable dye-stuff can be deposited.

6. The image-transferable sheet of claim **1**, wherein said image-reception layer is provided in a separable manner, through the intermediary of a weak-sticking adhesive layer, on one surface of said substrate sheet.

7. The image-transferable sheet of claim **6**, wherein a parting agent layer is provided on one surface of said image-reception layer.

8. The image-transferable layer of claim **6**, wherein a protecting film layer is provided between said image-reception layer and said weak-sticking adhesive layer.

9. The image-transferable sheet of claim **8**, wherein the inter-relationship between said protecting film layer and said weak-sticking adhesive layer is a separable relationship.

[57] **ABSTRACT**

An objective lens for application to an image apparatus of which the size of the image pickup surface is changeable over between a first mode of a first aspect ratio and a second mode of a second aspect ratio has first optical member for extending the focal length of the objective lens, second optical member for shrinking the focal length of the objective lens, an operating member, and a transmitting mechanism for transmitting the operating force of the operating member to the first optical member under the first mode, and transmitting the operating force to the first and second optical member under the second mode, and by the operation of the operating member, under the first mode, the first optical member is removably insertable into the optical path of the objective lens, and under the second mode, the first and second optical member are removably insertable into the optical path of the objective lens.

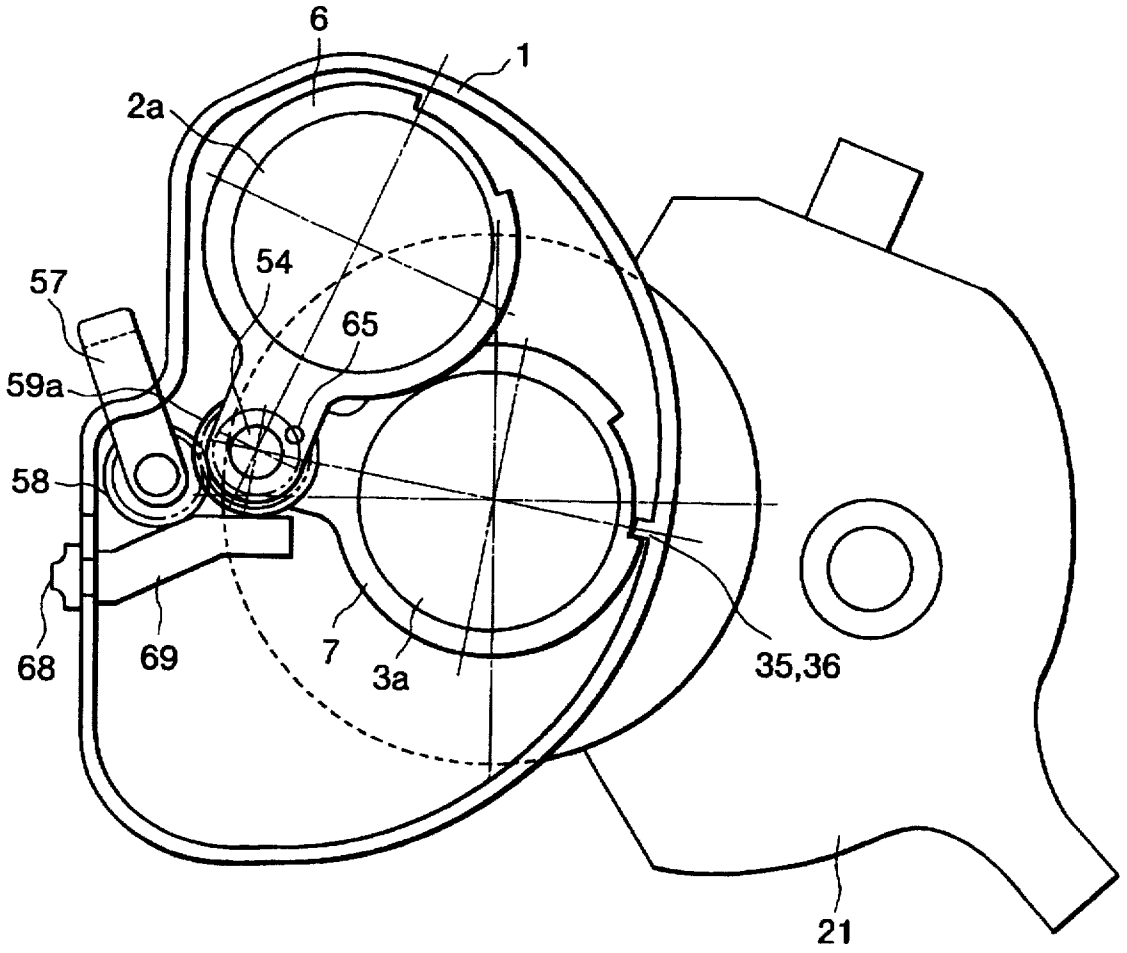
FIG. 27



OBJECTIVE LENS FOR IMAGE PICKUP APPARATUS WITH SIZE OF IMAGE PICKUP SURFACE CHANGEABLE BETWEEN ASPECT RATIOS

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to a lens barrel applicable to an image pickup apparatus capable of changing an aspect ratio, and particularly to a lens barrel in which a converting lens unit for changing over the aspect ratio is adapted to be removably provided in a portion of a photo-taking system when, for example, the aspect ratio of an effective image field is reversibly changed from 4:3 to 16:9.

2. Related Background Art

The width to length ratio, the so-called aspect ratio of the effective image pickup surface (image field) of an ordinary television camera, a video camera or the like is 4:3. In contrast with this, recently, the EDTV system having the aspect ratio of image field of 16:9 is being put into practical use as the broadcasting system of the next generation. Therefore, recently, in order to cope with both of the ordinary TV system and the EDTV system of the aspect ratio 16:9, there have been proposed various cameras (image pickup apparatuses) which can selectively use the aspect ratio 16:9 and the aspect ratio 4:3.

For example, in a camera of the image pickup tube type, the deflection area of an electron beam is electrically changed over to thereby change the width to length ratio (the aspect ratio) while keeping the diagonal length of the image field. However, to carry out this system by the use of a solid state image pickup element such as a CCD element, it is necessary to do as follows.

In a camera using a CCD element in which as shown in FIG. **11** of the accompanying drawings, the original aspect ratio of an image pickup surface **111** is 16:9, use is made of the whole area **112** of an image field of an aspect ratio 16:9. On the other hand, when an image field of an aspect ratio 4:3 which is a part area of an image pickup element of this size is to be photographed, as shown in FIG. **10** of the accompanying drawings, the right and left of a photo-taking surface **101** is not used, but only the area **102** of an image field of an aspect ratio 4:3 in the central portion is used.

When the image pickup surface of the image pickup element is thus partly used, the diagonal length of the image field becomes short and therefore, an image obtained by a photo-taking lens cannot be effectively used, and this leads to the disadvantage that the diagonal angle of view becomes narrow or sensitivity is reduced. That is, supposing that only the aspect ratio is simply changed, there axises the problem that the angle of view varies on a monitor.

Heretofore, in a TV camera or the like, use has been made of a system in which an extender is removably inserted into a portion of a photo-taking system (zoom lens) to thereby vary the focal length range of the whole system. In an extender constructed with a view to extend the focal length of the whole system to a longer one, the fact that the aspect ratio is changed, thereby the diagonal image field becomes narrow means that the focal length is apparently further extended. This poses no problem because in a state in which the extender is used, the focal length is in a direction to become longer, but in a state in which the extender is not used, the focal length on the wide angle side shifts to the telephoto side, and this becomes a great problem.

In contrast, in Japanese Laid-Open Patent Application No. 6-230279, there is proposed a method of disposing a lens unit for changing the image size (for example, an image field **103** indicated by dots-and-dash line in FIG. **10**) on a turret provided for an extender, and removably inserting a converting lens unit for shrinking the focal length by the rotation of the turret (hereinafter referred to as the "shrinker") into an optical path to thereby avoid the above-noted disadvantage. That is, a lens for preventing any variation in the angle of view even if the aspect ratio varies is prepared on the turret.

In the method proposed in the above-mentioned Japanese Laid-Open Patent Application No. 6-230279, the turret system is used for the changeover of the extender. Therefore, this system is very effective in the case of a large photo-taking lens like, for example, a lens for a studio camera.

However, in a camera system like a portable handy camera wherein a photographer effects photographing carrying the camera on his shoulder, it is usual to manually change over the extender and therefore, the new provision of the turret leads to the arising of the following problems.

(i) The addition of the turret and a rotating mechanism therefor to the photo-taking system greatly increases the weight of the handy camera system.

(ii) Heretofore, in a photo-taking lens for a handy camera, the changeover of the extender has been realized by the vertical or horizontal changeover operation of a changeover lever. To rotate the turret, it is usual to accomplish it by rotating a dial, a knob or the like connected to the turret. By this operation, not only the shrinker but also the extender are changed over, and this gives a feeling of physical disorder to the photographer accustomed to the conventional lens operation, while it takes much time to effect the changeover, and a hindrance comes to arise when a scene quick in movement is to be photographed.

(iii) The changeover mechanism becomes bulky and the area of the track on which the photo-taking lens moves is enlarged and therefore, when the focusing, zooming or iris operation is to be manually performed, an index provided on the circumference of the lens becomes difficult to see and a hindrance arises in the operation.

(iv) After the aspect ratio has once been selected on the camera side during photographing, if the photographer, in spite of having been conscious of only the selection of one-to-one magnification and the extender as before without being conscious of the presence or absence of the shrinker, makes a mistake in the selection, the image field will be eclipsed in some cases. That is, under a mode of an aspect ratio of 16:9, if the shrinker is inserted into the optical path, there will arise the inconvenience that the phenomenon of the light around the image field being eclipsed occurs. Accordingly, a photographer who performs the manual operation must constantly take care of the relation between the aspect ratio and the shrinker even during photographing.

SUMMARY OF THE INVENTION

It is a first object of the present invention to provide a relatively compact lens barrel applicable to a photographing apparatus of which the aspect ratio of the image pickup surface is changeable over.

It is a second object of the present invention to improve the operability of the changeover of a mode in which the aspect ratio varies.

According to a preferred embodiment of the present invention, an objective lens applicable to an image pickup apparatus of which the size of the image pickup surface is changeable over between a first mode of a first aspect ratio and a second mode of a second aspect ratio has first optical

means for extending the focal length of said objective lens, second optical means for shrinking the focal length of said objective lens, an operating member, and a transmitting mechanism for transmitting the operating force of said operating member to said first optical means under said first mode, and transmitting the operating force of said operating member to said first and second optical means under said second mode, and by the operation of said operating member, under said first mode, said first optical means is removably insertable into the optical path of said objective lens, and under said second mode, said first and second optical means are removably insertable into the optical path of said objective lens.

Further features of the present invention will become apparent from the following detailed description taken in conjunction with the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a cross-sectional view of a lens barrel according to an embodiment of the present invention.

FIGS. **2A**, **2B** and **2C** are a side cross-sectional view and the like of the lens barrel according to an embodiment of the present invention (when the aspect ratio is 16:9).

FIG. **3** is a perspective view of the whole of a camera according to an embodiment of the present invention.

FIG. **4** is a cross-sectional view of the lens barrel according to an embodiment of the present invention.

FIG. **5** is a cross-sectional view of the lens barrel according to an embodiment of the present invention.

FIG. **6** is a cross-sectional view of the lens barrel according to an embodiment of the present invention.

FIG. **7** is a side cross-sectional view of the lens barrel according to an embodiment of the present invention (when the aspect ratio is 4:3).

FIG. **8** is a cross-sectional view of a lens barrel according to an embodiment of the present invention.

FIG. **9** is a cross-sectional view of a lens barrel according to an embodiment of the present invention.

FIG. **10** shows an image circle at an aspect ratio of 4:3.

FIG. **11** shows an image circle at an aspect ratio of 16:9.

FIG. **12** is a cross-sectional view of a lens barrel according to another embodiment of the present invention.

FIGS. **13A** and **13B** are side cross-sectional views of the lens barrel according to another embodiment of the present invention.

FIG. **14** is a side cross-sectional view of a lens barrel according to another embodiment of the present invention.

FIG. **15** is a cross-sectional view of the lens barrel according to another embodiment of the present invention.

FIG. **16** is a cross-sectional view of a lens barrel according to another embodiment of the present invention.

FIG. **17** is a cross-sectional view of the lens barrel according to another embodiment of the present invention.

FIG. **18** is a cross-sectional view of a lens barrel according to still another embodiment of the present invention.

FIGS. **19A** and **19B** are side cross-sectional views of the lens barrel according to still another embodiment of the present invention.

FIG. **20** is a cross-sectional view of the lens barrel according to still another embodiment of the present invention.

FIGS. **21A** and **21B** are cross-sectional views of the lens barrel according to still another embodiment of the present invention.

FIG. **22** is a side cross-sectional view of the lens barrel according to still another embodiment of the present invention.

FIG. **23** is a cross-sectional view of a lens barrel according to still another embodiment of the present invention.

FIG. **24** is a side cross-sectional view of the lens barrel according to still another embodiment of the present invention.

FIG. **25** is a cross-sectional view of the lens barrel according to still another embodiment of the present invention.

FIG. **26** is a side cross-sectional view of the lens barrel according to still another embodiment of the present invention.

FIG. **27** is a cross-sectional view of the lens barrel according to still another embodiment of the present invention.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

FIG. **1** is a cross-sectional view of the essential portions of Embodiment 1 of the present invention, FIGS. **2A**, **2B** and **2C** are side views of the essential portions of FIG. **1**, FIG. **3** is a pictorial view of the essential portions of an image pickup apparatus according to the present invention, and FIGS. **4** and **5** are illustrations of Embodiment 1 of the present invention.

FIGS. **2A**, **2B** and **2C** show the case of an aspect ratio 16:9 and one-to-one magnification mode (mode A) (both of an extender and a shrinker are absent in an optical path).

FIG. **4** shows the case of an aspect ratio 16:9 and two times mode (mode B) (the extender is inserted in the optical path).

FIG. **5** shows the case of an aspect ratio 4:3 and 2.427 times mode (mode D) (the extender is inserted in the optical path).

FIG. **6** shows the case of an aspect ratio 4:3 and one-to-one magnification mode (mode C) (the shrinker is inserted in the optical path).

In the figures, the reference numeral **1** designates a housing containing an interchangeable lens unit therein. The housing **1** contains therein an extender **2***a* for enlarging the focal length and a shrinker **3***a* for shrinking the focal length shown in FIG. **7**. The housing **1** is provided between a photo-taking lens body **26** having a zoom lens and a camera body **27** (FIG. **3**).

In FIG. **3**, the reference numeral **28** denotes a photographer, and the reference numeral **29** designates the photographer's eyeballs. In FIG. **1**, the reference numeral **1-1** denotes a photo-taking optical path area, and La designates the optical axis thereof. The reference numeral **1-2** denotes an upper retraction area, and the reference numeral **1-3** designates a lower retraction area.

In FIGS. **2A**, **2B** and **2C**, the reference numeral **2** denotes an extender barrel having an extender unit **2***a*. In these figures, there is shown a case where the extender is comprised of an enlarging system lens having two times the photographing magnification and the focal length range of the whole system is varied to two times toward a longer one (two times mode). The reference numeral **3** designates a shrinker barrel holding a converting lens **3***a* to be inserted into an optical path correspondingly to the time when an image size (aspect ratio) is converted. In these figures, there is shown a case where the shrinker is comprised of a shrinking system lens having 0.824 times as the photograph-

ing magnification. Accordingly, in the mode A and mode C which will be described later, substantially the same angle of view is maintained in spite of the aspect ratio having been varied.

The reference numeral **4** denotes a rotary shaft which corresponds to the center of rotation of the extender barrel **2**. The reference numeral **5** designates a rotary shaft which corresponds to the center of rotation of the shrinker barrel **3**. The reference numeral **6** denotes a sector which fixes the rotary shaft **4** and the extender barrel **2**. The reference numeral **7** designates a sector which fixes the rotary shaft **5** and the shrinker barrel **3**. The reference numeral **8** denotes a changeover lever as an operating member for selectively removably inserting the extender barrel **2** and the shrinker barrel **3** into the optical path. The reference character **8***a* designates a lever shaft on which the changeover lever **8** is mounted. The reference numeral **9** denotes a lever for changing over the mode from a mode of an aspect ratio (second aspect ratio) 4:3 to a mode of an aspect ratio (first aspect mode) 16:9 or conversely. The reference numeral **10** designates a gear fixedly mounted on the lever shaft **8***a*. The reference numeral **11** denotes a gear constituting an element of extender changeover means. The gear **11** is fixed to the sector **6** and is in meshing engagement with the gear **10**. The reference numeral **12** designates a gear as shrinker changeover means. The gear **12** is fixed to the sector **7** and is in meshing engagement with a clutch gear **14**.

The clutch gear **14** constitutes an element of connecting means, is slidable in the axial direction of a shaft **13** and is rotatable with the rotation of the lever **9**. That is, the clutch gear **14**, as shown in FIG. **2**C, has a slot **14***c* in the central portion thereof, and a pin **13***a* fixed to the shaft **13** is engaged with the slot **14***c* so that the clutch gear may be slidable only in the axial direction. A gear **14***b* at the right of the clutch gear has a cut-away portion in a portion thereof and is adapted to be connected and disconnected with a stopper **18** which will be described later. The gear **14***a* of the clutch gear is normally in meshing engagement with the gear **12** and slides to thereby mesh with both of the gear **12** and an idler gear **15** and connect these two gears together. The idler gear **15** is normally in meshing engagement with the gear **10**. The reference numeral **16** denotes a spring resiliently holding the extender barrel **2** and the sector **6**. The reference numeral **17** designates a spring resiliently holding the shrinker barrel **3** and the sector **7**. The reference numeral **18** denotes a stopper as connection releasing means provided in the housing **1**. The stopper **18** regulates the meshing engagement between the gear **14** and the idler gear **15** and the releasing thereof. The reference numeral **19** designates a spring biasing the clutch gear **14** leftwardly as viewed in FIG. **2**A. The reference numeral **20** denotes a spring biasing the shaft **13** leftwardly as viewed in FIG. **2**A. The reference numeral **21** (FIG. **1**) designates a driving grip provided sideways of the photo-taking lens **26**.

In the present embodiment, the conversion of the aspect ratio and the enlargement (magnification) of the zoom range are coped with in a state in which one of the extender and the shrinker is removably inserted into a portion of the zoom lens (photo-taking system) **26**, for example, the optical path of a relay lens or in a state in which none of the extender and the shrinker is inserted. The construction of the used states of the extender and the shrinker in each mode at this time is as shown in Table 1 below.

TABLE 1

Aspect ratio	Enlargement magnification of zoom range	Lens unit disposed on the optical axis (area 1-1) of a portion (relay lens) of photo-taking system	Area 1–2	Area 1–3	Mode symbol	Corresponding figure
16:9	one-to-one	none	extender 2	Shrinker 3	mode A	FIG. 1
16:9	two times	extender 2	none	shrinker 3	mode B	FIG. 4
4:3	one-to-one (0.824 time at 16:9)	shrinker 3	extender 2	none	mode C	FIG. 6 (FIG. 7)
4:3	2.427 times	extender 2	none	shrinker 3	mode D	FIG. 5 (FIG. 7)

As shown in Table 1, there are four modes (photographing conditions) for two aspect ratios desired by the photographer. Actually, there are three kinds of disposition, i.e., a case where the extender and the shrinker are absent in the optical path (mode A), a case where the extender is disposed in the optical path (mode B, mode D), and a case where the shrinker is disposed in the optical path (mode C). As described with respect to the prior art, this is from the judgment that from the situation of use of the extender, the correction in a direction to extend the focal length is unnecessary. Accordingly, even when the same extender of two times is used, in the case of a mode of use of an extender of an aspect ratio 4:3, from

2/0.824=2.427,

the focal length of the whole photo-taking system becomes a focal length of apparently 2.427 times.

Operation will now be described.

FIGS. **1**, **2**A, **2**B and **2**C show a case where the aspect ratio is 16:9 and the whole system not using the extender is in mode A of one-to-one magnification (aspect ratio 16:9, one-to-one magnification mode). In this case, as shown in Table 1, the extender barrel **2** and the shrinker barrel **3** are both disposed at positions retracted from the optical axis La.

When in this state, the changeover lever **8** is operated, the lever shaft **8***a* on which the changeover lever **8** is mounted is rotated and the gear **10** is also rotated. Since the gear **10** is in meshing engagement with the gear **11**, the gear **11** is rotated to thereby rotate the sector **6**. Thereby, as shown in FIG. **4**, the extender barrel **2** is disposed on the optical axis La. At this time, the mode becomes mode B (aspect ratio 16:9, two times mode) in which the aspect ratio is 16:9 and the focal length of the whole system has been enlarged to two times.

Also, when conversely, the changeover lever **8** is returned, the same member is reversely rotated and the extender barrel **2** retracts from the optical axis La. In the case of this mode of the aspect ratio 16:9, the gear **14***a* of the clutch gear and the gear **15** provided on the shrinker barrel **3** side do not touch each other at all. Accordingly, the shrinker barrel **3** remains retracted from the optical path. At this time, the mode returns to the mode (aspect ratio 16:9, one-to-one magnification mode) in which the aspect ratio is 16:9 and the focal length range of the whole system is one-to-one magnification free of any variation.

Thus, the present embodiment adopts a construction in which when the mode of the aspect ratio (first aspect ratio)

16:9 is selected, the shrinker is inhibited from entering and only the extender barrel **2** can be changed over by the changeover lever **8**.

Accordingly, under this mode, any reduction in the quantity of light around the image field is prevented by the insertion of the shrinker into the optical path.

Description will now be made of the case of a mode of the aspect ratio (second aspect ratio) 4:3.

Description will first be made of the changeover from the mode A to the mode C when the aspect ratio is changed on the camera body side with the photo-taking system being in one-to-one magnification state.

For the changeover from the mode A shown in FIGS. **1**, **2A**, **2B** and **2C** to the mode C shown in FIG. **6**, the mode changeover lever **9** is rotated. Thereupon, immediately before the rotating operation of the lever **9** is terminated, the clutch gear **14** so far regulated by the stopper **18** comes out of engagement with the stopper **18** and is moved to the left of the shaft **13** as viewed in FIG. **2A** by the biasing force of the spring **19**, and the gear **14***a* of the clutch gear comes into meshing engagement with the gear **15**. Thereby, the extender barrel **2** and the shrinker barrel **3** are connected together. The rotation of the lever **9** is transmitted to the gear **12** by the gear **14***a* of the clutch gear and the center of the optical axis of the shrinker barrel **3** is moved to a position which coincides with the center of the optical axis La, through the sector **7**. Thereby, the mounting of the shrinker **2***a* onto the optical axis is effected and the changeover from the mode A to the mode C is effected.

In this state (mode C), as previously described, the operating force of the operating lever **8** is always transmitted to the shrinker **3***a* through a connecting mechanism. That is, since the gear **14***a* of the clutch gear is in meshing engagement with the gear **12**, the shrinker **3***a* becomes operatively associated with the extender by the operating lever **8** being rotatively operated, and the changeover from the mode C to the mode D becomes possible. Of course, the changeover from the mode D to the mode C can also be accomplished by the operation of the operating lever **8**.

Description will now be made of the changeover from the mode C to the mode A in which nothing is inserted into the optical path and a mechanism therefor. For the changeover from the mode C shown in FIG. **6** to the mode A, the shaft **13** shown in FIG. **7** is pressed and moved rightwardly as viewed in the figure by fingers, while the lever **9** fixed to the same shaft is rotated in the original direction. By the shaft **13** being deviated, the clutch gear **14** is also moved rightwardly as viewed in the figure against the force of the spring **19** and comes out of meshing engagement with the idler gear **15**. Thereafter, the lever **9** is rotated to its original position, whereby the gear **14***a* of the clutch gear is normally in meshing engagement with the gear **12** and therefore, through the sector **7**, the shrinker barrel **3** comes to the area **1-3** in which it was originally positioned. On the other hand, the gear **14***b* is again caught by the stopper **18** due to its axial movement and rotation, and by releasing the fingers, the shaft **13** is returned to its original position by the spring **20** after the rotation of the lever **9**, and stays in a position shown in FIGS. **2A** to **2C**. Thereby, the changeover of the aspect ratio from the mode C to the mode A is effected.

What has been described above is the changeover of the aspect ratio. By this and the above-described extender changeover method, the changeover of all modes is made possible.

The mutual changeover between the mode B and the mode D is effected by electrical processing in the camera body with the extender **2***a* disposed in the optical path.

In the present embodiment, as described above, the changeover to each mode is made easy by the construction in which:

- provision is made of the connecting means and connection releasing means which makes the operation of only changing over the shrinker and the extender by only one changeover operation of the operating means in accordance with the aspect ratio and which can be selected by the photographer;
- provision is made of the connecting means and connection releasing means which can effect the extender changeover operation and the connecting lens unit changeover operation at a time by the converting lens unit changeover operation;
- the center of the rotational movement during the changeover of the extender and the converting lens unit is divided and the retraction location of the lens unit from the optical axis is secured at a position whereat the photographer can confirm the index and a numerical value corresponding thereto;
- some of the gears change their positions in parallelism to the rotary shaft to thereby come out of meshing engagement and effect connection and the releasing of the connection; and
- provision is made of the shaft and the gear movable in the axial direction and transmitting only the rotational force and weighted by the spring and having a convex portion formed on a portion outside the rotary shaft, and the convex portion interferes with the stopper by the angle of rotation of the gear to thereby change the position of the gear.

FIG. **8** is a schematic view of the essential portions of Embodiment 2 of the present invention. This embodiment, as compared with Embodiment 1, is one in which the disposition of the barrels is vertically reversed (in this state, one-to-one magnification of an aspect ratio 4:3). That is, design is made such that the extender barrel **2** is retracted downwardly (the area **1-3**) and the shrinker barrel **3** is retracted upwardly (the area **1-2**). The reference numerals in this figure designate the same parts as those in Embodiment 1.

The reference numeral **30** designates a gear corresponding to the gear **14** in Embodiment 1 and movable in the thrust direction, the reference numeral **31** denotes a gear corresponding to the gear **10** and fixed to the extender changeover lever, and the reference numeral **32** designates an idler gear which is normally in meshing engagement with the gear **11** and the gear **31**. The operation and the movement of the barrels are the same as those in Embodiment 1, and the internal mechanism is also the same as that in Embodiment 1 except the position of the idler and therefore, detailed description of the operation need not be made.

As described above, the disposition of the barrels can be done anyway, depending on the positional relation of the idler gear.

FIG. **9** is a schematic view of the essential portions of Embodiment 3 of the present invention. This embodiment, as compared with Embodiment 2 of FIG. **8**, is one in which the operating system is vertically reversed (in this state, one-to-one magnification of an aspect ratio 4:3). The reference numerals in this embodiment designates the same parts as those in Embodiments 1 and 2. The reference numeral **33** denotes an idler gear corresponding to the idler gear **15** in Embodiment 1, and the reference numeral **34** designates a gear corresponding to the gear **10** and fixed to the extender changeover lever. The only difference of this embodiment

from Embodiment 2 is that the changeover direction of the extender is converse, and the operation of this embodiment is similar to that of Embodiment 2 and therefore need not be described. As described above, the direction of operation can be anyway, depending on the positional relation of the idler gear.

In Embodiment 1, the magnification of the extender has been described with respect to the case of two times, but may be any other magnification. Also, when for a camera having an image pickup element of which the aspect ratio of the image pickup surface is 4:3, an image field of an aspect ratio 16:9 which is an area thereof is to be photographed, a vertical portion of the image field is not used, but the area of 16:9 of the central portion may be used, or in such case, the magnification of the shrinker may be changed to 0.917 time and may be made to correspond thereto. Also, even when the aspect ratio differs, a shrinker magnification corresponding thereto may likewise be adopted and may be made to correspond thereto.

According to the present invention, as described above, in the photo-taking system having the converting lens (shrinker) for the changeover of the aspect ratio and the extender, there can be achieved an image pickup apparatus capable of changing over the aspect ratio in which a driving mechanism for effecting the removable insertion of both lenses into the optical path is appropriately set, whereby irrespective of the use or non-use of the shrinker, by only the operation of removably inserting the extender into the optical path, photographing can be effected easily at one-to-one magnification or a different magnification (focal length range).

Particularly, the present invention can cope with a camera with the aspect ratio changeover function which enables the quick extender operation by the operation of the changeover lever similar to that in the prior art to be performed without giving a feeling of physical disorder to a photographer accustomed to the photographing operation of a zoom lens for the conventional handy camera with an extender.

Also, the photographer, after he has once selected an aspect ratio, can be conscious of only the selection of one-to-one magnification and the extender as before and therefore, these makes it unnecessary for the photographer to newly learn to use the new function of changing over the aspect ratio, and can effectively prevent the eclipse of the photographed image which is a mistake absolutely unallowable in photographing.

Also, it becomes possible to minimize the area of the movement locus of the lens and very much simplify the entire changeover mechanism and therefore, as compared with the turret type according to the prior art, it is possible to make the entire photographing system light in weight. At the same time, the shape made compact as compared with the turret type does not spoil the visual confirmability of a scale for operation, index lines, etc. disposed on the circumference of the lens.

An embodiment improved over the above-described embodiments will now be described with reference to FIGS. **12** to **17**. The improved points are that the clutch gear **14** and the stopper **18** in the above-described embodiments are eliminated and that the shaft **5** is improved to thereby improve the operability. The members designated by the other reference numerals perform the same functions and therefore need not be described in detail.

The reference character **5***a* designates a small gear as an element of converting lens changeover means. The small gear **5***a* is fixed to the rotary shaft **5**.

The reference character **5***b* denotes a large gear as an element of the converting lens changeover means. The large gear **5***b* is fixed to the rotary shaft **5**. The reference numeral **13** designates a shaft gear constituting an element of connecting means and fixed to the lever **9**. A large gear **13***a* and a small gear **13***b* are secured to the shaft **13***c* of the shaft gear **13**. The small gear **5***a*, the large gear **5***b* and the shaft gear **13** together constitute an element of a speed reducing mechanism. The gear **13***a*, as shown in FIG. **13B**, has a cut-away portion in a portion thereof, and this cut-away portion is in such relationship as not to mesh with the gear **15** in the case of a mode of 16:9.

The shaft **13***c* is slidable in the axial direction thereof and is rotatable with the rotation of the lever **9**. The shaft **13***c* is such that by its sliding, the large gear **13***a* meshes with the idler gear **15** and the small gear **5***a* (FIGS. **13A** and **13B**) or the small gear **13***b* meshes with the large gear **5***b* (FIG. **14**). The idler gear **15** is normally in meshing engagement with the gear **10**.

The construction of the used states of the extender and the shrinker in each mode at this time is as follows when shown analogically to the table shown below.

TABLE 2

Aspect ratio	Enlargement magnification of zoom range	Lens unit disposed on the optical axis (area 1-1) of a portion (relay lens) of photo-taking system	Area 1–2	Area 1–3	Mode symbol	Corresponding figure
16:9	one-to-one	none	extender 2	shrinker 3	mode A	FIG. 12 FIG. 14
16:9	two times	extender 2	none	shrinker 3	mode B	FIG. 15
4:3	one-to-one (0.824 time at 16:9)	shrinker 3	extender 2	none	mode C	FIGS. 13A, 13B FIG. 16
4:3	2.427 times	extender 2	none	shrinker 3	mode D	FIG. 17

Under such a construction, when the aspect ratio is 16:9, the gear **13***a* and the gear **15** are not in meshing engagement with each other and therefore, by the operating lever **8** being rotated, only the extender **2** of two times becomes removably insertable onto the optical axis La (FIGS. **12**, **13A**, **13B** and **15**). That is, the changeover of the mode A and the mode B becomes possible by the operation of the operating lever **8**.

Description will now be made of the operation of changing over the mode from the mode of the aspect ratio 16:9 to the mode of the aspect ratio 4:3. The changeover from the mode A (the converting lens is absent on the optical axis La) to the mode C is effected as follows.

The shaft **13** is first pressed and slidden by fingers against the spring **20** to thereby bring the small gear **13***a* into meshing engagement with the gear **5***b*. Subsequently, the lever **9** is rotated to thereby insert the shrinker **3** into the optical path (the mode C). By releasing the fingers, the shaft slides leftwardly and now the gear **13***a* comes into meshing engagement with the gear **15** and thus, the rotative operation of the operating lever **8** is transmitted to the shrinker **3**.

That is, the rotation of the operating lever **8** is transmitted to the gears **15**, **13***a* and **5***a*, and the extender and the shrinker are always operatively associated with each other, and the changeover from the mode C to the mode D or the converse mode changeover becomes possible.

Conversely, for the changeover from the mode of the aspect ratio 4:3 to the mode of the aspect ratio 16:9, the mode is first set to the mode C, whereafter the shaft **13***c* is pressed by fingers and the gear **13***b* is brought into meshing engagement with the gear **5***b*, whereafter the lever **8** is rotated to its original position, whereupon the shrinker is retracted from the optical axis La. By releasing the fingers, the original state is restored.

In the present embodiment, the diameter of the gear **13***b* of the gears meshing with each other during the changeover of the aspect ratio is made smaller than the diameter of the gear **5***a*, whereby the operating force required to removably insert the shrinker can be made small and the operability is successfully improved.

An embodiment of another form will now be described with reference to FIGS. **18** to **22**.

FIG. **18** is a cross-sectional view of the essential portions of the present embodiment, FIGS. **19**A and **19**B are side views of the essential portions of FIG. **18**, and FIGS. **20** to **22** are illustrations of the present embodiment.

FIGS. **19**A and **19**B show the case of the aspect ratio 16:9 and one-to-one magnification mode (both of the extender and the shrinker are absent in the optical path).

FIG. **20** shows the case of the aspect ratio 16:9 and two times mode (the extender is inserted in the optical path).

FIGS. **21**A and **21**B show the case of the aspect ratio 4:3 and 2.427 times mode (the extender is inserted in the optical path).

FIG. **22** shows the case of the aspect ratio 4:3 and one-to-one magnification mode (the shrinker is inserted in the optical path).

Elements designated by the same reference characters as in the aforedescribed embodiment perform similar functions and therefore need not be described.

In FIGS. **18** to **22**, the reference numeral **34** designates a rotary shaft which corresponds to the center of rotation of the extender barrel **2**. The reference numeral **35** denotes a rotary shaft which corresponds to the center of rotation of the shrinker barrel **3**. The reference numeral **6** designates a sector which holds the rotary shaft **34** and the extender lens **2**. The reference numeral **7** denotes a sector which holds the rotary shaft **35** and the shrinker lens **3**. The reference numeral **38** designates a changeover lever as an operating member which selectively removably mounts the extender lens **2** and the shrinker lens **3** in the optical path. The reference numeral **39** denotes a lever shaft on which the changeover lever **38** is mounted. The reference numeral **30** designates a changeover knob as an element of connection releasing means and aspect ratio setting means. The changeover knob **30** is operated with the changeover from the mode of the aspect ratio (second aspect ratio) 4:3 to the mode of the aspect ratio (first aspect ratio) 16:9. The reference numeral **31** denotes a gear as extender changeover means. The gear **31** is fixed to the sector **6** and in FIG. **18**, it is in meshing engagement with a clutch gear (connecting means) **33**. The reference numeral **32** designates a gear as converting lens changeover means. The gear **32** is fixed to the sector **7** and is capable of meshing with the clutch gear **33**.

The clutch gear **33** is slidable in the axial direction of the lever shaft **39** and rotatable with the rotation of the lever shaft **39**. The clutch gear **33** slides to thereby mesh with only the gear **31** or with both of the gear **31** and the gear **32**. The reference numeral **34** denotes a pin which transmits the rotation of the lever shaft **39** to the clutch gear **33**. The reference numeral **35** designates a stopper which holds the sector **6** for holding the extender barrel **2** on the optical axis.

The reference numeral **36** denotes a stopper which holds the sector **7** for holding the shrinker barrel **3** on the optical axis. The reference numeral **37** designates a stopper which holds the sector **6** in a position wherein the extender barrel **2** is retracted from the optical axis. The reference numeral **38** denotes a stopper which holds the sector **7** in a position wherein the shrinker barrel **3** is retracted from the optical axis La of the photo-taking system. The reference numeral **41** designates a spring which resiliently holds the extender barrel **2** and the sector **6**. The reference numeral **40** denotes a spring which resiliently holds the shrinker barrel **3** and the sector **7**.

In the present embodiment, with one of the extender and the shrinker removably inserted or neither of them inserted in a portion of the zoom lens (photo-taking system), for example, the optical path of a relay lens, the changeover of the aspect ratio and the enlargement (magnification) of the zoom range are coped with. The construction of the used states of the extender and shrinker in each mode at this time is as shown in the table below.

TABLE 3

Aspect ratio	Enlargement magnification of zoom range	Lens unit disposed on the optical axis of a portion (relay lens) of photo-taking system	Corresponding figure
16:9	one-to-one	none	FIG. 18
16:9	two times	extender	FIG. 20
4:3	one-to-one	shrinker	FIG. 22
4:3	2.427 times	extender	FIGS. 21A, 21B

As shown in this table, there are four modes (photographing conditions) for two aspect ratios desired by the photographer. Actually, there are three kinds of disposition, i.e., a case where the extender and the shrinker are absent in the optical path, a case where the extender is disposed in the optical path, and a case where the shrinker is exposed in the optical path. As described with respect to the prior art, this is from the judgment that from the situation of use of the extender, the correction in a direction to extend the focal length is unnecessary. Accordingly, even when the same extender of two times is used, in the case of a mode of use of an extender of the aspect ratio 4:3, from

$$2/0.824=2.427,$$

the focal length of the whole photo-taking system becomes a focal length of apparently 2.427 times.

In the case of a mode in which the aspect ratio is 16:9 (a mode of the aspect ratio 16:9), the shrinker barrel **3** is always in a state retracted from the optical axis La. By the extender changeover lever **38** being operated, only the extender barrel **2** is removably inserted onto the optical axis to thereby vary the focal length range of the whole system to one-to-one magnification (one-to-one magnification mode) and two times (two times mode). Also, in the case of a mode in which the aspect ratio is 4:3 (a mode of the aspect ratio 4:3), the extender changeover means **31** and the shrinker changeover means **32** are connected together by the connecting means **33** which is a clutch gear so that one of the shrinker barrel **3** and the extender barrel **2** may be disposed on the optical axis La without fail by one operation of the operating member **38**. That is, the shrinker barrel **3** and the extender barrel **2** are connected together by the clutch gear **33** so as to be moved at a time by one operation of the changeover lever **38**.

The operation at this time will now be described in accordance with the operation of the changeover lever **38**.

FIGS. **18**, **19**A and **19**B show cases where the aspect ratio is 16:9 and the whole system not using the extender is at one-to-one magnification (the aspect ratio 16:9, one-to-one magnification mode). At this time, as shown in the table above, the extender barrel **2** and the shrinker barrel **3** are both disposed at positions retracted from the optical axis La.

When in this state, the changeover lever **38** is operated, the lever shaft **39** on which the changeover lever **38** is mounted is rotated and the clutch gear **33** is also rotated therewith through the pin **34**. Since the clutch gear **33** is in meshing engagement with the gear **31**, the gear **31** is rotated to thereby rotate the sector **6**. Thereby, as shown in FIG. **20**, the extender barrel **2** is disposed on the optical axis La. At this time, the mode becomes a mode in which the aspect ratio is 16:9 and the focal length range of the whole system has been enlarged to two times (the aspect ratio 16:9, two times mode).

Also, when conversely, the changeover lever **38** is returned to its original position, the same member is reversely rotated to thereby retract the extender barrel **2** from the optical axis La. In the meantime, the clutch gear **33** does not at all touch the gear **32** provided on the shrinker barrel **3** side and accordingly, the shrinker barrel **3** remains retracted from the optical path. At this time, the mode becomes a mode in which the aspect ratio is 16:9 and the focal length range of the whole system is unchanged, i.e., one-to-one magnification (the aspect ratio 16:9, one-to-one magnification mode).

As described above, in the present embodiment, when the aspect ratio (first aspect ratio) 16:9 mode is selected, only the extender lens is changed over by the changeover lever **38**.

Description will now be made of the case of a mode of the aspect ratio (second aspect ratio) 4:3.

As previously described, in the present invention, mode changeover is effected by the aspect ratio setting means **30** with the extender **2***a* disposed on the optical axis La and therefore, the changeover lever **38** is once operated to thereby dispose the extender barrel **2** on the optical axis La.

Here, the changeover knob **30** is rotated to effect mode changeover and the clutch gear **33** is pushed leftwardly as viewed in FIG. **19**A by a projection **30***a* provided integrally with the changeover knob **30**. As a result, as shown in FIGS. **21**A and **21**B, the clutch gear **33** slides on the lever shaft **39** and is fixed at a position in which it meshes with the gear **32** disposed in advance so as to mesh with the clutch gear **33**. In this state, the changeover lever **38** is in the position of extender ON and therefore, when it is returned to its original position, the extender barrel **2** is retracted from the optical axis by the transmission of the rotation of the clutch gear **33** and the gear **31** as in the case of the aspect ratio 16:9 mode.

The rotation is likewise transmitted to another gear **32** with which the clutch gear **33** is in meshing engagement, and the sector **7** is rotated about the rotary shaft **35** through the gear **32**, and the shrinker barrel **3** becomes operatively associated with the extender barrel **2**, whereby the extender barrel **2** is moved toward the optical axis conversely to being retracted from the optical axis, and becomes positioned on the optical axis. Here, the angles by which the sector **6** and the sector **7** are rotatable are substantially the same and the speed reduction ratios of the clutch gear **33** and the gear **31** and of the clutch gear **33** and the gear **32** are the same.

Also, the meshing engagement among the gears **31**, **32** and **33** is provided with a play sufficient to absorb the irregularity of the angle of rotation of each sector in the manufacture thereof. Therefore, design is made such that the sector **7** reliably strikes against the stopper **38** when the stopper **35** for positioning the extender barrel **2** at a position on the optical axis La is regulating the rotation of the sector **6**.

Also, design is made such that the sector **6** reliably strikes against the stopper **7** when the stopper **36** for positioning the shrinker barrel **3** at a position on the optical axis La is regulating the rotation of the sector **7**.

Thus, as shown in FIG. **22**, the changeover knob **30** is rotated, whereafter the changeover lever **38** is operated, whereby the extender barrel **2** may be retracted from the optical axis and at the same time, the shrinker barrel **3** may be disposed on the optical axis. Thereby, there is brought about a mode of an aspect ratio 4:3 and one-to-one magnification (the aspect ratio 4:3, one-to-one magnification mode).

When from this state, the changeover lever **38** is again returned to its original position, the shrinker barrel **3** is retracted from the optical axis and at the same time, the extender barrel **2** becomes again positioned on the optical axis. Thereby, there is brought about a mode in which the aspect ratio is 4:3 and the focal length range of the whole system has been displaced by 2.427 times toward a longer one (the aspect ratio 4:3, 2.427 times mode).

In the present embodiment, even in the case of a photographing mode of the aspect ratio 4:3, the shrinker barrel **3** and the extender barrel **2** become removably inserted in operatively associated relationship with each other, and after a mode has once been set, as in the case of the aspect ratio 16:9, the extender operation is made possible by only the operation of the changeover lever **38**, like the prior-art photo-taking lens which does not constitute a shrinker. After the extender has been returned onto the optical axis, the mode changeover knob **30** is again rotated, that is, the connection of the connecting means **33** is released to return it to its original position, whereupon photographing at the aspect ratio 16:9 again becomes possible.

It has been described that when the mode changeover knob **30** is operated when the extender barrel **2** is on the optical axis as described above, the mode changeover of the aspect ratio 16:9 and the aspect ratio 4:3 is possible, but when the photographer effects mode changeover by mistake during photographing in the aspect ratio 16:9 mode and at one-to-one magnification, the extender barrel **2** and the shrinker barrel **3** will become operatively associated with each other while being both retracted from the optical axis, and the changeover lever **38** will become unmovable in any direction.

In order to avoid the photographer's wrong operation so as not to fall into such a state, in the present embodiment, when as shown in FIGS. **21**A and **21**B, the changeover lever **38** is in one-to-one magnification position, a portion (inhibiting means) **38***a* of this changeover lever **38** is disposed so as to cover the mode changeover knob **30**. Thus, design is made such that the changeover during one-to-one magnification which poses a problem in operation is made impossible and the photographer never operates wrongly.

While in the present embodiment, the angle of retraction at which the extender barrel **2** is retracted from the optical axis and the angle at which the shrinker barrel **3** is retracted from the optical axis have been described as being substantially the same, a great angle of retraction may be secured for only the extender barrel **2** or only the shrinker barrel **3**, and the speed reduction ratios between the clutch gear **33** and the gear **31** and between the clutch gear **33** and the gear **32** referred to in FIGS. **19**A and **19**B may be changed to ones conforming to the angle of retraction.

FIG. **25** shows the case of the aspect ratio 16:9, one-to-one magnification mode (neither of the extender **2***a* and the shrinker (converting lens) **3***a* is present in the optical path).

FIGS. **23** and **24** show the case of the aspect ratio 16:9, two times mode (the extender is inserted in the optical path).

FIGS. **26** and **27** show the case of the aspect ratio 4:3, one-to-one magnification mode (the shrinker is inserted in the optical path).

The reference numeral **54** designates a rotary shaft which corresponds to the center of rotation of the extender barrel **2** and of the shrinker barrel **3**. The reference numeral **6** denotes a sector which fixes the rotary shaft **54** and the extender barrel **2**. The reference numeral **7** designates a sector which files the rotary shaft **54** and the shrinker barrel **3**. The reference numeral **57** denotes a changeover lever as an operating member on which the extender barrel **2** and the shrinker barrel **3** are mounted for selective removable insertion into the optical path. The reference numeral **58** designates a lever shaft on which the changeover lever **57** is mounted.

The lever shaft **58** has a gear **58***a* thereon. The reference numeral **59** denotes a gear member fixed to the rotary shaft **54**. A gear **59***a* provided on the outer periphery of the gear member **59** is shown as being in meshing engagement with the gear **58***a* on the lever shaft **58** in FIGS. **23** and **24**. The rotary shaft **54**, the sector **6** and the gear member **59** together constitute an element of extender changeover means. The rotary shaft **54**, the sector **7**, etc. together constitute an element of converting lens changeover means.

The reference numeral **60** designates a clutch knob. The reference numeral **61** denotes a connecting pin which connects a clutch body **62** and the clutch knob **60** together. The clutch body **62** is operatively associated with the rotation of the clutch knob **60** and the connecting pin **61** and is rotatable about the rotary shaft **54**. The reference numeral **63** designates a spring which biases the clutch body **62** toward the optical axis La. The reference numeral **64** denotes a clutch pin fixed to the clutch body **62**. The clutch pin **64** slides in the direction of the optical axis to thereby effect the connection thereof to the gear member **59** and the release of the connection. The reference numeral **65** designates a clutch pin fixed to the clutch body **62** and connected to the sector **7**.

The reference numeral **68** denotes a mode fixing switch, and the reference numeral **69** designates a mode fixing plate which is fixed to the mode fixing switch **68** and prevents the connection between the clutch pin **64** and the gear member **59**. The mode fixing switch **68**, the clutch knob **60** and the clutch body **62** together constitute an element of mode changeover means.

In the present embodiment, the construction of the used states of the extender and shrinker in each mode is as shown in the table below.

TABLE 4

Aspect ratio	Enlargement magnification of zoom range	Lens unit disposed on the optical axis of a portion (relay lens) of photo-taking system	Corresponding figure
16:9	one-to-one	none	FIG. 25
16:9	two times	extender	FIGS. 23 and 24
4:3	one-to-one	shrinker	FIGS. 26 and 27
4:3	2.427 times	extender	FIGS. 23 and 24
4:3	1.214 times	none	FIG. 25

In the present embodiment, as shown in the table above, there are five modes (photographing conditions) for two aspect ratios desired by the photographer. Actually, there are three kinds of disposition, i.e., a case where the extender and the shrinker are absent in the optical path, a case where the extender is disposed in the optical path, and a case where the shrinker is disposed in the optical path. As described with respect to the conventional art, this is from the judgment that from the situation of use of the extender, the correction in a direction to extend the focal length is unnecessary. Accordingly, even when the same extender of two times is used, in the case of a mode of use of an extender of the aspect ratio 4:3, from

2/0.824=2.427,

the focal length of the whole photo-taking system becomes a focal length of apparently 2.427 times.

Also, in the case of the mode of the aspect ratio 4:3, if the extender and the shrinker are both retracted from the optical path, as the reason why the shrinker is required, the focal length will extend toward the telephoto side as previously described and therefore, a hindrance will occur in the photographing at a wide angle. However, if the shrinker is constructed and this problem is solved, it will **6**e possible to utilize this nature as in the present embodiment and utilize an extender of apparently low magnification as being inserted. In this case, the apparent magnification of the extender is 1.214 times which is an inverse number of the magnification of the shrinker.

In the present embodiment, when a mode in which the aspect ratio is 16:9 (the aspect ratio 16:9 mode) is set by aspect ratio setting means (not shown) on the camera body side, the shrinker barrel **3** is always in its retracted state from the optical axis La.

The changeover lever **57** is operated to thereby removably insert only the extender barrel **2** onto the optical axis and vary the focal length range of the whole system to the one-to-one magnification (one-to-one magnification mode) of FIG. **25** and the two times (two times mode) of FIG. **23**. Also, in the case of the mode in which the aspect ratio is 4:3 (the aspect ratio 4:3 mode), by the operation of the changeover lever **57**, the shrinker barrel **3** or the extender barrel **2** may be positioned on the optical axis or both of them may be positioned off the optical axis. That is, by the operation of the changeover lever **57**, their positions are changed to those of FIGS. **23**, **25** and **27**.

The operation at this time will now be described in accordance with the operation of the changeover lever **57**.

FIGS. **23** and **24** show a case where the aspect ratio is 16:9, the extender is used and the whole system is at two times (the aspect ratio 16:9, two times mode). At this time, as shown in the previous table, the extender barrel **2** is disposed on the optical axis and the shrinker barrel **3** is disposed in a position retracted from the optical axis La.

When in this state, the changeover lever **57** is operated, the lever shaft **58** on which the changeover lever **57** is mounted is rotated and the gear **59***a* is also rotated therewith through the gear **58***a*. Since the gear member **59** is fixed to the sector **6**, it rotates the sector **6**. Thereby, as shown in FIG. **25**, the extender barrel **2** is retracted from the optical axis La. At this, the mode becomes a mode in which the aspect ratio is 16:9 and the focal length range of the whole system is one-to-one magnification (the aspect ratio 16:9, one-to-one magnification mode).

When conversely, the changeover lever **57** is returned to its original position, the same member is reversely rotated and the extender barrel **2** is positioned on the optical axis La. In the meantime, the clutch pin **64** provided on the clutch body **62** operatively associated with the shrinker barrel **3** side is prevented from being connected to the gear member **59** by the mode fixing plate **69**. Accordingly, the shrinker

barrel **3** remains retracted from the optical path. At this time, the mode becomes a mode in which the aspect ratio is 16:9 and the focal length range of the whole system is two times (the aspect ratio 16:9, two times mode).

As described above, in the present embodiment, when the aspect ratio (first aspect ratio) 16:9 mode is selected, the operation of the extender is effected by only the changeover operation of the changeover lever **57** as in the prior-art photo-taking lens which does not constitute a shrinker.

Description will now be made of the case of the mode of the aspect ratio (second aspect ratio) 4:3.

When the aspect ratio 4:3 mode is selected by the aspect ratio setting means (not shown) on the camera body side or the lens side, the mode fixing switch **58** is released on the lens side and the mode fixing plate **69** is slidden and retracted. The clutch knob **60** is then rotated to thereby fit the clutch pin **64** biased by the spring **63** into an aperture formed in the gear member **59**. Thereby, the connection between the converting lens changeover means and the extender changeover means or the operating member is effected (when the aspect ratio is 16:9, the clutch knob **60** is slidden in the direction of the optical axis against the force of the spring **63** to thereby release the connection between the clutch pin **64** and the gear member **59**, and then the mode fixing switch **68** is changed over to thereby release the connection between the converting lens changeover means and the extender changeover means.

First, the retraction of the extender barrel **2** from the optical axis to the positions of FIGS. **23** to **25** is effected by rotating the changeover lever **57** as in the aspect ratio 16:9 mode previously described. However, as shown in the previous table, in the aspect ratio 4:3 mode, use is made with the case of FIG. **25** where the extender is absent as 1.214 times, and with the case of FIG. **23** where the extender is present as 2.427 times.

The changeover lever **57** is then further rotated from the state of FIG. **25**. By this operation of the changeover lever **57**, the lever shaft **58** is rotated and the clutch body **62** and the sector **7** are rotated about the rotary shaft **54** through the gear **58***a* and the clutch pin **64**, whereby the shrinker barrel **3** is disposed on the optical axis.

Thereby, as shown in FIG. **26**, the shrinker barrel **3** is positioned on the optical axis. At this time, the mode is a one-to-one magnification mode of the aspect ratio 4:3.

If the mode fixing switch **68** is changed over by a procedure converse to the above-described operation, the mode can be returned to the mode of the aspect ratio 16:9.

In the present invention, design is made such that the changeover shaft of the changeover lever **57** is left of the optical axis as viewed from the camera side, but alternatively, design may be made such that the changeover shaft is right of the optical axis. Also, design may be made such that the shrinker barrel **3** is retracted upwardly and the extender barrel **2** is retracted downwardly.

In the present embodiment, the magnification of the extender has been described as two times, but the extender may be designed at any other magnification. Also, when for a camera having an image pickup element of which the aspect ratio of the image pickup surface is 4:3, the image field of the aspect ratio 16:9 which is an area thereof is to be photographed, a vertical portion of the image field is not used, but the central area of the aspect ratio 16:9 may be used or in this case, the magnification of the shrinker may be changed to 0.917 times, thereby coping with it. Also, even when the aspect ratio differs, a shrinker magnification conforming thereto may likewise be adopted to thereby cope with it.

According to the present invention, as described above, there can be achieved an image pickup apparatus capable of changing over the aspect ratio wherein in a photo-taking system having a converting lens (shrinker) and an extender for the changeover of the aspect ratio, a driving mechanism for effecting the removable insertion of the both lenses into the optical path is appropriately set, whereby the extender or the shrinker may easily or may not be positioned in the optical path and photographing can be effected easily at a predetermined aspect ratio and one-to-one magnification or different magnifications (focal length range).

Particularly, the present invention can cope with a camera with the aspect ratio changeover function which does not give a feeling of physical disorder to any photographer accustomed to the photographing operation of a zoom lens for a prior-art handy camera with an extender and which enables a quick extender operation by the operation of a changeover lever similar to that of the prior art.

Also, after the photographer has once selected an aspect ratio, he can be conscious of only the selection of one-to-one magnification and the extender as in the prior art and therefore, these make it unnecessary for the photographer to newly learn to use the new function of changing over the aspect ratio, and the eclipse of a photographed image which is a mistake absolutely unallowable in photographing can be effectively prevented.

Also, in the photographing in the aspect ratio 4:3 mode, the extender function of the order of 1.2 times can be realized without newly adding any optical system besides the shrinker prepared for one-to-one magnification. Thus, even when during photographing in a dark place, the use of an extender of two times reduces the quantity of light to half and therefore it is difficult to enlarge the focal length, it becomes possible to minimize the reduction in the quantity of light and make the focal length on the telephoto side equal to that of a lens ranking above by one class, and an extender of a little over 2.4 times can be provided and the range of selection can be more widened for the photographer.

What is claimed is:

1. An objective lens for application to an image pickup apparatus of which the size of the image pickup surface is changeable over between a first mode having a first aspect ratio and a second mode having a second aspect ratio, said objective lens comprising:

first optical means for extending the focal length of said objective lens;

second optical means for shrinking the focal length of said objective lens;

an operating member; and

a transmitting mechanism for transmitting the operating force of said operating member to said first optical means under said first mode, and transmitting the operating force of said operating member to said first and second optical means under said second mode;

wherein by the operation of said operating member, under said first mode, said first optical means is removably insertable into the optical path of said objective lens,

and under said second mode, each of said first and second optical means is removably insertable into the optical path of said objective lens.

2. An objective lens according to claim 1, wherein said first optical means is rotatable about a first shaft, said second optical means is rotatable about a second shaft, and said first and second optical means are rotated about said first and second shafts, respectively, whereby they are removably insertable into the optical path of said objective lens.

3. An objective lens according to claim 1, wherein the first aspect ratio is 16:9.

4. An objective lens according to claim 1, wherein the second aspect ratio is 4:3.

5. An objective lens according to claim 1, wherein said transmitting mechanism inhibits the transmission of the operating force of said operating member under said first mode.

6. An objective lens according to claim 2, wherein the center of rotation of said operating member has a rotatable gear thereon, said first and second shafts have a first gear and a second gear, respectively, thereon, the teeth of said rotatable gear and said first gear normally mesh with one another, and under said second mode, said rotatable gear and said second gear mesh with each other.

[57] **ABSTRACT**

A method for recognizing a three-dimensional objective in which a two-dimensional image is obtained from the same viewing point as a distance image obtained by picking up the objective in a three-dimensional space and the two-dimensional image is utilized to previously limit an existence zone of the objective under detection for the distance image and to perform objective detecting operation over the partial distance image in the limited zone, thereby realizing a sufficiently high speed detection of, in particular, the three-dimensional objective.

METHOD OF UTILIZING A TWO-DIMENSIONAL IMAGE FOR DETECTING THE POSITION, POSTURE, AND SHAPE OF A THREE-DIMENSIONAL OBJECTIVE

BACKGROUND OF THE INVENTION

The present invention relates to a method for recognizing an objective in a three-dimensional space and, more particularly, an objective recognition method for detecting the position, attitude or posture and shape of an objective.

DESCRIPTION OF RELATED ART

For recognizing a three-dimensional objective, there have conventionally been suggested a method in which objective position detection is carried out by extracting a cluster in a space of parameters indicative of the positional posture of an objective obtained based on correspondences between all edge segments in an image and all arris or ridge lines of an objective model as disclosed in Japanese Patent Laid-Open Publication No. 2-230478. In another method an objective to be checked is considered to be an objective model comprising a plurality of rigid bodies and joints having degrees of freedom of rotation connected to the bodies. Posture candidates for each of the rigid bodies are found based on correspondences between features (such as designated segments or designated points) in an image and the objective model. An image of the objective image is estimated from the respective posture candidates and collated with the image to thereby determined a suitable posture as disclosed in Japanese Patent Laid-Open Publication No. 4-54409.

In the former method, it is necessary to make correspondences between all the edge segments in the image and all the arris lines of the objective model. Thus, when the target objective has a complicated shape, the number of edge segments in an image and the number of arris lines in an objective model become large, which disadvantageously results in that a lot of time is required for making the correspondences and a detection accuracy becomes bad. Even in the latter method, when an objective has a flexible structure, the numbers of rigid bodies and joints become large. So final detection of the three-dimensional posture of an objective requires lots of time.

Meanwhile, for the purpose of recognizing an objective having such a shape as a cylindrical shape, there is suggested such a method for realizing high-speed detection of an objective as shown in Japanese Patent Laid-Open Publication No. 6-29695. In this method, an objective to be checked is photographed obliquely by two image pick-up means to obtain two images. Curve edges are extracted from the two images, some of the curve edges when located within a predetermined distance range being regarded as edges in an identical elliptical line. The center of a right circle is regarded as photographed as the center of the ellipse in the images. The centers of the upper and lower ellipses are calculated and made associated with each other from the two images. The centers of right circles corresponding to the upper and lower ellipses are calculated based on the trigonometrical survey. The orientation or direction of a line segment connecting the calculated two centers is calculated to find a central line for the cylinder, thereby determining the position and posture of the cylindrical body.

However, this method has a problem that, when it is desired to recognize a ring-shaped objective or a plurality of cylindrical objectives, combinations of curve edges not in an identical circle are erroneously regarded as in the identical circle, and some edges in the lower cylindrical surface

become positioned off the screen, leading to the fact that it becomes impossible to measure the direction of the central line of the cylindrical objective, i.e., its posture. Further, when the center of a circle is projected to an image, the center will be projected as offset from the circle center in the image so long as the plane containing the circle is not perpendicular to the optical axis of the image pick-up means. Furthermore, since nearly half of edges of the lower circle are hidden as unseen, the center accuracy of the circle calculated based on such edges tends to be low. Accordingly, the values of the position and posture thus obtained have been low in accuracy and reliability.

SUMMARY OF THE INVENTION

It is therefore an object of the present invention to provide an objective recognition method for realizing high-speed detection with a high accuracy.

In accordance with an aspect of the present invention, the above objective is attained by providing an objective recognition method which comprises the steps of obtaining a two-dimensional image from the same viewing point as a distance image obtained by photographing an objective in a three-dimensional space, specifying a partial image for the two-dimensional image, applying the specified two-dimensional partial image to the distance image to extract a partial image for the distance image, and subjecting the distance partial image to an objective detecting operation.

In accordance with another aspect of the present invention, there is provided an objective recognition method wherein a two-dimensional image is obtained from the same viewing point as a distance image obtained by photographing an objective in a three-dimensional space, an inertia principal axis and gravity center of a target objective image in the two-dimensional image, the distance image is projected onto a plane passing through the inertia principal axis and perpendicular to the two-dimensional image, an inertia principal axis and gravity center of a target objective image in a projected plane, and a position and posture of an inertia principal axis of the target objective in the three-dimensional space is detected from the 2 obtained inertia principal axes and the 2 obtained gravity centers.

In accordance with yet a further aspect of the present invention, there is provided an objective recognition method wherein an edge image and an intensity gradient direction image are obtained from gray images obtained by photographing an objective having a circular shape in a three-dimensional space from a plurality of directions, an edge image as a reference is created through stereo image processing and a disparity image is created from the reference image and the other edge image, only curved edges are extracted from the reference edge image, a circle is extracted from the curved edges, and a position and posture of the extracted circle are detected with use of three-dimensional information found from the disparity of edge points of the extracted circle.

In the present invention, in the objective detecting operation, the two-dimensional image is utilized to previously restrict the existence zone of the objective under detection in the distance image, and the objective detecting operation is carried out over the distance partial image of the restricted zone. Thus, the present invention can realize the high-speed detecting operation when compared to the prior art wherein detecting operation is carried out over all zones of the distance image. In this case, the specification of the partial image of the two-dimensional image may be carried out on the basis of the shape pattern of the surface of the

target objective, the statistical image feature of texture, the color or brightness classification, or the two-dimensional geometrical feature derived from the three-dimensional geometrical feature of the target objective.

While the present invention is susceptible of various modifications and alternative constructions, certain illustrated embodiments hereof have been shown in the drawings and will be described below in detail. It should be understood, however, that there is no intention to limit the invention to specific forms disclosed, but on the contrary, the intention is to cover all modifications, alternative constructions and equivalents falling within the spirit and scope of the invention.

BRIEF EXPLANATION OF THE DRAWINGS

These and other features of the present invention will become apparent from the following description, with reference to the accompanying drawings, in which:

FIG. **1** is a flowchart for explaining the operation of an embodiment of a system of the present invention;

FIG. **2** is a block diagram of the system of the embodiment of FIG. **1**;

FIG. **3** is a perspective view of an example of objectives under detection in the embodiment of FIG. **1**;

FIG. **4***a* is a diagram for explaining a two-dimensional image of the exemplary objectives in the embodiment of FIG. **1**;

FIG. **4***b* is a diagram for explaining a distance image of the exemplary objectives in the embodiment of FIG. **1**;

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

The present invention will be detailed in connection with illustrated embodiments. First and second features of the present invention involving using a distance image and a two-dimensional image photographed from the same viewing point as the distance image. Though there are various ways of creating the distance image, explanation will be made in connection with a case where the distance image is created from a stereoscopic image, i.e., from two-dimensional images. In FIG. **2**, reference symbols **10***a* and **10***b* denote television cameras for capturing stereo images. An image photographed by one **10***a* of the television cameras **10***a* and **10***b* connected to a two-dimensional image memory **4** is used as a stereo reference image. Images photographed by the television cameras **10***a* and **10***b* are associated with each other in a stereo image processor **2**, and distances calculated based on the associated result are mapped onto the stereo reference image to generate a distance image in a three-dimensional image generator **3**. The two-dimensional image acquired by one television camera **10***a* is stored in the two-dimensional image memory **4**. An objective existence zone extractor **5**, on the basis of the two-dimensional image and distance image, extracts an objective existence zone in which the objective is present, and a three-dimensional position/posture detector **6** detects a three-dimensional position or posture of the objective based on the objective existence zone and the distance image in its vicinity.

FIG. **3** shows an example of objectives to be detected, FIG. **4***a* is a two-dimensional image I2 of the exemplary objectives, and FIG. **4***b* is a distance image I3 thereof. Areas which are differently hatched in the distance image I3 stand for different heights of the objectives. This representation is also applied to cases which will be described later.

Explanation will first be made as to how to extract an objective existence zone using a shape pattern present on a surface of an objective under detection undetectable from the distance image. The extraction of an objective existence

zone by the objective existence zone extractor **5** is carried out by means of pattern matching in the case of FIG. **5**. For example, when a letter "B" is present on a surface of an objective under detection, the letter "B" is used as a detection pattern. Pattern matching is carried out between the two-dimensional image **I2** and the detection pattern to extract a part corresponding to a matching score equal to or larger than a threshold value and to use as an objective existence zone **A1** a zone including the extracted part and covering a circle having a center corresponding to a gravity center **G1** of the extracted part as shown in FIG. **6**. An objective detecting operation is carried out over a partial image of the distance image **I3** corresponding to the objective existence zone **A1**. This objective detecting operation may be realized not only by the two methods already explained in connection with the prior art but also by another method which will be explained later.

For setting the objective existence zone **A2**, as shown in FIGS. **7** and **8**, edges may be extracted from the two-dimensional image **I2**, a part corresponding to an edge intensity equal to or larger than a threshold value may be extracted, an objective existence zone **A2** having a center corresponding to a gravity center **G2** of the extracted part may be set, and objective detecting operation may be carried out over a partial image of the distance image **I3** corresponding to the objective existence zone **A2**. This objective detecting operation utilizes the fact that differences in the statistical image features of the objective texture appear as different edge densities in the two-dimensional image **I2**.

When only one of a plurality of rectangular parallelopipeds located in their center is red in color and the other rectangular parallelopipeds are blue, as shown in FIG. **9**, color extraction (red extraction in the illustrated example) may be carried out from the two-dimensional image **I2** to extract a part having a red component equal to or larger than a threshold value. And as shown in FIG. **10**, an objective existence zone **A3** having a center corresponding to a gravity center **G3** of the extracted part may be set and objective detecting operation may be performed over a partial image of the distance image **I3** corresponding to the objective existence zone **A3**. It goes without saying that a specific part may be extracted based on its brightness in place of the color. In this case, it will be noted that an objective existence zone is set on the basis of an extracted part of a two-dimensional image having a target component equal to or larger than its threshold value and an image corresponding to the set zone is used as a partial image of the two-dimensional image.

In addition to the above, the existence zone of an objective under detection may be previously limited by utilizing two-dimensional geometrical features derived from three-dimensional geometrical features. FIG. **11** shows a case where a two-dimensional geometrical feature comprised of two straight lines connected in the form of a letter T is utilized. More specifically, first, an objective **120** shown in FIG. **12** is photographed to obtain such a two-dimensional image **I2** as shown in FIG. **13***a* and such a distance image **I3** as shown in FIG. **13***b*. In this case, a two-dimensional geometrical feature appears as such a T-shape connection of two straight lines as shown by a reference numeral **130**. Next, edges are extracted from the two-dimensional image **I2** and subjected to a Hough transform to detect straight lines, an intersection point of the detected lines is extracted, the presence or absence of a T-shaped connection is judged, whereby an intersection point **G4** in the T-shaped connection is extracted as shown in FIG. **14**. And a zone having a predetermined range and having a center corresponding to the intersection point **G4** of the T-shaped connection is applied to a distance image **I3** to detect a three-dimensional position or posture of the objective from a distance partial image.

As shown in FIGS. **15** and **16**, an inertia principal axis **EA1** and a gravity center **G5** are detected from the two-dimensional image **I2**, and the distance image **I3** is projected onto a plane P passing through the Inertia principal axis **EA1** and perpendicular to the two-dimensional image **I2**. When an inertia principal axis **EA2** and a gravity center **G6** are detected from the projected image as shown in FIG. **17**, the posture of the inertia principal axis can be detected from the two inertia principal axes **EA1** and **EA2** and the position of the inertia principal axis can be detected from the gravity centers **G5** and **G6**.

Further, as shown in FIG. **18**, after the posture and position of the inertia principal axis are detected as mentioned above, an inertia principal axis and gravity center for the objective model are found and made to coincide with the posture and position of the detected inertia principal axis, the objective model is rotated on the inertia principal axis to find a coincidence or matching degree between the objective model and target objective, and a three-dimensional position and posture of the objective can be detected on the basis of the position and posture of the target model when the matching degree becomes maximum. In this case, since the position and posture of the inertia principle axis representative of the position and posture of the objective in the three-dimensional space are used as fixed references, that is, since 5 of 6 degrees of freedom of the objective in the three-dimensional space are restricted, the position and posture of the objective in the three-dimensional space can be accurately detected at a high speed.

As will be seen from a two-dimensional image **I2** shown in FIG. **20***a* and from a distance image **I3** shown in FIG. **20***b*, when a plurality of such objectives as shown in FIG. **12** are piled, a predicted height of an existence position of an objective to be detected is set as a pre-processing, a zone higher than the predicted height is extracted from the distance image **I3** (see FIG. **21***a*), and a zone having the same position as in the image is extracted from the two-dimensional image **I2** (see FIG. **21***b*), as shown in FIG. **19**. Thereafter, the zone restricted by the predicted height references of a two-dimensional image **I2'** and distance image **I3'** is subjected to such processing as mentioned above (in the illustrated example, which is the same as the processing shown in FIG. **11**) to detect a three-dimensional position and posture of the objective.

Such a three-dimensional objective recognition method can be applied to objective inspection situations. For example, FIG. **23** shows a case where a rectangular column **8** is inserted into a square hole **70** of a base **2** and it is desired to examine whether or not the rectangular column **8** was inserted in the square hole perpendicularly (θ=90°) to the base **2**. FIG. **22** shows a flowchart for explaining the operation when the aforementioned pattern matching is employed. That is, such a two-dimensional image **I2** as shown in FIG. **24***a* and such a distance image **I3** as shown in FIG. **24***b* are obtained from stereo images of two television cameras. In more detail, a circle **80** (which may be replaced by an opening or a screw hole) on the top surface of the rectangular column **8** is used as a detection pattern, an objective existence zone is restricted in a similar way to the foregoing embodiment, and then a position and posture of the rectangular column **8** in the three-dimensional space are detected. On the basis of the detection result, a tilt θ of the rectangular column **8** is found to judge whether the inserted state is good or not.

FIGS. **25** to **28** show an example of a detection method in which a position and posture of an objective are detected based on a distance partial image extracted by utilizing the aforementioned texture. More specifically, when such an objective **8** as shown in FIG. **26** is present, a partial image corresponding to the top surface of the objective **8** is extracted from a distance image obtained by photographing the objective **8** and based on the texture, and three-dimensional information obtained from the partial image is applied to find a plane Pa containing the top surface of the objective **8** in the three-dimensional space as shown in FIG. **27**. The plane Pa can be obtained by calculating coefficients a, b and c in the following equation by the least squares method.

$$ax+by+cz+1=0$$

Next, as shown in FIG. **27**, three-dimensional positions of points on the top surface of the objective are rotated on an origin Po of a camera image coordinate system so that a normal Paz of the plane Pa coincides with a Z axis of the image coordinate system as shown in FIG. **28***a*, and the positions are then projected onto a plane (in this case, an X-Y plane Pxy of the above image coordinate system) of a reference coordinate system with use of x and y coordinate values of the points on the top surface of the objective after rotated. A projected image thus obtained and a previously-registered template image M (such as shown in FIG. **28***b*) are subjected to a pattern matching therebetween to find a position and posture of the objective of the projected image. The found objective position is subjected to an inverse transformation to find a position and posture of the top surface of the objective before the above rotation. In order to detect the position and posture of the objective on the two-dimensional image, the pattern matching with the template image has been employed in the illustrated example, but it goes without saying that another method such as a generalized Hough transform can be employed.

In the foregoing embodiment, the two-dimensional image has been obtained from the same viewing point as the distance image obtained by picking up the objective in the three-dimensional space, the zone to be subjected to the detecting operation of the position and posture of the target objective has been extracted and restricted, and the inertia principal axis and gravity center of the target objective have been extracted on the basis of two-dimensional image. However, when he target objective has such a shape as a circular cylinder, a circular part is extracted by utilizing an edge image, and a position, posture and radius of the circle are measured to realize higher speed recognition of the objective.

In this case, such a system as shown in FIG. **29** comprises two cameras **11** and **12** for photographing an objective **18** illuminated by an illuminator **19**, A/D converters **13** and **14** for converting analog image signals from the both cameras **11** and **12** into digital image signals, frame memories **15** and **16** for storing the digital image signals therein, and a processor **17** connected to the frame memories **15** and **16**. With this system, parallel stereo conversion is carried out through the stereo image processing of an edge image, that is, the two cameras **11** and **12** are matched in their orientation and focal distance, the image signals are converted into images so that the corresponding pixels of the two images coincide with each other in the Y coordinate value to thereby realize efficient corresponding point search, and a disparity corresponding to a difference between the X coordinate values of the two calculated images is photographed by the camera **11** and mapped onto an extracted edge image (stereo reference image) to create a disparity image. When a distance image is required, conversion from disparity to distance is added. For example, in the case where circular cylindrical objectives **18***a*, **18***b* and **18***c* having different heights are located as shown in FIG. **30**, when the objectives are photographed from their upper side by the two cameras, such an edge image IE for the stereo reference image as shown in FIG. **31***a* and such a disparity image ID as shown in FIG. **31***b* are obtained. In FIG. **31***b*, a thicker line indicates a higher objective.

The images stored in the frame memories **15** and **16** through the image acquisition are subjected to the parallel stereo conversion to obtain an edge image and a gradient direction image based on the converted image. In order to extract edges from the images, a Sobel operator as shown in FIG. **71** is used. Upon application of this operator, the center of the operator is moved to a target pixel, the intensity values of pixels adjacent to the target pixel are multiplied by the values of the operator, whereby gradient magnitudes Gx and Gy in the X and Y directions, gradient intensity |G| and gradient direction θ are calculated with respect to all the pixels. When I(x,y) denotes the intensity of a pixel at a coordinate point [x,y], the gradient magnitudes Gx and Gy in the X and Y directions are expressed by the following equations.

$$Gx(x,y)=\{I(x+1,y-1)+2I(x+1,y)+I(x+1,y+1)\}-\{I(x-1,y-1)+2I(x-1,y)+I(x-1,y+1)\}$$

$$Gy(x,y)=\{I(x-1,y-1)+2I(x,y-1)+I(x+1,y-1)\}-\{I(x-1,y+1)+2I(x,y+1)+I(x+1,y+1)\}$$

Using Gx and Gy, the gradient intensity |G| and the gradient direction θ at each pixel position are found as follows. Images of pixels having such values are referred to as gradient intensity image and gradient direction image, respectively.

$$|G|=(Gx^2+Gy^2)^{1/2}$$

$$\theta=\tan^{-1}(Gy/Gx)$$

After a threshold value is provided for the value of the gradient intensity |G| and the gradient intensities for pixels having gradient intensities lower than the threshold value are set at 0, points having the highest gradient intensities in the vicinity, i.e., the gradient intensities in the form of a ridge line are extracted as edge points, such an edge image IE as shown in FIG. **32***a* is obtained. And only curved components **321** and **322** are extracted from the edge image of the stereo reference image as shown in FIG. **32***b*, and a circular component **322** is extracted from the extracted curved components as shown in FIG. **32***c*.

A disparity is calculated in the aforementioned manner on the basis of the two stereo edge images through the stereo image processing, the calculated disparity is mapped onto the edge image of the stereo reference image to create a disparities image, three-dimensional positions at points on the circular edge are calculated from the corresponding parts of the circular disparities image extracted in the aforementioned manner, and a central position and posture of a circle of the top surface of the circular cylindrical objective **18** are measured based on the calculated three-dimensional position information to thereby recognize a position and posture of the objective **18**.

The extraction of only the curved components from the edge image of the stereo reference image can be carried out,

for example, by extracting straight lines through Hough transform and by erasing edges present within a predetermined distance from the extracted straight lines. Explanation will be made as to the case where three types of such objectives **18***a*. **18***b* and **18***c* as shown in FIG. **35** are conveyed along a conveyor **92** and the target objective **18** is one of three types of such objectives, and as to how to select the target objective from the three types of objectives. As shown in FIG. **37**, an edge image is created through parallel stereo conversion and creation of a gradient magnitude image and a gradient direction image. In this case, a camera **11** for photographing an image to be used as a stereo reference image acquires the image of the objective **18** nearly right from its top, whereupon such an edge image as shown in FIG. **36***a* is obtained. When the edge image is subjected to a Hough transform to extract straight lines therefrom and edges present within a predetermined distance from extracted straight lines **126** and **127** are erased, edges **122** to **125** resulting from the conveyor **92** can be erased. Thus only a circular edge **121** of the top surface of the objective **18** can be extracted. And when three-dimensional positions at points on the circular edge are calculated from the disparity of the extracted circle and when a central position and radius of the circle of the top surface of the objective **18** are measured from the calculated three-dimensional position information, the objective **18** can be specified as one of the three types of objectives shown in FIG. **35** on the basis of the measured central position (height) and radius.

Meanwhile, when the circular cylindrical objectives **18**, **18***a*, **18***b* and **18***c* have straight line components in the edges of their top surface as shown in FIGS. **38** and **39**, mere erasing of edges present within a predetermined distance from the extracted straight lines also causes part of curved lines to be erased. To avoid such disadvantage, as shown in FIGS. **40** and **41**, it is arranged to erase edges which are present within a predetermined distance from extracted straight lines **177**, **178**, **179**, **17***a*, **17***b* and **17***c* and which have values within a predetermined value from 90° in the angle between their gradient direction and straight line direction vector. This enables realization of erasure of straight line edges while preventing partial erasing of a circular edge **171** as shown in FIG. **40***b*.

The erasure of straight line components from the edge image while leaving curve components may be realized by such a method as shown in FIGS. **42** to **45**. That is, edge points are found from an edge image of a stereo reference image for storage, points surrounded by a found target edge point **201** are searched clockwise from its right side to find the presence of another edge point as shown in FIG. **43***a*, storing operation of an edge point which gradient direction is different from the gradient direction of the previously-stored edge point **201** by a predetermined value or less as the next target edge point is continued, in the presence of the edge point, until no edge point is found at the points around the target edge point **201**. When the number of such edge points stored exceeds a predetermined value, such edge points are assembled into edge groups **431** to **435** as shown in FIG. **43***b*. For each edge group, as shown in FIG. **44**, an angle **224** made between a segment connecting an edge start point **221** and a middle point **222** and a segment connecting the edge start point **221** and an end point **223** is examined so that, when only such an edge that has the angle exceeding a predetermined value is left, only curved edges **431**, **434** and **435** can be extracted as shown in FIG. **45***a* and such circular edges **434** and **435** as shown in FIG. **45***b* can be extracted from the edges of FIG. **45***a*.

The extraction of circular edges from curved edges may be carried out in the following manner. First, a method shown in FIG. **46** utilizes the fact that the objective **18** has in its lower side substantially no corresponding parts in its left and right side images and thus its disparity detection ratio becomes considerably low. When the calculated disparities of curved edges **261**, **262** and **263** are examined from such an edge image having only curved edges as shown in FIG. **47***a*, the curved edges **262** and **263** are almost calculated in their disparity as shown by a binary image of edge points with the disparities calculated in FIG. **47***b*. Since the curved edge **261** has no corresponding parts in the left and right side images and its disparity is not calculated yet, when curved edges whose already-calculated disparity ratios are smaller than a predetermined value are deleted, the curved edge **261** is deleted, which results in that only the curved edges **262** and **263** on the top surface of the objective can remain left as shown in FIG. **47***c*, from which the edges **262** and **263** can be extracted to form a circle.

When the objective **18** has such a ring shape as shown in FIG. **49**, since the top surface of the objective has two circular edges, only one (the outer circular edge in FIG. **49**) of the circular edges is extracted. More specifically, an edge image IE for the objective **18** is as shown in FIG. **50***a* and, when straight line components are erased from the edge image, such an edge image IE2 as shown in FIG. **50***b* is obtained. When the objective **18** is seen bright on the background, and a gradient direction **335** of an edge **331** for the outer ring is directed inwardly of the circle while a gradient direction **336** of an edge **332** for the outer ring is directed outwardly of the circle as shown in FIG. **51**, coefficients a and b and constant r can be found by the least squares method in accordance with a right-circle application equation which follows.

$$X^2+Y^2+ax+by+r=0$$

When the right-circle application equation is applied to the single edge **332** of the top surface to calculate a center (−a/2,−b/2) **334** of the circle, any one **339** of points of the right-circle edge is selected, a direction toward the calculated center **334** of the circle from the selected point **339** is found, and such an edge of the top surface is extracted that a difference between the direction **338** and the gradient direction **336** of the selected point is a predetermined value (90 °) or less. Even with respect to edges **331**, **33***a*, **33***b*, **33***c*, **33***d*, **33***e* and **33***f* of the top surface other than the edge **332**, when the aforementioned operation is carried out to calculate a difference between the direction of gradient of a point of each edge and the direction from the point toward the center of the right circle, and when edges of the top surface having such differences of a predetermined value (90°) or less are extracted, such an edge image IE3 of a stereo reference image with the inner-side circular edges **332**, **33***a*, **33***c* and **33***e* removed as shown in FIG. **50***c* can be obtained. In this connection, when the predetermined value for the difference is selected to be higher than 90°, the outer-side circular edges **331**, **33***b*, **33***d* and **33***f* are erased while the inner-side circular edges **332**, **33***a*, **33***c* and **33***e* are left.

An embodiment of FIG. **52** is designed so that, when such circular cylindrical objectives **18** as shown in FIG. **53** are piled and thus its edge image IE is as shown in FIG. **54***a*, a highest-level one of the piled objectives is detected to measure its position and posture. Among a plurality of curved edges present in the edge image, an edge having the maximum disparity because of its highest-level location is selected and the selected edge is set to be a reference edge

381 as shown in FIG. 54*a*, and it is examined whether or not the reference edge 381 forms part of a circle. When the reference edge cannot be regarded as part of the circle, the edge having a disparity larger next to the edge 381 is selected as a reference edge and it is examined whether or not the edge forms part of the circle. The above operation is repeated until the reference edge capable of forming part of the circle is found. Thereafter, the other edges are denoted by reference numerals 382, 383, . . . in an increasing order of the distance from the reference edge 381 and it is examined in the above numeral order whether or not the other edges form part of the same circle. Those of the edges judged to form part of the same circle as the reference edge are contained in the same group as the reference edge. Such processing is also carried out over other edges having distances of a predetermined value or less from the reference edge so that edges 381. 383. 384 and 386 having the same circle are assembled as shown in FIG. 54*b*, on the basis of which a position and posture of the highest-level objective 18 can be detected.

In an embodiment of FIG. 55, an edge having the largest disparity due to the highest-level location of the target objective is selected from the edge image of FIG. 54*a*. The selected edge is used as a reference edge 381, and the other edges are denoted by reference numerals 382, 383, . . . in an increasing order of the distance from the reference edge 381. Thereafter, coefficients a, b, h, g and f are found by the least squares method in accordance with an equation (to be applied to ellipse) which follows.

$$ax^2+by^2+2hxy+2gx+2fy=1$$

An ellipse is applied to the reference edge 381 to calculate its center coordinate point (xo,yo). As shown in FIG. 56, a straight line 413 passing through a point 417 of the reference edge and a center 412 of an ellipse 411 intersects the ellipse at two intersection points 414 and 415, and, when a distance 416 of one 414 of the two intersection points closer to the edge point 417 therefrom exceeds a predetermined value at any points of the reference edge, the reference edge is not regarded as a circle component and a next reference edge is arbitrarily selected. When the distance does not exceed the predetermined value, on the other hand, the reference edge is regarded as a circle component, the reference edge 381 is combined with the edge 382 in the vicinity thereof, and the coefficients a, b, h, g and f are found in the above equation by the least squares method, whereby the ellipse is applied to the reference edge to calculate its center coordinate point (xo,yo). And distances between the points of the reference edge 381 and edge 382 in its vicinity and the found ellipse are found. When the found distances are all less than a predetermined value, the reference edge 381 and the edge 382 in its vicinity are judged to form part of the same circle. When even a single one of the distances is not less than the predetermined value, the edges are judged not to form part of the same circle and the reference edge 381 is combined with the next edge 383 in its vicinity to perform the aforementioned operation. When a series of operations is repeated until edges to be combined become null, edges belonging to the same circle can be combined into one. In this conjunction, the center coordinate point (xo,yo) of the above ellipse is expressed as follows.

$$xo=(hf/bg)/(ab-h^2)$$

$$yo=(hg/af)/(ab-h^2)$$

An embodiment shown in FIG. 57 is also intended to detect a highest-level one of a plurality of circular cylindrical objectives 18 piled as shown in FIG. 58. FIG. 59*a* shows an edge image IE of such objectives of FIG. 58. In FIG. 59*a*, a reference edge 441 corresponds to the highest-level edge having the maximum disparity. In this case, according to the method of the above embodiment, when the edge 442 to be detected as part of the same circle as the reference edge 441 cannot be detected due to the tilted objective or the like, it may be erroneously judged that the edge 443 is to be combined with the reference edge 441. In the illustrated example, in order to avoid such error, when the reference edge 441 and the edge 443 are judged to form part of the same circle according to the method of the above embodiment, final judgement of the same circle is carried out only when a difference is within a predetermined range between the direction of a normal of a plane 453 made with use of three-dimensional information found based on the disparity of any two points of the reference edge 441 and any one point of the other edge 443 and the direction of a normal of a plane 454 made with use of three-dimensional information found based on the disparity of any two points of the edge 443 and any one point of the reference edge 441 except for the selected two points, as shown in FIG. 60. Through the above operation, the circular edge 441 of the top surface of the highest-level objective can be extracted as shown in FIG. 59*b*.

Explanation will be directed to the operation after the extraction of the circular edges of the top surface of the circular cylindrical objective. In an embodiment of FIGS. 61 to 63, as in the case of FIG. 25, three-dimensional positions of points are calculated based on the disparity of the extracted circle edges, and coefficients a, b and c are calculated by the least squares method in accordance with the following equation (to be applied to plane).

$$ax+by+cz+1=0$$

Then, a plane Pa containing the top surface of the objective 18 is found as shown in FIG. 62, three-dimensional positions of points in the top surface of the objective are rotated on an origin po of a camera coordinate system so that a normal Paz of the plane Pa coincides with the Z axis of the camera coordinate system as shown in FIG. 63, and coefficients a, b and constant r are found by the least squares method in accordance with the following equation (to be applied to right circle) to calculate a center position 491 and radius 492 of the right circle after the rotation.

$$x^2+y^2+ax+by+r=0$$

In the illustrated example, the camera coordinate system is employed as a reference coordinate system. A center position 486 of the right circle of the top surface of the objective 18 is calculated through inverse transformation (to before the rotation) of the center position 491 of the calculated right circle to obtain a position, posture and radius of the objective 18. In the calculation of the right circle after the coordinate system rotation, coefficients a, b, h, g and f are found in the above ellipse application equation by the least squares method and conversion to a standard ellipse is carried out to obtain a position and posture of the elliptical cylinder as well as a major and minor radii thereof.

In an embodiment of FIG. 64, three-dimensional positions of points on the top surface of the objective are rotated on the origin po of the above image coordinate system as

mentioned above so that the normal Paz of the plane Pa coincides with the Z axis of the coordinate system, after which certain edge points are removed so that a distance **493** (difference from the Z coordinate value) of the found plane Pa from the edge points of the circle after the rotation in the three-dimensional space exceeds a predetermined value. With use of the x and y coordinate values of edge points of the top surface of the objective **18** after the rotation except for the above edge points, coefficients a and b and constant r are found by the least squares method in accordance with the right-circle application equation to calculate a center position **491** and radius **492** of the right circle after the rotation. In this connection, the camera coordinate system is used as a reference coordinate system. And a center position **486** of the right circle of the top surface of the objective **18** is calculated through inverse transformation (to before the rotation) of the center position **491** of the calculated right circle to obtain a position, posture and radius of the objective **18** after the coordinate system rotation. In the calculation of the right circle after the coordinate system rotation, further, coefficients a, b, h, g and f are found by the least squares method in accordance with the aforementioned ellipse application equation; and a position and posture of the elliptical cylinder as well as a major and minor radii thereof are obtained through conversion to standard ellipse.

In an embodiment of FIG. **65**, three-dimensional positions of points on the top surface of the objective are rotated on the origin po of the above image coordinate system as mentioned above so that the normal Paz of the plane Pa coincides with the Z axis of the coordinate system, after which certain points are so removed that a distance (difference from the Z coordinate value) of the found plane Pa from the edge points of the circle after the rotation in the three-dimensional space exceeds a predetermined value, a plane Pa in the three-dimensional space containing the edge of the top surface of the circular cylindrical objective **18** is again found by the least squares method, and three-dimensional positions of points of the top surface of the objective are rotated on the origin po of the camera coordinate system so that the normal Paz of the found plane Pa coincides with the Z axis of the coordinate system. Thereafter, with use of the x and y coordinate values of edge points of the top surface of the objective **18** after the rotation except for the above edge points, coefficients a and b and constant r are found by the least squares method in accordance with the right-circle application equation to calculate a center position **491** and radius **492** of the right circle after the rotation. And a center position **486** of the right circle of the top surface of the objective **18** is calculated through inverse transformation before the rotation) of the center position **491** of the calculated right circle to obtain a position, posture and radius of the objective **18** after the coordinate system rotation. Even in this case, in the calculation of the right circle after the coordinate system rotation, further, coefficients a, b, h, g and f are found by the least squares method in accordance with the aforementioned ellipse application equation, and a position and posture of the elliptical cylinder as well as a major and minor radii thereof are obtained through conversion to standard ellipse.

In an embodiment of FIG. **66**, three-dimensional positions of points are calculated based on the disparity of the extracted circle edges as mentioned above, and coefficients a, b and c are calculated by the least squares method in accordance with the aforementioned plane applying equation to find a plane Pa containing the top surface of the objective **18**. Further, as shown in FIG. **67**, a sphere **531** containing the right circle of the top surface of an objective **18** in a three-dimensional space is found by the least squares method. When a sphere is applied, since the right circle of the top surface is present on the same plane, the sphere is not uniquely determined. However, the center of the sphere is restricted to the extent that the center is present on a straight line perpendicular to the above plane Pa and passing through the center of the right circle present on the plane. Further, since the found sphere may be any sphere so long as its radius is larger than the right circle of the top surface and the sphere contains the right circle of the top surface, when any one value of any one of center coordinate axes of the sphere is fixed, the sphere can be determined. In the present embodiment, the Z coordinate value of the center of the sphere was fixed to a Z coordinate value c_o different by more than the radius of the right circle from the Z coordinate values of the objective existence zone. In other words, an equation for the sphere was expressed as follows to find coefficients a and b and constant R by the least squares method.

$$x^2+y^2+z^2+ax+by-2c_oz+R=0$$

A center **533** of the right circle of the top surface of the circular cylindrical objective **18** is found by calculating an intersection point between the plane Pa and a straight line passing through a center **532** of the sphere and having the same direction vector as a normal vector **537** of the plane Pa. A radius **534** is found by subtracting a square of a distance **536** between the center of the sphere and the center of the right circle from a square of a radius **535** of the sphere to find a subtraction and then by finding a square root of the subtraction. Accordingly, even in this case, a position, posture and radius of the objective **18** can be found.

An embodiment of FIGS. **68** to **70** shows an example where the present invention is applied to automatic assembling work. More in detail, as shown in FIG. **69**, when it is desired to assemble a part **541** having two holes and a part **542** having two projections by means of robot, positions and posture of the holes and projections are detected to detect positions and postures of the parts **541** and **542**.

More specifically, an edge image IE (see FIG. **70***a*) of a stereo reference image, a gradient direction image and a disparity image are created and curved edges are extracted from the edge image. That is, such 4 circular edges **701** to **704** as shown in FIG. **70***b* are extracted. When the direction of a segment connecting the middle point and centers of corresponding 4 circles **543** to **546** in a three-dimensional space as well as the direction of a normal of a plane defined by the 2 circles are calculated from the 4 circle edges, the position and posture of the part **542** having the two projections are determined. When the similar operation is carried out for the remaining 2 circles, the position and posture of the part having the two holes are determined.

In accordance with the present invention, as has been explained in the foregoing, a two-dimensional image is obtained from the same viewing point as a distance image obtained by photographing an objective in a three-dimensional space, a partial image in the two-dimensional image is specified, the specified two-dimensional partial image is applied to the distance image to extract a partial image from the distance image, and objective detecting operation is carried out over the distance partial image. That is, upon the objective detecting operation, an existence zone of the objective under detection in the distance image is previously restricted by utilizing the two-dimensional image, and the objective detecting operation is carried out over a distance partial image of the restricted zone. As a

result, it will be appreciated that the present invention can realize a relatively high detecting operation when compared with the prior art for performing detecting operation over all the zones of the distance image.

What is claimed is:

1. A method for detecting a position, posture and shape of an objective, the method comprising the steps of:

obtaining a two-dimensional image of the objective from the same viewing point as a distance image obtained by photographing the objective in a three-dimensional space;

specifying a partial image in the two-dimensional image;

extracting a partial image of a distance image at a position corresponding to the position of the specified partial image of the two-dimensional image; and

subjecting the partial image of the distance image to an objective detecting operation.

2. The objective recognition method as set forth in claim 1, wherein the step of specifying the partial image for the two-dimensional image is carried out based on shape pattern.

3. The objective recognition method as set forth in claim 1, wherein the step of specifying the partial image for the two-dimensional image is carried out based on statistical image features of texture.

4. The objective recognition method as set forth in claim 1, wherein the step of specifying the partial image for the two-dimensional image is carried out based on color or brightness.

5. The objective recognition method as set forth in claim 1, wherein the step of specifying the partial image for the two-dimensional image is carried out based on two-dimensional geometrical feature derived from three-dimensional geometrical feature of the target objective.

6. The objective recognition method as set forth in claim 1, wherein, as a pre-processing, a specific zone indicative of a specified height is extracted from the distance image and the partial image is specified from a two-dimensional image for the specified zone.

7. The objective recognition method as set forth in claim 1, wherein, upon objective detecting operation, three-dimensional information obtained from a distance partial image is applied to a plane, the three-dimensional information is rotated on an origin of a camera coordinate system to cause a normal of the plane to coincide with a Z axis of the camera coordinate system, the three-dimensional information after the rotation is projected onto an X-Y plane of the coordinate system, a projected image is collated with a previously-registered model to find a temporary position and posture of the target objective, the temporary position and posture are subjected to an inverse transformation to calculate a position and posture of the target objective before the rotation.

8. An objective recognition method comprising the steps of:

obtaining a two-dimensional image from the same viewing point as a distance image obtained by photographing an objective in a three-dimensional space;

specifying a partial image for the two-dimensional image;

applying the specified two-dimensional partial image to the distance image to extract a partial image for the distance image; and

subjecting the distance partial image to an objective detecting operation, wherein three-dimensional information obtained from the distance partial image is applied to a plane, the three-dimensional information is rotated on an origin of a camera coordinate system to cause a normal of the plane to coincide with a Z axis of the camera coordinate system, the three-dimensional information is then projected onto an X-Y plane of the coordinate system, a projected image is collated with a previously-registered model to find a temporary position and posture of the target objective, the temporary position and posture are subjected to an inverse transformation to calculate a position and posture of the target objective before the rotation.

[57] **ABSTRACT**

An objective lens device comprising in order from the lens closest to an object side, a negative meniscus first lens whose concave side faces the object side; a positive second lens; a positive meniscus third lens whose convex side faces an image side; a negative meniscus fourth lens whose concave side faces the object side; a negative meniscus fifth lens whose convex side faces the object side; and a positive sixth lens. The fifth and sixth lenses are cemented together to form a cemented lens subunit. The objective lens device contains six lenses in its entire lens structure, has a long back focus, and provides excellent optical properties over an entire field.

OBJECTIVE LENS DEVICE

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to an objective lens device with a photographic field angle of about 45 degrees and an f-number of about 2.8, and, more particularly, to a retrofocusing type objective lens device suitable for use in a small camera utilizing a solid-state image pick-up device, having a long back focus, and good optical properties over an entire field.

2. Description of the Related Art

In recent years, the production of smaller cameras such as video cameras utilizing a solid-state image pickup device has caused a demand for smaller and brighter objective lens devices. In such cameras, it is necessary to dispose various optical members, such as lowpass filters or color-correcting filters, between the rearmost portion of the lens device and image pickup device. Therefore, objective lens devices need to have a relatively long back focus. In the case of cameras utilizing a color image pickup device, it is desirable that they provide excellent telecentric properties at an image side in order to prevent color shading.

Hitherto, wide angle lens devices as objective lens devices utilizing 6 to 7 lenses in their lens structure and having a long back focus have been disclosed, for example, in Japanese Patent Laid-Open Nos. 54-151442, 55-45007, and 56-22406. Objective lens devices have also been disclosed, for example, in Japanese Patent Laid-Open No. 1-214812 and U.S. Pat. No. 3,297,394, in which aberrations are corrected by a negative meniscus lens whose convex side faces an object, or by a cemented lens subunit. These objective lens devices are designed primarily for 35-mm film cameras, so that these lens devices cannot be regarded as satisfactory objective lens devices utilizing a solid-state image pickup device because they do not have a sufficiently long back focus and sufficient telecentric properties.

Objective lens devices with a simple lens construction and having sufficiently long and satisfactory telecentric properties have been disclosed, for example, in Japanese Patent Laid-Open Nos. 64-61714, 61-123810, and 63-81309. The objective lens devices disclosed in Japanese Patent Laid-Open Nos. 64-61714 and 61-123810 are wide angle objective lens devices, and the objective lens device disclosed in Japanese Patent Laid-Open No. 63-81309 is a standard angle objective lens device. Japanese Patent Publication No. 58-40166 discloses a retrofocusing type telecentric lens system having a back focus that is longer than the focal distance.

Generally, in order for the back focus to be long, it is desirable to construct the lens system into a retrofocusing type lens system in which the front lens unit has a strong negative refractive power and the rear lens unit has a positive refractive power. However, various aberrations, such as spherical aberration, coma, distortion, astigmatism, etc. occur more frequently because the entire lens system becomes asymmetrical when it is a retrofocusing type, and the absolute value of the negative refractive power of the front lens unit must be made larger in order for the back focus to be long. This has made it extremely difficult to correct each of the various aberrations satisfactorily.

Attempting to obtain a sufficiently long back focus results in such problems as a longer overall length of the objective lens device and a larger diameter of the front lens unit.

In addition, for an objective lens device utilizing a color image pickup device, the lens units near the object side tend to be large, when an attempt is made to make the optical system into one that is telecentric at an object side. This causes nonaxial aberration to occur more often.

SUMMARY OF THE INVENTION

Accordingly, an object of the present invention is to form a suitable lens structure in order to provide an objective lens device having a back focus long enough to allow various optical members, such as a filter, to be disposed between the rear end of the lens and an imaging plane, having a smaller first focusing lens unit, being telecentric at an image side, having a photographic angle of about 45 degrees and an f-number of about 2.8, and which is corrected for various aberrations over an entire field.

To this end, the present invention provides an objective lens device which comprises in order from the lens closest to an object side, a negative meniscus first lens whose convex side faces the object side, a positive second lens, a positive meniscus third lens whose convex side faces an image side, a negative meniscus fourth lens whose convex side faces the object side, a negative meniscus fifth lens whose convex side faces the object side, and a positive sixth lens. The fifth lens and the sixth lens are cemented together, forming a cemented lens subunit.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a cross sectional view of a lens device of Numerical Example 1 of the present invention.

FIGS. **2A**, **2B**, and **2C** illustrate graphs showing the aberrations of the lens device of Numerical Example 1 of the present invention.

FIG. **3** is a cross sectional view of a lens device of Numerical Example 2 of the present invention.

FIGS. **4A**, **4B**, and **4C** illustrate graphs showing the aberrations of the lens device of Numerical Example 2 of the present invention.

FIG. **5** is a cross sectional view of a lens device of Numerical Example 3 of the present invention.

FIGS. **6A**, **6B**, and **6C** illustrate graphs of the aberrations of the lens device of Numerical Example 3 of the present invention.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

FIG. **1** is a cross sectional view of a lens device of Numerical Example 1 of the present invention, while FIGS. **2A**, **2B**, and **2C** illustrate graphs of the aberrations of the lens device of Numerical Example 1 when an object is at infinity. FIG. **3** is a cross sectional view of a lens device of Numerical Example 2 of the present invention, while FIGS. **4A**, **4B**, and **4C** illustrate graphs of the aberrations of the lens device of Numerical Example 2 when the object is at infinity. FIG. **5** is a cross sectional view of a lens device of Numerical Example 3 of the present invention, while FIGS. **6A**, **6B**, and **6C** illustrate graphs showing the aberrations of the lens device of Numerical Example 3 when the object is at infinity.

According to the present invention, the objective lens device comprises six lenses. They are, in order from the lens closest to an object side, a negative meniscus first lens **G1**, a positive second lens **G2**, a positive meniscus third lens **G3** whose convex side faces an image side, a negative meniscus fourth lens **G4** whose convex side faces the object side, a negative meniscus fifth lens **G5** whose convex side faces the object side, and a positive biconvex sixth lens **G6**. The fifth

lens G5 and the sixth lens G6 are cemented together to form a cemented lens subunit G56. A stop SP is disposed between the second lens G2 and the third lens G3. In the figures, G denotes a glass block such as a face plate or an optical filter, and IP denotes an image plane.

The objective lens device of the present embodiment is formed by two retrofocusing lens units, one composed of the negative first lens G1 and the positive second lens G2, and the other composed of the negative third lens G3, the negative fourth lens G4, and the cemented lens subunit G56. By virtue of such a construction, the back focus can be made sufficiently long such that the principal point at the image side is positioned closer to the image side.

Here, the lens system is considered as being formed by two lens units, a front lens unit composed of the first lens G1 and the second lens G2, and a rear lens unit composed of the third to sixth lenses G3 to G6. The front lens unit is a substantially afocal system which consists of negative first lens G1 and positive second lens G2. The air gap between the first lens G1 and the second lens G2 can be reduced by setting the refractive powers of the negative first lens G1 and the positive second lens G2 at high values, with the afocal magnification maintained, which leads to reduction of the diameter of the first lens G1. When the refractive powers are set at high values, the high refractive power of the second lens G2 causes a large astigmatism. The astigmatism of the second lens G2 is corrected by the negative fourth meniscus lens G4 whose convex side faces the object side. Comatic aberration of the first lens G1 and that of the second lens G2 are also corrected by the fourth lens G4. Oblique aberration is corrected by the cemented lens subunit formed by cementing the fifth lens G5 and the sixth lens G6 and having the convex side facing the object side.

In the present embodiment, by virtue of the above-described lens structure, the objective lens device contains relatively few lenses, aberrations are properly corrected over the entire field, and the objective lens device is particularly suitable for a photographic system utilizing a solid-state image pickup device, has a relatively long back focus, and is telecentric at the image side.

In the present embodiment, the objective lens device has long back focus and good optical properties from its particular shape.

It is to be noted that in order for the back focus to be easily set to a predetermined value, for oblique aberrations, such as distortion, to be properly corrected, and for the optical properties over the entire field to be satisfactorily corrected, only at least one of the following conditions need to be satisfied.

$$(1\text{-}1)\quad -7 < \frac{R9+R8}{R9-R8} < -1 \qquad (1)$$

where R8 and R9 represent the radius of curvature of the surface at the object side and that at the image side of the fourth lens, respectively.

Condition 1 is related to the shape of the negative meniscus fourth lens G4. When the ratio is less than the lower limit and the meniscus fourth lens G4 is more curved, not only are astigmatism and coma corrected excessively, but also higher-order aberration occurs. On the other hand, when the value exceeds the upper limit and the fourth lens G4 becomes a plano-convex lens, the fourth lens G4 no longer is effective in correcting astigmatism and coma. Therefore, it is not preferable that the ratio be less than the lower limit or be greater than the upper limit.

$$(1\text{-}2)\quad N1 < N2 \qquad (2)$$

where N1 and N2 denote, respectively, the refractive indices of the materials of the first lens and the second lens, with the second lens being a meniscus-shaped lens whose convex side faces an image side.

Coma occurring at the surface at the image side of the first lens G1 is corrected by the second lens G2 which is formed into a meniscus lens whose convex side faces an image side. It corrects coma along with the fourth lens G4 which is also formed into a meniscus lens.

Condition 2 is related to the refractive indices of the materials of the first lens G1 and the second lens G2. In common retrofocusing type lens systems, the Petzval's sum tends to be too small. But in the lens structure of the present invention, the Petzval's sum tends to be positively large. The Petzval's sum is a proper value when the material of the second lens G2 has a higher refractive index than the first lens G1. When N1 becomes greater than N2, and the refractive index of the material of the first lens G1 becomes high, the Petzval's sum increases in the positive direction, thus increasing the curvature of field. Therefore, it is not desirable that N1 be greater than N2.

$$(1\text{-}3)\quad 0.1 < D3/R4 < 0.3 \qquad (3)$$

where D3 represents the thickness of the second lens, and R4 denotes the radius of curvature of the lens surface at the image side of the second lens.

Condition 3 is related to the thickness (of the center) of the second lens G2. When the second lens G2 is of the proper thickness, distortion that occurs in the negative first lens G1 is corrected. When the value is less than the lower limit, and the second lens G2 is thinner, it becomes difficult to produce the lens because the edge thickness becomes smaller. In addition, when the value becomes less than the lower limit of Condition 3, and the curvature of the lens surface at the image side is low, distortion is not sufficiently corrected. On the other hand, when the value is greater than the upper limit, and the second lens G2 is thicker, the size of the lens system becomes larger. In addition, when the value exceeds the upper limit of Condition 3, and the curvature of the lens surface at the image side becomes too large, not only is distortion corrected in excess, but also higher order aberration occurs. Therefore, it is not preferable that the value be greater than the upper limit or be less than the lower limit.

(1-4) When an object at infinity is in focus, and a nearby object is to be brought into focus, the entire lens system or the third to sixth lenses are integrally moved toward the object side.

In changing the focusing object from an object at infinity to a nearby object by an objective lens device in the present embodiment, good optical properties are provided by moving the entire lens system to an object side. The first lens G1 and the second lens G2 are as a whole substantially afocal, so that focusing is performed by integrally moving the lens unit composed of the third lens G3 to the sixth lens G6, whereby variations in aberration that occur during focusing are properly corrected. The lens unit has a focusing sensitivity of about 1.

(1-5) Either light control means used by an iris stop, or light control means by switching various apertures, or light control means with a fixed aperture is disposed between the second lens and the third lens, or between the third lens and the fourth lens.

An iris stop, or a so-called turret-type stop used by switching various apertures, or a fixed aperture type stop is disposed in front of or behind the third lens G3 in order to facilitate exposure control, without any shading, and to obtain good optical properties over the entire field. When a color image-pickup device is used as the image pickup means, it is desirable that the lens system be telecentric at the image side. This is achieved by disposing a stop, as mentioned above, as a result of which aberrations are properly corrected.

$$(1\text{-}6)\quad 3<|tk/f| \qquad (4)$$

where tk denotes the position of the exit pupil of the system, measured from the sixth lens surface at the image plane side, and f denotes the focal length of the entire lens system.

Condition 4 is related to the position of the exit pupil of the lens system, measured from the surface of the last lens in the objective lens device. When the tk/f ratio is less than the lower limit of Condition 4 and the exit pupil is closer to the lens system, color shading or the like occurs in a camera using a color image pickup device. Therefore, it is not preferable that the tk/f ratio be less than the lower limit.

Numerical examples of the present invention will now be described. In the numerical examples, Ri denotes the radius of curvature of a surface of an i-th lens surface in order of lenses from the lens closest to an object side, Di denotes the thickness of an i-th lens in order of lenses from the lens closest to the object side and air gap, and Ni and Vi denote, respectively, the refractive index and the Abbe constant of a glass of an i-th lens in order of lenses from the lens closest to the object side. R13 and R14 each represent the radius of curvature of a surface of a glass block, such as a face plate or an optical filter. The relationships between each of the above-described conditions and the numerical values of the numerical examples are given below in Table 1.

As can be understood from the foregoing description, according to the present invention, a proper lens structure makes it possible to provide an objective lens device having a back focus that is long enough to allow various optical members, such as a filter, to be disposed between the objective lens device and an imaging plane, having a smaller front lens unit diameter, having telecentric properties at an image side, having a photographic field angle of about 45 degrees, having an f-number of about 2.8, and excellent optical properties, with the various aberrations corrected over the entire field.

What is claimed is:

1. An objective lens device comprising in order from the lens closest to an object side:

a negative meniscus first lens whose convex side faces the object side;

a positive second lens;

a positive meniscus third lens whose convex side faces an image side;

a negative meniscus fourth lens whose convex side faces the object side;

a negative meniscus fifth lens whose convex side faces the object side; and

a positive sixth lens;

wherein said fifth lens and said sixth lens are cemented together to form a cemented lens subunit.

2. An objective lens device according to claim **1**, satisfying the condition

$$-7<\frac{R9+R8}{R9-R8}<-1,$$

wherein **R8** and **R9** represent the radius of curvature of a surface at the object side of said fourth lens and the radius of curvature of a surface at the image side of said fourth lens, respectively.

3. An objective lens device according to claim **1**, further satisfying the condition **N1<N2**, wherein **N1** and **N2** denote

the refractive indices of the materials of said first lens and said second lens, respectively, with said second lens being a meniscus lens whose convex side faces the image side.

4. An objective lens device according to claim 1, further satisfying the condition $0.1<|D3/R4|<0.3$, wherein D3 represents the thickness of said second lens, and R4 represents the radius of curvature of a surface at the image side of said second lens.

5. An objective lens device according to claim 1, wherein when an object at infinity is in focus and a nearby object is to be brought into focus, an entire lens system is moved, or said third lens to sixth lens are integrally moved toward the object side.

6. An objective lens device according to any one of claims 1 to 5, further comprising one of light control means including an iris stop, light control means including switching of a plurality of apertures, and light control means with a fixed aperture, said light control means being disposed between said second lens and third lens, or between said third lens and said fourth lens.

7. An objective lens device according to claim 1, further satisfying the condition $3<|tk/f|$, wherein tk represents the position of an exit pupil of the lens system, measured from a surface at the image side of said sixth lens, and wherein f represents a focal length of the entire lens system.

[57] **ABSTRACT**

A stereoscopic objective lens system for video endoscopes and borescopes includes two full-diameter doublets and two identical half-diameter ball lenses. The full-diameter doublets collimate object points, imaging object points to infinity. The full-diameter doublets present equal-angle pairs from symmetrically disposed object points to the ball lenses. This equal-angle property enables accurate object/image mapping onto the final stereo image pair such that all parts of each left/right image can be mapped to within a fraction of a video pixel to each other.

STEREO VIDEO ENDOSCOPE OBJECTIVE LENS SYSTEMS

BACKGROUND OF THE INVENTION

This invention relates generally to optical lens systems, and, more particularly, relates to stereoscopic objective lens designs adapted for use in stereo video endoscopes.

Medical endoscopes are widely utilized to view internal regions of the human body during diagnostic, surgical, and other medical procedures. Endoscopes typically include a long, thin, rigid or semi-rigid optical cylinder affixed to a viewing mechanism. The cylinder is sufficiently narrow to be inserted through a small opening in the body, which may be natural or surgical. When the endoscope is inserted and positioned for use, an image of the object being viewed is formed at an inserted end of the endoscope by an objective lens. The image passes through a series of relay lenses down the cylinder to an eye lens or video camera at a viewing end of the endoscope.

In recent years, researchers have attempted to improve the imaging available through endoscopic devices by developing stereoscopic video endoscopes. These endoscopes present an apparently three-dimensional image on a video monitor. The stereoscopic effect is created by producing two optical images—a left image and a right image—through the endoscope. The left and right optical images are presented by the endoscope to left and right image sensors, which may be charge-coupled device (CCD) cameras or other image sensing devices. The sensing devices convert the left and right optical images into left and right video images which are then presented as alternating left/right images on a monitor, at a switching rate higher than the flicker-sensing limit of the human eye, so that observed images appear flicker-free.

The images are alternately switched from a left-hand polarization mode to a right-hand polarization mode, such that, for example, the left image has a left-hand polarization and the right image has a right-hand polarization. In accord with this example, the observer wears polarized glasses in which the left lens has the left-hand polarization and the right lens has the right-hand polarization. Thus, the left eye sees only images from the left channel of the endoscope system and the right eye sees only images from the right channel, resulting in stereoscopic viewing.

The following United States and foreign patents disclose examples of stereo endoscopes, some of which utilize video imaging and display elements:

U.S. Pat. No. 4,061,135
U.S. Pat. No. 4,615,332
U.S. Pat. No. 4,651,201
U.S. Pat. No. 4,862,873
U.S. Pat. No. 4,873,572
U.S. Pat. No. 4,895,431
U.S. Pat. No. 5,122,650
U.S. Pat. No. 5,191,203
EP Patent No. 211,783

In particular, U.S. Pat. No. 4,061,135 discloses a binocular endoscope in which images are transmitted from the viewed object to the viewing station through an optical system utilizing a dove prism and mechanical linkage to compensate for rotation effects.

U.S. Pat. No. 4,615,332 discloses a binocular endoscope having flexible light guides and binocular eyepieces.

U.S. Pat. No. 4,651,201 discloses a stereoscopic video endoscope including two image guides and an illumination light guide. The image guides are optically coupled to a stereoscopic viewer for three dimensional viewing. The viewer includes couplings for attaching miniature video camera that can be connected to a head mounted stereoscopic video display.

U.S. Pat. No. 4,862,873 discloses a stereo endoscope having two light guides for carrying images of an object an electro-optical imaging assembly. A lens system directs light from the object to the objective end of the light guides. Illuminating light is transmitted to the object from the opposite end of one light guide, thereby illuminating the object. Simultaneously, the image transmitted through the other optical guide is conducted to the imaging assembly.

U.S. Pat. No. 4,873,572 discloses a stereo endoscope having a CCD camera module and two image-forming lens systems that form two object images. The object images are integrated and directed to the CCD camera to provide a stereoscopic output. The lens systems include red, green, and blue color filters disposed at the camera imaging surface.

U.S. Pat. No. 4,895,431 discloses an endoscope apparatus that generates a three-dimensional image of an object from overlapping images recorded by a camera. The endoscope includes an insertion module and a movable end section capable of being deflected through an angle. A first image is recorded with the end section positioned at a first angle. A second image, partially overlapping the first image, is recorded after moving the end section to a second angle. The relative position of the movable end section is detected by an encoder that generates position signals for input to a microprocessor, which utilizes the position signals to generate a three-dimensional image of the object.

U.S. Pat. No. 5,122,650 discloses a stereo video endoscope objective lens system using six doublet lenses to generate pixel mapped left-right images for stereo viewing.

U.S. Pat. No. 5,191,203 discloses a stereo video endoscope objective lens system using lenses having a graded index of refraction to generate pixel mapped left-right images for stereo viewing.

European Patent No. 211,783 discloses a stereo video endoscope in which two light pipes deliver two images of the same object. These images are presented by a binocular device to the user's eyes to show a three dimensional image of the target. The apparatus includes two television cameras and video recorders for recording the images. The recorded images can be displayed on separate screens and viewed by a binocular viewing system.

Most conventional stereo endoscopes, however, share a number of deficiencies associated with their objective lens systems. These problems include a bulky and unwieldy configuration; high cost and complexity of fabricating the objective lens system; and the less than optimal optical performance afforded by conventional objective lens systems.

An additional problem associated with conventional stereo video endoscope objectives involves the requirement that all portions of each left/right image be mapped to within a fraction of a video pixel to each other. This pixel mapping condition is a significant optical design constraint, because the object-to-image ray paths through the lens system are quite different for the left and right image points associated with a common object point.

Accordingly, it is a general object of the present invention to provide improved stereo endoscope objective lens systems that overcome the problems associated with conventional designs.

A more specific object is to provide an improved stereo endoscope objective lens system having optical elements that facilitate assembly of the system.

It is another object of the invention to provide an improved stereo endoscope objective lens system having elements that are substantially less expensive to manufacture than the elements of conventional systems.

A further object is to provide an improved stereo endoscope objective lens system having optical performance characteristics that are substantially superior to the performance characteristics of conventional systems.

Another object of the invention is to provide a stereo objective lens system affording a pixel mapped image.

The above and other objects and advantages of this invention will become more readily apparent when the following description is read in conjunction with the accompanying drawings.

SUMMARY OF THE INVENTION

The foregoing objects are attained by the invention, which provides an improved stereo endoscope objective lens system for video imaging in medical endoscopes and industrial borescopes.

One aspect of the invention includes two full-diameter (D) doublets disposed along an optical axis, and a left/right stereo lens pair. The stereo lens pair includes a set of two spherical, or ball lenses, each having a cylindrical lateral surface with a circular cross-section having a diameter D/2. The full-diameter doublets substantially collimate object points, i.e., image them substantially to infinity. The stereo lens pair is disposed to collect light from the second doublet, with the optical axis of each ball lens being substantially parallel, and offset by D/4 from the optical axis of the doublets.

The doublets and the stereo lens pair cooperate so that the doublets present equal angle light ray pairs from symmetrically disposed object points to the ball lenses of the stereo lens pair. The left and right ball lenses generate left and right images respectively, at an image plane, where corresponding portions of those images are mapped to within a selected distance of each other.

In a further aspect of the invention, the ball lenses are particularly advantageous compared to the prior art, because they can be most economically fabricated in production quantities. This is advantageous because these small lenses are inherently difficult to manufacture.

In another aspect of the invention, the large collimator doublets provide accurate object/image mapping onto the final stereo image pair. In this design, the larger, and hence easier to fabricate doublets carry the corrective burden, so that the smaller, more difficult to manufacture lenses can be made a simple as possible.

The invention will next be described in connection with certain illustrated embodiments; however, it should be clear to those skilled in the art that various modifications, additions and subtractions can be made without departing from the spirit or scope of the claims.

The invention will next be described in connection with certain illustrated embodiments; however, it should be clear to those skilled in the art that various modifications, additions and subtractions can be made without departing from the spirit or scope of the claims.

BRIEF DESCRIPTION OF THE DRAWING

For a fuller understanding of the nature and objects of the invention, reference should be made to the following detailed description and the accompanying drawings, in which:

FIG. **1** is a schematic diagram depicting a stereo video endoscope utilizing an objective lens system constructed in accordance with the invention;

FIG. **2** is an optical schematic diagram depicting an objective lens system constructed in accordance with the invention, showing light rays transmitted through the system;

FIG. **3** is an optical schematic diagram depicting an objective lens system constructed in accordance with the invention, identifying optical surfaces, and

FIGS. **4A–4D** show ray intercept and optical path difference curves the embodiment of FIGS. **2** and **3**.

DESCRIPTION OF ILLUSTRATED EMBODIMENTS

FIG. **1** depicts the invention, an endoscope objective system **100**, utilized in a stereo video endoscopy system **1** for generating stereoscopic images of an object **12**. The system **1** principally includes a stereoscopic endoscope **10** containing objective system **100**; sensing modules **152, 154**; switching module **156**; and a monitor **158**. In addition to objective lens system **100**, the endoscope **10** includes conventional relay lenses or optical fibers **150** for transmitting light collected by the endoscope objective system **100** to light sensing modules **152, 154**.

The endoscope objective system **100** generates left and right optical images of the object **12** that are processed by sensing elements **152, 154** and video switching module **156** in a known manner to display an apparently three-dimensional image of the object **12** on video monitor **158**.

The stereoscopic effect is created by producing two optical images—a left image and a right image —through the endoscope objective system **100**. The left and right optical images generated by the objective system **100** are presented by the relay lens or optical fiber system **150** to left and right image sensors **152, 154**, which can be conventional charge-coupled device (CCD) cameras or other image sensing devices. The CCD elements operate in a known manner to convert the light collected by the objective system **100**, and transmitted by the relay lenses or optical fibers **150**, into electrical signals representative of the left and right optical images of the object **12**.

Conventional video switching circuitry **156** transmits the electronic signals representative of left and right video images as alternating left-right images on the monitor **158**. In accord with known video practice, these alternating images are presented at a switching rate higher than the flicker-sensing limit of the human eye, so that observed images appear flicker-free.

Moreover, the images can be alternately switched from a left-hand polarization mode to a right-hand polarization mode, such that, for example, the left image has a left-hand polarization and the right image has a right-hand polarization. The observer wears polarized glasses in which the left lens has the left-hand polarization and the right lens has the right-hand polarization. Thus, when the observer views the monitor **158**, the left eye sees only images from the left channel of the endoscope system and the right eye sees only images from the right channel, resulting in stereoscopic viewing. Video switching and display equipment of this type is commercially available from Stereographics, Inc. of San Rafael, Calif.; and from Tektronix Corp., of Beaverton, Oreg.

The accuracy and quality of the image displayed on monitor **158** is controlled by the performance of the endo-

scope objective system **100**, which is the subject of the present invention.

FIGS. **2** and **3** depict an objective lens system **100** constructed in accordance with the invention, showing light rays transmitted through the system.

The objective system **100** of FIGS. **2** and **3** include a first doublet **110** and a second doublet **112** positioned in sequence along and centered about a common system axis **100***a*, followed by a stereo lens set **113**. Both doublets have circular cross sections with a diameter D. The lens set **113** includes a pair of matched, cylindrical side wall ball lenses **114**, **116**, each having a circular cross-section with diameter D/2, extending along an associated one of ball lens axes **114***a* and **116***a* which are parallel to, and spaced apart by D/2 from, the system axis **100***a*. The two doublets **112**, **114** cooperate to collimate object points, i.e., image them to infinity.

Those skilled in the art will appreciate that the lenses of the objective system **100** depicted in FIGS. **2** and **3** define a sequence of **12** optical surfaces. A working example of a set of lenses for objective system **100** is set forth below in Table A. Reference numerals S2–S7, S9 and S10 shown in FIG. **3** correspond to numerals **2–7**, **9** and **10** respectively in the "SURFACE" column of Table A. As those skilled in the an will appreciate, surfaces **1**, **8**, **11**, and **12** do not correspond to physical surfaces and are indicated in Table A for convenience of analysis. FIG. **3** shows reference designations S2–S7, S9 and S10 overlaid onto the system of FIG. **2**.

TABLE A

SURFACE	RADIUS	THICKNESS	GLASS
1	—	−3.678088	AIR
2	—	3.000000	SIO2 C
3	−3.650000	1.200000	SF1 C
4	3.101000	0.983255	AIR
5	15.121014	3.000000	LAKN12 C
6	−5.000000	2.500000	F4 C
7	−4.443995	1.400000	AIR
8	—	2.200000	AIR
9	2.500000	5.000000	BK7 C
10	−2.500000	1.046744	AIR
11	—	0.001000	BK7 C
12	—	—	AIR

In Table A, the numerical values in the "RADIUS" and "THICKNESS" columns are set forth in millimeters. The "GLASS" descriptions are standard optical glass characterizations as found in the product catalog of the Schott Glass Company of Germany. The "THICKNESS" column refers to the distance to the next optical surface. The "RADIUS" column refers to the radii of curvature of the respective curved surfaces. For example, Table A describes lens **116** as a ball lens because surfaces **9** and **10** have 2.5, and −2.5 millimeter radii of curvature, respectively, and the distance between surfaces **9** and **10** is 5 millimeters. Lenses **114** and **116** are ball (or spherical) lenses that have been ground to have cylindrical lateral surfaces, with a circular cross-section (transverse to the respective axes **114**A and **116**A) having a diameter that is one half of the diameter of doublets **110** and **112**.

In this working example, the diameters are 6.0 millimeters for the doublets **110** and **112**, and 3.0 millimeters for the ball lenses **114** and **116**. The image diameters are 1.5 millimeters.

The system **100** is designed so that all parts of each left/right image are mapped to within a selected distance of each other such that stereoscopic image quality is maintained. For video applications, this selected distance is typically a fraction of a video pixel. This is a difficult condition to satisfy, because the object-to-image ray paths through the lens system are quite different for the left and right image points of a common object point. The ray paths shown in FIG. **2** demonstrate how differently an object point is imaged through the lens elements for the left and right images.

The objective system **100** depicted in FIGS. **2** and **3** is able to map all parts of each left/right image to within a fraction of a video pixel to each other, because the large collimator doublets present equal-angle pairs from symmetrically disposed object points to the small ball lenses **114**, **116**. This exact equal-angle solution results in an accurate object/image mapping onto the final stereo image pair.

The accuracy and minimized distortion of the system of Table A is shown in the respective ray intercept curves shown in FIGS. **4**A–**4**D. In each of those figures, for an identified object point the ray intercepts are shown as a function of relative aperture height.

Objective system **100**, as described in Table A and shown in FIGS. **2** and **3**, achieves accurate object/image mapping with simpler and fewer components than those used in prior art devices. Doublets **110** and **112** are relatively easy to manufacture compared to those used in prior art systems because they do not have any highly curved surfaces, nor do they have any curved surfaces that are nearly planer. Further, lenses **114** and **116** are identical and are made from widely available ball or spherical lenses.

As indicated in FIG. **1**, the endoscope objective system **100** can be utilized in connection with optical fiber elements or a set of relay lenses **150**, an example of which is described in the above-referenced U.S. Pat. No. 5,122,650.

Alternatively, an endoscope constructed in accordance with the invention can employ a conventional CCD array mounted within the same housing as the objective system. The CCD array can include left and right sensing elements **152**, **154**, disposed to receive the optical images generated at the output of ball lenses **114**, **116** i.e. at surface **12**. The design and construction of CCD elements having more than one photosensitive region in a monolithic package is well known in the art. The electrical signals generated by the CCD array can be conducted from the housing by a conventional conduit. This configuration eliminates the requirement for a relay lens system or optical fibers.

The system **100** depicted in FIGS. **2** and **3** offers advantages for use in medical endoscopes and industrial borescopes. The configuration offers the advantage of being adaptable to fit into a small tube diameter, as small as 2 millimeters. The design also affords high resolution and low distortion for diagnostic and surgical use, and for high-accuracy industrial measurement applications. The design is also relatively easy and inexpensive to produce.

The invention may be embodied in other specific forms without departing from the spirit or essential characteristics thereof. The present embodiments are therefore to be considered in all respects as illustrative and not restrictive, the scope of the invention being indicated by the appended claims rather than by the foregoing description, and all changes which come within the meaning and range of equivalency of the claims are therefore intended to be embraced therein.

Having described the invention, what is claimed as new and secured by Letters Patent is:

1. A stereoscopic objective lens system for a stereo video endoscope, the objective lens system converting light propa-

gated from an object and received at an objective end of the objective system to pixel-mapped left and right optical images of said object at an image plane end of the objective system, the objective lens system comprising:

A. a first collimator doublet lens element proximate to the objective end for collecting light from points on the object, said first doublet lens having a first optical axis, a selected diameter and a selected optical power,

B. a second collimator doublet lens for collecting light from said first collimator doublet lens, said second collimator doublet lens being disposed adjacent to said first collimator doublet lens and having an optical axis substantially collinear with the optical axis of the first collimator doublet lens, said second collimator doublet lens having a selected diameter and a selected optical power, whereby said first and second collimator doublet lenses cooperate to image the object points substantially to infinity so that light transmitted by the second collimator doublet lens from the object points is substantially collimated,

C. a right/left stereo lens pair, said pair including a right ball lens and a left ball lens, said right and left ball lenses being adjacent to said second collimator doublet lens and disposed for collecting light from said second collimator doublet lens, said right ball lens and said left ball lens each having a respective optical axis substantially parallel to the optical axis of the second collimator doublet lens,

wherein said first and second collimator doublet lenses and said right/left stereo lens pair cooperate so that the first and second collimator doublet lenses present equal-angle light ray pairs from symmetrically disposed object points to the ball lenses of said right/left stereo lens pair,

whereby said right ball lens generates a right image at the image plane, and said left ball lens generates a left image at the image plane, such that corresponding portions of each right/left image are mapped to within a selected distance of each other.

2. A lens system according to claim **1** wherein the diameter of said second collimator doublet lens is approximately equal to the diameter of said first collimator doublet lens.

3. A lens system according to claim **2** wherein said right ball lens is substantially identical to said left ball lens.

4. A lens system according to claim **3** wherein said left ball lens and said right ball lens each have a circular cross-section transverse to the respective optical axes of said right ball lens and said left ball lens.

5. A lens system according to claim **3** wherein the diameters of said right ball lens and said left ball lens are substantially equal to one-half the diameter of said first and second collimator doublet lenses, and said optical axes of said right ball lens and said left ball lens are off-set from said optical axis of said first and second collimator doublet lenses by one-fourth the diameter of said first and second collimator doublet lenses.

6. A lens system according to claim **5** wherein said left ball lens and said right ball lens each have a circular cross-section transverse to the respective optical axes of said right ball lens and said left ball lens.

7. A stereoscopic objective lens system for a stereo video endoscope, the objective lens system converting light propagated from an object and received at an objective end of the objective system to pixel-mapped left and right optical images at an image plane end of the objective system, the objective lens system comprising:

A. a collimator lens system proximate to the objective end for collecting light propagated from points on the object, said collimator lens system having a defined optical axis, a selected diameter and a selected optical power, whereby said collimator lens system images the object points substantially to infinity so that light transmitted by said collimator lens system from the object points is substantially collimated,

B. a right/left stereo lens pair, said pair including a right ball lens and a left ball lens, said right and left ball lenses being adjacent to said collimator lens system and disposed for collecting light from said collimator lens system, said right ball lens and said left ball lens each having a respective optical axis substantially parallel to the optical axis of the collimator lens system,

wherein said collimator lens system and said right/left stereo lens pair cooperate so that the collimator lens system presents equal-angle light ray pairs from symmetrically disposed object points to the ball lenses of said right/left stereo lens pair,

whereby said right ball lens generates a right image at the image plane, and said left ball lens generates a left image at the image plane, such that corresponding portions of each right/left image are mapped to within a selected distance of each other.

8. A lens system according to claim **7** wherein said collimator lens system comprises a first collimator doublet lens and a second collimator doublet lens, the diameter of said second collimator doublet lens being approximately equal to the diameter of said first collimator doublet lens.

9. A lens system according to claim **8** wherein said right ball lens is substantially identical to said left ball lens.

10. A lens system according to claim **9** wherein said left ball lens and said right ball lens each have a circular cross-section transverse to the respective optical axes of said right ball lens and said left ball lens.

11. A lens system according to claim **8** wherein the diameters of said right ball lens and said left ball lens are substantially equal to one-half the diameter of said first and second collimator doublet lenses, and said optical axes of said right ball lens and said left ball lens are off-set from said optical axis of said first and second collimator doublet lenses by one-fourth the diameter of said first and second collimator doublet lenses.

12. A lens system according to claim **11** wherein said left ball lens and said right ball lens each have a circular cross-section transverse to the respective optical axes of said right ball lens and said left ball lens.

[57] **ABSTRACT**

A wide-angle objective lens is comprised, from the object side, of a first lens component which is a negative meniscus lens having its convex surface facing the object side, a second lens component which is a meniscus lens having its convex surface facing the object side and having positive refractive power, a third lens component which is a cemented meniscus lens comprising a positive lens and a negative lens cemented together and having its convex surface facing the object side and having positive refractive power, a fourth lens component which is a positive meniscus lens having its concave surface facing the object side, and a fifth lens component which is a negative meniscus lens having its concave surface facing the object side. The wide-angle objective lens has a stop disposed between the second lens component and third lens component, and satisfies predetermined conditions.

COMPACT WIDE-ANGLE OBJECTIVE LENS

This is a continuation of application Ser. No. 08/173,084 filed Dec. 27, 1993 (U.S. Pat. No. 5,528,428), which is a continuation-in-part of application Ser. No. 08/080,971 filed Jun. 24, 1993 (abandoned), which is a continuation of application Ser. No. 07/973,614 filed Nov. 9,1992 (abandoned).

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to a wide-angle objective lens for cameras, and particularly to a compact, large aperture, wide-angle objective lens suitable for use in a 35 mm format lens shutter camera or a 35 mm format camera with a range finder.

2. Related Background Art

Biogon type, abiogon type, etc. are known as symmetrical type wide-angle lenses having a negative, positive, negative refractive power distribution. The biogon type wide-angle lens can cover a wide angle of view and can make distortion small. Also, its refractive power distribution is a negative, positive, negative refractive power distribution and therefore, as compared with a symmetrical type wide-angle lens of a positive, negative, positive refractive power distribution such as a topogon type wide-angle lens, the biogon type wide-angle lens has an advantage that the quantity of marginal light is great and moreover the diameters of fore and rear lenses can be made small.

Various wide-angle lenses of negative, positive, negative construction are known as the developed types of the biogon type wide-angle lens. They are known, for example, from Japanese Utility Model Publication No. 43-30782, U.S. Pat. No. 3,829,198, U.S. Pat. No. 4,211,472, Japanese Laid-Open Patent Application No. 56-140311, etc.

Examples in which the F-number is made small are shown in Japanese Utility Model Publication No. 43-30782 and U.S. Pat. No. 4,211,472. Examples which comprise a small number of lens components are shown in U.S. Pat. No. 3,829,198 and Japanese Laid-Open Patent Application No. 56-140311.

However, the biogon type wide-angle lens generally suffers from the disadvantages that the total thickness of the lens system (the thickness from that surface of the lens which is most adjacent (nearest) to the object side to that surface of the lens which is most adjacent to the image side) is great and that the F-number is large.

In the lens systems shown in U.S. Pat. No. 3,829,198 and Japanese Laid-Open Patent Application No. 56-140311, the number of lens components is small but the correction of spherical aberration is deficient and therefore, the F-number cannot provide a large aperture. They also have suffered from the disadvantages that the total thickness of the lens system is very great and that the spacing between the front unit and the rear unit of the lens system in which a diaphragm is placed is too narrow and therefore great limitations must be imposed upon the structure of an aperture stop, a shutter unit, a lens barrel, etc.

In the lens system shown in Japanese Utility Model Publication No. 43-30782, the total thickness of the lens system is very great. Moreover the diameters of the fore and rear lenses are great. This is against the desire to make the lens system compact. In the lens system shown in U.S. Pat. No. 4,211,472, the F-number provides a large aperture but the total thickness of the lens system is great, and this is against the desire to make the lens compact. Also, the shape of coma is bad and therefore, if the lens system is left in its original condition, it is necessary to apply a limitation to the light beam and the quantity of marginal light becomes very small, and this has not been preferable.

Further, in the lens system of Japanese Laid-Open Pat. No. Application No. 54-70826, the symmetry of the refractive power distributions on both sides of a stop is destroyed, the air space between a negative lens component disposed on the object side and a positive lens component and the air space between the positive lens component and a negative lens component disposed on the image side are both widened and, a wide-angle of view and a large aperture can be obtained. However, this lens system has the disadvantages that the great air spaces result in a great total thickness of the lens system and that the height of a ray of light passing through the lens component remote from the stop becomes far from the optical axis and therefore the effective diameter of each lens becomes large.

Further, Gaussian type, Topogon type, etc. are known as symmetrical type lenses having positive, negative, positive refractive power distribution.

The positive, negative, positive symmetrical type lens is advantageous for large aperture, but cannot cover a wide-angle of view, and conversely, the aforedescribed negative, positive, negative symmetrical lens can cover a wide-angle of view, but has the disadvantage for large aperture.

In the positive, negative, positive symmetrical type lens, the off-axis light beam passing through the lens component remote from the stop passes a location remote from the optical axis and therefore, when an attempt is made to achieve a wide-angle, the effective diameters of the front and rear lenses become large, and this results in the bulkiness of the optical system. Accordingly, when an attempt is made to achieve a wide-angle, a negative, positive, negative symmetrical type lens is desirable.

Thus, it has been difficult to provide an optical system which satisfies the condition that a wide-angle can be achieved by a symmetrical type lens and the optical system is compact with a large aperture.

The positive, negative, positive symmetrical type lens and the negative, positive, negative symmetrical type lens are generally of a construction advantageous in the correction of distortion and chromatic aberration. When in such symmetrical type lenses, the whole lens system is axially moved to effect focusing (so-called whole axial movement system), the fluctuation of off-axis aberration can be suppressed to a certain degree.

However, where the whole axial movement system is used in the optical system as disclosed in Japanese Laid-Open Pat. No. Application No. 54-70826 wherein the symmetry of the refractive power arrangement of the negative, positive, negative symmetrical type lens is greatly destroyed in order to make the optical system bright, there has been a problem that the fluctuation of off-axis aberration becomes great.

SUMMARY OF THE INVENTION

Accordingly, it is an object of the present invention to solve the above-noted problems peculiar to the prior art and to provide a symmetrical type wide-angle lens which realizes the small total thickness and great aperture of the lens system and which is compact and bright as well as small in distortion.

To achieve the above object, a wide-angle objective lens according to the present invention comprises, in succession

from the object side, a first lens component comprising a negative meniscus single lens having its convex surface facing the object side, a meniscus-shaped second lens component having its convex surface facing the object side and having positive refractive power, a stop, a third lens component comprising a cemented meniscus lens comprising a positive lens and a negative lens cemented together and having its convex surface facing the object side and having positive refractive power, a fourth lens component comprising a positive meniscus single lens having its concave surface facing the object side, and a fifth lens component comprising a negative meniscus single lens having its concave surface facing the object side, and is constructed into a negative, positive, negative refractive power arrangement as a whole, and when the focal length of said first lens component is f_1 and the focal length of said fifth lens component is f_5 and the radius of curvature of that surface of said third lens component which is most adjacent to the image side is r_{32} and the radius of curvature of that surface of said fourth lens component which is most adjacent to the object side is r_{41}, said wide-angle objective lens is designed to satisfy at least one of the following conditions:

$$0.02 \leqq |t_1/f_1| \leqq 0.1$$

$$0.01 \leqq |t_4/f_5| \leqq 0.08$$

$$-0.85 \leqq (r_{32}+r_{41})/(r_{32}-r_{41}) < 0.90,$$

where

t_1: the air space on the optical axis from that surface of the first lens component which is most adjacent to the image side to that surface of the second lens component which is most adjacent to the object side,

t_4: the air space on the optical axis from that surface of the fourth lens component which is most adjacent to the image side to that surface of the fifth lens component which is most adjacent to the object side.

By constructing the objective lens as described above, it becomes possible to correct, in particular, curvature of image field, astigmatism and coma, and a wide-angle lens which is compact, large aperture and high in performance can be realized.

It is a further object of the present invention to provide a wide-angle lens which suffers little from the fluctuation of off-axis aberration caused by focusing and which is compact with a large aperture and covers a wide-angle of view.

To achieve the above object, the present invention has a stop, and a first lens unit and a second lens unit that are disposed on the object side of the stop and on the image side of the stop, respectively. The first lens unit and the second lens unit are designed such that, during focusing, the first and second lens units are moved on the optical axis toward the object side and the amounts of movement of the lens units on the optical axis differ from each other.

Other objects, features and effects of the present invention will become fully apparent from the following detailed description of the invention taken in conjunction with the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** shows the lens construction of a first embodiment of the present invention.

FIG. **2** shows the lens construction of a second embodiment of the present invention.

FIG. **3** shows the lens construction of a third embodiment of the present invention.

FIGS. **9**A and **9**B are schematic views schematically showing the refractive power arrangements in ninth to thirteenth embodiments of the present invention and in which objects are at infinity and a near distance, respectively.

FIG. **10** shows the lens construction of the ninth to twelfth embodiments of the present invention.

FIG. **11** shows the lens construction of the thirteenth embodiment of the present invention.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

Some embodiments of the present invention will hereinafter be described in detail with reference to the accompanying drawings.

FIGS. **1** to **8** show the lens constructions of first to eighth embodiments, respectively, of the present invention. The wide-angle lenses according to the present invention, as shown in FIGS. **1** to **8**, comprise, in succession from the object side, a first lens component **L1** comprising a negative meniscus single lens having its convex surface facing the object side, a meniscus-shaped second lens component **L2** having its convex surface facing the object side and having positive refractive power, a third lens component **L3** comprising a cemented meniscus lens comprising a positive lens and a negative lens cemented together and having its convex surface facing the object side and having positive refractive power, a fourth lens component **L4** comprising a positive meniscus single lens having its concave surface facing the object side, a fifth lens component **L5** comprising a negative meniscus single lens having its concave surface facing the object side, and a stop between the second lens component **L2** and the third lens component **L3**, is constructed into a negative, positive, negative refractive power arrangement as a whole, and is designed to satisfy at least one of the following conditions:

$$0.02 \leqq |t_1/f_1| \leqq 0.1 \quad (1)$$

$$0.01 \leqq |t_4/f_5| \leqq 0.08 \quad (2)$$

$$-0.85 \leqq (r_{32}+r_{41})/(r_{32}-r_{41}) \leqq 0.90 \quad (3)$$

where

t_1: the air space on the optical axis from that surface of the first lens component **L1** which is most adjacent to the image side to that surface of the second lens component **L2** which is most adjacent to the object side,

t_4: the air space on the optical axis from that surface of the fourth lens component **L4** which is most adjacent to the image side to that surface of the fifth lens component **L5** which is most adjacent to the object side,

f_1: the focal length of the first lens component **L1**,

f_5: the focal length of the fifth lens component **L5**,

r_{32}: the radius of curvature of that surface of the third lens component **L3** which is most adjacent to the image side,

r_{41}: the radius of curvature of that surface of the fourth lens component L4 which is most adjacent to the object side.

As described above, the lens construction of the present invention is comprised of the first lens component L1 and the fifth lens component L5 each having negative refractive power, and the second lens component L2, the third lens component L3 and the fourth lens component L4 each having positive refractive power, and is a negative, positive, negative refractive power arrangement as a whole.

The first lens component L1 and the fifth lens component L5 each are a negative meniscus lens having its concave surface facing the stop S to sufficiently correct curvature of image field and astigmatism. By the negative meniscus lenses being thus used, it becomes possible to make the angle of view greater and increase the quantity of marginal light.

In a lens having a great angle of view, the correction of astigmatism and curvature of image field is important and it is necessary that the Petzval sum be an appropriate value.

Generally, in case of a lens of a negative, positive, negative refractive power arrangement having symmetry with respect to the stop S, as the air space between a lens unit adjacent to the object side and a positive lens unit and between a negative lens unit adjacent to the image side and the positive lens unit become wider, the degree of freedom of aberration correction increases more, and the Patzval sum can be made into an appropriate value.

However, where these air spaces are made great, the Patzval sum can be made into an appropriate value and this is advantageous for aberration correction, but the diameters of the fore and rear lenses become large and this is not preferable. Conversely, where these air spaces are made small, the Patzval sum increases to the positive and the correction of negative astigmastism and curvature of image field becomes difficult. So, where the refractive power of the first lens component L1 and of the fifth lens component L5 is made great to alleviate the Patzval sum, it will adversely affect coma, and this is not preferable.

The Patzval sum which is the cause of these problems can be improved to a certain degree by setting the refractive indices of the positive lens and the negative lens to appropriate values.

According to the present invention, in the symmetrical type wide-angle lens as disclosed in Japanese Utility Model Publication No. 43-30782, it becomes possible to divide the cemented positive lens disposed rearwardly of the stop into two lens components L3 and L4, effect the correction of spherical aberration by that surface r_{32} of the third lens component L3 which is most adjacent to the image side and that surface r_{41} of the fourth lens component L4 which is most adjacent to the object side, and make the F-number small. Further, since the cemented positive lens is divided into two lens components, the degree of freedom of aberration correction increases and it is possible to correct curvature of image field and astigmatism better.

The aforementioned conditional expressions of the present invention will hereinafter be described in detail.

Conditional expressions (1) and (2) are conditions regarding the correction of astigmatism and curvature of image field and compactness.

If the lower limit of conditional expression (1) is exceeded, the following two cases ① and ② are conceivable.

① A case where the air space t_1 between the first lens component L1 and the second lens component L2 is small; and

② A case where the focal length f_1 of the first lens component L1 is great.

In case ①, positive distortion increases and the correction of spherical aberration becomes impossible, and the F-number cannot be made small. In case ②, the Patzval sum increases to the positive and therefore, the correction of negative astigmastism and curvature of image field becomes impossible.

On the other hand, if the upper limit of conditional expression (1) is exceeded, the following two cases ③ and ④ are conceivable.

③ A case where the air space t_1 between the first lens component L1 and the second lens component L2 is great; and

④ A case where the focal length f_1 of the first lens component L1 is small.

In case ③, there is an advantage in aberration correction, but the diameter of the fore lens and the total thickness of the lens system become great and this is against the desire for compactness, and thus is not preferable. In case ④, the Patzval sum decreases, but the coma under the principal ray increases to the negative in a portion which is great in the angle of view, and this is not preferable.

If the lower limit of conditional expression (2) is exceeded, the following two cases ⑤ and ⑥ are conceivable.

⑤ A case where the air space t_4 between the fourth lens component L4 and the fifth lens component L5 is small; and

⑥ A case where the focal length f_5 of the fifth lens component L5 is great.

In case ⑤, the correction of spherical aberration becomes impossible and the F-number cannot be made small. In case ⑥, the Patzval sum increases to the positive and the correction of negative astigmatism and curvature of image field becomes impossible, and a good image plane cannot be obtained.

On the other hand, if the upper limit of conditional expression (2) is exceeded, the following two cases ⑦ and ⑧ are conceivable.

⑦ A case where the air space t_4 between the fourth lens component L4 and the fifth lens component L5 is great; and

⑧ A case where the focal length f_5 of the fifth lens component L5 is small.

In case ⑦ the degree of freedom with which the Patzval sum is made into an appropriate value increases and this is advantageous in correcting astigmatism and curvature of image field, but the total thickness of the lens system becomes great and this is against the desire for compactness, and thus is not preferable. In case ⑧, the correction of spherical aberration becomes impossible and further, the fluctuation of the coma above the principal ray by the angle of view becomes great and this is not preferable.

Conditional expression (3) is a condition regarding the shape of the air space between the third lens component L3 and the fourth lens component L4, and is concerned with coma, curvature of image field and astigmatism.

If the upper limit of conditional expression (3) is exceeded, the Patzval sum will increase to the positive and cannot be made into an appropriate value and the correction of astigmatism and curvature of image field will become difficult, and a good image plane cannot be obtained. Also, the shape of coma will exhibit a sharp tendency toward inner coma, and this is not preferable.

If conversely, the lower limit of conditional expression (3) is exceeded, a good Patzval sum will be obtained, but aberrations of high orders will occur in a portion which is great in the angle of view and astigmatism will become

great. Also, the shape of coma will exhibit a great tendency toward outer coma, and this is not preferable.

It is desirable that in order to correct spherical aberration, curvature of image field and astigmatism and to form the lens compactly, the wide-angle lens according to the present invention be designed to further satisfy the following conditions:

$$0.20 \leqq |r_{42}/f| \leqq 0.55 \quad (4)$$

$$0.40 \leqq D/f \leqq 1.00, \quad (5)$$

where

f: the focal length of the entire lens system,

r_{42}: the radius of curvature of that surface of the fourth lens component **L4** which is most adjacent to the image side,

D: total thickness of the lens system.

Conditional expression (4) is concerned with the correction of spherical aberration.

If the upper limit value of conditional expression (4) is exceeded, it will become impossible to correct positive spherical aberration, and this is not preferable.

If, conversely, the lower limit value of conditional expression (4) is exceeded, it will become impossible to correct negative spherical aberration, and this is not preferable.

Now, the wide-angle lens of the present invention is characterized in that, as compared with popular symmetrical type wide-angle lenses, its back focal length differs little, but the total thickness of the lens is very small. This makes it possible to make the lens barrel into the sunk barrel type to thereby contain it compactly when the lens of the present invention is used in a compact lens shutter camera or a camera with a range finder, and it is more realistic and effective to make the total thickness of the lens system small than to shorten the back focal length.

So, conditional expression (5) sets a condition for prescribing the total thickness of the lens system, i.e., the length from that surface of the first lens component **L1** which is most adjacent to the object side to that surface of the fifth lens component **L5** which is not adjacent to the image side.

If the lower limit value of conditional expression (5) is exceeded, the difference in height between the on-axis ray and the off-axis ray will become small in the lens far from the stop S and the degree of freedom will be deficient and thus, it will become impossible to correct the on-axis aberration and the off-axis aberration independently of each other.

If conversely, the upper limit value of conditional expression (5) is exceeded, the Patzval sum can be made into an appropriate value and a better image plane performance will be obtained, but this is against the desire for compactness and is therefore against an object of the present invention.

Also, it is desirable that in order to correct curvature of image field and astigmatism better, the first lens component **L1**, the third lens component **L3** and the fifth lens component **L5** be designed to satisfy the following conditions:

$$0.04 < N_{31} - N_{32} < 0.25 \quad (6)$$

$$N_1 < 1.70 \quad (7)$$

$$N_5 < 1.70, \quad (8)$$

where

N_{31}: the refractive index of the positive lens **L3** disposed on the object side in the third lens component **L3** for d-line,

N_{32}: the refractive index of the negative lens disposed on the image side in the third lens component **L3** for d-line,

N_1: the refractive index of the first lens component **L1** for d-line,

N_5: the refractive index of the fifth lens component **L5** for d-line.

Conditional expression (6) represents the difference between the refractive indices of the position lens disposed on the object side in the third lens component **L3** and the negative lens disposed on the image side in the third lens component **L3** for d-line.

If the lower limit value of conditional expression (6) is exceeded, the Patzval sum will increase to the positive and therefore, it will become impossible to correct negative curvature of image field and astigmatism.

If conversely, the upper limit value of conditional expression (6) is exceeded, a better Patzval sum will be obtained, but aberrations of high orders will occur in a portion which is great in the angle of view and astigmatic difference will be created, and this is not preferable.

Conditional expressions (7) and (8) are concerned with curvature of image field and astigmatism.

If the upper limit values of these conditional expressions are exceeded, the Patzval sum will increase to the positive and therefore, the correction of curvature of image field and negative astigmatism will become impossible and a good image plane will not be obtained.

Another embodiment of the present invention has a first lens unit and a second lens unit disposed with a stop interposed therebetween, on the object side of the stop and on the image side of the stop, respectively, said first lens unit comprising, in succession from the object side, a first lens component of negative refractive power and a second lens component of positive refractive power, said second lens unit comprising a third lens component of positive refractive power and a fourth lens component of negative refractive power, said first lens unit and said second lens unit being designed such that during focusing, they are moved on the optical axis toward the object side and the amounts of movement of said lens units on the optical axis differ from each other.

The present invention as a whole is of a negative, positive, negative refractive power arrangement. The first lens component of negative refractive power in the first lens unit disposed at a location remote from the stop and the fourth lens component of negative refractive power in the second lens unit are negative meniscus lenses having their concave surfaces facing the stop in order to sufficiently correct curvature of image field and astigmatism. The use of the negative meniscus lenses leads to the achievement of a wider angle and the provision of the action of increasing the quantity of marginal light.

The present invention makes the first lens unit and the second lens unit take their share of the correction of on-axis aberration and the correction of off-axis aberration. Specifically, there are the following two kinds of sharing:

(a) To achieve a wide-angle and yet make the refractive power of the first lens unit small in the positive, thereby correcting the off-axis aberration well with the first lens unit, and make the refractive power of the second lens unit great in the positive and divide the positive lens component in the second lens unit into two lens components, thereby correcting the on-axis aberration well with the second lens unit and making the optical system bright.

(b) To achieve a wide-angle and yet make the refractive power of the second lens unit small in the positive,

thereby correcting the off-axis aberration well with the second lens unit, and make the refractive power of the first lens unit great in the positive and divide the positive lens component in the first lens unit into two lens components, thereby correcting the on-axis aberration well with the first lens unit and making the optical system bright.

In the present invention, as described in items (a) and (b) above, the lens units forward and rearward of the stop S are made to take their share of the correction of the on-axis aberration and the correction of the off-axis correction to thereby enable the optical system to be bright, but correspondingly thereto, the symmetry of the refractive power on both sides of the stop is destroyed. Therefore, when focusing is effected by the use of the whole axial movement system, it becomes impossible to suppress the fluctuation of the off-axis aberration well.

So, the fluctuation of the off-axis aberration, when focusing is effected by the use of the whole axial movement system, will hereinafter be considered with respect to the following two types of optical systems in which the refractive power distribution on both sides of the stop is asymmetrical,

(I) Petrofocus Type; and

(II) Telephoto Type.

In the case of (I) above, the refractive power arrangement on both sides of the stop is negative and positive and the pupil magnification exceeds 1. Therefore, when the object position moves from the infinity state to a short distance, positive astigmatism occurs.

In the case of (II) above, the refractive power arrangement on both sides of the stop is positive and negative and the pupil magnification is smaller than 1. Therefore, when the object position moves from the infinity state to a short distance, negative astigmatism occurs.

In the present embodiment, when focusing by the whole axial movement is effected, the construction of item (a) above corresponds to (I) above, and when the object position moves from the infinity state to a short distance, positive astigmatism occurs. According to the definition of the third-order aberration coefficient in *Lens Designing Method* by Yoshiya Matsui, the third-order aberration coefficient III of the second lens unit exhibits the positive (+). Therefore, if the amount of axial movement of the second lens unit is made small relative to the amount of axial movement of the first lens unit, positive astigmatism could be suppressed well and the fluctuation of off-axis aberration caused during focusing could be suppressed.

Conversely, the construction of item (b) above corresponds to (II) above, and when the object position moves from the infinity state to a short distance, negative astigmatism occurs. At this time, the third-order aberration coefficient III of the second lens unit exhibits the negative (−). Therefore, if the amount of axial movement of the second lens unit is made great relative to the amount of axial movement of the first lens unit, the fluctuation of off-axis aberration caused during focusing could be alleviated.

As described above, the present invention effects focusing by the use of the so-called floating system that makes the amounts of axial movement of the first lens unit and the second lens unit different from each other during focusing, thereby enabling the fluctuation of off-axis aberration caused by focusing to be suppressed well.

In the present invention, it is desirable that with the above-described construction, the following conditional expression (9) or (10) be satisfied.

$$0<\Delta\cdot\phi/(\phi_a-\phi_b)<0.2 \quad (9)$$

$$0.3<|\phi 1/\phi|<0.95 \quad (10)$$

where

ϕ_a: the refractive power of the first lens unit,

ϕ_b: the refractive power of the second lens unit,

ϕ: the refractive power of the whole lens system,

Δ: an amount defined by the following equation:

$$\Delta=(\delta 1-\delta 2)/67\ 2$$

when the amount of movement of the first lens unit during focusing is $\delta 1$ and the amount of movement of the second lens unit is $\delta 2$,

$\phi 1$:the refractive power of the first lens component.

Conditional expression (9) is a condition for suppressing the fluctuation of aberration in short distance focusing very well.

If the upper limit value of conditional expression (9) is exceeded, the correction of the fluctuation of off-axis aberration caused by focusing will become excessive. If conversely, the lower limit value of conditional expression (9) is exceeded, the correction of the fluctuation of off-axis aberration caused by focusing will become deficient. Accordingly, it is preferable that the range of this condition be satisfied.

Conditional expression (10) is a condition for achieving the balance of the shortening of the full length and the effective diameter of the front lens.

If the upper limit value of conditional expression (10) is exceeded, the refractive power of the first lens component will become great to the negative and therefore, the diverging action will become strong and the back focal length will become too great. If conversely, the lower limit value of conditional expression (10) is exceeded, the refractive power of the first lens component will become small to the negative and the height of the ray of off-axis light passing through the first lens component will become far from the optical axis, and if an attempt is made to obtain the amount of marginal light, the effective diameter of the front lens will become great, which will lead to the bulkiness of the optical system, and this is not preferable.

The lens constructions of the embodiments of the present invention will hereinafter be described in greater detail.

All of Embodiments 1 to 7, as shown in FIGS. **1** to **7**, are lens systems of two groups G1 and G2 constituting component construction comprising, in succession from the object side, a first lens component L1 which is a negative meniscus lens having its convex surface facing the object side, a second lens component L2 which is a cemented positive meniscus lens comprising a biconvex lens and a biconcave lens, a stop S, a third lens component L3 which is a cemented positive meniscus lens comprised of a biconvex lens and a biconcave lens, a fourth lens component L4 which is a positive meniscus lens having its concave surface facing the object side, and a fifth lens component L5 which is a negative meniscus lens having its concave surface facing the object side.

Also, Embodiment 8, as shown in FIG. **8**, is a lens of five-unit six-component construction comprising, in succession from the object side, a first lens component L1 which is a negative meniscus lens having its convex surface facing the object side, a second lens component L2 which is a positive meniscus lens having its convex surface facing the object side, a stop S, a third lens component L3 which is a cemented positive meniscus lens comprised of a biconvex lens and a biconcave lens, a fourth lens component L4 which is a positive meniscus lens having its concave surface facing

the object side, and a fifth lens component L5 which is a negative meniscus lens having its concave surface facing the object side.

The numerical data of the respective embodiments of the present invention will be shown in Tables 1 to 8 below. In these tables, f represents the focal length, F_{NO} represents F-number and 2_{ω} represents the angle of view. The numbers at the left end represent the order from the object side, r represents the radius of curvature of each lens surface, d represents the spacing between adjacent lens surfaces, and the refractive index n and Abbe number ν are values for d-line (λ=587.6 nm).

By using popular aspherical lenses, it is of course possible to introduce an aspherical surface into the first lens component **L1** or the fifth lens component **L5** of the present invention to thereby correct astigmatism and curvature of

image field better and achieve a wide-angle, and to introduce an aspherical surface into the second lens component L2, the third lens component L3 or the fourth lens component L4 to thereby further correct spherical aberration and achieve a great relative aperture.

FIGS. 9A and 9B schematically show the refractive power arrangements of ninth to thirteenth embodiment of the present invention. FIG. 9A shows the refractive power arrangement when the object position is in the infinity state, and FIG. 9B shows the refractive power arrangement when the object position is in a short distance state. It is shown in FIGS. 9A and 9B that as the object position moves from the infinity to the short distance, the first lens unit G1 and the second lens unit G2 move toward the object side.

Each of the ninth to twelfth embodiments, as shown in FIG. 10, is of a construction which comprises, in succession from the object side, a first lens component L1 which is a negative meniscus lens having its convex surface facing the object side, a second lens component L2 which is a cemented lens of positive refractive power comprising a biconvex lens and a biconcave lens cemented together and having its convex surface facing the object side as a whole, a third lens component L3 comprising a cemented lens component of positive refractive power comprising a biconvex lens having its convex surface of sharper curvature facing the image side and a biconcave lens cemented thereto and having its convex surface facing the object side as a whole, a fourth lens component L4 which is a positive lens component having its concave surface facing the object side, and a fifth lens component L5 which is a negative meniscus lens having its convex surface facing the image side, a stop S being disposed between the second lens component L2 and the third lens component L3.

The numerical data of the ninth to twelfth embodiments of the present invention are given below. In the data Tables below, the numbers at the left end represents the order from the object side, r represents the radius of curvature of each lens surface, d represents the spacing between adjacent lens surface, and the refractive index n and Abbe number ν are values for d-line (λ=587.6 nm).

The thirteenth embodiment, as shown in FIG. **11**, is of a construction which comprises, in succession from the object side, a first lens component **L1** which is a negative meniscus lens having its convex surface facing the object side, a second lens component **L2** which is a positive meniscus lens having its convex surface of sharp curvature facing the object side, a third lens component **L3** which is and a positive lens component comprising a biconcave lens having its concave surface of sharper curvature facing the image side and a biconvex lens having its convex surface of sharper curvature facing the object side, said biconcave lens and said biconvex lens being cemented together, a fourth lens component **L4** of positive refractive power comprising a biconcave lens and a biconvex lens cemented together and having its convex surface facing the image side as a whole, and a fifth lens component **L5** which is a negative meniscus lens having its convex surface facing the image side, a stop S being disposed between the third lens component **L3** and the fourth lens component **L4**.

The numerical data of the thirteenth embodiment of the present invention are given below. In the data Table below, the numbers at the left end represents the order from the object side, r represents the radius of curvature of each lens surface, d represents the spacing between adjacent lens surfaces, and the refractive index n and Abbe number ν are values for d-line (λ=587.6 nm).

By using popular aspherical lenses in the ninth to thirteenth embodiments of the present invention, introducing an aspherical surface into the first lens component **L1** or the fifth lens component **L5**, it is possible to correct astigmatism and curvature of image field better and achieve a wider angle. By introducing an aspherical surface also into the second lens component **L2**, the third lens component **L3**, or the fourth lens component **L4**, it is of course possible to correct spherical aberration further and achieve a greater aperture.

According to the present invention, there can be achieved a wide-angle lens which is compact and high in performance

and as small as the order of F 2.8. The present invention can be used not only in 35 mm format cameras, but also in large format cameras. Further, when focusing is effected by general axial movement, the fluctuations of aberrations are very small and a good performance can be obtained.

What is claimed is:

1. A wide-angle objective lens system comprising, in the order from an object side:

a first negative lens component having a concave surface facing an image side;

a second lens component having positive refractive power and having a convex surface facing the object side;

a third lens component having a convex surface facing the object side;

a fourth lens component including a positive meniscus single lens having a concave surface facing the object side; and

a fifth lens component including a negative meniscus single lens having a concave surface facing the object side,

wherein said lens system satisfies the following condition:

$$0.40 \leqq D/f \leqq 1.00$$

where

f: the focal length of the entire lens system,

D: the total thickness of the lens system.

2. A wide-angle objective lens system according to claim **1**, wherein said lens system satisfies the following condition:

$$0.20 \leqq |r_{42}/f| \leqq 0.55$$

where

r_{42}: the radius of curvature of a surface of the fourth lens component which is nearest to the image side.

3. A wide-angle objective lens system comprising, in order from an object side:

a first negative lens component having a concave surface facing an image side;

a meniscus-shaped second lens component having positive refractive power and having a convex surface facing the object side;

a meniscus-shaped third lens component having a convex surface facing the object side;

a fourth lens component including a positive meniscus single lens having a concave surface facing the object side; and

a fifth lens component including a negative meniscus single lens having a concave surface facing the object side,

wherein said lens system satisfies the following condition:

$$0.40 \leqq D/f \leqq 1.00$$

where

f: the focal length of the entire lens system,

D: the total thickness of the lens system.

4. A wide-angle objective lens system according to claim **3**, wherein said lens system satisfies the following condition:

$$0.20 \leqq |r_{42}/f| \leqq 0.55$$

where

r_{42}: the radius of curvature of a surface of the fourth lens component which is nearest to the image side.

5. A wide-angle objective lens system comprising, in order from an object side:

a first lens unit including, in order from the object side, a first lens component having negative refractive power and a second lens component having positive refractive power;

a stop; and

a second lens unit having positive refractive power,

wherein said lens system consists of seven lenses and satisfies the following condition:

$$0.4 < D/f \leqq 1.0$$

where

f: the focal length of the entire lens system,

D: the total thickness of the lens system.

6. A wide-angle objective lens system according to claim **5**, wherein said lens system satisfies the following condition:

$$0.3 < |\phi 1/\phi| < +0.95$$

where

$\phi 1$: the refractive power of the first lens component,

ϕ: the refractive power of the whole lens system.

7. A wide-angle objective lens system according to claim **6**, wherein said lens system satisfies the following conditions:

$$0.02 \leqq |t1/f1| \leqq 0.1$$

$$N1 < 1.70$$

where

t1: an air space on an optical axis of the lens system between a surface of the first lens component which is nearest to an image side and a surface of the second lens component which is nearest to the object side,

f1: the focal length of the first lens component,

N1: the refractive index of the first lens component for d-line.

[57] **ABSTRACT**

The invention provides an immersion microscope objective which has a magnification of about 100× and a high numerical aperture of the order of 1.65, and is particularly excellent in axial optical properties. The first lens unit G_1 consists of a cemented doublet of a plano-convex lens and a meniscus lens concave on the object side and a positive meniscus lens concave on the object side, three in all; the second lens unit G_2 consists of a cemented triplet of double-convex, double-concave and double-convex lenses; the third lens unit G_3 consists of a cemented doublet of double-convex and double-concave lenses; the fourth lens unit G_4 consists of a cemented doublet of a double-convex lens and a negative meniscus lens concave on the object side; the fifth lens unit G_5 consists of a cemented doublet of double-convex and double-concave lenses; and the sixth lens unit G_6 consists of a cemented doublet of double-concave and double-convex lenses. The lens located on the side proximate to the object has a refractive index of at least 1.6.

IMMERSION MICROSCOPE OBJECTIVE

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to an immersion microscope objective, and more particularly to an immersion microscope objective of the apochromatic class which enables the numerical aperture (NA) to exceed 1.4.

2. Prior Art

Of vital importance for a microscope objective is to allow it to have a high numerical aperture (NA), thereby increasing the resolving power. In this regard, numerous proposals have so far been made in the art. For instance, JP-A 61(1986)-275813 and 4(1992)-311703 disclose microscope objectives which have a numerical aperture of 1.4, are well corrected in terms of chromatic aberration, and are improved in terms of the flatness of image surface as well. Since the immersion oil used has a refractive index of about 1.52, however, it is virtually impossible to achieve a further high numerical aperture, because the axial bundle from an object point on the axis is so diffused that much difficulty is involved in lens design per se. Thus, no objective with NA>1.4 is available.

An objective with NA>1.4 belongs virtually to an unheard-of technology. In recent years, however, microscopes have been used in various ways and differential interference has been used in high-tech fields so that the image can be magnified for video camera observation. The objective of the present invention, as will be explained later, can find some way to the realm of the unknown.

Set out below are objectives which are different in specifications from, but similar in construction to, the microscope objective according to the present invention. JM-B 41(1966)-12378 is not directed to an immersion objective, as can be seen from an NA of 0.8 and a magnification of 65×, but the third lens unit disclosed is similar in shape to the third lens unit of the invention which is one feature of the present invention. It is here to be understood that the present invention distinguishes over JM-B 41-12378 in that the first lens unit does not include a cemented doublet with the cemented surface being concave on the object side and the second lens unit includes no cemented triplet.

U.S. Pat. Nos. 3,700,311 and 4,373,785 are directed to an immersion objective having an NA of 1.3 and a magnification of 100×, which is identical with the present invention in terms of the first, fifth and sixth lens units and similar to the present invention in terms of the shape of the third and fourth lens units as well. However, the present invention distinguishes over them in that the second lens unit includes no cemented triplet and the third lens unit has positive refracting power. In this connection, it is to be noted that the third lens unit of the present invention is characterized by having negative refracting power.

SUMMARY OF THE INVENTION

The present invention has been made in view of such problems as mentioned in association with the prior art, and has for its object the provision of an immersion microscope objective which can have a numerical aperture higher than a conventionally achieved numerical aperture of 1.4 and has particularly improved axial optical performance.

According to one aspect of the present invention, the above-mentioned object is achieved by the provision of an immersion microscope objective which comprises, in order from the object side, a first lens unit having positive refracting power in its entirety and including a cemented lens with the cemented surface being concave on the object side; a second lens unit including a cemented lens of two or more lens components and having positive refracting power in its entirety; a third lens unit including a convex surface on its side proximate to the object, with the surface proximate to the image being strongly concave on the image side, and having negative refracting power in its entirety; a fourth lens unit including a strongly convex surface on its side proximate to the object and having positive refracting power in its entirety; a fifth lens unit including a convex surface on its side proximate to the object, with the surface proximate to the image being concave on the image side; and a sixth lens unit including a concave surface on its side proximate to the object, with the surface proximate to the image being convex on the image side.

According to another aspect of the present invention, there is provided an immersion microscope objective which comprises, in order from the object side, a first lens unit having positive refracting power in its entirety and including a cemented lens with the cemented surface being concave on the object side; a second lens unit including a cemented lens of two or more lens components and having positive refracting power in its entirety; a third lens unit including a convex surface on its side proximate to the object, with the surface proximate to the image being strongly concave on the image side, and having negative refracting power in its entirety; a fourth lens unit including a convex surface on its side proximate to the object and having positive refracting power in its entirety; a fifth lens unit including a convex surface on its side proximate to the object, with the surface proximate to the image being concave on the image side; and a sixth lens unit including a concave surface on its side proximate to the object, with the surface proximate to the image being convex on the image side, said immersion microscope objective further conforming to the following condition (1):

$$0.2<R_3/R_4<1.3 \quad (1)$$

where R_3 is the radius of curvature of the surface of the third lens unit that is proximate to the image side and R_4 is the radius of curvature of the surface of the fourth lens unit that is proximate to the object side.

Still another aspect of the present invention, there is provided an immersion microscope objective including a plurality of lens units with an immersion oil being applied to the object side of the lens surface proximate to the object for observation, characterized in that the lens proximate to the object side has an index of refraction of at least 1.6.

Preferably, the immersion microscope objective comprises, in order from the object side, a first lens unit having positive refracting power in its entirety and including a cemented lens with the cemented surface being concave on the object side, a second lens unit having positive refracting power in its entirety, a third lens unit having negative refracting power in its entirety, a fourth lens unit having positive refracting power in its entirety, a fifth lens unit with the concave surface being located on the image side, and a sixth lens unit with the concave surface being located on the object side.

Preferably, the second lens unit includes a cemented triplet.

Preferably, the second lens unit includes a cemented triplet consisting of positive, negative and positive lenses, and has positive refracting power in its entirety.

Preferably, the third lens unit includes a convex surface on its side proximate to the object with the surface proximate to the image being strongly concave on the image side, and has negative refracting power in its entirety.

Preferably, the fourth lens unit includes a convex surface on its side proximate to the object, and has positive refracting power in its entirety.

Preferably, the fifth lens unit includes a convex surface on its side proximate to the object with the surface proximate to the image being concave on the image side.

Preferably, the sixth lens unit includes a concave surface on its side proximate to the object with the surface proximate to the image being convex on the image side.

It is then preferable to conform the following condition (1):

$$0.2<R_3/R_4<1.3 \quad (1)$$

where R_3 is the radius of curvature of the surface of the third lens unit that is proximate to the image side and R_4 is the radius of curvature of the surface of the fourth lens unit that is proximate to the object side.

It is also preferable to conform to the following condition (2):

$$f/f_3<-0.01 \quad (2)$$

where f_3 is the focal length of the third lens unit and f is the overall focal length of the objective lens system.

A detailed account will now be given of why the above-mentioned lens arrangements are used and how they work.

To impart a high numerical aperture to the microscope objective an immersion oil having an index of refraction of at least 1.6 is used, and to reduce the occurrence of spherical aberration the index of refraction of the lens proximate to the object side must be at least 1.6.

In the present invention, the front lens of the first lens unit is formed of a cemented lens, while the index of refraction of the object-side lens is made as high as possible with the cemented surface being concave on the object side. This is to reduce the quantity of spherical aberration produced as much as possible.

Within the second lens unit there is disposed a cemented lens consisting of two or more lens components. This is effective for correction for axial chromatic aberration. With a luminous flux incident on the third lens unit, the flux is converged by the convex surface proximate to the object side and negative refracting power is exerted by the surface proximate to the image side, which is strongly concave on the image side. The flux is then diffused by this negative refracting power, but it is again converged by the convex surface of the fourth lens unit that is proximate to the object side. In the case of such a high-magnification and high-numerical aperture type objective, some considerable negative spherical aberration occurs because the overall positive refracting power of the lens system is strong. A point important for objective design is how negative refracting power is ensured for correction for spherical aberration. In the present invention, this is achieved by the so-called air lens effect of the negative refracting power, while an air separation is located between the surface of the third lens unit proximate to the image side and the surface of the fourth lens unit proximate to the object side.

The flux is further converged by the fourth lens unit of positive refracting power, and then allowed to be incident on so-called Gauss lens units, i.e., the fifth and sixth lens units, so that the flatness of the resultant image surface can be secured.

For satisfactory correction for aberrations, it is required to comply with the following condition (1):

$$0.2<R_3/R_4<1.3 \quad (1)$$

where R_3 is the radius of curvature of the surface of the third lens unit that is proximate to the image side and R_4 is the radius of curvature of the surface of the fourth lens unit that is proximate to the object side.

The ratio of R_3 and R_4 should lie within the range defined by condition (1), partly because negative refracting power is needed for correction for spherical aberration and partly because too strong negative refracting power puts the whole aberrations in an ill-balanced state. When the upper limit of 1.3 is exceeded, the whole aberrations are ill balanced because the positive refracting power of the surface of the fourth lens unit proximate to the object side becomes too strong. When the lower limit of 0.2 is not reached, the whole aberrations are again ill balanced because the negative refracting power of the surface of the third lens unit proximate to the image side becomes too strong.

To secure the negative refracting power required for correction for spherical aberration, it is effective to comply with the following condition (2):

$$f/f_3<-0.01 \quad (2)$$

where f_3 is the focal length of the third lens unit and f is the overall focal length of the objective lens system.

In this connection, the value corresponding to condition (2) in JM-B 41-12378 is −0.0031, indicating weak negative refracting power. All other conventional objectives have positive refracting power and so depart from condition (2).

Still other objects and advantages of the invention will in part be obvious and will in part be apparent from the specification.

The invention accordingly comprises the features of construction, combinations of elements, and arrangement of parts which will be exemplified in the construction hereinafter set forth, and the scope of the invention will be indicated in the claims.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a sectional view of Example 1 of the immersion microscope objective according to the present invention,

FIG. **2** is a sectional view of Example 3 of the immersion microscope objective according to the present invention,

FIG. **3** is a sectional view of an image formation lens used in combination with the objective of each example,

FIGS. **4**(*a*) to **4**(*c*) are aberration diagrams showing the spherical aberration, astigmatism and distortion of Example 1,

FIGS. **5**(*a*) to **5**(*c*) are aberration diagrams showing the spherical aberration, astigmatism and distortion of Example 2,

FIGS. **6**(*a*) to **6**(*c*) are aberration diagrams showing the spherical aberration, astigmatism and distortion of Example 3, and

FIGS. **7**(*a*) and **7**(*b*) schematically show the construction of a microscope with which the inventive objective is used, and illustrate the end portion of the objective on an enlarged scale.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

Examples 1 to 3 of the immersion microscope objective according to the present invention will now be explained by way of example but not by way of limitation.

Lens data on each example will be enumerated later. FIG. **1** is a sectional view of the lens arrangement of Example 1. Example 2 is substantially similar in construction to Example 1, and so is not illustrated. FIG. **2** is a sectional view of the lens arrangement of Example 3.

In each of Examples 1 and 2, the first lens unit G_1 consists of a cemented doublet of a plano-convex lens and a meniscus lens concave on the object side and a positive meniscus lens concave on the object side, three in all; the second lens unit G_2 consists of a cemented triplet of double-convex, double-concave and double-convex lenses; the third lens unit G_3 consists of a cemented doublet of double-convex and double-concave lenses; the fourth lens unit G_4 consists of a cemented doublet of a double-convex lens and a negative meniscus lens with the concave surface being located on the object side; the fifth lens unit G_5 consists of a cemented doublet of double-convex and double-concave lenses; and the sixth lens unit G_6 consists of a cemented doublet of double-concave and double-convex lenses.

In Example 3, the first lent unit G_1 consists of a cemented doublet of a plano-convex lens and a meniscus lens with the concave surface being located on the object side and a positive meniscus lens with the concave surface being located on the object side, three in all; the second lens unit G_2 consists of a cemented doublet of a negative meniscus lens with the convex surface being located on the object side and a double-convex lens, two in all; the third lens unit G_3 consists of a cemented doublet of double-concave and double-convex lenses; the fourth lens unit G_4 consists of a cemented doublet of a double-convex lens and a negative meniscus lens with the concave surface being located on the object side; the fifth lens unit G_5 consists of a cemented doublet of double-convex and double-concave lenses; and the sixth lens unit G_6 consists of a cemented doublet of double-concave and double-convex lenses.

Enumerated below will be numerical data on each example. The symbols used hereinafter but not hereinbefore have the following meanings:

r_1, r_2, . . . the radii of curvature of the lens surfaces as indicated in order from the object side

d_1, d_2, . . . the separations between the lens surfaces as indicated in order from the object side

n_{d1}, n_{d2}, . . . the d-line indices of refraction of the lenses as indicated in order from the object side

ν_{d1}, ν_{d2}, . . . the Abbe's number of the lenses as indicated in order from the object side.

In both Examples 1 and 2, the focal length is f=1.8, the magnification is 100×, the numerical aperture is NA=1.65, and the working distance is 0.1289. They are both of the immersion type, and the refractive indices of the immersion oil used here are n_d=1.78035, n_C=1.76883, n_F=1.80975 and n_g=1.83503. Notice that the affixes d, C, F and g represent values with respect to the d-, C-, F- and g-lines. The d-line index of refraction, Abbe's number and thickness of the cover glass used are designed to be n_d=1.7865, ν_d=50.0 and d=0.17 mm.

In Example 3, the focal length is f=1.8, the magnification is 100×, the numerical aperture is NA=1.25, and the working distance is 0.1329. This is again of the immersion type, and the indices of refraction of the immersion oil used are n_d=1.51548, n_C=1.51198, n_F=1.52394 and n_g=1.53088. The d-line index of refraction, Abbe's number and thickness of the cover glass used are designed to be n_d=1.521, ν_d=56.02 and d=0.17 mm.

Each of the above-exemplified objective is used in combination with an image-formation lens the data on which are given below by way of example, and one section of which is shown in FIG. **3**. In the data, r_1', r_2', . . . are the radii of the lens surfaces as indicated in order from the object side; d_1', d_2', . . . are the separations between the lens surfaces as indicated in order from the object side; n_{d1}', n_{d2}', . . . are the d-line indices of refraction of the lenses as indicated in order from the object side; and ν_{d1}', ν_{d2}', . . . are the Abbe's number of the lenses as indicated in order from the object side.

r_1'=68.7541, d_1'=7.7321, n_{d1}'=1.48749, ν_{d1}'=70.20
r_2'=−37.5679, d_2'=3.4742, n_{d2}'=1.80610, ν_{d2}'=40.95
r_3'=−102.8477, d_3'=0.6973
r_4'=84.3099, d_4'=6.0238, n_{d3}'=1.83400, ν_{d3}'=37.16
r_5'=−50.7100, d_5'=3.0298, n_{d4}'=1.64450, ν_{d4}'=40.82
r_6'=40.6619

The separation between each objective and the image-formation lens of FIG. **3** may lie somewhere between 50 mm and 170 mm. The spherical aberrations (a), astigmatisms (b) and distortions (c) of Examples 1, 2 and 3 at a typical separation of 105 mm are shown in FIGS. **4**, **5** and **6**. However, it is to be understood that similar aberrations are observed at separations of 50 mm to 170 mm.

A brief account will now be given of the schematic construction and action of the microscope on which the inventive immersion microscope objective is used. The immersion microscope is schematically shown in FIG. **7**(*a*), and an end portion of the objective is shown in FIG. **7**(*b*) on an enlarged scale. A microscope proper Ms is made up of an objective Ob, an eyepiece Ep, a specimen table St, and the like. An immersion oil Oi is added dropwise onto a cover glass Cg, while placed on the specimen table St is a specimen S held between a slide Sg and the cover glass Cg. As the objective Ob is brought close to the cover glass Cg, the gap between the objective Ob and the cover glass Cg is filled with the immersion oil Oi. With the gap between the objective Ob and the specimen S filled with the immersion oil Oi, it is possible to observe the image of the specimen with a magnification higher than would be possible with a dry objective system including an air gap layer, because a high-NA luminous flux from the specimen S is incident on the objective lens, contributing to image formation. In addition, the resultant image is improved in view of aberrations.

According to the present invention as explained above, it is possible to provide an immersion microscope objective which can have a magnification of about 100× and a high NA of the order of 1.65 and is particularly improved in terms of axial optical properties.

What we claims is:

1. An immersion microscope objective comprising, in order from an object side:

a first lens unit having positive refracting power as a whole, said first lens unit including a cemented lens with a cemented surface being concave on an object side;

a second lens unit having positive refracting power as a whole and including a cemented lens of at least two lens components;

a third lens unit having negative refracting power as a whole, said third lens unit including a convex surface on an object side, and said third lens unit being concave on an image side surface;

a fourth lens unit having positive refracting power as a whole and including a convex surface on an object side;

a fifth lens unit including a convex surface on an object side, and said fifth lens unit being concave on an image side; and

a sixth lens unit including a concave surface on an object side, said sixth lens unit being convex on an image side.

2. An immersion microscope objective comprising, in order from an object side:

a first lens unit having positive refracting power as a whole and including a cemented lens with a cemented surface being concave on an object side;

a second lens unit having positive refracting power as a whole and including a cemented lens of at least two lens components;

a third lens unit having negative refracting power as a whole, said third lens unit including a convex surface on an object side, and said third lens unit being concave on an image side surface;

a fourth lens unit having positive refracting power as a whole and including a convex surface on an object side surface;

a fifth lens unit including a convex surface on an object side, said fifth lens unit being concave on an image side; and

a sixth lens unit including a concave surface on an object side, said sixth lens unit being convex on an image side;

said immersion microscope objective further conforming to the following condition (1):

$$0.2<R_3/R_4<1.3 \quad (1)$$

where R_3 is a radius of curvature of said image side surface of said third lens unit, and R_4 is a radius of curvature of said object side surface of said fourth lens unit.

3. An immersion microscope objective comprising:

a plurality of lens units with an immersion oil being applied to a lens surface of a foremost object side for observation;

a foremost object side lens of said plurality of lens units having an index of refraction of at least 1.6.

4. An immersion microscope objective comprising, in order from an object side:

a first lens unit having positive refracting power as a whole and including a cemented lens with a cemented surface being concave on an object side;

a second lens unit having positive refracting power as a whole;

a third lens unit having negative refracting power as a whole;

a fourth lens unit having positive refracting power as a whole;

a fifth lens unit with a concave surface being located on an image side; and

a sixth lens unit with a concave surface being located on an object side.

5. The immersion microscope objective according to claim 3, wherein said plurality of lens units comprise, in order from an object side:

a first lens unit having positive refracting power as a whole and including a cemented lens with a cemented surface being concave on an object side;

a second lens unit having positive refracting power as a whole;

a third lens unit having negative refracting power as a whole;

a fourth lens unit having positive refracting power as a whole;

a fifth lens unit with a concave surface being located on an image side; and

a sixth lens unit with a concave surface being located on an object side.

6. The immersion microscope objective according to claim 4, wherein:

said second lens unit includes a cemented triplet.

7. The immersion microscope objective according to claim 3, wherein:

said plurality of lens units include a first lens unit on an object side of said immersion microscope objective, said first lens unit having a positive refracting power as a whole and including a cemented lens with a cemented surface being concave on an object side.

8. The immersion microscope objective according to claim 4, 5 or 6, wherein:

said second lens unit includes a cemented triplet consisting of a positive lens, a negative lens, and a positive lens.

9. The immersion microscope objective according to claim 4, 5 or 6, wherein:

said third lens unit includes a convex surface on an object side, said third lens unit being concave on an image side.

10. The immersion microscope objective according to claim 4, 5 or 6, wherein:

said fourth lens unit includes a convex surface on an object side.

11. The immersion microscope objective according to claim 4, 5 or 6, wherein:

said fifth lens unit includes a convex surface on an object side.

12. The immersion microscope objective according to claim 4, 5 or 6, wherein:

said sixth lens unit is convex on an image side.

13. The immersion microscope objective according to claim 4, 5 or 6, said immersion microscope objective satisfying the following condition (1):

$$0.2<R_3/R_4<1.3 \quad (1)$$

where R_3 is a radius of curvature of an image side surface of said third lens unit, and R_4 is a radius of curvature of an object side surface of said fourth lens unit.

14. The immersion microscope objective according to claim 4, 5 or 6, said immersion microscope objective satisfying the following condition (2):

$$f/f_3<-0.01 \quad (2)$$

where f_3 is a focal length of said third lens unit, and f is an overall focal length of said immersion microscope objective.

15. An immersion microscope objective according to claim 3, wherein:

said foremost object side lens of said plurality of lens units has an index of refraction of at least 1.7.

16. An immersion microscope objective according to claim 7, wherein:

said foremost object side lens of said plurality of lens units has an index of refraction of at least 1.7.

[57] **ABSTRACT**

The invention is directed to a microscope having an objective corrected to infinity and a pivotable binocular viewing unit. A tube lens is arranged downstream of the objective. The microscope includes at least one two-lens tube lens having a focal intercept greater than 200 mm as well as a tiltable mirror element and a further deflecting element mounted between the tube lens and the binocular viewing unit.

FIG. 3

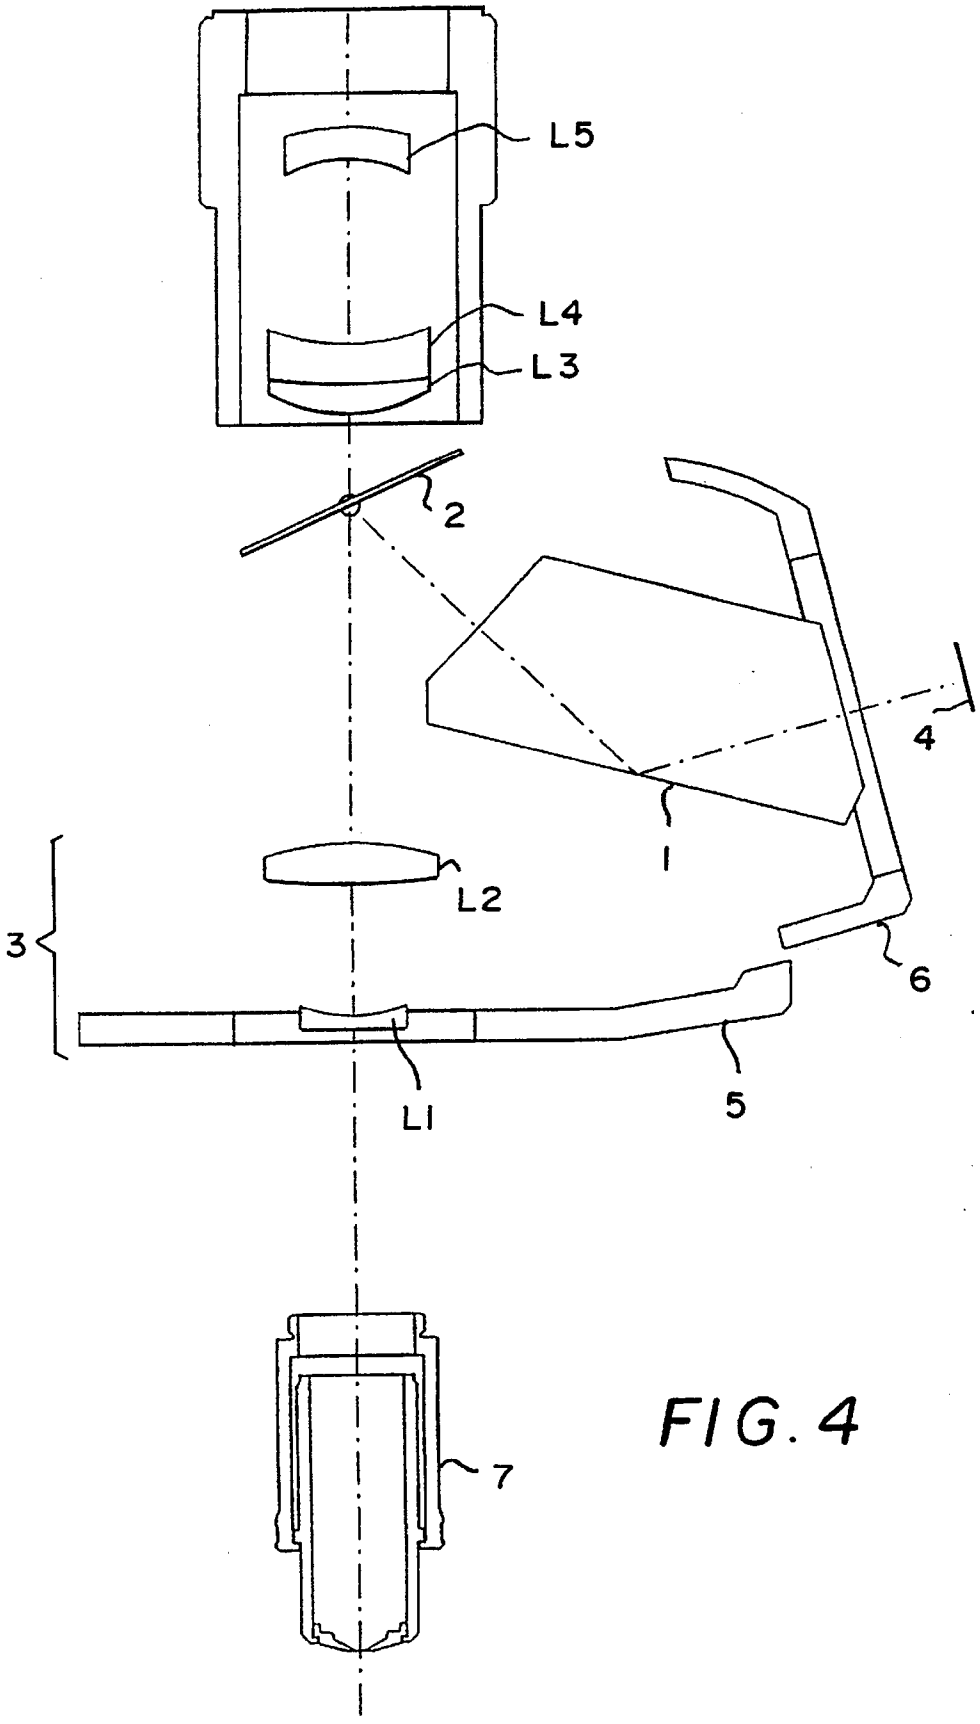

FIG. 4

MICROSCOPE HAVING AN OBJECTIVE CORRECTED TO INFINITY

FIELD OF THE INVENTION

The invention relates to a microscope having an objective corrected to infinity and a tube lens for generating an intermediate image in the intermediate image plane of a binocular viewing unit.

BACKGROUND OF THE INVENTION

Microscopes of this kind are offered as basic equipment by many microscope manufacturers. An inverted and reversed image is provided in the ocular because of the simple configuration which enables transmission of an image via two fixed deflections by a Bauernfeind prism. In this configuration, the movement of the object and of the ocular intermediate-image are mutually opposing and the users of these apparatus have become accustomed thereto.

For ergonomic reasons, there is a need for the user to have the viewing elevation and viewing angle so as to be changeable. For this purpose, many solutions for microscopes having objectives corrected to form an image in a finite focal plane are known wherein a variation of viewing elevation and viewing angle is provided. These apparatus have a common mirror surface which is also pivoted by about half of the angle when pivoting the binocular viewing unit containing the ocular. In this connection, reference can be made to German published patent application 3,334,690 as well as German Patent 1,098,233, German patent publication 218,692 and German utility model registration 7,931, 427. Reference can also be made to U.S. Pat. Nos. 4,798, 451; 4,643,541; and 4,576,450. A binocular viewing unit of this kind, which is configured in a simple manner, is disclosed in European published patent application 0,627, 642 for a stereomicroscope; however, here too, the objective is without a tube lens and is corrected to form an image in a finite focal plane.

Except for different basic configurations, all these solutions however have at least one of the following disadvantages:

(a) a high number of optical elements and the complexity associated therewith as well as possible image errors and contrast reduction;

(b) an additional intermediate image which is required because of the long optical path whereby the ocular intermediate image is generated so as to be erect and laterally correct in an unaccustomed manner;

(c) high mechanical complexity because several elements on different axes must be moved coupled to each other and at precise angles;

(d) a tube factor of greater than 1 because the path to the intermediate image is too long; and,

(e) the inability to realize an output for a camera in a simple manner.

One problem in this context is that conventional single-lens tube lenses, which are adapted to the microscope, have a focal length in the range of approximately 160 to 200 mm with a body magnification of 1 being pregiven. This relatively high focal length is countered by the requirement that an adapter between the body tube of the microscope and the camera should be realized with the shortest structural length possible.

The focal intercept (approximately 160 mm) of the tube lenses which are conventional for this type of microscope does not permit the image to be transmitted into the intermediate image plane when additional optical planar surfaces such as mirrors or prisms are required for pivoting the binocular viewing unit.

SUMMARY OF THE INVENTION

In view of the foregoing, it is an object of the invention to enable the viewing elevation and viewing angle of the binocular viewing unit holding the oculars to be changed and nonetheless maintain the total number of optically effective surfaces and mechanical rotational axes at a minimum. It is a further object of the invention to maintain the image position which is customary for the basic equipment, that is, inverted and reversed. It is still another object of the invention that the tube lens unit directly downstream of the objective have a magnification (tube factor) of 1 without intermediate imaging and to realize a compact camera adapter in a simple manner. The configuration of the invention is compact and space saving.

The microscope of the invention is for viewing an object and includes: an objective defining an optical axis and conducting a light beam coming from the object; the objective being corrected to infinity; a frame; a binocular viewing unit pivotally mounted on the frame so as to pivot through a predetermined angle relative to the frame; a tube lens unit mounted on the frame and arranged on the optical axis downstream of the objective as seen in the direction of the light beam; the tube lens unit including at least a first lens and a second lens arranged on said optical axis and having a focal intercept of greater than 200 mm; a first deflecting element mounted downstream of the tube lens unit for deflecting at least a component beam of the beam out of the optical axis; and, a second deflecting element pivotally mounted on the frame for deflecting the component beam into the binocular viewing unit.

A pivotal binocular viewing unit is realized with the microscope of the invention for which only two deflections and one rotational axis are adequate and wherein a magnification of 1 is nonetheless maintained without it being necessary to generate an intermediate image.

For this purpose, the deflection element (fixed or switchable) is configured as a mirror or a deflecting prism if a simple binocular viewing unit per se is desired or as a partially-transmitting mirror or splitting cube if a binocular tube with a camera adapter is desired in addition to the simple binocular viewing unit.

The tiltable mirror is entrained in a manner known per se via suitable gearing and tilts by an angular amount half of the tilt of the binocular viewing unit as disclosed, for example, in U.S. Pat. No. 2,132,122 incorporated herein by reference.

BRIEF DESCRIPTION OF THE DRAWINGS

The invention will now be described with reference to the drawings wherein:

FIG. **1** is a schematic perspective view of a first embodiment of the microscope of the invention;

FIG. **2** is a side elevation schematic view of the microscope shown in FIG. **1** equipped with an adapter for a camera;

FIG. **3** is a schematic plan view of the binocular viewing unit of the microscope of FIG. **2** as seen in the direction of arrow A thereof; and,

FIG. **4** is a schematic of a further embodiment of the microscope of the invention also equipped with an adapter.

DESCRIPTION OF THE PREFERRED EMBODIMENTS OF THE INVENTION

A tube lens unit **3** includes the lenses **L1** and **L2** and is mounted on a tube support **5** downstream of the microscope

objective **7** (see FIG. **2**). The objective **7** defines an optical axis **22** and conducts a light beam coming from an object (not shown) and the lenses L1 and L2 are arranged on this axis.

A deflection prism **1** includes a partially-transmitting face F at which the light beam coming from an object is split into a first component beam and a second component beam. The first component beam is deflected at the face F and the second component beam passes through the face F to a camera adapter **10** mounted downstream of the partially-transmitting face F. The camera adapter **10** comprises three lenses L3, L4 and L5. A camera **11** is shown mounted on the adapter **10** in FIG. **2**.

After being deflected at face F, the first component beam reaches the intermediate image plane **4** of the oculars via a tilt mirror **2** and the support **6** of a binocular viewing unit **12**. As shown in FIG. **3**, the binocular viewing unit **12** includes a beam splitter **14** for splitting the first component beam deflected by tilt mirror **2** into first and second subcomponent beams for respective ones of the oculars **18** and **19**. The first subcomponent beam passes via deflecting prism **15** to ocular **18** and the second subcomponent beam is deflected by deflecting cube **16** into glass cube **17** and then to ocular **19**.

The tilt mirror **2** is coupled so as to pivot (arrow **20**) with the pivoting movement of the binocular viewing unit **12** and tilts by half the pivot angle of the binocular viewing unit **12**. The tilting movement of binocular viewing unit **12** is schematically represented by double arrow **22**. This tilting movement and associated coupling of the tilt mirror is well known in the art and is described, for example, in U.S. Pat. No. 2,132,122, incorporated herein by reference.

The binocular tube assembly includes the binocular viewing unit **12**, tilt mirror **2**, prism **1** and tube lens unit **3** and has a tube length which extends from binocular viewing unit **12** to the tube lens unit **3**. The binocular tube assembly includes the tube lens unit **3** in order to adapt the assembly to the tube length and should not affect the overall magnification of the microscope. For this reason, the tube lens unit **3** has a magnification of one (1).

The tube lens unit **3** (lenses L1 and L2) generates the required long intercept distance (focal intercept) for the visual output in that the two lenses L1 and L2 are so configured that the amounts of the individual focal lengths thereof are 0.4±0.05 of the total focal length (that is, the focal length of the composite of lenses L1 and L2). The first lens L1 (viewed in the direction of light) is a diverging lens made of flint glass having a refractive index of 1.55±0.05 and an Abbe number of **43** to **47** and the lens L2 is a converging lens made of crown glass of Abbe number **65** to **69** and the distance of the mutually adjacent principal planes is 0.15 to 0.19 of the total focal length of the tube lens unit **3**.

In this way, and except for the image plane displacement, an excellent image correction is obtained, that is, axial and off-axis image errors such as chromatic aberration and spherical aberration in the image center, color magnification difference, distortion, coma, and astigmatism up to the field edge are eliminated.

The binocular viewing unit **12** is configured to have the longest possible focal intercept. In contrast, adapter **10** is configured to have the shortest possible focal intercept in order to keep its overall structural length, measured along the optical axis, at a minimum.

Furthermore, with the given individual focal lengths, the Petzval sum is zero as a condition for field flattening. The lens system L3 to L5 of adapter **10** functions to realize the conventional coupling dimension for the camera output and generates a short focal intercept by displacing the common principal plane. The common principal plane here is the plane common to the entire lens system (L3, L4 and L5) of the adapter **10**. The common principal plane lies forward of the intermediate image and is that plane in which the image side principal point is disposed. The principal plane in the following embodiment lies forward of lens L3.

A first element (L3, L4) is a converging composite lens having the focal length of 1.1 to 1.2 of the total focal length and the second element L5 is at least one diverging individual lens made of crown glass having the refractive index of 1.48 to 1.53 with the Abbe number **68** to **72** and a focal length of 0.5 to 0.6 of the total focal length. The principal plane spacing is 0.18 to 0.22 of the total focal length. In this way, the same imaging quality is obtained as at the visual output.

The principal plane spacing here is the spacing between the principal plane of composite lens (L3, L4) and the principal plane of the individual lens L5. The intermediate image generated by the adapter **10** lies in the spacing of the focal intercept which is in the plane of the film of the camera **11**.

The following table provides data on an advantageous embodiment of the lens systems (L1, L2) as well as (L3 to L5). The intercept distance here is 238 mm.

Lens	Glass Type	Radius of Curvature	Distance (mm)
L1	LLF1	r1 = infinite	d1 = 2.5
		r2 = 34.475	
			d2 = 26.4
L2	BK10	r3 = 124.099	d3 = 4.0
		r4 = −44.342	
L3	FK5	r5 = 24.939	d4 = 4.2
		r6 = 87.217	
L4	BaF52	r7 = 33.741	d5 = 5.9
			d6 = 30.9
L5	FK5	r8 = −18.970	d8 = 4.5
		r9 = −34.975	

In FIG. **4**, a tilt mirror **2** is mounted in the beam path downstream of the tube lens unit **3**. The tilt mirror **2** is configured so as to be partially transmitting for generating a camera beam path with the lens system of the invention. The deflecting prism **1** follows the tilt mirror **2**. In this case, the prism executes a movement coupled directly to the movement of the support **6** of the binocular viewing unit (not shown in FIG. **4**). Reference numeral **7** identifies the microscope objective of the microscope.

It is understood that the foregoing description is that of the preferred embodiments of the invention and that various changes and modifications may be made thereto without departing from the spirit and scope of the invention as defined in the appended claims.

What is claimed is:

1. A microscope for viewing an object comprising:

an objective defining an optical axis and conducting a light beam coming from the object;

said objective being corrected to infinity;

a frame;

a binocular viewing unit pivotally mounted on said frame so as to pivot through a predetermined angle relative to said frame;

a tube lens unit mounted on said frame and arranged on said optical axis downstream of said objective as seen in the direction of said light beam;

said tube lens unit including at least a first lens and a second lens arranged on said optical axis and having a focal intercept of greater than 200 mm;

a first deflecting element mounted downstream of said tube lens unit for deflecting at least a component beam of said beam out of said optical axis; and,

a second deflecting element pivotally mounted on said frame for deflecting said component beam into said binocular viewing unit.

2. The microscope of claim **1**, wherein said first deflecting element is a deflecting prism and said second deflecting element is a tiltable mirror.

3. The microscope of claim **2**, further comprising:

an adapter for interfacing a camera with said microscope;

said adapter being arranged on said optical axis downstream of said deflecting prism;

said component beam being a first component beam and said deflecting prism having a partially-transmitting surface whereat said light beam is split to form said first component beam deflected toward said mirror and a second component beam passing through said partially-transmitting surface along said optical axis and into said adapter; and,

said adapter including first and second lenses for transmitting said second component beam into the camera.

4. The microscope of claim **1**, wherein said first deflecting element is a tiltable mirror and said second deflecting element is a deflecting prism.

5. The microscope of claim **4**, further comprising:

an adapter for interfacing a camera with said microscope;

said adapter being arranged on said optical axis downstream of said tiltable mirror;

said component beam being a first component beam and said tiltable mirror being a partially-transmitting mirror whereat said light beam is split to form said first component beam deflected toward said deflecting prism and a second component beam passing through said partially-transmitting mirror along said optical axis and into said adapter; and,

said adapter including first and second lenses for transmitting said second component beam into the camera.

6. The microscope of claim **1**, said tube lens unit including first and second lenses having first and second individual focal lengths and said first and second lenses conjointly defining a total focal length; said first and second lenses being so configured that said individual focal lengths are each 0.4±0.05 of said total focal length; said first lens being the first lens in said direction of said light beam and said first lens being a diverging lens made of flint glass having a refractive index of 1.55±0.05 and an Abbe number in the range of 43 to 47; and, said second lens being a converging lens made of crown glass having an Abbe number in the range of 65 to 69; and, said first and second lenses defining mutually adjacent respective principal planes conjointly defining a spacing therebetween corresponding to 0.19 of said total focal length.

7. The microscope of claim **3**, said adapter including a first lens having a first focal length and a second lens having a second focal length; said first and second lenses conjointly defining a total focal length; said first and second lenses defining mutually adjacent respective principal planes which are shifted to provide a short focal intercept in that said first lens is a converging composite lens with said first focal length being 1.1 to 1.2 of said total focal length and said second lens is a diverging lens made of crown glass having a refractive index of 1.48 to 1.53 and an Abbe number in the range of 68 to 72 and said second focal length being 0.5 to 0.6 of said total focal length; and, said principal planes conjointly defining a spacing therebetween corresponding to 0.18 to 0.22 of said total focal length.

[57] **ABSTRACT**

A broad-bandwidth interferometric device is adapted for longitudinal insertion into a cylinder cavity to produce irradiance signals at multiple vertical-scanning positions as a function of optical path differences between a reference mirror incorporated in the probe and the cylinder-wall surface. The light-source beam is passed through an objective lens placed longitudinally in the cylinder and then divided by a beam splitter disposed in fixed relation to the cylinder wall to produce a test beam directed radially to the wall and a reference beam directed axially to a reference mirror disposed in fixed relation to the lens. During scanning, the objective lens and reference mirror are translated together, while the beam splitter remains stationary with respect to the cylinder wall, thereby varying the position of the focal point of the test beam and providing the vertical-scanning effect required to produce interference fringes and a corresponding map of the tested cylinder surface. In order to reduce the length of the instrument, the reference beam may be folded to the side by a reflective surface and the reference mirror may be positioned perpendicularly to the main axis of the instrument. In that case, the lens, fold mirror and reference mirror are all translated together, while the beam splitter remains stationary and fixed with the test surface.

ORTHOGONAL-SCANNING MICROSCOPE OBJECTIVE FOR VERTICAL-SCANNING AND PHASE-SHIFTING INTERFEROMETRY

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention is related in general to the field of interferometry and, in particular, to a novel device for measuring the surface roughness of cylinder walls in internal combustion engines.

2. Description of the Related Art

The surface roughness of cylinder walls in internal combustion engines is critical to good performance and durability. When the surface is too smooth, engine oil is thoroughly cleaned away by the recurring scraping action of piston rings over the cylinder walls, thereby greatly reducing lubrication to the parts and correspondingly increasing wear and tear. On the other hand, when the surface is too rough, the rings abut unevenly against the cylinder walls creating nonuniform lubricant distribution, which results in lubricant losses and nonuniform pressure distribution between the abutting surfaces, in turn also producing excessive wear and tear. In the ideal situation, the interior walls of cylinders have a very uniform surface with sufficient microscopic roughness to retain lubricant particles within uniformly-distributed recesses in the wall, such that the surface is never fully depleted of lubricant by the scraping action of the rings. Experience has shown that an average roughness of about 0.2 to 1.5 microns is desirable for standard automobile and truck internal-combustion engines.

In view of this objective, engine manufacturers inspect cylinder walls and measure their surface roughness as normal quality-control steps. The instruments used consist of borescopes, optical devices capable of showing small details of internal features, including imperfections and cracks, and stylus profilometers, mechanical devices for measuring the topography of the cylinder wall, typically with a limited three-dimensional resolution. Boroscopes are not very useful in testing for surface roughness because their resolution is not sufficient to identify problem spots; in addition, they provide a view of the cylinder wall but do not produce a quantified profile of the tested surface. The stylus instruments operate on contact, thereby affecting the tested surface, and have no ability to perform three-dimensional measurements.

Accordingly, there is a need for a better instrument for the purpose of rapidly, reliably and non-destructively measuring the roughness of cylinder walls. This invention is directed at providing a novel instrument and procedure based on non-contact interferometric principles for measuring the surface roughness of cylinder walls.

BRIEF SUMMARY OF THE INVENTION

One primary goal of this invention is an interferometer suitable for scanning a test surface placed orthogonally from, or at an angle with, the direction of motion of the scanning mechanism.

Another important object of the invention is a non-contact instrument and method for mapping the surface profile of a cylinder wall over a large scanning range, preferably up to several millimeters.

Another basic objective is a technique for cylinder walls based on optical measurements that permit higher vertical resolution than currently available with stylus-profilometry technology.

Another objective is a device and a method for measuring surface-roughness of cylinder walls more rapidly and reliably than with prior-art procedures.

Another goal is an instrument that makes it possible to obtain three-dimensional measurements of the profile of a test surface.

Finally, another goal is a method and apparatus that are suitable for implementation with relatively minor modifications to existing interferometric surface profilers.

Therefore, according to these and other objectives, the principle of interferometry, in particular vertical scanning interferometry (VSI), is applied to measuring the relative height of peaks and valleys in the surface of a cylinder wall to produce a topographic map of the tested area. The invention consists preferably of a broad-bandwidth interferometric device or probe adapted for longitudinal insertion into a cylinder cavity to produce irradiance signals at multiple vertical-scanning positions as a function of optical path differences between a reference mirror incorporated in the probe and the cylinder-wall surface. The light-source beam is passed through an objective lens placed longitudinally in the cylinder and then divided by a beam splitter disposed in fixed relation to the cylinder wall to produce a test beam directed radially to the wall and a reference beam directed axially to a reference mirror disposed in fixed relation to the lens. During scanning, the objective lens and reference mirror are translated together, while the beam splitter remains stationary with respect to the cylinder wall, thereby varying the position of the focal point of the test beam and providing the vertical-scanning effect required to produce interference fringes and a corresponding map of the tested cylinder surface. In order to reduce the length of the instrument, the reference beam may be folded to the side by a reflective surface and the reference mirror may be positioned perpendicularly to the main axis of the instrument. In that case, the lens, fold mirror and reference mirror are all translated together, while the beam splitter remains stationary and fixed with respect to the test surface.

Various other purposes and advantages of the invention will become clear from its description in the specification that follows and from the novel features particularly pointed out in the appended claims. Therefore, to the accomplishment of the objectives described above, this invention consists of the features hereinafter illustrated in the drawings, fully described in the detailed description of the preferred embodiment and particularly pointed out in the claims. However, such drawings and description disclose but one of the various ways in which the invention may be practiced.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a simplified schematic representation of a conventional vertical-scanning interferometer.

FIG. **2** is a schematic representation of the interference microscope objective portion of a cylinder-bore scanner according to one embodiment of the present invention, wherein the reference mirror is translated vertically to perform vertical-scanning interferometric measurements on a stationary cylinder wall placed at right angle to the axis of the stationary objective lens and beam splitter.

FIG. **3** is a schematic representation of the interference microscope objective portion of a cylinder-bore scanner according to the preferred embodiment of the present invention, wherein the objective lens and reference mirror are translated vertically to perform vertical-scanning interferometric measurements on a stationary cylinder wall placed at right angle to the axis of the objective lens through a stationary beam splitter.

FIG. 4 is a schematic representation of the optical effect of scanning the device of FIG. 3.

FIG. 5 is a variation of the device of FIG. 3 comprising a fold mirror reflecting the reference beam to the side of the objective's optical axis in order to shorten the length of the instrument.

FIG. 6 is another variation of the device of FIG. 3, wherein the bean splitter is rotatable about the optical axis of the instrument, thereby enabling it to view and test sample surfaces in all radial directions.

DESCRIPTION OF THE PREFERRED EMBODIMENTS OF THE INVENTION

The heart of this invention lies in the recognition that vertical-scanning interferometry can be performed on the surface of the interior wall of an internal-combustion cylinder by modifying a conventional interference microscope objective so that the objective lens and the reference mirror are translated together along the optical axis in the longitudinal direction of the cylinder, while the beam splitter is kept stationary with respect to the test surface, that is, the cylinder wall, which is disposed orthogonally to the direction of scanning. Such configuration results in vertical scanning of the wall surface even though no radial movement occurs within the cylinder.

The invention is applicable to both vertical scanning-interferometry (VSI) and phase-shifting interferometry (PSI), but it is mostly practical only when a rough surface is being measured; that is, when VSI is the suitable interferometric method. Therefore, the invention will be described in terms of vertical-scanning interferometry but it is understood that it should not be so limited.

Vertical scanning interferometry is a technique where broad bandwidth light, such as white light, is used as a light source in an interferometer and the degree of modulation, or contrast, of interference fringes produced by the instrument is measured for various distances between a test surface and the reference surface of the interferometer (each distance corresponding to a different optical path difference, OPD) to determine surface height. The method typically involves vertical scanning of a reference arm of the interferometer with respect to a stationary sample and calculation of the relative modulation of the intensity signal as a function of vertical position.

As illustrated in simple schematic form in FIG. 1, typical interferometric equipment **10** comprises a light source **12** directing a beam L of light through an illuminator **14** toward a beam splitter **16**, which reflects the light downward in the direction of a test surface S. The light reflected by the beam splitter **16** passes through an objective lens **22** focused on the test surface S. The objective lens **22**, a beam splitter **24** and a reference mirror together **26** constitute an interference microscope assembly **20** adapted for relative movement with respect to the test surface, so that two light beams LR and LT are generated for producing interference fringes. The reference beam LR is focused on the surface of the reference surface **26**, while the test beam LT is focused on the test or sample surface S. Note that the test beam LT is shown for simplicity as coaxial with the optical axis of the objective lens **22**, but in practice it may be shifted either by design or by optics imperfections to a parallel or slightly angular position by the beam splitter **24**, as would be obvious to one skilled in the art. The beams reflected from the reference mirror **26** and the test surface S pass back up through the optics of the objective lens **22** and upward through the beam splitter **16** to a solid-state detector array **28** in a camera **30** in coaxial alignment with the objective **22**, so that two light beams produce interference fringes as a result of the optical path difference between the reference mirror and the test surface S. The imaging array **28** normally consists of individual charge-coupled-device (CCD) cells or other sensing apparatus adapted to detect and record a two-dimensional array of signals corresponding to interference effects produced by the interferometer as a result of light reflected at individual x-y-coordinate pixels in the surface S and received at corresponding individual cells in the array. Appropriate electronic hardware is provided to process the signals generated by each cell and transmit digitized light-intensity data D to a microprocessor for processing. The reference arm **20**, containing the microscope objective **22**, beam splitter **24** and reference surface **26** incorporated within it, is adapted for vertical movement (along the z coordinate) to focus the image of the sample surface S on the detector array **28**. Thus, an interference-fringe map is generated by detecting the intensity of the light signal received in each cell of the array **28**.

In conventional vertical-scanning interferometry, a profile of the surface S is produced by repeating irradiance measurements at different, normally constant-interval OPD's between the microscope objective **20** and the test surface S (that is, at different elevations of the scanning unit), so as to provide information concerning the variation of light intensity at each pixel as the corresponding optical path difference is varied systematically with respect to an initial reference point. Thus, the position of the scanning unit corresponding to maximum interference at each pixel is determined and used, based on the distance from the reference point, to calculate the height of the surface at that pixel. Either the interference microscope assembly **20** or the test surface S is moved vertically (vertical scanning) to produce these repeated measurements. It is noted that this type of interference microscope conforms to the configuration of a special type of Michelson interferometer.

The prior art discloses various ways by which VSI may be implemented to determine surface height by calculating the degree of fringe modulation, or contrast, of the interference fringes produced at the light detector for various OPD's between the test surface and the reference surface of the interferometer. All methods involve vertical scanning of the interference microscope assembly (or its equivalent components, in the case of other types of interferometers) with respect to a stationary sample, or viceversa. The components of the interference microscope objective **20** (lens **22**, beam splitter **24** and reference mirror **26**) are kept in fixed relation and move together to maintain a fixed focused optical path to the reference mirror while the sample S is scanned. This arrangement allows large vertical scans (in the order of hundreds of microns, up to several millimeters, depending on the scanning mechanism utilized); this scanning range ensures that different portions of the sample S, successively appearing within the focal depth of the lens **22**, produce observable interference fringes during the entire scan.

In order to measure the roughness of a cylinder wall with an interferometric device adapted to scan vertically along the cylinder's main axis and test a surface disposed orthogonally thereto, the positions of the test and reference surfaces in FIG. 1 necessarily would have to be inverted, as shown in the schematic view of FIG. 2, to reflect the coaxial position of the cylinder wall with respect to the optical axis A of the objective lens **22**. According to one aspect of the present invention, such a configuration (shown for simplicity with a single objective lens **22** receiving collimated light L) could

be used to perform vertical scanning interferometry by translating the reference surface **26** in the direction of arrows A1 along the optical axis of the objective lens using a scanning mechanism **40** fixedly mounted on a support surface **42**, but the scanning range of such a device would be limited to a fraction of the depth of focus of the lens **22**. When scanning outside the focal depth, in practice no useful fringes are produced because the vertical resolution is greatly degraded. Therefore, while viable as a solution for measuring a relatively smooth surface (for example, an F/4 objective lens will provide a useful scanning range of about 10 microns with visible light), the configuration of FIG. **2** is not practical for cylinder walls with greater peak-to-valley roughness.

The main aspect of the present invention concerns the idea of performing vertical scanning by translating the objective lens **22** and the reference mirror **26** together, while keeping the beam splitter **24** fixed with respect to the test surface S (i.e., with respect to the cylinder wall). As shown in the schematic representation of FIG. **3**, the objective-lens/mirror assembly **44** is translated in the direction of arrows A2 along the optical axis of the objective lens using a scanning mechanism **40** fixedly mounted on a support surface **42**. Because of the fixed distance between the lens **22** and the reference mirror **26**, the mirror remains in focus during the entire range of translation. At the same time, as the distance between the lens **22** and the splitter **24** varies, so will the position of the focal plane of the test beam LT, thereby providing a variable OPD for producing fringes during scanning.

FIG. **4** illustrates the effect of the simultaneous and equal translation of the objective lens **22** and the reference mirror **26** along the direction of arrows A3. The initial position, shown in solid line, results in a test focal plane **46** determined by the initial distance between the lens and the beam splitter **24**. As the lens **22** is moved closer to the splitter **24** by a distance d (the result is shown in broken line), the reference mirror **26** remains in the reference focal plane because the distance between the lens and the mirror is unchanged, but the test focal plane is shifted away. Thus, during the translation corresponding to the two lens and reference mirror positions indicated in FIG. **4**, the focal plane of the test beam travels through the same distance d and successively produces interference fringes corresponding to points found in focus on the scanned surface. Therefore, the scanning range can be extended as needed to cover the roughness of the sample surface.

According to this principle, the preferred embodiment of the present invention consists of an interferometric probe adapted for longitudinal insertion in the cavity of a cylinder and comprising a microscope objective lens and a reference surface disposed in fixed relation to one another and adapted to translate together along the cylinder's axis during vertical scanning. The probe also comprises a stationary beam splitter to produce a test beam projecting radially (orthogonally to the optical axis of the objective lens) and focused on the cylinder wall. In operation, the probe of the invention is inserted longitudinally into the cavity of a cylinder such that the optical axis of the objective lens **22** is parallel to the main axis of the cylinder. As would be obvious to those skilled in the art of interferometry, the probe must be rigidly secured to a supporting structure so that its position relative to the target surface can be finely adjusted. The probe is placed in such a way that the target surface on the wall of the cylinder is within the focal depth of the test beam LT. Conventional VSI is then carried out by translating the objective-lens/mirror assembly **44** in the direction of arrows A2 (FIG. **3**) and the relative height of each surface pixel is measured by estimating the peak of the corresponding modulation envelope from the intensity measurements collected during scanning. Note that the curvature of the test surface (the internal wall of a cylinder) is accounted for and eliminated by appropriate software that is conventionally used when interferometric measurements are performed on curved surfaces. It is also noted that the interferometric arrangement of FIG. **3** can be used for phase-shifting measurements as well when a smooth surface is being tested. In such cases, though, conventional configurations would be just as effective and probably preferred.

As those skilled in the art would readily understand, the concept of this invention could be applied as well in a system where the test beam is projected at an angle (which may or may not be 90 degrees) from the optical axis A of the objective lens and from the scanning direction of the interferometer, and where the test beam is then focused on a test surface placed perpendicularly to the test beam. The principles of the invention apply to any such configuration as well because a vertical translation of the objective-lens/mirror assembly **44** in the direction of arrows A2 will produce the same amount of translation of the focal plane **46** along the test beam's axis, such that height measurements can be made of a test surface lying within that plane. In practice, though, if the angle between the optical axis of the objective lens and the test beam is small (measured with respect to the direction of the lens' focal point), the test and reference surfaces will be too close to each other for practical implementation. In addition, the beam splitter would have to be very large to reflect the test beam at a small angle with respect to the reference beam. If the angle is large, the test beam will be reflected back toward the objective lens, with comparable undesirable effects. Therefore, for optimal performance the test beam should be close to orthogonal to the optical axis of the objective lens. In practice, it is expected that any angle between about 25 and 155 degrees could be implemented in a straightforward manner for most applications. Smaller and larger angles would require special design configurations that may be harder to implement and, therefore, not preferred.

The concept of the invention could also be implemented by directing the reference beam LR out of the beam splitter **24** at an angle with respect to the optical axis A of the objective lens **22**. This configuration would require coordinating the translation of the objective lens and of reference mirror in such a way that the reference mirror would remain in focus throughout the scanning procedure, while the beam splitter would remain stationary. As well understood in the art, this could be accomplished by translating the objective lens and the reference mirror vertically by different amounts (the relative motion would depend on the geometry and optical characteristics of the beam splitter), or by translating each along its respective axis by the same amount. The relationship between the vertical movement of the objective lens and the vertical movement of the reference beam's focal plane is a function of the structural configuration of the beam splitter **24** and is well understood in the art. Accordingly, appropriate correction would be made as a function of the angle between the reference beam and the optical axis of the objective lens to account for the proportionate (but unequal) vertical displacement of the focal plane with respect to that of the objective lens. Note that the term "vertical" is used here to indicate the direction of scanning of the interferometer, but any other scanning direction would be equivalent for the purposes of this invention.

FIG. **5** illustrates a refinement of the concept of the present invention which may be preferred for applications

where the length of the probe is crucial and needs to be as compact as possible to conform to limited space requirements. In order to shorten the tip of the probe, a fold mirror **48** is placed within the reference beam LR to divert it to the side (preferably, but not necessarily, at 90 degrees). This allows the placement of the reference mirror **26** at the focal length in a direction appropriate for shortening the physical length of the probe. Obviously, this embodiment of the invention is optically equivalent to the one illustrated in FIG. **3**.

In still another embodiment of the invention illustrated schematically in FIG. **6**, the beam splitter **24**, which is stationary along the optical axis A of the objective lens **22**, is made rotatable around such axis (arrows A4) so as to provide flexibility with respect to the radial direction of the test beam LT. This feature enables use of the probe of the invention to project the test beam in any direction on a plane perpendicular to the lens' optical axis and scan any surface placed in parallel to the probe. For example, it can be used to test the entire circumference of the inside wall of a cylinder, as shown in the figure where dotted and solid lines correspond to two alternative positions of the beam splitter **24**. Note that this feature is illustrated in FIG. **6** with reference to the embodiment of FIG. **3**, but it could be implemented in equivalent fashion with the probe of FIG. **5**.

Thus, the present invention exploits the optical effect of translating a microscope objective lens and a reference mirror together along the lens' optical axis while maintaining a beam splitter in stationary position to reflect the test beam radially therefrom to carry out vertical scanning interferometry on a test surface disposed in parallel to the direction of scanning. This procedure is not limited by the focal depth of the objective lens and, therefore, it can be implemented over a wide scanning range, constrained only by the characteristics of the mechanism utilized to effect the scanning translation. With the motorized devices recently introduced in the art, the present invention has been used over a scanning range of about one millimeter and it is expected that VSI will soon be carried out reliably over a scanning of several millimeters.

Various changes in the details, steps and components that have been described may be made by those skilled in the art within the principles and scope of the invention herein illustrated and defined in the appended claims. Therefore, while the present invention has been shown and described herein in what is believed to be the most practical and preferred embodiments, it is recognized that departures can be made therefrom within the scope of the invention, which is not to be limited to the details disclosed herein but is to be accorded the full scope of the claims so as to embrace any and all equivalent processes and products.

We claim:

1. In a device for executing interferometric measurements at multiple distances between a reference surface and a test surface disposed in aligned optical paths to a light-intensity sensor, wherein a scanning means is used to effect a relative translation between the reference surface and the test surface to achieve said multiple distances at which light-intensity outputs are produced, wherein said light-intensity outputs are used to calculate a surface-height output corresponding to a profile of the test surface, and wherein the test surface is disposed orthogonally to a direction forming a first angle with a scanning direction of the interferometer, an interference microscope that comprises:

(a) an objective lens having an optical axis and a focal plane;

(b) a beam splitter aligned with the optical axis of the objective lens, said beam splitter producing a reference beam and producing a test beam directed substantially along said direction forming a first angle with the scanning direction of the interferometer and toward said test surface placed substantially within the focal plane of said test beam;

(c) a reference surface disposed substantially within the focal plane of said reference beam; and

(d) scanning means for translating the objective lens and the reference surface together while the beam splitter and test surface remain stationary.

2. The device of claim **1**, wherein said beam splitter is rotatable around said optical axis.

3. The device of claim **1**, wherein said first angle is substantially 90 degrees.

4. The device of claim **2**, wherein said first angle is substantially 90 degrees.

5. The device of claim **1**, further comprising a fold mirror placed between the beam splitter and the reference surface in fixed relation to the objective lens to divert the reference beam toward a direction at a second angle with said optical axis of the objective lens.

6. The device of claim **5**, wherein said first angle is substantially 90 degrees.

7. The device of claim **5**, wherein said second angle is substantially 90 degrees.

8. The device of claim **5**, wherein said first angle is substantially 90 degrees and said second angle is substantially 90 degrees.

9. The device of claim **5**, wherein said beam splitter is rotatable around said optical axis.

10. The device of claim **9**, wherein said first angle is substantially 90 degrees.

11. The device of claim **9**, wherein said second angle is substantially 90 degrees.

12. The device of claim **9**, wherein said first angle is substantially 90 degrees and said second angle is substantially 90 degrees.

13. In a device for executing interferometric measurements at multiple distances between a reference surface and a test surface disposed in aligned optical paths to a light-intensity sensor, wherein a scanning means is used to effect a relative translation between the reference surface and the test surface to achieve said multiple distances at which light-intensity outputs are produced, wherein said light-intensity outputs are used to calculate a surface-height output corresponding to a profile of the test surface, and wherein the test surface is disposed orthogonally to a scanning direction of the interferometer, an interference microscope that comprises:

(a) an objective lens having an optical axis and a focal plane;

(b) a beam splitter aligned with the optical axis of the objective lens, said beam splitter producing a reference beam directed substantially along said optical axis and producing a test beam directed substantially along said direction forming a first angle with the scanning direction of the interferometer and toward said test surface placed substantially within the focal plane of said test beam;

(c) a reference surface disposed in fixed relation to the objective lens and substantially within the focal plane of said reference beam; and

(d) scanning means for translating the objective lens and the reference surface together along said optical axis while the beam splitter and test surface remain stationary.

14. A method of executing interferometric measurements at multiple distances between a reference surface and a test surface disposed in aligned optical paths to a light-intensity sensor, wherein a scanning means is used to effect a relative translation between the reference surface and the test surface to achieve said multiple distances at which light-intensity outputs are produced, wherein said light-intensity outputs are used to calculate a surface-height output corresponding to a profile of the test surface, and wherein the test surface is disposed orthogonally to a direction forming a first angle with a scanning direction of the interferometer, said method comprising the following steps:

(a) providing an objective lens having an optical axis and a focal plane;

(b) providing a beam splitter aligned with the optical axis of the objective lens and adapted to produce a reference beam directed along said optical axis and a test beam directed along said direction forming a first angle with the scanning direction of the interferometer toward said test surface;

(c) providing a reference surface disposed in fixed relation to the objective lens and substantially within the focal plane of said reference beam;

(d) providing scanning means for translating the objective lens and reference surface together along said optical axis;

(e) placing a test surface substantially within the focal plane of said test beam; and

(f) translating said objective lens and reference surface together along said optical axis to perform interferometric measurements while the beam splitter and test surface remain stationary.

15. The method of claim 14, wherein said first angle is substantially 90 degrees.

16. The method of claim 14, wherein said beam splitter is rotatable around said optical axis.

17. The method of claim 16, wherein said first angle is substantially 90 degrees.

18. The method of claim 14, wherein said step (c) further comprises providing a fold mirror placed between the beam splitter and the reference surface in fixed relation to the objective lens to divert the reference beam toward a direction at a second angle with said optical axis of the objective lens; and wherein said step (f) further comprises translating the fold mirror together with the objective lens and the reference surface.

19. The method of claim 18, wherein said first angle is substantially 90 degrees.

20. The method of claim 18, wherein said second angle is substantially 90 degrees.

21. The method of claim 18, wherein said first angle is substantially 90 degrees and said second angle is substantially 90 degrees.

22. The method of claim 18, wherein said beam splitter is rotatable around said optical axis.

23. The method of claim 22, wherein said first angle is substantially 90 degrees.

24. The method of claim 22, wherein said second angle is substantially 90 degrees.

25. The method of claim 22, wherein said first angle is substantially 90 degrees and said second angle is substantially 90 degrees.

26. A method of executing vertical-scanning interferometric measurements at multiple distances between a reference surface and a test surface disposed in aligned optical paths to a light-intensity sensor, wherein a scanning means is used to effect a relative translation between the reference surface and the test surface to achieve said multiple distances at which light-intensity outputs are produced, wherein said light-intensity outputs are used to calculate a surface-height output corresponding to a profile of the test surface, and wherein the test surface is disposed in parallel to the scanning direction of the interferometer, said method comprising the following steps:

(a) providing an objective lens having an optical axis and a focal plane;

(b) providing a beam splitter disposed in fixed relation to the objective lens, aligned with the optical axis thereof, and adapted to produce a reference beam directed along said optical axis and a test beam directed radially from the optical axis toward a test surface;

(c) providing a reference surface substantially within the focal plane of said reference beam;

(d) providing scanning means for translating the reference surface along said optical axis; and

(e) placing a test surface substantially within the focal plane of said test beam; and

(f) translating said reference surface along said optical axis to perform vertical-scanning while the objective lens and the beam splitter remain stationary.

27. The method of claim 26, wherein said beam splitter is rotatable around said optical axis.

[57] **ABSTRACT**

A high performance, large aperture, long focal length visible waveband objective lens system (**60**) comprises a telephoto objective lens group (**48**) spaced from a focusing lens group (**49**) and an auxiliary lens group (**54**), all supported in a support assembly (**43**) of fixed length. The lens groups are aligned on a common optical axis (**40**) and arranged to form a real image (**34**) in image space (**42**) from radiation entering the system (**60**) from a real object in object space (**41**). The telephoto objective lens group (**48**) is stationary and comprises a positively powered lens element (A) and a negatively powered lens sub-group (**50**) containing a quintuplet lens group (**51**) with lens elements (B, C, D, E, F) and a lens element (G). The quintuplet lens group includes two lens elements (C and E) of liquid materials which exhibit highly abnormal partial dispersions and one solid glass lens element (F) which exhibits slightly abnormal partial dispersion In addition, the liquid materials of lens elements (C) and (E) exhibit very large changes in refractive index with temperature and the material of lens element (F) exhibits a compensating large change in refractive index with temperature. The remaining lens elements of the system are common optical glass and exhibit substantially normal partial dispersions.

OBJECTIVE LENS SYSTEM

This invention relates to an optical objective lens system for cameras and the like and, in particular, to a large aperture, high performance, long focal length lens system using a combination of solid lenses and liquid lenses.

BACKGROUND OF THE INVENTION

High performance optical systems, such as for cinematography, require superior polychromatic optical performance and athermal characteristics. Previously, the design of large aperture, high performance, long focal length lens systems for the visible waveband has been limited by practical issues concerning length, volume, weight, cost and the availability of large dimensional sizes of raw material, especially glasses that exhibit abnormal dispersion characteristics. Catadioptric lenses do offer a significant reduction in overall length but they have the disadvantage of producing donut shaped images of out of focus point objects which, in many applications including cinematography, high definition television ("HDTV") and advanced television ("ATV") is unnatural and highly distracting or even disturbing to a viewer. In comparison, telephoto lenses offer reasonable compactness in terms of length and volume but demand multiple lens elements in the front objective grouping. These elements, apart from producing large weight, necessitate the use of abnormal dispersion glass or crystalline materials which are high in cost with limited availability or which may even be unavailable in large sizes. Aspheric surfaces can be used in the front objective grouping to reduce the quantity of lens elements required but aspheric surfaces are difficult to manufacture, are high in cost and do not eliminate the need for abnormal dispersion materials. Liquid optical materials which exhibit abnormal and highly abnormal dispersion characteristics, sometimes referred to as abnormal dispersion liquids (ADLs), offer an alternative to using abnormal dispersion glasses and crystals. However, liquid lens elements need to be supported and sealed by solid elements, for example, between two glass elements in a glass/liquid/glass cell which can be heavy in weight, especially when located in the front objective grouping because of the large diameter of the elements. If two compensating ADLs are employed, then the weight will be increased even more by the two glass/liquid/glass elements. In addition, liquid optical materials tend to exhibit large changes in refractive index with temperature changes, as compared to solid lens materials, which causes defocusing as well as loss of chromatic aberration control thus making the liquid lens system unusable at elevated and depressed temperatures.

SUMMARY OF THE INVENTION

It is an object of this invention to provide a large aperture, high performance, long focal length lens system for the visible waveband that is low in weight, relatively inexpensive, athermal and has superior polychromatic optical performance. For accomplishing that object, the lens system of this invention comprises a stationary telephoto objective lens grouping incorporating two liquid lens elements, a movable first focus lens grouping, a movable second focus lens grouping and a stationary auxiliary lens grouping which internally houses an optical stop or iris, all aligned on a common optical axis. By virtue of the telephoto objective design configuration, which contains a single spherically surfaced primary objective lens element and a rear telephoto lens grouping formed by quintuplet and singlet lenses, the system is compact and inexpensive with low weight.

The two independently movable focus lens groupings provide continuous focusing at a constant aperture over a focus range extending from an infinity object distance to a close focus object to image distance with an object to image magnification ratio of less than 3:1.

The two liquid elements, because of their highly abnormal dispersions, have low optical powers and therefore do not significantly affect the monochromatic aberration balance of the system. However, the system is well corrected for chromatic aberration. Furthermore, because the two liquid lens elements have opposite powers, they substantially compensate and correct the system as a whole for thermally induced defocus and aberration variations caused mainly by the very large changes in refractive index with temperature of the liquid materials. Although, the quintuplet lens group is formed by five elements, three glass and two liquid, the very thin liquid elements contribute very little to the overall weight of the quintuplet lens. The rear element of the quintuplet, which is farthest from the primary objective element, is preferably made of a glass or crystalline material that exhibits slightly abnormal dispersion and change in refractive index with temperature thus providing the system with a more consistent level of high performance at all operating temperatures. Apart from the two liquid elements and one rear element of the quintuplet lens, all remaining elements of the system can be made of standard glasses or other types of material which are low in cost and readily available from various vendors.

Another object of the present invention is to provide a large aperture high performance, long focal length lens system with a compact telephoto objective lens configuration which utilizes two abnormal dispersion liquid elements and one partly abnormal dispersion glass element. A still further object of the present invention is to provide a long focal length lens system which is low in weight and cost and provides a close focusing capability from an infinity object distance to a minimum focus distance magnification, object to image, of less than 3:1. A further object of the present invention is to provide a long focal length lens system which is substantially passively athermal both in constancy of image focus and quality over an extended range of object to image focus distances.

Other objects and advantages of the present invention will appear from the following description of a preferred embodiment and the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is an optical diagram of the objective lens system of the present invention;

FIG. **2** is an enlarged diagrammatic view of a portion of the lens system shown in FIG. **1**; and

FIGS. **3A**, **3B** and **3C** are optical diagrams of the optical system shown in FIG. **1** with the focus lens groupings adjusted to different positions for three representative focus positions.

DESCRIPTION OF A PREFERRED EMBODIMENT OF THE INVENTION

A preferred embodiment of the present invention is now described by way of a design example with accompanying Figures and Tables.

As depicted in FIG. **1**, an optical system **60** comprises an objective lens arrangement **47** containing a plurality of spherically surfaced lens elements in lens groupings **48**, **49**, **54** aligned on an optical axis **40** wherein a positively

powered, stationary, primary telephoto objective lens element "A" with refractive surfaces **1**, **2** collects radiation from an object plane OP in object space **41** and relays said radiation to a negatively powered, stationary, secondary telephoto objective group **50**, which relays said radiation to a positively powered, axially movable first focus group **52**, which relays said radiation to a negatively powered, axially movable second focus group **53**, which relays said radiation to a weakly powered, stationary, auxiliary lens group **54** which produces a real image at image plane **34** in image space **42**. The real image at plane **34** may be received by film in a camera or the like in a conventional manner. The shapes of the lens elements illustrated in the FIGS. are only generally representative of the exact shapes, radii, thicknesses and sizes which are set forth below in Table I, to be discussed below. FIGS. **1**, **3A**, **3B** and **3C** include representative ray trace lines extending from immediately in front of lens element A through the optical system **60** to image plane **34**.

The secondary telephoto objective group **50**, comprises a quintuplet lens sub-group **51** as depicted in greater detail in FIG. **2**, with lens elements B, C, D, E, F having lens refractive surfaces **3**, **4**, **5**, **6**, **7**, **8** and a singlet lens G with refractive surfaces **9**, **10**. It should be noted that for convenient reference, the two refractive "surfaces" of each of the two liquid lens elements C and E have been designated by the same reference number as the solid lens element refractive surface that contains that liquid because they are coincidental and coextensive therewith, such as, rear surface **4** of solid lens element B is the front surface **4** of liquid lens element C, rear surface **5** of liquid lens element C is the front surface **5** of solid lens element D, etc., whereby there are only six numerals 3–8 for the ten refractive surfaces of the five lens elements. The lens elements C and E are of liquid optical materials known as abnormal dispersion liquids (ADLs), as described below more fully, and the lens elements B, D and F are of solid lens material. The liquid lens element C is captured between solid lens elements B and D and the liquid lens element E is captured between solid lens elements D and F, with the five lens elements permanently assembled, in a conventional manner, to form the quintuplet (i.e. five integrated lenses) lens subgroup **51**. The liquid materials for the liquid lens elements C and E are selected to be complimentary or self-compensating for their respective optical characteristics (as well as the optical characteristics of the system). Specifically, it is preferred that liquid lens C be an ADL that provides chromatic correction, such as an ADL manufactured by Cargille Laboratories, Inc., Cedar Grove, N.J., USA and marketed by Lockheed Martin under the Code No. 642134. However, the ADL for liquid lens C also has the characteristic of causing substantial defocusing, as compared with glass lens materials, in response to temperature changes. Thus, the ADL for liquid lens element E is selected to provide optical power which compensates for the defocusing by liquid lens element C caused by temperature changes, such as an ADL manufactured by Cargille Laboratories, Inc. and marketed by Lockheed Martin under the Code No. 295990. However, the ADL for lens element E degrades the chromatic correction accomplished by lens element C and, therefore, the specific ADLs selected for lens elements C and E cannot completely compensate for both temperature changes (i.e. the system is not athermal) and chromatic aberrations (i.e. image quality). Thus, it is preferred that solid lens element F be made from a glass or crystalline having a refractive index and thermal expansion which are relatively moderately temperature sensitive and a dispersion which is relatively partly abnormal, such as a glass made and sold by Ohara Corp. under the Code No. 438950 and name FPL **53** or the equivalent. In the preferred embodiment, the remaining solid lens elements B and D of the quintuplet lens **51** are preferably made from an inexpensive optical glass. It is to be understood that one or more of the other lens elements B, D or G of the secondary telephoto objective group **50** or the primary telephoto objective lens element A or even the lens elements of the first focus group **52** may be made of glass or crystalline material having the afore-described properties of lens element F rather than or in addition to lens element F for providing the thermal, chromatic and other corrections not compensated for by the liquid lens elements C and E without departing from the present invention.

The first focus group **52** comprises three lens elements H, I, J with refractive surfaces **11**, **12**, **13**, **14**, **15**, **16** and the second focus group **53** comprises three lens elements K, L, M with surfaces **17**, **18**, **19**, **20**, **21** wherein the lens elements K, L form a doublet lens **55**. Again, as with the quintuplet lens **51**, the identical facing surfaces of lens elements K and L that are joined are identified as a single refractive surface **18**. The auxiliary group **54** comprises a first singlet lens N with refractive surfaces **22**, **23**, an optical stop or iris P, a first doublet lens **56** formed by lens elements R, S with refractive surfaces **24**, **25**, **26**, a field stop T, a second doublet lens **57** formed by lens elements V, W with refractive surfaces **27**, **28**, **29**, a second singlet lens X with refractive surfaces **30**, **31** and a third singlet lens Y with refractive surfaces **32**, **33**. As noted above, all of the lens elements H-N, R, S, V, W, X and Y may be of a common optical glass material. The optical system **60** is supported by a structure **43** which preferably is made of a light weight material, such as aluminum.

The construction of the optical system **60** is such that the distance on the optical axis **40** between the vertex of refractive surface **1** of lens element A to the real image plane **34** is fixed and remains constant, except for thermal expansion and contraction in the support structure **43**. The first focus group **52** and the second focus group **53** are axially movable along the optical axis **40**, as shown by the arrows **52A** and **53A**, respectively, in FIG. **1**, in a conventional manner by conventional mechanisms without changing the length of the optical system **60**. The supporting structure **43** is constructed to support all of the lens elements (A-N, R, S, V, W, X and Y) in series in that order on the optical axis **40** and at a maximum aperture diameter.

FIGS. **3A**, **3B** and **3C** diagrammatically illustrate the optical system **60** with the first focus group **52** and the second focus group **53** moved to their respective positions for three different representative distances from the object plane OP to the image plane **34**. Specifically, FIG. **3A** shows the focus positions (i) of the first and second focus groups **52** and **53** for an object to image distance of infinity, FIG. **3B** shows the focus positions (ii) of the first and second focus groups **52** and **53** with an object to image distance of 3863.492 mm, and FIG. **3C** shows the focus positions (iii) of the first and second focus groups **52** and **53** for an object image distance of 2105.921 mm, which is the minimum focus distance for the optical system **60** to provide high performance optical characteristics. The positions of the first and second focus groups **52** and **53** and the respective object to image distances shown in FIGS. **3A**, **3B** and **3C**, respectively, correspond to the Separation distances set forth in Table I (described and set forth below). The difference in the respective numbers for object to image distance in FIGS. **3B** and **3C** and the Separation between the Object Plane OP and refractive surface **1** of lens element A in Table I is simply

the length (668 mm) of the optical system **60** between the vertex of refractive surface **1** of lens element A to the image plane **34**. The second focus group **53** moves over a substantial range of approximately 67 mm for providing most of the focusing function of the optical system **60** while the first focus group **52** moves only a small amount of less than 4 mm for refining the focus by correcting or balancing aberrations that result from the substantial movement of the second focus group **53**, which distances are also represented in Table I below, and from the lens group **48**, as shown by the different positions of the ray trace lines through lens group **48** in FIGS. 3A, 3B and 3C.

Specific data for all of the lens elements of optical system **60**, including surface separations, radii, material (type, code and name) and aperture diameter are set forth in the following Table I, wherein "Separation" is the distance between one Surface and the next Surface (objective plane OP, refractive surfaces **1–33** and image plane **34**), and the "Type" of the "Material" is the material between that surface and the next surface progressing downwardly in Table I. The Separation for surfaces OP, **10**, **16** and **21** are given at three representative focus distances, assuming the overall length of optical system **60** from the vertex of surface **1** of lens element A to the image plane **34** remains constant at 668 mm (i.e. ignoring thermal changes), and those focus distances are specifically set forth in the Separation column, opposite Object Plane OP. In other words, for example, for an intermediate focus distance of 3195.492 mm from the object plane OP to the refractive surface **1** of lens element A, the distance between the rear refractive surface **10** of the lens element G to the front refractive surface **11** of the lens element H is 8.168 mm and the latter distance changes as the focus distance changes because the first focus group **52** which includes lens element H moves axially for focusing. The "Aperture Diameter" at the Image Plane **34** given in Table I is actually the image diameter based on paraxial data. All data in Table I is given at a temperature of 20° C. (68° F.).

The "Radius of Curvature" values set forth in Table I have a positive value when the center of the radius of curvature of that refractive surface is closer to the image space **42** than is the vertex of that refractive surface and a negative value when the center of the radius curvature of that refractive surface is closer to the object space **41** than is the vertex of that refractive surface.

In Table I, the Code and Name of the Material for all of the solid lens elements are based on glass lenses manufactured and marketed by Ohara Corporation but many of the glasses are available from other sources and may be substituted if such glasses are substantially similar in optical and mechanical properties, especially refractive index, dispersion, thermal expansion and change of refractive index with temperature. The liquid lens elements C and E in Table I are manufactured by Cargille Laboratories, Inc. and marketed by Lockheed Martin, but any equivalent ADLs may be used. The refractive indices of the ADLs, as supplied by Lockheed Martin from actual test data, for the liquid lens elements C and E for five representative wavelengths and at three different temperatures are set forth in the following Table II.

TABLE II

Liquid Lens	Temperature		Refractive Indices at wavelengths (nanometers)				
Element	°C.	°F.	656.3	587.6	546.1	486.1	435.8
C	20	68	1.630387	1.642690	1.653508	1.678028	1.716612
C	40	104	1.619870	1.631899	1.642414	1.666424	1.704113

The image quality of the optical system **60** has been computed theoretically in accordance with accepted optical principles and programs to provide image quality data in terms of modulation, i.e. contrast, of the modulation transfer function (commonly known by the acronym MTF), the results of which are shown in the following Table III. The image quality data in terms of MTF was calculated on the basis of a temperature of 20° C. for three focal distances and at temperatures of 0° C. and 40° C. at the nominal design focus distance, as shown in Table III, and the data assumed an all aluminum support structure **43**. The glass coefficients of refractive index and expansion with temperature were obtained from commonly available data publications produced by the vendor, Ohara Corporation. The refractive index of the two liquid lens elements C and E were obtained from the vendor, Lockheed Martin. The liquid thermal expansion coefficients of the ADLs of the two liquid lens elements C and E are of no consequence and were not considered because the ADLs are constrained by the surrounding glass elements and conventional mounting elements that include bellows or reservoirs (external to the optical area of use) that accommodate the volumetric change in the ADLs. With these parameters, the approximate polychromatic MTF performance (all at the best focus averaged over the field) in terms of percent (%) Modulation at Radial (R) and Tangential (T) azimuths for wavelengths of 656.3, 587.6, 546.1, 486.1 and 435.8 nanometers with respective weightings of 70, 80, 90, 75, 60 and full field % distortion and % relative illumination, with a normalized field position for maximum image heights equal to 14.45 mm are shown in Table III.

TABLE III

Object to Image Distance	Temperature		0	½		¾		Full			% Relative
(mm)	°C.	°F.	R & T	R	T	R	T	R	T	% Distortion	Illumination
Infinity	20	68	82.1	82.5	81.8	84.4	77.0	84.6	67.9	0.4	51
3863.94	20	68	84.2	84.7	83.2	84.2	79.1	83.1	71.6	0.4	56
2105.92	20	68	75.1	74.1	75.0	75.6	75.6	77.6	71.9	0.4	57

3863.94	0	32	72.4	70.1	70.7	68.0	68.0	65.2	62.8	0.4	56

Table III illustrates that the optical system **60** is optimized for maximum performance at object to image distances from about three meters to infinity at a temperature of 20° C. (68° F.). The system full aperture is f/2.75 at all focus distances and temperatures. The spectral waveband of the optical system is 435.8 to 656.3 nanometers. At 20° C. (68° F.) and for an object at infinity distance, the effective focal length (EFL) of this optical system is approximately 692.9 mm. The telephoto ratio of the EFL to the overall length of approximately 668 mm (measured from the vertex of surface **1** of lens element A to the image surface **34**) is 668/692.9 equals 0.964. Generally, for a lens to be considered telephoto, the telephoto ratio should be less than 1.0. Although the telephoto ratio of 0.964 of the optical system **60** is not much less than 1.0, this is the result of optionally

selected design features of the internal housing optics that consume considerable length along the optical axis **40**, such as the first and second independently movable focus groups **52** and **53**. The telephoto ratio can easily be reduced to less than 0.9 by excluding one or more of the optional design features described above. The focus range of the optical system **60**, as measured axially from the object to the image plane **34** at 20° C. is from infinity to 2.106 meters (6'10.9") and has a close focus magnification of 2.53:1 (object:image). The temperature range of the optical system **60**, as designed and described above, is 0° C. (32° F.) to 40° C. (104° F.) with a nominal design temperature of 20° C. (68° F.). However, this optical system will maintain a high level of performance over at least an extended temperature range of −10° C. to +50° C., although some degradation of image quality may be observed at high temperatures. It should be noted that within the temperature range of −10° C. to +50° C., the ADLs of the liquid lens elements C and E will not solidify and, of course, the solid lens elements will not liquify. The optical system **60** provides the required "high performance" as measured by the polychromatic MTF being greater than 70% and preferably greater than 80% (on axis) and 60% to 70% (off axis) over the field, as shown by the values set forth in Table III.

It should be noted that while the liquid materials or ADLs of the liquid lens elements C and E have been described as partly or highly "abnormal" and the material of the solid lens element F has been described as a glass or crystalline that is relatively moderately temperature sensitive and relatively partly "abnormal" that these descriptions relate to the differences in characteristics of those materials from normal, classical or standard optical materials, usually glass. Here, the material of solid lens element F is described as having a dispersion which is relatively partly abnormal only by comparison to the liquid material of liquid lens element C which is highly abnormal compared to other glasses but indeed the solid lens element F is substantially abnormal when compared to normal glasses. It will readily appear to those skilled in the art from the teachings of this invention that numerous variations in the materials for the liquid lens elements and the solid lens elements, whether available now or in the future, may be adopted without departing from the teachings of this invention so long as the resultant optical system **60** is athermal and corrected for chromatic aberrations and other aberrations.

What is claimed is:

1. A visible waveband optical system comprising, an objective lens for delivering visible radiation emanating from an object space to a radiation detecting device, said objective lens including a plurality of lens elements in a plurality of lens groupings mounted in spaced apart relationship on a common support assembly and aligned on a common optical axis, a first lens grouping adjacent the object space formed by a telephoto objective lens comprising primary and secondary lens groups, said first lens grouping arranged to accept visible radiation from the object space and remaining lens groupings are sequentially arranged to accept and relay said radiation from the first lens grouping to form a real image thereof at an external image surface, said primary lens group formed by a single lens element, said secondary lens group formed by a quintuplet lens and a singlet lens element, said primary lens group being positively powered and made of a glass material having a refractive index and expansion which are substantially temperature insensitive and a dispersion which is substantially normal, the secondary lens group being negatively powered with said quintuplet lens being formed by a sandwich of three solid lens elements and two liquid lens elements in a solid/liquid/solid/liquid/solid configuration, said liquid lens elements being separate from each other, two of said solid lens elements made of glass materials having a refractive index and expansion which are substantially temperature insensitive and a dispersion which is substantially normal, a third solid lens element of said three solid lens elements made of at least one of either a glass or crystalline material having a refractive index and expansion which are temperature sensitive and a dispersion which is abnormal, said two liquid lens elements being visibly transmissive optical liquids having refractive indices which are temperature sensitive and the dispersions which are abnormal, and said singlet lens element of said secondary lens group is made of glass material having a refractive index and expansion which are substantially temperature insensitive and a dispersion which is substantially normal, said optical system being such that chromatic and thermal aberrations introduced by lens element refractive index, dispersion and expansion and displacements caused by the expansion of said support assembly are compensated by said two liquid lens elements and said third solid lens element of glass or crystalline material so that the optical system is rendered substantially passively athermal both in constancy of image position and image quality.

2. The optical system of claim **1** further comprising an internal focusing lens group.

3. The optical system of claim **1**, further comprising two internal focusing lens groups.

4. The optical system of claim **2** or **3**, wherein said focusing lens groups are internally movable relative to the support assembly, said support assembly having a fixed length.

5. The optical system of claim **4**, further comprising an auxiliary lens group for forming an image.

6. The optical system of claim **5** wherein said lens groups are arranged on the common axis in the order of said primary lens group, said quintuplet lens, said singlet lens element, said two focusing lens groups, and said auxiliary lens group.

7. The optical system of claim **1**, wherein said singlet lens element is made of one of either a glass or a crystalline material having a refractive index and expansion which are temperature sensitive and a dispersion which is abnormal, and said quintuplet lens has three solid elements made of glasses, the refractive index and expansion of which are substantially temperature insensitive and the dispersions of which are substantially normal.

8. The optical system as claimed in claim **1**, wherein said common support assembly is made of aluminum.

9. A visible waveband optical system, comprising, an objective lens group having a single lens element and a quintuplet lens aligned on a common axis and substantially spaced from each other with said quintuplet lens being closer to an image plane, said quintuplet lens comprised of first, second and third solid lens elements and first and second liquid lens elements with said first liquid lens element formed between said first and second solid lens elements and said second liquid lens element formed between said second and third solid lens elements, said first and second liquid lens elements being of two different visibly transmissive optical liquids having temperature sensitive refractive indices and abnormal dispersions for producing chromatic and thermal aberration corrections, two of said solid lens elements being of glass materials having refractive indexes and coefficients of thermal expansion which are substantially temperature insensitive, and the remaining one of the three solid lens elements having a refractive index and a coefficient of thermal expansion which are temperature

sensitive for producing chromatic and thermal aberration corrections that are uncorrected by said two liquid lens elements.

10. The optical system of claim **9**, wherein said single lens element is positively powered for receiving radiation from an object and transmitting the radiation to said quintuplet lens.

11. The optical system of claim **9** or **10**, wherein said quintuplet lens is negatively powered.

12. The optical system of claim **11**, further comprising a focusing lens group.

13. The optical system of claim **11**, further comprising two focusing lens groups, wherein each focusing lens group is independently movable along the common axis.

14. The optical system of claim **13**, further comprising an auxiliary lens group for forming an image on said image plane.

15. The optical system of claim **14**, wherein said lens groups are arranged on the common axis in the order of said single positively powered lens element, said quintuplet lens, said two focusing lens groups, and said auxiliary lens group.

16. The optical system of claim **9**, wherein said optical liquid of said first liquid lens element has a refractive index and abnormal dispersion for producing primarily chromatic correction, and said optical liquid of said second liquid lens element has characteristics for producing primarily thermal aberration correction.

17. The optical system of claim **16**, wherein said optical liquid of said second liquid lens primarily corrects thermal aberrations created by said first liquid lens.

18. The optical system of claim **16**, wherein said first liquid lens is located on a side of said second solid lens that is closer to said single lens element.

19. The optical system of claim **9** or **18**, wherein said remaining one of the three solid lens elements is located on a side of said quintuplet lens farther than said two solid lens elements from said single lens element.

20. A visible waveband optical system, comprising, an objective lens group having a single lens element and a quintuplet lens aligned on a common axis and substantially spaced from each other with said quintuplet lens being closer to an image plane, said quintuplet lens comprised of first, second and third solid lens elements and first and second liquid lens elements with said first liquid lens elements formed between said first and second solid lens elements and said second liquid lens element formed between said second and third solid lens elements, said first and second liquid lens elements being of two different visibly transmissive optical liquids having temperature sensitive refractive indices and abnormal dispersions for producing chromatic and thermal aberration corrections, said objective lens group also having a second single lens and a focusing lens group, at least one lens element of said single lens element, second single lens element, first, second and third solid lens elements and said focusing lens group being of a solid material having a refractive index and a coefficent of thermal expansion for producing chromatic and thermal aberration corrections that are uncorrected by said two liquid lens elements.

21. The optical system of claim **20**, wherein said single lens element is positively powered for receiving radiation from an object and transmitting the radiation to said quintuplet lens, and said quintuplet lens is negatively powered.

22. The optical system of claim **21**, wherein said second single lens is said one lens element.

23. The optical system of claim **22** wherein said lens groups and elements are arranged on the common axis in the order of said single lens element, said quintuplet lens, said second single lens and said focusing lens group.

24. The optical system of claim **20**, wherein said optical liquid of said first liquid lens element has a refractive index and abnormal dispersion for producing primarily chromatic correction, and said optical liquid of said second liquid lens element has characteristics for producing primarily thermal aberration correction.

25. The optical system of claim **24**, wherein said optical liquid of said second liquid lens primarily corrects thermal aberrations created by said first liquid lens.

26. The optical system of claim **24**, wherein said first liquid lens is located on a side of said second solid lens that is closer to said single lens element.

27. A visible waveband optical system comprising:

lens elements, groups and subgroups supported and arranged on a common axis from an end closer to an object to an end closer to an image formed by the optical system, in the following order;

a first single lens A,

a quintuplet lens having lens elements B, C, D, E and F,

a second single lens G,

a first focusing lens group having lens elements H, I and J,

a second focusing lens group having lens elements K, L and M, and

an auxiliary lens group having a lens element N, an iris P, lens elements R and S, a field stop T, and lens elements V, W, X and Y;

wherein said lens elements C and E are of optical liquid materials and the remaining lens elements are of solid materials, and

wherein the lens elements, groups and subgroups have characteristics with respect to an object plane and an image plane at three representative focus distances, as follows;

[57] **ABSTRACT**

This invention has as its object to eliminate flare light as a cause of low contrast. A microscope objective lens has, in the following order from the object side, a front group having positive refracting power to convert a beam from an object into a convergent beam, and having a positive meniscus lens element with a concave surface facing the object side, and a cemented lens component disposed at the image side of the positive meniscus lens, and a rear group having negative refracting power, constituted by cementing a negative lens element and a positive lens element, and disposed at the image side of the front group. A last cemented lens component, disposed nearest to the image side, of the cemented lens component in the front group satisfies:

$$|R_1|/f>100 \quad (1)$$

$$|R_2|/f>20 \quad (2)$$

where R_1 is the radius of curvature of a lens surface on the object side of the last cemented lens component, R_2 is the radius of curvature of a lens surface on the image side of the last cemented lens component, and f is the focal length of the microscope objective lens.

MICROSCOPE OBJECTIVE LENS AND MICROSCOPE USING THE SAME

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to a microscope objective lens and, more particularly, to a metal microscope objective lens. Furthermore, the present invention relates to a microscope using the microscope objective lens.

2. Related Background Art

A conventional dry-system microscope objective lens has a lens arrangement disclosed in, e.g., Japanese Patent Publication No. 4-26446.

More specifically, a conventional dry-system microscope objective lens has a front group G_1 having positive refracting power and a rear group G_2 having negative refracting power, as shown in FIG. **1**. Furthermore, the front group G_1 having positive refracting power has, in the following order from the object side, a positive meniscus lens element with a concave surface facing the object side, a positive cemented lens component, and a meniscus lens component with a convex surface facing the object side. The rear group G_2 having negative refracting power has a cemented lens of two negative lenses and one positive lens.

As shown in FIG. **1**, in the front group G_1, a lens nearest to the image side is a meniscus lens with a concave surface facing the object side, which is obtained by cementing a biconvex single lens and a biconcave single lens to each other. The cemented lens, nearest to the image side, in the front group G_1 has almost no refraction effect, as can be seen from FIG. **1**.

SUMMARY OF THE INVENTION

According to the present invention, there is provided a microscope objective lens which comprises, in the following order from the object side, a front group of positive refracting power which has a positive meniscus lens element with a concave surface facing the object side, and a cemented lens component, and converts beams from an object into convergent beams, and a rear group of negative refracting power, which is disposed at the image side of the front group and has a cemented lens of a negative lens element and a positive lens element, wherein a cemented lens, nearest to the image side, out of the cemented lens component in the front group satisfies:

$$|R_1|/f>100 \quad (1)$$

$$|R_2|/f>20 \quad (2)$$

where R_1 is the radius of curvature of a lens surface, nearest to the object side, of the cemented lens, nearest to the image side, in the front group, R_2 is the radius of curvature of a lens surface, nearest to the image side, of the cemented lens, nearest to the image side, in the front group, and f is the focal length of the microscope objective lens.

The microscope objective lens of the present invention preferably satisfies:

$$\nu_{21}>50 \quad (3)$$

$$\nu_{22}>50 \quad (4)$$

where ν_{21} is the Abbe's number of the negative lens element in the rear group, and ν_{22} is the Abbe's number of the positive lens element in the rear group.

Furthermore, in order to achieve an apochromatic microscope objective lens, the positive meniscus lens component with the concave surface facing the object side in the front group has at least three positive meniscus lens elements, and at least two positive meniscus lenses of the at least three positive meniscus lenses preferably satisfy:

$$\nu>90 \quad (5)$$

where ν is the Abbe's number of each of the at least two positive meniscus lenses.

The present invention will be more fully understood from the detailed description given hereinbelow and the accompanying drawings, which are given by way of illustration only and are not to be considered as limiting the present invention.

Further scope of applicability of the present invention will become apparent from the detailed description given hereinafter. However, it should be understood that the detailed description and specific examples, while indicating preferred embodiments of the invention, are given by way of illustration only, since various changes and modifications within the spirit and scope of the invention will be apparent to those skilled in the art from this detailed description.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a drawing to show the conventional dry-system microscope objective lens.

FIGS. **2** to **4** are drawings to explain the relation among a refraction surface, an incident light ray and a reflected light ray.

FIG. **5** is a drawing to show an imaging lens.

FIG. **6** is a view showing the lens arrangement of the embodiment 1.

FIGS. **7** to **10** are graphs to show various aberrations of the embodiment 1.

FIG. **11** is a graph to show chromatic coma at the maximum incident height in the embodiment 1.

FIG. **12** is a view showing the lens arrangement of the embodiment 2.

FIGS. **13** to **16** are graphs to show various aberrations of the embodiment 2.

FIG. **17** is a graph to show chromatic coma at the maximum incident height in the embodiment 2.

FIG. **18** is a view showing the lens arrangement of the embodiment 3.

FIGS. **19** to **22** are graphs to show various aberrations of the embodiment 3.

FIG. **23** is a graph to show chromatic coma at the maximum incident height in the embodiment 3.

FIG. **24** is a sectional view to show an example of a metal microscope using the objective lens shown in FIG. **6**.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

In general, in a metal microscope, a microscope objective lens also serves as an illumination optical system for the microscope since an object to be examined is observed with reflected light. More specifically, in a general microscope objective lens, light rays propagate only from the object side toward the image side, while in a metal microscope objective lens, light rays propagate not only from the object side toward the image side, but also from the image side toward the object side.

The conventional dry-system microscope objective lens shown in FIG. **1** is applied to a metal microscope objective

lens. When observation light from an object to be examined propagates through the conventional dry-system microscope objective lens shown in FIG. 1, no problem is posed. However, when illumination light propagates through the conventional dry-system microscope objective lens shown in FIG. 1 in a direction opposite to the observation light from the object to be examined, the illumination light is reflected by a specific surface, and flare light is generated. As a result, the contrast is lowered, resulting in difficult observation. Note that in this specification, flare light means stray light which reaches an image upon reflection by a lens surface.

In the case of the conventional dry-system microscope objective lens shown in FIG. 1, boundary surfaces r_{16} and r_{18} of the cemented lens, nearest to the image side, in the front group G_1 with the air cause harmful reflections. As described above, the cemented lens, nearest to the image side, in the front group has almost no refraction effect. For this reason, light rays, which are incident from the image side on the cemented lens, nearest to the image side, in the front group as illumination light, are reflected by a refraction surface in the same direction as the incident light rays, as can be seen from FIG. 1.

The above-mentioned phenomenon will be explained in detail below with reference to FIG. 2. FIG. 2 shows a case wherein the center of the curvature (indicated by a mark ○ in FIG. 2), on an optical axis 2, of a refraction surface 1 agrees with the central position (indicated by a mark x in FIG. 2), on the optical axis 2, where an incident light ray N diverges (or converges). In this case, a refracted light ray K which is incident on and refracted by the refraction surface 1 does not undergo refraction by the refraction surface 1 at all, and its state is equivalent to that of the incident light ray N which is transmitted through the refraction surface 1. Also, in this case, a reflected light ray H which is incident on and reflected by the refraction surface 1 propagates along the same optical path as the incident light ray N in a direction opposite thereto. This is because the normal to the refraction surface 1 coincides with the incident light ray N, and the incident light ray N is perpendicularly incident on the incident point on the refraction surface 1.

When the center of the curvature of the refraction surface substantially coincides with the central position where the incident light ray diverges (or converges), the central position where the reflected light ray reflected by the refraction surface converges (or diverges) also substantially coincides with the center of the curvature of the refraction surface.

In this manner, the reflected light, which is reflected in the same direction as the incident light ray, forms an image together with the observation light. The contrast of the formed image is lowered due to the presence of such flare light, resulting in very poor appearance of the image upon actual observation.

In the present invention, as shown in FIG. 3, the center of the curvature of the refraction surface does not coincide with the central position where a light ray diverges (or converges). In this manner, the present invention can eliminate flare light.

In FIG. 3, the central position (indicated by a mark x in FIG. 3), on the optical axis 2, where the light ray diverges is present between the center of the curvature (indicated by a mark ○ in FIG. 3) of the refraction surface 1, and the refraction surface 1. In this case, an incident light ray N incident on the refraction surface 1 is reflected in a direction to separate from the optical axis 2, as shown in FIG. 3. A reflected light ray H which is incident on and reflected by the refraction surface 1 finally reaches the inner wall of the lens barrel of a microscope. Note that the inner wall of the lens barrel of the microscope is painted in black or is lined with filling, and the light ray which has reached the inner wall of the lens barrel of the microscope disappears.

Conditions (1) and (2) above quantitatively define the above-mentioned requirements. If the objective lens satisfies these conditions (1) and (2), a microscope objective lens which can eliminate flare light can be realized. If conditions (1) and (2) are not satisfied, as described above, a light ray which is incident as illumination light is reflected in substantially the same direction as an incident light ray, and is combined with observation light, thus increasing flare light. When the lower limit of condition (1) is set to be 150, and the lower limit of condition (2) is set to be 25, better results are expected. Furthermore, when the lower limit of condition (1) is set to be 200, and the lower limit of condition (2) is set to be 30, very good results are expected.

Furthermore, in the present invention, conditions (3) and (4) above are preferably satisfied. Conditions (3) and (4) are those for eliminating flare light generated at the cemented surfaces in the rear group. In the case of the conventional dry-system microscope objective lens shown in FIG. 1 as well, the rear group G_2 generates flare light, which is smaller than that generated by the cemented lens, nearest to the image side, in the front group G_1. In a method of eliminating flare light in this case, as shown in FIG. 4, in principle, the central position (indicated by a mark x in FIG. 4) where an incident light ray N diverges is located at a side opposite to the refraction surface 1 with respect to the center of the curvature of the refraction surface 1. In a case shown in FIG. 4, the incident light ray N incident on the refraction surface 1 is reflected in a direction toward the optical axis 2. The reflected light ray finally reaches the inner wall of the lens barrel of the microscope, which wall is painted in black or is lined with filling, and disappears. Thus, the amount of flare light generated at the cemented surfaces can be reduced. If conditions (3) and (4) are not satisfied, flare light increases inconveniently.

As another method of eliminating flare light generated at the cemented surfaces, a method of setting the refractive index difference before and after the cemented surface to be zero or nearly zero is available. However, when the refractive index difference is set to be zero or nearly zero, the cemented surface inconveniently loses its effect of deflecting a light ray, and the degree of freedom of aberration correction decreases by one.

Furthermore, in the present invention, condition (5) above is preferably satisfied. Condition (5) is one for achieving an apochromatic microscope objective lens with high magnification. If condition (5) is not satisfied, chromatic coma increases, and an apochromatic microscope objective lens cannot be achieved. If chromatic coma increases, an image suffers color smearing, resulting in very poor appearance of the image. In this specification, the chromatic coma means coma with respect to respective wavelengths (colors).

In the present invention, condition (6) below is preferably satisfied:

$$|R_3/f|<5 \quad (6)$$

where R_3 is the radius of curvature of a cemented surface of the cemented lens, nearest to the image side, in the front group.

Condition (6) is one for satisfactorily correcting various aberrations. When the range of this condition is exceeded, especially chromatic aberration increases, and an apochromatic microscope objective lens with high magnification as

the object of the present invention cannot be achieved. When the upper limit of condition (6) is set to be 4.6, a better result is expected. Furthermore, when the upper limit of condition (6) is set to be 4.2, a very good result is expected.

The embodiments of the present invention will be described hereinafter. All the embodiments are designed as infinity systems. When a microscope objective lens of each embodiment is actually used, an imaging lens shown in, e.g., FIG. **5** is disposed at the image side of the objective lens. Table 1 below summarizes data of the imaging lens shown in FIG. **5**.

TABLE 1

Surface Number No.	Radius of Curvature r	Central Thickness Interval d	Refractive Index n_d	Abbe's Number ν_d
1	52.00	6.50	1.61720	54.0
2	−87.00	2.00	1.74950	35.2
3	350.00	8.50		
4	49.00	5.00	1.66755	42.0
5	0.00	2.50	1.61266	44.4
6	31.00	158.78		

Focal Length f = 204

Tables 2 to 4 presented later summarize data of Embodiments 1 to 3. In each table, numerals in the leftmost column represent the order of lens surfaces from the object side, and n_d and ν_d are respectively the refractive index and Abbe's number for the d-line (λ=587.6 nm). Also, W.D. represents a value corresponding to the operating distance, i.e., the distance between the object surface and the apex of the frontmost lens surface. The value of the focal length is one defined by data without using an imaging lens.

FIGS. **7** to **10**, FIGS. **13** to **16**, and FIGS. **19** to **22** respectively graphs showing various aberrations of the respective embodiments at the respective use magnifications when an imaging lens is also used. These graphs show spherical aberration, astigmatism, coma, and distortion for the d-line (λ=587.6 nm), and graphs showing spherical aberration also show curves for the C-line (λ=656.3 nm), the F-line (λ=486.1 nm), and the g-line (λ=435.8 nm).

Furthermore, FIGS. **11**, **17**, and **23** show chromatic coma at the maximum incident height in the respective embodiments. Each of FIGS. **11**, **17**, and **23** shows not only a curve for the d-line (λ=587.6 nm), but also curves for the C-line (λ=656.3 nm), the F-line (λ=486.1 nm), and the g-line (λ=435.8 nm), as in graphs showing spherical aberration.

EMBODIMENT 1

FIG. **6** is a view showing the lens arrangement of this embodiment. The lens arrangement will be described below with reference to FIG. **6**.

A front group G_1 has, in the following order from the object side, positive meniscus lens elements: a first positive meniscus lens L_1 with a concave surface facing the object side, and second and third positive meniscus lenses L_2 and L_3 each with a concave surface facing the object side as positive meniscus lens elements; and cemented lens components: a first cemented lens consisting of a negative lens L_4 with a concave surface facing the image side and a biconvex positive lens L_5, a second cemented lens consisting of a negative lens L_6 with a concave surface facing the image side and a biconvex positive lens L_7, a third cemented lens consisting of a negative lens L_8 with a concave surface facing the object side and a biconvex positive lens L_9, and a fourth cemented lens consisting of a biconvex positive lens L_{10} and a biconcave negative lens L_{11}. A rear group G_2 has a negative lens constituted by cementing a biconcave negative lens L_{12} as a negative lens element, and a positive meniscus lens L_{13} with a concave surface facing the image side as a positive lens element.

Table 2 below summarizes data of Embodiment 1. FIGS. **7** to **10** are graphs showing various aberrations of the lens of this embodiment, and FIG. **11** is a graph showing chromatic coma at the maximum incident height in this embodiment.

$R_1/f = 582$
$R_2/f = 38$
$R_3/f = -4.06$

Furthermore, Table 5 below summarizes the flare coefficients of the respective embodiments. The flare coefficient is defined by (the amount of light which is reflected by a given surface whose reflectance is assumed to be 100%, and reaches a detection system)/(the amount of light incident on the surface). Note that the product of the flare coefficient and the reflectance of the surface corresponds to the actual flare amount.

TABLE 5

	Embodiment 1	Embodiment 2	Embodiment 3

r_{18}	0.005	0.005	0.009
r_{19}	0.001	0.001	0.001
r_{20}	0.001	0.001	0.001
r_{21}	0.069	0.061	0.069
Total	0.153	0.141	0.157

As can be seen from Table 5, the objective lenses of Embodiments 1 to 3 generate very small flare light.

As can be seen from FIGS. **7** to **10**, FIGS. **13** to **16**, and FIGS. **19** to **22**, respective aberrations are satisfactorily corrected. In particular, on-axis chromatic aberration is corrected very satisfactorily.

Furthermore, as can be seen from the chromatic coma states in the respective embodiments shown in FIGS. **11**, **17**, and **23**, chromatic coma is corrected very satisfactorily.

As described above, according to the embodiments described above, an apochromatic objective lens with high magnification free from flare light can be realized.

Note that the present invention is not limited to the above-mentioned embodiments. In each of the above embodiments, an infinity-system objective lens has been

exemplified. However, by slightly modifying the rear group G_2, a finite-system objective lens can be easily realized. Needless to say, a microscope objective lens according to the present invention can be used not only in a metal microscope but also generally in a dry-system microscope.

FIG. **24** is a sectional view showing an example of a metal microscope using the objective lens shown in FIG. **6**. Referring to FIG. **24**, an object **10** to be observed such as a wafer is placed on a stage **12**, and it can be observed via an eyepiece lens **14** or photographed by a camera attached to a camera attachment portion **16**. The object **10** to be observed is supported by the stage **12** to be movable in two directions perpendicular to the optical axis indicated by an alternate long and short dash line, and in a direction parallel to the optical axis. The arrangement of the metal microscope will be described below.

A halogen lamp **18** emits a light beam for illuminating the object **10** to be observed, and illumination light is polarized by a polarization filter **20**. The optical path of the illumination light which is converted into predetermined polarized light via the polarization filter **20** is deflected through 90° by a polarization beam splitter **22**. The illumination light is transmitted through a quarter-wave plate **24**, is transmitted through an imaging lens **26** shown in FIG. **5**, and is then transmitted through an objective lens **28** shown in FIG. **6**. The illumination light emerging from the objective lens **28** illuminates the surface of the object **10** to be observed. Observation light reflected by the surface of the object **10** to be observed is transmitted through the objective lens **28**, the imaging lens **26**, and the quarter-wave plate **24** in a direction opposite to that described above. Since this light beam is transmitted through the quarter-wave plate **24** twice, it is transmitted through the polarization beam splitter **22** this time. The observation light transmitted through the polarization beam splitter **22** is split into two light beams by a prism **30** having a semi-transparent reflection film. One light beam reaches the eyepiece lens **14**, and the other light beam reaches the camera attachment portion **16**. Since the prism **30** is constituted by combining two prisms, the optical path of the observation light which propagates toward the camera attachment portion **16** is not deflected by the prism **30**.

From the invention thus described, it will be obvious that the invention may be varied in many ways. Such variations are not to be regarded as a departure from the spirit and scope of the invention, and all such modifications as would be obvious to one skilled in the art are intended for inclusion within the scope of the following claims.

What is claimed is:

1. A microscope objective lens comprising:

a front group having positive refracting power to convert a beam from an object into a convergent beam, and having a positive meniscus lens element with a concave surface facing the object side, and a plurality of cemented lens components disposed at the image side of said positive meniscus lens; and

a rear group having negative refracting power, having a negative lens element and a positive lens element which is cemented with said negative lens element, and disposed at the image side of said front group,

wherein said cemented lens component disposed nearest to the image side in said front group satisfies:

$$|R_1|/f>100$$

$$|R_2|/f>20$$

where R_1 is a radius of curvature of a lens surface on the object side of said last cemented lens component, R_2 is a radius of curvature of a lens surface on the image side of said last cemented lens component, and f is a focal length of said microscope objective lens.

2. A microscope objective lens according to claim **1**, wherein said microscope objective lens satisfies:

$$\nu_{21}>50$$

$$\nu_{22}>50$$

where ν_{21} is an Abbe's number of said negative lens element in said rear group, and ν_{22} is an Abbe's number of said positive lens element in said rear group.

3. A microscope objective lens according to claim **1**, wherein said positive meniscus lens element with the concave surface facing the object side in said front group comprises at least three positive meniscus lenses, and

at least two positive meniscus lenses of said at least three positive meniscus lenses satisfy:

$$\nu>90$$

where ν is an Abbe's number of each of said at least two positive meniscus lenses.

4. A microscope objective lens according to claim **2**, wherein said positive meniscus lens element with the concave surface facing the object side in said front group comprises at least three positive meniscus lenses, and

at least two positive meniscus lenses of said at least three positive meniscus lenses satisfy:

$$\nu>90$$

where ν is an Abbe's number of each of said at least two positive meniscus lenses.

5. A microscope objective lens according to claim **1**, wherein said objective lens is used with an imaging lens, disposed at the image side of said objective lens, for focusing a beam emerging from said rear group.

6. A microscope comprising:

a stage for supporting an object to be observed;

a light source system for supplying illumination light for illuminating the object to be observed supported by said stage;

light guide means for deflecting an optical path of the illumination light emitted from said light source system in a direction of the object to be observed; and

a microscope objective lens for guiding the illumination light from said light guide means toward the object to be observed, and acting on light reflected by the object to be observed,

wherein said light guide means guides light reflected by the object to be observed and transmitted through said microscope objective lens in a direction different from the direction of said light source system, and

said microscope objective lens comprises:

a front group having positive refracting power to convert a beam from the object to be observed into a convergent beam, and having a positive meniscus lens element with a concave surface facing the object to be observed, and a plurality of cemented lens components disposed at the image side of said positive meniscus lens; and

a rear group having negative refracting power, having a negative lens element and a positive lens element which is cemented with said negative lens element, and disposed at the image side of said front group,

in which said cemented lens component disposed nearest to the image side in said front group satisfies:

$$|R_1|/f>100$$

$$|R_2|/f>20$$

where R_1 is a radius of curvature of a lens surface on the side of the object to be observed of said last cemented lens component, R_2 is a radius of curvature of a lens surface on the image side of said last cemented lens component, and f is a focal length of said microscope objective lens.

7. A microscope according to claim **6**, further comprising an imaging lens for focusing a beam emerging from said rear group.

8. A microscope according to claim **6**, further comprising:

a polarization filter disposed between said light source system and said light guide means; and

a quarter-wave plate disposed between said light guide means and said microscope objective lens, and

wherein said light guide means comprises a polarization beam splitter.

9. A microscope according to claim **6**, further comprising an eyepiece lens for receiving light reflected by the object to be observed and transmitted through said microscope objective lens and said light guide means.

10. A microscope according to claim **6**, further comprising a camera attachment portion to which a camera for photographing the object to be observed based on light reflected by the object to be observed and transmitted through said microscope objective lens and said light guide means is attached.

[57] **ABSTRACT**

A non-flexible endoscope comprises a slender insert section which is capable of being inserted from a leading end thereof into cavities of living bodies, an objective lens system for forming a primary image within the insert section, and a relay lens system for transmitting said primary image so as to form a secondary image, wherein the insert section satisfies the following condition:

$$0.3<D_1/D_2<0.7$$

wherein the reference symbol D_1 represents a distance as measured from a first surface of the objective lens system to the primary image and the reference symbol D_2 designates a distance as measure from the first surface of the objective lens system to the secondary image.

NON-FLEXIBLE ENDOSCOPE WITH OBJECTIVE LENS SYSTEM AND RELAY LENS SYSTEM

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to a non-flexible endoscope to be used widely in the medical field, and mainly a non-flexible endoscope which can be manufactured at a cost low enough to be disposable.

2. Description of the Prior Art

In the recent trend of surgical operations in the medical field, medical techniques are exercised increasingly in conditions of minimum contacts with higher parasites by using endoscopes and treating tools developed exclusively for operations in such conditions. Since affected parts which conventionally required laparotomy for medical treatments can now be treated in the conditions of minimum contacts with the higher parasites under observation through endoscopes for lessening burdens of patients by reducing days of hospitalization, etc., further development is expected for the surgical operations under observation through endoscopes.

Dependently on structures of insert sections of endoscopes which are to be inserted into body cavities, the endoscopes are classified into two types: flexible endoscopes and non-flexible endoscopes. Out of these two types, the non-flexible endoscopes which provide images of higher qualities are used for surgical operations under observation. The non-flexible endoscopes has another merit that they are bearable of autoclaving.

In the recent days where a serious problem is posed by hospital infections, it is remarkably important to sterilize medical tools and instruments, and autoclaving apparatuses are more widespread than the other types of sterilizers. It is therefore necessary to configure the endoscopes so as to have structures bearable of autoclaving.

For the non-flexible endoscopes which have no flexible section, it is rather easy to select materials and structures which are bearable of autoclaving. It is therefore general in practice to repeatedly use non-flexible endoscopes bearable of autoclaving while sterilizing these instruments after individual uses.

On the other hand, attempts are made to configure the non-flexible endoscopes themselves so as to be disposable for preventing hospital infections from being caused through repeated use of the non-flexible endoscopes. In order to configure the non-flexible endoscopes so as to be disposable, it is necessary to configure them so that they can be manufactured as low costs while maintaining practical utilities thereof.

FIG. 1 shows a conventional non-flexible endoscope and an observation optical system used therein. The conventional optical system of this conventional non-flexible endoscope consists of a short objective lens system O disposed in a leading end of an insert section 1 to be inserted into body cavities and a relay lens system R disposed in the insert section 1 almost over the entire length thereof, and an eyepiece lens system E disposed in a grip section 2: these lens systems being integrated with one another in a main body of the non-flexible endoscope.

This conventional non-flexible endoscope is configured so as to permit observing, through the eyepiece lens system E, an image which is formed by the objective lens system O and relayed ordinarily in three cycles by the relay lens system R. This relay lens system consists of fundamental lens units each being symmetrical with regard to a vertical axis perpendicular to the right-to-left direction and is configured so as to relay an image in a plurality of cycles.

It is for the purpose of obtaining required brightness in an optical system that an image is relayed in a plurality of cycles in the optical system for the non-flexible endoscopes such as the conventional example described above.

Since insert sections of non-flexible endoscopes have small outside diameters and large effective lengths, it is necessary for maintaining brightness of images transmitted through the insert sections to enlarge numerical apertures of relay lens systems by increasing numbers of relay cycles. In case of an optical system which uses an insert section having a given effective length in combination with a relay lens system having a given fundamental composition and a given outside diameter, a numerical aperture of the relay lens system is determined dependently on a length required for a single relay cycle and therefore proportional to a number of relay cycles to be performed by the relay lens systems.

The conventional non-flexible endoscope shown in FIG. 1 hardly allows the main body thereof to be disposable due to a fact that the relay lens system R used for composing the optical system thereof comprises a large number of lens elements and the optical system requires too high a manufacturing cost. When the manufacturing cost of the optical system is reduced simply by reducing the number of relay cycles or the number of the lens elements disposed in the relay lens system as a whole, the length required for a single relay cycle is shortened, thereby reducing the numerical aperture of the relay lens system.

For the reason described above, the optical system for the conventional non-flexible endoscope does not allow to lower the manufacturing cost thereof while reserving the brightness required therein.

SUMMARY OF THE INVENTION

A primary object of the present invention is to provide a non-flexible endoscope using an optical system which comprises an extremely small number of lens elements to be discarded, or is configured so as to prevent an operating cost thereof from being enhanced by discarding the lens elements.

Another object of the present invention is to provide a non-flexible endoscope using an optical system which comprises a small number of lens elements, can be manufactured at a low cost and is bright enough for practical use.

A still another object of the present invention is to provide a non-flexible endoscope using an optical system which has a numerical aperture of brightness enlarged or enhanced by prolonging an objective lens system so as to shorten a distance for transmission of an image through a relay lens system.

The non-flexible endoscope according to the present invention has a far end (an end farthest from an observer) and a near end (an end nearest the observer), and comprises an insert section which is used for inserting the far end of the non-flexible endoscope into body cavities to be observed and an eyepiece section which is to be connected to a near end of the insert section. The insert section accommodates an objective lens system, whereas the eyepiece section accommodates an eyepiece lens system which directly receives rays from a primary image formed by the objective lens system and allows these rays to emerge therefrom as rays nearly in parallel with one another. The insert section and the eyepiece section are attachable and detachable to and from each other.

In an optical system which is to be used in the non-flexible endoscope according to the present invention, the objective lens system consists of a first negative lens component and a second positive lens component which has a magnification satisfying the following condition (1):

$$0.7<|\beta_2|<1.5 \quad (1)$$

wherein the reference symbol β_2 represents the magnification of the second lens component.

Further, it is desirable that the objective lens system forms a primary image at a position located in the vicinity of the near end of the insertion section, or satisfies the following condition (2):

$$0.7<D_1/D_e<1.5 \quad (2)$$

wherein the reference symbol D_1 represents a distance as measured from a first surface of the objective lens system to the primary image and the reference symbol D_e designates an effective length of the insert section. Meant by "an effective length of the insert section" is a length of a section which has a small outside diameter and is to be inserted into a truncal or a sheath.

Further, it is desirable for correction of chromatic aberration to configure the objective lens system so as to satisfy the following condition (3):

$$n_1>n_2,\ \nu_1<\nu_2 \quad (3)$$

wherein the reference symbols n_1 and n_2 represent refractive indices of the first lens component and the second lens component respectively, and the reference symbols ν_1 and ν_2 designate Abbe's numbers of the first lens component and the second lens component respectively.

Furthermore, it is desirable to compose the first lens component of the objective lens system of a single plano-convex lens element, and configure the second lens component as a cemented lens component which consists of a positive lens element and a negative lens element, and satisfies the following condition (4):

$$n_p<n_N,\ \nu_P>\nu_N \quad (4)$$

wherein the reference symbols n_p and n_N represent refractive indices of the positive lens element and the negative lens element respectively of the second lens component, and the reference symbol ν_P and ν_N designate Abbe's numbers of the positive lens element and the negative lens element respectively of the second lens component.

Moreover, the non-flexible endoscope according to the present invention consists of a slender insertion section which is to be inserted into cavities of living bodies for observing these cavities and a grip section which is to be kept outside the cavities: and comprises an optical system which consists of an objective lens system disposed on the side of the leading end in the insert section for forming primary image in the insert section, a relay lens system disposed in the insert section for relaying the primary image for forming a secondary image at a near end (an end located on the side opposite to the leading end) of the insert section or in the grip section and an eyepiece lens system disposed in the grip section for deflecting rays coming from the secondary image so as to be parallel with one another or in an observable condition; and is configured so as to satisfy the following condition (5):

$$0.3<D_1/D_2<0.7 \quad (5)$$

wherein the reference symbol D_2 represents a distance as measured from a first surface to the secondary image.

Moreover, it is desirable that an optical system which is to be used in the non-flexible endoscope according to the present invention (an optical system of a type comprising a relay lens system) adopts an objective lens system composed of a first lens component consisting only of a single negative lens element and a second lens component consisting only of a positive lens element which satisfies the following condition (6):

$$0.5<|\beta_2|<2.0 \quad (6)$$

wherein the reference symbol β_2 represents a magnification of the second lens component.

For the optical system of the non-flexible endoscope according to the present invention of the type which comprises the relay lens system as described above, it is desirable to dispose a primary field lens component in the vicinity of the primary image at a location satisfying the following condition (7):

$$|D_3/D_2|\leqq 0.1 \quad (7)$$

wherein the reference symbol D_3 represents a spacing to be reserved between the primary image and the field lens component.

Moreover, it is desirable to control the relay lens system so as to have a magnification β_R satisfying the following condition (8):

$$-2<\beta_R<-0.5 \quad (8)$$

In addition, when the optical system of the non-flexible endoscope according to the present invention is of a type which uses a relay lens system configured so as to perform a single cycle of image relaying or a plurality of cycles of image relaying, it is desirable for shortening the relay lens system to satisfy the following condition (9):

$$0.3<D_1/D_R<2.0 \quad (9)$$

wherein the reference symbol D_R represents a distance required for a single cycle of image relaying.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** shows a sectional view illustrating a composition of a conventional optical system for non-flexible endoscopes;

FIG. **2** shows a sectional view illustrating a configuration of the non-flexible endoscope according to the present invention;

FIG. **3** shows a sectional view illustrating another example of the non-flexible endoscope according to the present invention;

FIG. **4** shows a sectional view illustrating a configuration of the non-flexible endoscope shown in FIG. **3** when it is protected with a sterilizing cover;

FIG. **5**A, FIG. **5**B and FIG. **5**C show diagrams illustrating relationship between locations of lens components in an objective lens system to be used in the non-flexible endoscope according to the present invention and those of primary images to be formed by the objective lens systems;

FIG. 6A and FIG. 6B show sectional views exemplifying prisms for oblique viewing which are to be used in an objective lens system of the optical system of the non-flexible endoscope according to the present invention;

FIG. 7 shows a sectional view exemplifying a frame structure for an insert section of the non-flexible endoscope according to the present convention;

FIG. 8 shows a sectional view illustrating a composition of a first embodiment of the non-flexible endoscope according to the present invention;

FIG. 9 shows a sectional view illustrating a composition of a second embodiment of the non-flexible endoscope according to the present invention;

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

Now, the non-flexible endoscope according to the present invention will be described more detailedly below with reference to the preferred embodiments illustrated in the accompanying drawings.

FIG. **2** shows an embodiment of the non-flexible endoscope according to the present invention. In this drawing, the reference numeral **1** represents a cylindrical insert section which has a far end **1***a* and a near end **1***b*, and accommodates an objective lens system O. Further, the reference numeral **2** designates an eyepiece section which is attachable and detachable to and from the near end **1***b* of the insert section **1**, and accommodates an eyepiece lens system E. The reference symbols C_1 and C_2 denote cover glass plates which are disposed before and after the eyepiece lens system E. This non-flexible endoscope is to be inserted, from the side of the far end **1***a* of the insert section, into a location such as a body cavity or the similar part to be observed so that the objective lens system O forms an image of an object to be observed (image I_1) in the vicinity of the near end **1***b* of the insert section. Rays coming from this image are incident directly, or without passing through a relay lens system, onto the objective lens system disposed in the vicinity of the near end of the insert section and reimaged in the eyepiece lens system E by a front lens component of the eyepiece lens system E (image I_2). Rays coming from the image I_2 emerge from the eyepiece lens system E as rays nearly in parallel with one another so that an observer can receive these rays or observe an image of the object.

FIG. **3** shows a non-flexible endoscope which is configured for TV monitoring and uses an insert section **1** having the same composition as that of the insert section **1** shown in FIG. **2**, but can be equipped with a TV camera adaptor **3** and a TV camera **4** in place of the eyepiece section **2** shown in FIG. **2**. The TV camera adaptor **3** comprises an imaging lens system IL, whereas the TV camera **4** comprises an image pickup means such as a solid-state image pickup device. An objective lens system O forms an image of an object in the vicinity of a near end **1***b* of the insert section (image I_1). Rays coming from this image are incident directly, or without passing through a relay lens system, on the imaging lens system IL disposed in the TV camera adaptor **3**, which reimages an image of an object on a solid-state image pickup device disposed in the TV camera **4**. This image is presented on a display means such as a TV monitor for observation. In addition, the TV camera adaptor **3** and the TV camera **4** are attachable and detachable to and from each other.

Since the insert section **1** of the non-flexible endoscope shown in FIG. **2** or FIG. **3** can be detached from the eyepiece section **2** or the TV camera adaptor **3**, the insert section **1** can be discarded after it is practically used and contaminated. Further, the eyepiece section **2** or the TV camera adaptor **3** and the TV camera **4** can be reused in combination with a new insert section.

The non-flexible endoscope shown in FIG. **2** or FIG. **3** allows the eyepiece section or the TV camera adaptor and

the TV camera other than the insert section to be covered with a strilizing cover **8** as shown in FIG. **4**. The sterilizing cover **8** is integrated at one end thereof with the insert section **1** in FIG. **4**. Alternately, the sterilizing cover **8** may be elastically fitted over the insert sectional or fixed to the insert section **1** by an adequate fixing means. The sterilizing cover has a large opening at the other end.

When the sterilizing cover **8** is integrated with the insert section **1**, the eyepiece section or the TV camera adaptor, etc. can be protected with the sterilizing cover **8** by inserting the eyepiece section or the TV camera adaptor, etc. through the opening located at the other end and connecting the TV camera adaptor or the TV camera adaptor, etc. to the insert section **1**. When the sterilizing cover **8** is separate from the insertion section **1**, it is connected to the eyepiece section or the TV camera adaptor, etc., and then the sterilizing cover **8** is placed on the near end of the insert section **1** so as to cover the eyepiece section or the TV camera adaptor, etc. for maintenance in cleaner conditions. In FIG. **4**, the reference numeral **2** represents the eyepiece section shown in FIG. **2**, and the reference numeral **15** designates an adaptor for TV photographing which is detachable from the eyepiece section **2** and accommodates an imaging lens system for imaging nearly parallel rays emerging from an eyepiece lens system. A TV camera **4** shown in FIG. **4** is quite the same as that illustrated in FIG. **3**.

Now, an optical system to be used in the non-flexible endoscope according to teh present invention will be described detailedly below:

First, description will be made of an objective lens system to be disposed in the optical system. The objective lens system to be used in the non-flexible endoscope according to the present invention is long enough to extend almost over the entire length of the insertion section **1** and therefore has a composition which is largely different from that of an ordinary objective lens system for non-flexible endoscopes (an objective lens system for non-flexible endoscopes which uses a relay lens system for transmitting an image).

The objective lens system to be used in the non-flexible endoscope according to the present invention consists of a first lens component L_1 which is disposed in the vicinity of a far end **1***a* of an insert section **1** and has a negative refractive power, and a second lens component L_2 which is disposed at a middle location in the insert section **1** and has a positive refractive power.

In the objective lens system having the composition described above, the first lens component L_1 forms, in the vicinity of the far end **1***a* of the insert section **1**, a virtual image I' which is contracted on the order of an outside diameter of this lens component or smaller and the second lens component L_2 reimages the virtual image I' so as to form a primary image I_1 in the vicinity of the near end **1***b* of the insert section **1**. When the objective lens system comprises no aperture stop, a margin (a side surface) of the second lens component L_2 or a portion of a lens barrel functions as an aperture stop. When the first lens component L_1 is not disposed in the vicinity of the far end **1***a* and does not have a negative refractive power as shown in FIG. **5A**, it will undesirably hinder offaxial rays from passing through a pipe of the insert section. When the second lens component L_2 does not have a positive refractive power, it can hardly reimage the virtual image I' or when the second lens component L_2 is not disposed in the middle section of the insertion section **1**, brightness will be undesirably lowered due to eclipse of the offaxial rays or reduction of a numerical aperture.

Further, it is desirable that the second lens component L_2 satisfies the above-mentioned condition (1).

If $|\beta_2|$ exceeds the lower limit of 0.7 of the condition (1), a light bundle obtained on the object side will undesirably be thin, thereby lowering brightness in the optical system. If $[\beta_2]$ exceeds the upper limit of 1.5 of the condition (1), in contrast, the offaxial rays will be undesirably eclipsed, thereby producing eclipse of an image.

Further, it is desirable that the objective lens system forms the primary image in the vicinity of the near end **1***b* of the insert section **1**. For this reason, it is desirable to configure the objective lens system so as to satisfy the above-mentioned condition (2).

If D_1/D_e has a value smaller than the lower limit of 0.7 of the condition (2), the primary image I_1 will be formed in the pipe of the insert section **1**, whereby the offaxial rays will be eclipsed. If D_1/D_e has a value exceeding the upper limit of 1.5 of the condition (2), in contrast, the light bundle obtained on the object side will be thin and the objective lens system will have a small numerical aperture, thereby lowering brightness in the optical system.

For the objective lens system to be used in the non-flexible endoscope according to the present invention, it is desirable to compose the first lens component L_1 and the second lens component L_2 of small numbers of lens elements or select simple compositions for these lens components so that the insert section can be manufactured at a low cost. For this reason and for suppression of offaxial aberrations, it is desirable to compose the first lens component L_1 of a single negative lens element having a concave surface on the image side. Further, it is more desirable to configure this negative lens element so as to have a planar surface on the object side. Furthermore, it is desirable to configure the second lens component L_2 as a positive lens component consisting of a single positive lens element or a positive cemented lens component. The lens elements may be made of a glass material or a plastic material.

FIG. **6A** and FIG. **6B** show examples of objective lens systems to be used in the non-flexible endoscope according to the present invention in each of which a visual field changing prism for oblique viewing is disposed in a tip of the objective lens system and composed of a single prism as shown in the drawing. An ordinary visual field changing prism is composed of two or more prisms and requires a high manufacturing cost. For reducing a manufacturing cost of the objective lens system and configuring the insert section which comprises the prism in addition to the objective lens system so as to be disposable, it is desirable to compose the prism P of a single prism and dispose it after the first lens component L_1 as shown in FIG. **6A** or FIG. **6B**.

A first embodiment of the optical system which has the configuration described above for use in the non-flexible endoscope according to the present invention has a composition illustrated in FIG. **8** and numerical data listed below:

Embodiment 1

object distance = −30 (viewing diopter = $1m^{-1}$),
NA for incidence = 0.0032,
field angle = 60.2° image height = 125

$r_1 = \infty$

$r_{21} = -18.7960$			

$D_1 = 339.6$ mm, $D_e = 300$ mm, $D_1/D_e = 1.132$, $\beta_2 = -0.958$

wherein the reference symbols r_1, r_2, . . . represent radii of curvature on surfaces of respective lens elements, the reference symbols d_1, d_2, . . . designate thicknesses of the respective lens elements and air-spaces reserved therebetween, the reference symbols n_1, n_2, . . . denote refractive indices of the respective lens elements, and the reference symbols ν_1, ν_2, . . . represent Abbe's numbers of the respective lens elements.

In the numerical data listed above, r_1 through r_5 correspond to the objective lens system, r_7 through r_{21} correspond to the eyepiece lens system, $r_4=\infty$ represents an imaginary stop, $r_6=\infty$ designates the primary image and $r_{18}=\infty$ denotes the secondary image.

In the first embodiment of the optical system of the non-flexible endoscope according to the present invention, the objective lens system and the eyepiece lens system are disposed in the insert section and the eyepiece section respectively which are located on both sides of the primary image (r_6). Since the first embodiment uses no relay lens system, it comprises lens elements in a remarkably reduced number and the insert section accommodates only the objective lens system which is composed of an extremely small number of lens elements. Further, the optical system composed of the objective lens system and the eyepiece lens system adopted for the first embodiment has aberrations favorably corrected as illustrated in FIG. **46**A, FIG. **46**B, FIG. **46**C and FIG. **46**D. In these drawings, diopter is taken as the abscissa for visualizing each of spherical aberration, astigmatism and coma.

FIG. **9** shows a second embodiment of the optical system to be used in the non-flexible endoscope according to the present invention. The second embodiment is configured for use in the non-flexible endoscope according to the present invention which is of the type shown in FIG. **3**. The non-flexible endoscope shown in FIG. **3** has the insert section **1** which is to be connected to the TV camera adaptor **3** and further to the TV camera **4** as described above, and permits detaching the insert section **1** for discarding it after use. The TV camera adaptor and the TV camera may be integrated with each other so as to compose a TV camera comprising an imaging lens system so that the insert section **1** can be detachably connected to the TV camera and detached from the TV camera for discarding after use.

Each of the first embodiment and the second embodiment described above is configured on an assumption that the objective lens system is composed of the first lens component and the second lens component which consist of a single plano-concave lens element and a single biconvex lens element respectively made of multi-component type glass materials. The second biconvex lens element adopted as the second lens component is a symmetrical lens element which has the same radius of curvature on both surfaces thereof and requires no discrimination between a front surface and a rear surface thereof at an assembly stage thereof. Even when an asymmetrical lens element such as a plano-convex lens element is used as the second lens component and disposed mistaking its front surface for its rear surface, however, no serious problem is posed by variations of aberrations since the second lens component has a magnification nearly equal to 1× and functions also as an aperture stop. Accordingly, the second lens component requires nearly no consideration for its direction even when it has an asymmetrical shape.

In each of the first embodiment and the second embodiment, the plano-concave lens element used as the first lens component is made of a glass material which has a high refractive index and a medium dispersing power, whereas the biconvex lens element adopted as the second lens component is made of a glass material which has a low refractive index and a low dispersing power. In other words, the objective lens system is configured so as to satisfy the following condition (3):

$$n_1>n_2,\ \nu_1<\nu_2 \tag{3}$$

wherein the reference symbols n_1 and n_2 represent refractive indices of the first lens component and the second lens component respectively, and the reference symbols ν_1 and ν_2 designate Abbe's number of the first lens component and the second lens component respectively.

For the first lens component, it is suitable to select a glass material having a high refractive index for obtaining a low curvature on the concave surface thereof and a dispersing power which is not too strong to suppress lateral chromatic aberration. Further, for the second lens component which is composed of a single lens element, it is unnecessary to select a glass material which has an exceptionally low refractive index, but a glass material having a low dispersing power should desirably be selected for suppressing production of longitudinal chromatic aberration.

The second embodiment of the optical system for non-flexible endoscope which consists of the objective lens system and the imaging lens system has the numerical data which are listed below:

Embodiment 2

object distance = −30,
NA for incidence = 0.0033 (F number = 28.574)
field angle = 61.3° image height = 3.27

$r_1 = \infty$			
	$d_1 = 0.8000$	$n_1 = 1.80610$	$\nu_1 = 40.95$
$r_2 = 5.1410$			
	$d_2 = 167.5000$		
$r_3 = 87.8610$			
	$d_3 = 2.0000$	$n_2 = 1.51633$	$\nu_2 = 64.15$
$r_4 = \infty$ (stop)			
	$d_4 = 2.0000$	$n_3 = 1.51633$	$\nu_3 = 64.15$

-continued

Embodiment 2

$r_5 = -87.8610$			
	$d_5 = 167.6300$		
$r_6 = \infty$			
	$d_6 = 30.0000$		
$r_7 = 25.3040$			
	$d_7 = 3.0000$	$n_4 = 1.69680$	$\nu_4 = 55.52$
$r_8 = -15.5040$			
	$d_8 = 1.0000$	$n_5 = 1.69895$	$\nu_5 = 30.12$
$r_9 = \infty$			
	$d_9 = 45.2800$		
$r_{10} = 9.0340$			
	$d_{10} = 3.0000$	$n_6 = 1.51633$	$\nu_6 = 64.15$
$r_{11} = -5.9710$			
	$d_{11} = 1.0000$	$n_7 = 1.71736$	$\nu_7 = 29.51$
$r_{12} = 49.0230$			
	$d_{12} = 1.0000$		
$r_{13} = 9.0340$			
	$d_{13} = 3.0000$	$n_8 = 1.51633$	$\nu_8 = 64.15$
$r_{14} = -5.9710$			
	$d_{14} = 1.0000$	$n_9 = 1.71736$	$\nu_9 = 29.51$
$r_{15} = 49.0230$			

$D_1 = 339.6$ mm, $D_e = 300$ mm, $D_1/D_e = 1.132$, $\beta_2 = -0.958$

In the numerical data of the second embodiment described above, r_1 through r_5 correspond to the objective lens system and r_7 through r_{15} correspond to the imaging lens system for the TV camera. Further, r_4 represents an imaginary stop and r_6 designates a primary image.

The optical system preferred as the second embodiment of the present invention uses the objective lens system which is quite the same as that adopted for the first embodiment. Accordingly, the second embodiment uses no relay lens system and comprises an extremely small number of lens elements in the insert section thereof. The second embodiment has aberrations which are corrected favorably as illustrated in FIG. **47**A, FIG. **47**B, FIG. **47**C and FIG. **47**D.

FIG. **10** and FIG. **11** show a third embodiment and a fourth embodiment respectively of the optical system to be used in the non-flexible endoscope according to the present invention. Numerical data of these embodiments are listed below:

Embodiment 3

object distance = −30, NA for incidence = 0.002,
field angle = 70°

$r_1 = \infty$			
	$d_1 = 0.8000$	$n_1 = 1.49216$	$\nu_1 = 57.50$
$r_2 = 1.6894$ (aspherical surface)			
	$d_2 = 167.5000$

	$d_4 = 3.0000$	$n_3 = 1.51633$	$\nu_3 = 64.15$
$r_5 = -71.8444$			
	$d_5 = 167.5000$		
$r_6 = \infty$			

$D_1 = 339.8$ mm, $D_e = 300$ mm, $D_1/D_e = 1.133$, $\beta_2 = -0.957$

Only objective lens systems used in the third embodiment and the fourth embodiment are represented by FIG. **10**, FIG. **11** and the numerical data listed above. In the numerical data of the third embodiment, r_4 represents an imaginary stop and r_6 designates a primary image. In the numerical data of the fourth embodiment, r_4 represents an imaginary stop and r_6 designates a primary image.

The objective lens system used in the third embodiment is composed of lens elements made of plastic materials which may be acrylic resin materials or other plastic materials so far as they are optical materials having low dispersing powers. Further, the first lens component is a single plano-concave lens element having an image side concave surface which has such an aspherical surface as to lower curvature from an optical axis toward a margin thereof. The aspherical surface which has such a shape as to lower curvature from the optical axis toward the margin thereof is selected for correcting astigmatism and distortion by this aspherical surface itself. When the optical system is composed of lens elements which have only spherical surfaces, astigmatism will be remarkably overcorrected and barrel distortion will be produced. In the third embodiment, distortion is corrected to −1% at a maximum image height of the primary image. Furthermore, the second lens component is configured as a single biconvex lens element r_3, r_5 having the same radius of curvature on both surfaces thereof.

The aspherical surface used in the third embodiment has a shape expressed by the following formula (a):

$$z = \frac{y^2/r}{1+\sqrt{1-Py^2/r^2}} \qquad (a)$$

wherein the reference symbol z represents a distance as measured, in a direction along the optical axis of the aspherical surface, from an intersection between the aspherical surface and the optical axis, the reference symbol y designates a distance as measured from the optical axis, the reference symbol r denotes a radius of curvature on the reference sphere of the aspherical surface, and the reference symbol p represents a parameter expressing a shape of a guadratic surface.

This aspherical surface has no term of high order and is selectable for manufacturing aspherical lens elements at low costs.

The objective lens system adopted for the fourth embodiment of the optical system for non-flexible endoscope according to the present invention is composed of a first lens component consisting of a single plano-concave lens element and a second lens component consisting of a biconvex cemented lens component. Though the objective lens system adopted for the fourth embodiment which uses the second cemented lens component requires an additional lens element, it has a merit to favorably correct longitudinal chromatic aberration and spherical aberration. The cemented lens component is composed of a positive lens element which has a relatively low refractive index and a weak

dispersing power, and a negative lens element which has a high refractive index and a strong dispersing power.

In other words, this cemented lens component is configured so as to satisfy the following condition (4):

$$n_P<n_N,\ \nu_P>\nu_N \quad (4)$$

wherein the reference symbols n_P and n_N represent refractive indices of the positive lens element and the negative lens element respectively disposed in the cemented lens component, and the reference symbols ν_P and ν_N designate Abbe's numbers of the positive lens element and the negative lens element respectively disposed in the cemented lens component.

In the cemented lens component, the negative lens element may be disposed on the object side as shown in FIG. **11** or on the image side. Further, the cemented lens component may have a plano-convex or meniscus shape instead of the biconvex shape selected for the fourth embodiment.

FIG. **7** exemplifies a frame structure for the objective lens system. A tube **9** of an observation system shown in this drawing consists of a pipe which has an inside diameter just fitting over an outside diameters of the lens components and accommodates the objective lens system fixed with spacers **10**. The spacers **10** are made of a metal or a synthetic resin material and have inside surfaces which should desirably be treated into rougthened surfaces, preferably in black. If the spacers have inside surfaces which are specular surfaces having high reflectance, rays reflected by the inside surfaces of the spacers will reach an image surface, thereby undesirably producing flare.

Then, description will be made of an eyepiece lens system and an imaging lens system which are to be used in the optical system of the non-flexible endoscope according to the present invention.

The eyepiece lens system to be used in the optical system of the non-flexible endoscope according to the present invention has a composition illustrated in FIG. **8** (r_7 through r_{21}), for example, and has a role of a magnifying lens for observing a primary image I_1 (r_6) which is formed by the objective lens system. However, the objective lens system forms an inverted image and it is necessary to obtain an erect image with the optical system as a whole including the objective lens system. For this reason, the eyepiece lens system to be used in the optical system of the non-flexible endoscope according to the present invention is configured so as to perform a single cycle of image relaying within the eyepiece lens system itself and then form a secondary mage I_2 (r_{18}) which is to be observed. In other words, an image to be observed will undesirably be inverted when the secondary image I_2 is not formed in the eyepiece lens system itself. Further, the objective lens system has the simple composition and can hardly correct aberrations sufficiently by itself. Accordingly, the optical system of the non-flexible endoscope according to the present invention is configured so as to correct aberrations in the optical system as a whole including the objective lens system and the eyepiece lens system. That is to say, the eyepiece lens system is configured so as to correct mainly aberrations which cannot be corrected by the objective lens system.

In the first embodiment of the optical system of the non-flexible endoscope according to the present invention, for example, the objective lens system is composed only of a single lens component and undercorrects longitudinal chromatic aberration. For correcting this undercorrected longitudinal chromatic aberration, at least two cemented lens components are used in the eyepiece lens system so as to overcorrect longitudinal chromatic aberration in the eyepiece lens system, whereby the optical system as a whole favorably corrects longitudinal chromatic aberration by cancelling the longitudinal chromatic aberration undercorrected by the objective lens system with the longitudinal chromatic aberration overcorrected by the eyepiece lens system.

Further, when manufacturing precisions of parts are lowered for reducing a manufacturing cost of the objective lens system, positional variations of the primary image will be large in a direction along the optical axis, thereby degrading focusing accuracy. For correcting such degradation of focusing accuracy, it is desirable to equip the eyepiece lens system with a focusing mechanism. As the focusing mechanism for the eyepiece lens system, it can be considered to adopt a mechanism for moving the eyepiece lens system as a whole along the optical axis or an inner-focus type mechanism for moving some of lens components disposed in the eyepiece lens system along the optical axis.

Furthermore, it is desirable to dispose a field stop at a location of the secondary image I_2 or the primary image I_1 since a field stop disposed at such a location is capable of preventing a border of visual field being dim and hindering flare from being produced due to rays coming from outside the visual field.

Now, description will be made of the imaging lens system to be used in the non-flexible endoscope according to the present invention which is configured for observation on a TV monitor. This imaging lens system has a composition illustrated as r_7 through r_{15} in FIG. **9**, for example, and a role to relay the primary image I_1 formed by the objective lens system onto an image pickup surface of a solid-state image pickup device. Like the eyepiece lens system described above, the imaging lens system is configured so as to correct aberrations in the optical system as a whole including the objective lens system. Therefore, the imaging lens system is configured so as to correct aberrations which cannot be corrected by the objective lens system. Longitudinal chromatic aberration, in particular, is overcorrected by using at least two cemented lens components in the imaging lens system so that longitudinal chromatic aberration undercorrected by the objective lens system is corrected favorably in the optical system as a whole.

Also in case of the non-flexible endoscope configured for observation on a TV monitor, it is desirable to equip the TV camera adaptor with a focusing mechanism. It is possible to select, as the focusing mechanism, a mechanism for moving the imaging lens system as a whole or an inner-focus type mechanism for moving some of lens components disposed in the imaging lens system. Further, it is possible to prevent a border of a visual field from being dim and hinder flare from being produced due to rays coming from outside the visual field by disposing a stop at a location of the primary image.

Though the non-flexible endoscope according to the present invention is configured mainly for making certain parts thereof (the insert section) disposable, the configuration of the non-flexible endoscope according to the present invention is applicable also to non-flexible endoscopes which are configured to use parts thereof repeatedly without discarding them for lowering cost prices thereof. It is sufficient for such application to integrate the insert section **1** and the eyepiece section **2** so as to be inseparable from each other in the configuration illustrated in FIG. **2**. In case of the configuration illustrated in FIG. **3**, it is sufficient to integrate the insert section **1** and the TV camera adaptor **3** so as to be inseparable from each other. Further, it is possible

to integrate all of the insert section **1**, the TV camera adaptor **3** and the TV camera **4** so as to be inseparable from one another.

That is to say, it is possible to integrate the insert section with a photographing section accommodating the imaging lens system and a solid-state image pickup device so that they have an inseparable unit structure.

Even for the non-flexible endoscopes which are configured to use parts thereof repeatedly, the reduction in numbers of optical elements realized by the omission of relay lens systems provides merits from viewpoints of cost prices and assembling convenience thereof.

The non-flexible endoscope according to the present invention has the fundamental configuration which is characterized in that only the objective lens system is disposed in the insert section to be inserted into a location to be observed and that the objective lens system forms the primary image in the vicinity of the near end (an end surface located on the side opposite to the leading end) of the insert section. That is to say, the non-flexible endoscope according to the present invention is configured so as to permit composing an observation optical sysem by attaching the insert section comprising the objective lens system to the eyepiece section comprising the eyepiece lens system for observation of the object side or attaching a TV camera to the eyepiece section for picking up an image or observation on a TV monitor. However, the non-flexible endoscopes according to the present invention is essentially characterized in that the objective lens system is disposed in the insert section or the like described above so as to form a primary image at the near end (the end surface located on the side opposite to the leading end) of the insert section, thereby accomplishing the objects of the present invention.

Now, description will be made of a configuration of the non-flexible endoscope according to the present invention of a type which comprises a relay lens system disposed in an optical system thereof.

An optical system of the non-flexible endoscope according to the present invention which is of the type comprising a relay lens system consists of a slender insert section which is to be inserted into body cavities for observing interiors thereof and a grip section which is to be kept outside the cavities even during observation. Accommodated in the insert section are an objective lens system which is disposed on the side of a leading end of the insert section for forming a primary image and a relay lens system which serves for relaying the primary image so as to form a secondary image in the vicinity of a near end of the insert section or in the grip section, whereas the grip section accommodates an eyepiece lens system which receives rays coming from the secondary image and allows rays to emerge therefrom in a condition where they are made parallel with one another so as to be observable by human eyes. This optical system is characterized in that it satisfies the following condition (5):

$$0.3<D_1/D_2<0.7 \quad (5)$$

wherein the reference symbol D_1 represents a distance as measured from a leading end surface of the objective lens system to the primary image and the reference symbol D_2 designates a distance as measured from the leading end surface to the secondary image.

Speaking more concretely, the non-flexible endoscope according to the present invention described above has a configuration illustrated in FIG. **12**, for example, or consists of a slender insert section **1** which is to be inserted into cavities of living bodies and the like, and a grip section which is to be kept outside the cavities even during use of the non-flexible endoscope and comprises an eyepiece section **2** disposed in a near end thereof. Further, accommodated in the insert section **1** are an objective lens system O which is disposed in the leading end thereof, a primary field lens F_1 which is disposed in the vicinity of a primary image I_1 formed by the objective lens system O, and a relay lens unit R_1 which serves for relaying the primary image I_1 so as to form a secondary image I_2. Further, disposed in the grip section **5** is an eyepiece lens system E which converts rays coming from the secondary image I_2 into rays which are nearly parallel with one another so as to be observable by naked eyes. Furthermore, it is possible to attach the eyepiece section **2** to a TV camera system **6** for endoscopes which is configured as a separate unit comprising a solid-state image pickup device **11** and an imaging lens system IL.

Though the TV camera system **6** is mechanically integrated in FIG. **12**, it is possible to compose this system of a section **6*a*** comprising the imaging lens system IL and another section **6*b*** comprising the solid-state image pickup device so that the system is separable along the dashed line 6C shown in FIG. **12** into the two sections which are mechanically attachable and detachable to and from each other. In this case, the section **6*a*** which comprises the imaging lens system IL has a role of an adaptor for attaching the section **6*b***, or a TV camera head, to the non-flexible endoscope. When the TV camera **6** is configured so as to have a separable configuration described above, it provides a convenience to use various combinations of adaptors and TV camera heads which are prepared in plural kinds respectively.

A greatest characteristic of the optical system of the non-flexible endoscope according to the present invention which has the configuration described above lies in that a relay lens unit is configured so as to perform image relaying only in one cycle for reducing a number of lens elements to be used in the non-flexible endoscope and the objective lens system is configured so as to form the primary image nearly in the middle of a section from the leading end of the endoscope to the secondary image for preventing a numerical aperture from being reduced by the image relaying.

The optical system of the non-flexible endoscope according to the present invention comprises, in order from the side of the leading end thereof, the objective lens system O, the primary field lens F_1, the relay lens unit R_1 and the eyepiece lens system E: the objective lens system O serves for forming the primary image I_1 in the insertion section and the relay lens R_1 serves for forming the secondary image I_2 in the grip section **5** as described above. The primary field lens F_1 is disposed in the vicinity of the primary image I_1.

When a primary field lens is to be disposed on the side of the objective lens system O of a primary image I_1, it may be regarded as a lens component of the objective lens system O or when the primary field lens F_1 is to be disposed on the side of a relay lens unit R_1 of the primary image I_1, it may be considered as a lens component of the relay lens unit R_1.

In an ordinary case where a final image which is formed on the object side of the eyepiece lens system E is located in the vicinity of a near end of an insert section or in the grip section, the secondary image I_2 is formed as a final image on the optical system of the non-flexible endoscope according to the present invention. Accordingly, the distance as measured from the leading end of the insert section to the secondary image must be equal or longer to or than an effective length of the insert section. Though a smaller effective length of the insert section makes it possible to obtain a brighter optical system, the insert section has an

effective length which is determined almost dependently only on a length required for handling of a non-flexible endoscope and cannot be shorter than this length.

Since the location of the secondary image, out of the two images formed in the non-flexible endoscope according to the present invention, is determined as described above, the present invention selects a location of the primary image which is suited for obtaining a bright optical system.

FIG. **13**A, FIG. **13**B and FIG. **13**C show diagrams visualizing variations of numerical apertures to be caused by changing a location of a primary image. FIG. **13**A illustrates a case where the primary image I_1 is located in the middle between the leading end of the objective lens system O and the secondary image I_2 by prolonging the objective lens system O, FIG. **13**B visualizes a case where the location of the primary image I_1 is shifted toward the leading end by shortening the objective lens system O and FIG. **13**C shows a case where the location of the primary image I_1 is shifted toward the secondary image I_2 by remarkably prolonging the objective lens system O. Out of these drawings, FIG. **13**A shows a refractive power distribution which is most desirable for accomplishing the objects of the present invention, whereas FIG. **13**B shows a composition which is similar to that in the conventional optical system for non-flexible endoscopes which uses a short objective lens system O.

In each of FIG. **13**A, FIG. **13**B and FIG. **13**C wherein a relay lens unit R_1 has a magnification set at 1× and a primary field lens F_1 is overlapped with the primary image I_1, the objective lens system O has a numerical aperture on the side of incidence which is equal to a numerical aperture thereof on the side of emergence.

Numerical apertures are determined dependently on angles α which are formed between marginal rays and optical axes as shown in FIG. **13**A, FIG. **13**B and FIG. **13**C. Speaking concretely, a numerical aperture is defined as NA=sin α and a larger angle α makes it possible to obtain a brighter optical system.

Though the marginal rays are traced at an equal maximum height in FIG. **13**A, FIG. **13**B and FIG. **13**C, it is apparent that the angle α is the largest and permits obtaining a brightest optical system in the case shown in FIG. **13**A since a lens system which determines a limit of heights of the marginal rays is not either one of the objective lens system O and the relay lens unit R_1 in this case. In the case illustrated in FIG. **13**B, a limit of heights of the marginal rays is determined by the relay lens system R_1 only and the angle α is determined by a length of the relay lens unit R_1. In the case visualized in FIG. **13**C, a limit of heights of the marginal rays is determined by the objective lens system O only and the angle α is determined by a length of the objective lens system O. In the case illustrated in FIG. **13**A, in contrast, a limit of heights of the marginal rays is determined by both the objective lens system O and the relay lens unit R_1 either of which has a length shorter than that of the relay lens unit R_1 shown in FIG. **13**B or that of the objective lens system O shown in FIG. **13**C, whereby the location of the primary image I_1 shown in FIG. **13**A allows to form a large angle α which makes it possible to obtain a brightest optical system when outside diameters of the lens systems are predetermined to a definite value.

Apart from the qualitative description of the optical system of the non-flexible endoscope according to the present invention, it is quantitatively sufficient to configure the optical system so as to satisfy the abovementioned condition (5).

The reference symbol D_1/D_2 used in the condition (5) represents a parameter for varying brightness in the optical system and has a value of 0.5 in the condition illustrated in FIG. **13**A which permits configuring the optical system so as to be brightest.

Accordingly, brightness in the optical system will be lowered if D_1/D_2 has a value larger or smaller than 0.5. When brightness at D_1/D_2 is taken as 1, brightness at various values of D_1/D_2 is expressed by an equation of $1/\{1+|1-(2D_1/D_2)|\}^2$ or calculated as listed below:

D_1/D_2	Brightness
0.1, 0.9	0.31
0.2, 0.8	0.39
0.3, 0.7	0.51
0.4, 0.6	0.69
0.5	1

As is understood from the values tabulated above, brightness at D_1/D_2=0.3 or 0.7 is 0.51 times as high as that at D_1/D_2=0.5, or brightness is halved by lowering D_1/D_2 from 0.5 to 0.3 or enhancing it from 0.5 to 0.7. Since brightness is not allowed to be lower than that at D_1/D_2=0.3 or 0.7, it is necessary that the optical system satisfies the abovementioned condition (5). If the lower limit of 0.3 of the condition (5) is exceeded, the optical system will be set in the condition shown in FIG. **13**B or if the upper limit of 0.7 of the condition (5) is exceeded, the optical system will be set in the condition shown in FIG. **13**C, whereby brightness will be lowered to about ½ of that at D_1/D_2=0.5 or the optical system will be too dark for practical use.

It is possible to obtain at least 70% of the brightness at D_1/D_2=0.5 when the above-mentioned condition (5) is modified so as to have a lower limit of 0.4 and an upper limit of 0.6. It is therefore more desirable to configure the optical system so as to satisfy the following condition:

$$0.4<D_1/D_2<0.6$$

In FIG. **12**, the primary field lens F_1 is disposed in the vicinity of the primary image I_1 for transmitting a pupil of the objective lens system O to the relay lens unit R_1. Since a principal ray which emerges from the objective lens system O travels in a direction away from the optical axis, the principal ray cannot pass through the relay lens unit R_1 if the field lens is not disposed in the vicinity of the primary image, whereby an image will be eclipsed at a marginal portion of a visual field. For this reason, the primary field lens F_1 must be disposed in the vicinity of the primary image. When a surface of the field lens F_1 is overlapped with the primary image, however, dust or injury existing on the surface of the field lens F_1 will be imaged. It is therefore desirable to dispose the field lens F_1 so as to have air-contact surfaces located with narrow spacings reserved from the primary image I_1.

It is possible to carry out observation on a TV monitor which is essential for surgical operations under observation through an endoscope when a TV camera system for non-flexible endoscope is attached to a non-flexible endoscope comprising an optical system of the type which uses a relay lens system as described above. For such observation on a TV monitor, it is sufficient to connect a TV camera system **6** to a grip section **2** of a non-flexible endoscope as in the case of the non-flexible endoscope shown in FIG. **12**, for example, so that an imaging lens system IL disposed in the TV camera system for non-flexible endoscope forms a ternary image I_3 at a location coincident with a light receiving surface of a solid-state image pickup device for allowing this device to pick up the image.

Now, description will be made of an optical system which is of a type desirable for use in the non-flexible endoscope according to the present invention and comprises not only the objective lens system O described above but also a relay lens unit R_1. It is desirable to compose the objective lens system O of a first lens component which is disposed in the leading end of an insert section and has a negative refractive power and a second lens component which is disposed between the first lens component and a primary field lens, and has a positive refractive power. Such a refractive power distribution is selected for the objective lens system O so that a number of lens components to be disposed in the objective lens system O is reduced while required field angle thereof. The negative refractive power is imparted to the first lens component for allowing it to have a function for widening a field angle and the positive refractive power is imparted to the second lens component for allowing it to relay a virtual image formed by the first lens component so as to form a real image. The first lens component of the objective lens system O has the strongest negative refractive power out of lens components disposed in an observation optical system and is therefore effective also for correction of curvature of field. Further, the second lens component of the objective lens system O has a role of a pupil in the objective lens system. The refractive power distribution described above permits minimizing a number of lens components to be disposed in the objective lens system O, or allows this lens system to have a simplest composition.

In the configuration shown in FIG. **12**, the objective lens system is composed only of two lens elements, or a first lens component consisting of a single negative lens element and a second lens component consisting only of a positive lens element. However, a refractive power of the first lens component which consists of the single negative lens element may be insufficient for certain specifications of the optical system such as a field angle thereof and the first lens component can comprise an additional lens element having a negative refractive power. Further, the first lens component can comprise a lens element having a positive refractive power or be configured as a cemented lens component for favorably correcting lateral chromatic aberration and astigmatism. When the objective lens system is composed only of spherical lens elements, it produces barrel distortion. For correcting this distortion, it is sufficient to use an aspherical surface in the first lens component, on which the principal ray is high, so as to prevent the principal ray from being refracted excessively. Further, for correcting longitudinal chromatic aberration by the second lens component, it is sufficient to configure it so as to comprise a negative lens element having a strong dispersing power, or have a composition consisting of a positive lens element and a negative lens element. In this case, the positive lens element and the negative lens element may be cemented to each other or disposed as separate lens elements. It is most desirable that the second lens component has a magnification of approximately −1× or it should preferably have a magnification within a range from −2× to −0.5×. The objective lens system will have a pupil at a location largely apart from a middle between the leading end thereof and the primary image, whereby offaxial rays will undesirably be eclipsed if the second lens component has a magnification within a range defined by the following condition (6):

$$0.5<|\beta_2|<2.0 \tag{6}$$

wherein the reference symbol β_2 represents the magnification of the second lens component.

Next, a primary field lens may be disposed on either side of the primary image, i.e., on the side of the objective lens system or on the side of the relay lens, or so as to locate the primary image therein. When the primary field lens is too far from the primary image, however, an image will be eclipsed or intensities of the marginal rays will be lowered. Therefore, it is desirable that a distance D_3 as measured from the primary field lens to the primary image is within 10% of a value of D_2 mentioned above.

In other words, it is desirable to configure the objective lens system so as to satisfy the following condition (7):

$$|D_3/D_2|\leqq 0.1 \tag{7}$$

If the distance as measured from the primary field lens to the primary image exceeds 10% of D_2, the primary field lens itself will eclipse the offaxial rays, thereby causing eclipse of an image at marginal portions of a visual field or lowering of intensities of the marginal rays. The primary field lens must have a positive refractive power for transmitting a pupil and can have a function sufficient for this purpose when it is composed of a single positive lens element. For correcting lateral chromatic aberration and astigmatism, however, it is desirable to configure the primary field lens as a cemented lens component consisting of a positive lens element and a negative lens element.

Further, a relay lens unit need not have a symmetrical shape or a complicated composition, unlike the relay lens system used in the conventional optical system for non-flexible endoscopes which is configured so as to perform a plurality of image relay cycles.

The relay lens unit to be used in the optical system of the non-flexible endoscope according to the present invention can be composed simply by disposing a lens component having a positive refractive power nearly in the middle between the primary image and the secondary image, and this lens component has a role of a pupil of the relay lens unit. This lens component having the positive refractive power may be composed of a single positive lens element, but for correction of longitudinal chromatic aberration it is to be composed of a positive lens element and a negative lens element. The positive lens element and the negative lens element may be cemented to each other or disposed separately.

In the optical system of the non-flexible endoscope according to the present invention in which both the second lens component of the objective lens system and the relay lens unit have roles of pupils in an observation optical system, it is sufficient for correction of longitudinal chromatic aberration in the observation optical system to compose at least either of the second lens component and the relay lens unit of a combination of a positive lens element and a negative lens element.

In the optical system of the endoscope shown in FIG. **12**, the relay lens unit is configured as a cemented lens component consisting of a positive lens element and a negative lens element for correcting longitudinal chromatic aberration, whereas the second lens component of the objective lens system is composed of a single lens element.

In a case where aspherical surfaces are to be used for correcting spherical aberration, it is sufficient to configure at least either of the second lens component of the objective lens system or the relay lens unit so as to have an aspherical surface which has such a shape as to lower curvature toward a marginal portion thereof. As already described above, the relay lens unit should desirably have a magnification of approximately −1× or within a range defined by the following condition (8):

$-2<\beta_R<-0.5$

wherein the reference symbol β_2 represents the magnification of the relay lens system.

If the relay lens unit has a magnification largely deviated from the range defined above, the relay lens unit will have a pupil at a location largely deviated from the middle between the primary image and the secondary image, whereby the offaxial rays will be eclipsed.

The eyepiece lens system has a positive refractive power and can be composed sufficiently of a single positive lens element. For correcting lateral chromatic aberration and astigmatism, however, the eyepiece lens system may be composed of a positive lens element and a negative lens element which may be cemented to each other or disposed separately.

In the fundamental composition of the optical system of the non-flexible endoscope according to the present invention, no particular consideration is taken for an eye point of the eyepiece lens system. When positional control of the eye point is important in actual lens design, however, it is allowable to dispose a secondary field lens in the vicinity of the secondary image for positional control of the eye point by using a refractive power of the secondary field lens.

In the conventional non-flexible endoscope, a visual field mask is disposed at an imaging location for clarifying a range of a visual field to be observed. A visual field mask can be disposed also in the optical system of the non-flexible endoscope according to the present invention. In such a case, it is most desirable to dispose a visual field mask composed of a thin black metal sheet or the similar material at a location of the secondary image which imposes a weak spatial restriction, but such a visual field mask may be disposed at a location of the primary image or in the first lens component of the objective lens system on which the principal ray is low.

Listed below are numerical data of the preferred embodiments of the optical system of the non-flexible endoscape according to the present invention which is of the type described above (characterized in that it comprises at least an objective lens system and a relay lens system):

wherein the reference symbols r_1, r_2, . . . represent radii of curvature on surfaces of respective lens elements, the reference symbols d_1, d_2, . . . designate thicknesses of the respective lens elements and air-spaces reserved therebetween, the reference symbols n_1, n_2, . . . denote refractive indices of the respective lens elements, and the reference symbols ν_1, ν_2. . . represent Abbe's numbers of the respective lens elements.

The fifth embodiment of the present invention has a configuration shown in FIG. **12** and uses an optical system which has a composition illustrated in FIG. **14** on an enlarged scale. The fifth embodiment consists of: an objective lens system O (r_1 through r_5) which is composed of a first lens component consisting of a single negative plano-concave lens element and a second lens component consisting of a single biconvex positive lens element having the same radius of curvature on both surfaces thereof; a primary field lens F_1 (r_6 and r_7) which consists of a single positive biconvex lens element having the same radius of curvature on both surfaces thereof; a relay lens system R_1 (r_9 through r_{11}) which is composed of a cemented lens component having a positive refractive power, and consisting of a positive lens element and a negative lens element; and an eyepiece lens system (r_{13} and r_{14}) which is composed of a single biconvex lens element having the same radius of curvature on both surfaces thereof. The fifth embodiment is composed only of the six lens element for manufacturing at a low cost. Further, all the lens elements other than the plano-concave lens element and those used for composing the cemented lens component are symmetrical with regard to vertical axes perpendicular to the right-to-left direction and require no discrimination between sides to be set on the object side and the image side, thereby facilitating assembling procedures. Furthermore, a distance as measured from r_1 to r_8 corresponds to D_1, whereas a distance as measured from r_1 to r_{12} corresponds to D_2 when the fifth embodiment is combined with the imaging lens system IL (r_{15} through r_{29}) shown in FIG. **14**, the optical system has aberration characteristics illustrated in FIG. **48**A, FIG. **48**B, FIG. **48**C and FIG. **48**D. The reference symbol r_{30} used in FIG. **14** represents an imaging location I_n.

The sixth embodiment has a composition illustrated in FIG. **15** which is similar to that of the fifth embodiment, except for a cemented lens surface (r_{10}) which is set in an opposite direction. Aberration characteristics of the sixth embodiment are illustrated in FIG. **49**A, FIG. **49**B, FIG. **49**C and FIG. **49**D.

The seventh embodiment has a composition illustrated in FIG. **16** which is similar to that of the fifth embodiment, except for a first lens component of the objective lens system O which is composed of two negative plano-concave lens elements in the seventh embodiment. Speaking more concretely of the seventh embodiment, r_1 through r_7 correspond to the objective lens system O, r_8 and r_9 correspond to a primary field lens F_1, r_{11} through r_{13} correspond to a relay lens system R_1, r_{15} and r_{16} correspond to and eyepiece lens system E; r_{10} represents a primary image I_1, r_{14} designates a secondary image I_2, a distance as measured from r_1 to r_{10} corresponds to D_1, and a distance as measured from r_1 to r_{14} corresponds to D_2.

The seventh embodiment has aberration characteristics illustrated in FIG. **50**A, FIG. **50**B, FIG. **50**C and FIG. **50**D.

The eighth embodiment has a composition illustrated in FIG. **17** and is different from the fifth embodiment in that a second lens component of an objective lens system O is a positive cemented lens component consisting of a positive lens element and a negative lens element, and a relay lens system R_1 is composed of a single positive biconvex lens element having the same radius of curvature on both surfaces thereof in the eighth embodiment. In other words, the composition of the eighth embodiment is obtained by using the cemented lens component which is disposed in the relay lens system R_1 as the second lens component of the objective lens system O in the composition of the fifth embodiment. Accordingly, r_1 through r_5 corresponds to the objective lens system O, r_6 and r_7 corerspnod to a primary field lens F_1, r_9 and r_{10} correspond to a relay lens system R_1, and r_{12} and r_{13} correspond to an eyepiece lens system E in the eighth embodiment. Further, r_8 represents a primary image I_1, r_{11} designates a secondary image I_2, a distance as measured from r_1 to r_8 corresponds to D_1, and a distance as measured from r_1 to r_{11} corresponds to D_2.

The eighth embodiment has aberration characteristics which are visualized in FIG. **51**A, FIG. **51**B, FIG. **51**C and FIG. **51**D.

The ninth embodiment has a composition illustrated in FIG. **18** which is similar to that of the fifth embodiment, except for a primary field lens F_1 which is disposed on the side of a relay lens system R_1, or the right side of a primary image I_1 in the ninth embodiment. Speaking concretely, r_1 through r_5 correspond to an objective lens system O, r_7 and r_8 correspond to the primary field lens F_1, r_9 through r_{11} correspond to the relay lens system R_1, and r_{13} and r_{14} correspond to an eyepiece lens system E in the ninth embodiment. Further, a distance as measured from r_1 to r_6 corresponds to D_1 and a distance as measured from r_1 to r_{12} corresponds to D_2.

Aberration characteristics of the ninth embodiment are visualized in FIG. **52**A, FIG. **52**B, FIG. **52**C and FIG. **52**D.

The tenth embodiment has a composition illustrated in FIG. **19** which is characterized in that a primary image is formed in a primary field lens F_1. Accordingly, r_1 through r_5

correspond to an objective lens system O, r_6 through r_8 correspond to the primary field lens F_1, r_9 through r_{11} correspond to a relay lens system R_1, and r_{13} and r_{14} correspond to an eyepiece lens system E. Further, r_{17} represents a primary image I_1 formed in the primary field lens F_1 and r_{12} designates a secondary image I_2.

The tenth embodiment has aberration characteristics visualized in FIG. **53**A, FIG. **53**B, Fib. **53**C and FIG. **53**D.

The eleventh embodiment has a composition illustrated in FIG. **20** which is similar to that of the fifth embodiment wherein a distance as measured from r_1 to r_8 corresponds to D_1 and a distance as measured from r_1 to r_{12} corresponds to D_2. The eleventh embodiment uses aspherical surfaces on a first lens component and a second lens component of an objective lens system. Speaking more concretely, the eleventh embodiment adopts the aspherical surfaces as a surface r_2 of the first lens component which is disposed on the side of the second lens component and both r_3, r_5 surface of the second lens component. Further, the eleventh embodiment is designed on an assumption that all the lens elements other than those used for composing the cemented lens comopnent are to be made of an acrylic plastic material for reducing a manufacturing cost of the non-flexible endoscope according to the present invention through mass production. Furthermore, a concave surface r_2 of the first lens component of the objective lens system is configured as an aspherical surface having such a shape as to lower curvature toward a margin thereof for correcting distortion.

The aspherical surfaces used in the eleventh embodiment have shapes which are expressed by the above-mentioned formula (a).

Aspherical surfaces used in the other embodiments of the present invention also have shapes expressed by this formula.

The eleventh embodiment has aberration characteristics shown in FIG. **54**A, FIG. **54**B, FIG. **54**C and FIG. **54**D.

The twelfth embodiment has a composition visualized in FIG. **21** and is different from the fifth embodiment in that the twelfth embodiment uses a relay lens unit R_1 which is composed on a negative lens element and a positive lens element disposed separately, and has a positive refractive power. Speaking concretely, r_1 through r_5 correspond to an objective lens system O, r_6 and r_7 represent a primary field lens F_1, r_9 through r_{12} correspond to the relay lens unit R_1, and r_{14} and r_{15} designate an eyepiece lens system E. Further, r_8 denotes a primary image I_1, r_{13} represents a secondary image I_2, a distance as measured from r_1 to r_8 corresponds to D_1 and a distance as measured from r_1 to r_{13} corresponds to D_2. Furthermore, a concave surface r_2 of a first lens component of the objective lens system O which is located on the side of a second lens component, and both surfaces r_{11} and r_{12} of the positive lens element of the relay lens unit R_1 are configured as aspherical surfaces. Moreover, all the lens elements other than the negative lens element (r_9 and r_{10}) of the relay lens unit R_1 are made of an acrylic plastic material for reduction of the manufacturing cost of the non-flexible endoscope according to the present invention through mass production. Like the eleventh embodiment, the twelfth embodiment uses an aspherical surface as a concave surface r_2 of the first lens component which is disposed on the side of the second lens component for correcting distortion.

The twelfth embodiment has aberration characteristics visualized in FIG. **55**A, FIG. **55**B, FIG. **55**C and FIG. **55**D.

The thirteenth embodiment has a composition illustrated in FIG. **22** and uses, like the twelfth embodiment, a relay lens unit R_1 which is composed of a negative lens element and a positive lens element disposed separately. Speaking concretely, r_1 through r_5 correspond to an objective lens system O, r_6 and r_7 represent a primary field lens F_1, r_9 through r_{12} correspond to the relay lens unit R_1, r_{14} and r_{15} designate an eyepiece lens system E, r_8 denotes a primary image I_1, r_{13} represents a secondary image I_2, a distance as measured from r_1 to r_8 corresponds to D_1, and a distance as measured from r_1 to r_{13} corresponds to D_2. Further, a surface r_2 of a first lens component of the objective lens system O which is disposed on the side of a second lens component thereof, and both surfaces r_{11} and r_{12} of the positive lens elemenet of the relay lens unit R_1 are configured as aspherical surfaces. The thirteenth embodiment is configured on an assumption that all lens elements to be used for composing the optical system are to be made of plastic materials: the negative lens element of the relay lens system R_1 which is disposed on the side of the primary image I_1 to be made of a polycarbonate material and the other lens elements to be made of an acrylic plastic material.

Aberration characteristics of the thirteenth embodiment are visualized in FIG. **56**A, FIG. **56**B, FIG. **56**C and FIG. **56**D.

The fourteenth embodiment has a composition illustrated in FIG. **23** and is different from the fifth embodiment in that the fourteenth embodiment uses a secondary field lens F_2 (r_{13} and r_{14}) which is disposed on the side of an eyepiece lens system E, or right side, of a secondary image r_{12}. In the fourteenth embodiment, r_1 through r_5 correspond to an objective lens system O, r_6 and r_7 represent a primary field lens F_1, r_9 through r_{11} correspond to a relay lens unit R_1, r_{13} and r_{14} designate the above-mentioned secondary field lens F_2, r_{15} and r_{16} denote an eyepiece lens system E, r_8 represents a primary image I_1, r_{12} designates a secondary image I_2, a distance as measured from r_1 to r_8 corresponds to D_1, and a distance as measured from r_1 to r_{12} corresponds to D_2.

The fourteenth embodiment which uses the secondary field lens F_2 permits controlling a distance as measured from the eyepiece lens system E to an eyepiece attaching surface, or allows this distance to be shorter than the distances corresponding thereto in the other embodimetns.

The fourteenth embodiment has aberration characteristics which are visualized in FIG. **57**A, FIG. **57**B, FIG. **57**C and FIG. **57**D.

The fifteenth embodiment has a composition illustrated in FIG. **24** and is characterized in that an eyepiece lens system E is composed of a cemented lens component consisting of a negative lens element and a positive lens element. Speaking concretely of the fifteenth embodiment, r_1 through r_5 correspond to an objective lens system O, r_6 and r_7 represent a primary field lens F_1, r_9 through r_{11} correspond to a relay lens unit R_1, and r_{13} through r_{15} correspond to an eyepiece lens system E. Further, r_8 represents a primary image I_1, r_{12} represents a secondary image I_2, a dsitance as measured from r_1 to r_8 corresponds to D_1 and a distance as measured from r_1 to r_{12} corresponds to D_2.

Aberratin characteristics of the fifteenth embodiment are illustrated in FIG. **58**A, FIG. **58**B, FIG. **58**C and FIG. **58**D.

The sixteenth embodiment has a composition illustrated in FIG. **25** and is characterized in that an objective lens system O and a relay lens unit R_1 thereof comprise long rod-shaped lens components. Speaking concretely of the optical system preferred as the sixteenth embodiment, the objective lens system and the eyepiece lens system are composed of a negative plano-concave lens element, a first biconvex rod-shaped lens component, a second biconvex rod-shaped lens component, a third convex-planar rod-shaped lens component, and a cemented lens component

consisting of a positive lens element and a negative lens element. A pupil is located between the first and second rod-shaped lens components.

In the sixteenth embodiment, certain lens elements are replaced with air lenses. An airspace reserve between a surface of emergence (r_4) of the first rod-shaped lens component and a surface of incidence (r_6) of the second rod-shaped lens component functions as a biconcave air lens having a positive refractive power so that the objective lens system O is composed of a first lens component which consists of the plano-concave lens element (r_1 and r_2) and a surface of incidence of the first rod-shaped lens component, and a second lens component which consists of the air lens. Further, an airspace reserved between a surface of emergence (r_7) of the second rod-shaped lens component and a surface of incidence (r_9) of the third rod-shaped lens component forms rather a thick biconcave air lens which functions as a primary field lens F_1 in which a primary image I_1 is to be formed. The relay lens unit R_1 is composed of a surface of emergence (r_{10}) of the third rod-shaped lens component and a cemented lens component (r_{11} through r_{13}) to which all of a refractive power of the relay lens unit is imparted.

In addition, an eyepiece lens system E is composed of a positive biconvex lens element (r_{15} and r_{16}). The reference symbol r_8 represents a primary image I_1, the reference symbol r_{14} designates a secondary image I_2, a distance as measured from r_1 to r_8 corresponds to D_1 and a distance as measured from r_1 to r_{14} corresponds to D_2.

In the field of optical systems for non-flexible endoscopes, it is conventionally known that brightness can be enhanced by filling internal spaces thereof with glass materials and this conventional technique is applies to the sixteenth embodiment of the present invention.

The sixteenth embodiment, in which the airspaces reserved in each of the fifth to fifteenth embodiments are filled with a glass material having a high refractive index, provides an effect equivalent to shortening of an effective length of an insert section calculated in terms of an optical path length, whereby the sixteenth embodiment has a larger numerical aperture or is a brighter optical system. The sixteenth embodiment actually has an F number which is smaller than the F number of any one of the fifth to fifteenth embodiments.

Though the objective lens system O, the primary field lens F_1 and the relay lens unit R_1 are composed of the thin lens elements in each of the fifth to fifteenth embodiments, it is possible to use air lenses formed among three long rod-shaped lens components as in the case of the sixteenth embodiment.

From a fact that the sixteenth embodiment has a composition which is similar to that illustrated in FIG. **13**A when it is decomposed into the individual refracting surfaces, it will be understood that the sixteenth embodiment can accomplish the objects of the present invention.

The sixteenth embodiment has aberration characteristics which are visualized in FIG. **59**A, FIG. **59**B, FIG. **59**C and FIG. **59**D.

The seventeenth embodiment has a composition illustrated in FIG. **26**. From a viewpoint of the composition, the seventeenth embodiment is equivalent to the sixteenth embodiment in which the third rod-shaped lens component is omitted. Accordingly, an objective lens system O is composed of a first lens component which consists of a single negative plano-concave lens element (r_1 and r_2) and a surface of incidence (r_3) of a first rod-shaped lens component, and a second lens component which consists of an air lens (r_4 and r_6) formed between the first rod-shaped lens component and a second rod-shaped lens component in the seventeenth embodiment. A first field lens F_1 is composed of a surface of emergence (r_7) of the second rod-shaped lens component. In the specification of the non-flexible endoscope according to the present invention, a term "lens" may be used for expressing a refracting surface which has a refractive power. A relay lens unit R_1 is composed of a cemented lens component (r_9 through r_{11}) which consists of a positive lens element and a negative lens element. An eyepiece lens system E_1 is composed of a single positive biconvex lens element which has the same radius of curvature on both surfaces thereof.

The seventeenth embodiment is configured so as to have an F number which is as small as that of the sixteenth embodiment by composing the objective lens system O and the primary field lens F_1 of the long rod-shaped lens components. Though the primary field lens F_1 is composed not of a single lens element but of a single refracting surface, the seventeenth embodiment has such a refractive power distribution as that shown in FIG. **13**A and can accomplish the objects of the present invention.

In addition, a distance as measured from r_1 to r_8 corresponds to D_1 and a distance as measured from r_1 to r_{12} corresponds to D_2. Aberration characteristics of the seventeenth embodiment are visualized in FIG. **60**A, FIG. **60**B, FIG. **60**C and FIG. **60**D.

The sixteenth embodiment and the seventeenth embodiment use the long rod-shaped lens components. These long rod-shaped lens components need not be used as described with reference to these embodiments, but may be optionally disposed between the first lens component of the objective lens system and the secondary image I_2. These long rod-shaped lens components may be used so as to fill almost all spaces reserved between the first lens component of the objective lens system and the secondary image for brightening the optical systems or so as to fill only portions of the spaces so far as refractive power distributions are such as that shown in FIG. **13**A.

The eighteenth embodiment has a composition illustrated in FIG. **27**. In the eighteenth embodiment, an objective lens system O (r_1 through r_6) is composed of a first lens component consisting of a negative plano-concave lens element and a biconvex lens element, and a second lens component consisting of a single biconvex lens element; a relay lens unit R_1 (r_8 through r_{14}) is composed of a positive cemented lens component consisting of a negative lens element and a positive lens element, and a positive cemented lens component consisting of a positive lens element and a negative lens element; and an eyepiece lens system E (r_{16} and r_{17}) is composed of a positive lens element.

The eighteenth embodiment uses no primary field lens and has aberration characteristics visualized in FIG. **61**A, FIG. **61**B, FIG. **61**C and FIG. **61**D.

FIG. **47**A, FIG. **47**B, FIG. **47**C and FIG. **47**D through FIG. **61**A, FIG. **61**B, FIG. **61**C and FIG. **61**D, i.e., the graphs illustrating the aberration characteristics of the sixth through eighteenth embodiments, visualize aberration characteristics of the optical systems composed of sections from the objective lens systems to the eyepiece lens system when they are combined with the imaging lens system (r_{15} through r_{30}) used in the fifth embodiment.

Aberration characteristics only of the imaging lens system disposed in the TV camera (the imaging lens system IL shown in FIG. **14**) has aberration characteristics illustrated in FIG. **62**A, FIG. **62**B, FIG. **62**C and FIG. **62**D.

Since each of the embodiments is configured so as to correct aberrations sufficiently in the optical system consid-

ered as an independent section in the non-flexible endoscope according to the present invention, the optical system as a whole has favorable aberration characteristics even when it is combined with the imaging lens system.

The above-mentioned distance D_3, which is a distance as measured from the primary field lens F_1 to the primary image I_1, is defined as an optical path length as measured from the primary image to a refracting surface which is disposed at a shortest distance therefrom and has a positive refractive power. In such a case as the fifth embodiment wherein the field lens F_1 is disposed on the side of the objective lens system of the primary image I_1, the distance D_3 corresponds to a distance as measured from a surface of the primary field lens F_1 which is located on the side of the relay lens unit R_1 to the primary image. Further, in such a case as the ninth embodiment wherein the primary field lens F_1 is disposed on the side of the relay lens unit R_1 of the primary image, the distance D_3 corresponds to a distance as measured from the primary image to a surface of the primary field lens F_1 which is located on the side of the objective lens system O. Furthermore, in such a case as the tenth embodiment wherein the primary field lens F_1 is disposed at a location of the primary image I_1 or such a case as the sixteenth embodiment wherein an air lens is used as the primary field lens F_1, the distance D_3 corresponds to a distance, expressed in terms of an optical path length as measured from the primary image to one of surfaces of the primary field lens whichever is nearer the primary image. In addition, in the case of the eleventh embodiment or the sixteenth embodiment wherein the primary iamge I_1 is formed between both surfaces of the primary field lens, the distance may be measured from either of the surfaces to the primary image so far as it is unnecessary to consider a positive or negative sign of the distance D_3. In the seventeenth embodiment wherein the surface r_7 has a refractive power which has a role of the primary field lens F1, the distance D_3 corresponds to a distance as mesaured from the surface r_7 to the primary image.

Though all of the fifth through seventeenth embodiments are configured for straight viewing, the optical systems preferred as these embodiments are usable also for oblique viewing. FIG. **30** shows a sectional view illustrating the composition of an objective lens system of the non-flexible endoscope configured for straight viewing which can be modified for oblique viewing by disposing prisms **17***a* and **17***b* for oblique viewing on the side of the first lens component of the objective lens system in a section between the first lens component and the second lens component thereof. A narrow space reserved between the prism **17***a* and the prism **17***b* is filled with a medium such as air or a cementing agent having a low refractive index.

Rays coming from an object pass through the first lens component of the objective lens system O and the prism **17***a*, transmit through the medium having the low refractive index used for filling a space between the prism **17***a* and the prism **17***b*, and are reflected by a bottom surface of the prism **17***b* so as to reach a slant surface of the prism **17***b*, where the rays are totally reflected by a boundary surface between the slant surface and the medium having the low refractive index so as to travel toward the second lens component of the objective lens system. Though it is desirable to coat the bottom surface of the prism **17***b* with a reflective film of a metal such a aluminium, such a metallic film is unnecessary in a case where the rays can be totally reflected by using a prism having a high refractive index. Though it is desirable to select materials having high refractive indices for the prisms **17***a* and **17***b*, such materials are limited to glass materials and hardly allow to reduce manufacturing costs of the prisms. When the non-flexible endoscope according to the present invention is to be configured so as to be disposable, a manufacturing cost thereof can be reduced by selecting optical plastic materials such as acrylic plastic materials for the prisms **17***a* and **17***b*, and manufacturing these prisms by injection molding. Since the prisms made of such materials have low refractive indices, it is necessary for assuring total reflection on the slant surface of the prism **17***b* to fill an airspace reserved between the prisms **17***a* and **17***b* with air.

Though it is difficult to configure the objective lens system for the optical system of the non-flexible endoscope according to the present invention, in which heights of rays are larger than those in the objective lens system for the conventional non-flexible endoscope, so as to allow to dispose prisms for oblique viewing therein, it is possible to design an optical system for oblique viewing non-flexible endoscopes by selecting the composition described above which permits reserving sufficient effective diameters in prisms.

The optical system of the non-flexible endoscope according to the present invention of the type which accommodates the objective lens system and the relay lens system also comprises the eyepiece lens system E as shown in FIG. **28**. That is to say, the eyepiece lens system E is disposed after the secondary image I_2 as shown in FIG. **28**. However, the eyepiece lens system E may not be used as illustrated in FIG. **29**A and FIG. **29**B. In other words, the secondary image I_2 can be picked up directly by the solid-state image pickup device **11**. In this case, the observation optical system disposed in an non-flexible endoscope consists only of the objective lens system O and the relay lens system R_1, and the solid-state image pickup device **11** is disposed in the TV camera B for directly picking up the secondary image I_2.

By selecting the configuration described above for the non-flexible endoscope from which the insertion section **1**, the grip section **5** and the TV camera system **6** are detachable, it is pssible to obtain a merit that the endoscope has a simple configuration and is disposable at a low cost. Even when the non-flexible endoscope is not discarded, it can be exchanged with another non-flexible endoscope. Further, the endoscope can be configured so as to be bearable of autoclaving since it can have a configuration comprising no electrical system. Moreover, it is possible to obtain a non-flexible video scope by integrating the non-flexible endoscope with the TV camera.

FIG. **29**B shows an optical system which is configured so as to perform an additional relay cycle for the secondary image I_2 before image pickup. Speaking concretely, an imaging lens system IL is disposed in a TV camera B so as to allow an image pickup device **11** to pickup an image. The configuration illustrated in FIG. **29**B like that shown in FIG. **29**A, allows the TV camera to be detached from the non-flexible endoscope or to integrate the TV camera with the non-flexible endoscope.

The above-mentioned condition (9) should be satisfied also in the configuration illustrated in FIG. **29**A or FIG. **29**B. In this case, the optical system of the non-flexible endoscope according to the present invention comprises an objective lens system and a relay lens system which are disposed in order from the leading end in a slender insert section; is configured so that the objective lens system forms a primary image in the insert section and the relay lens system forms a secondary image by relaying the primary image; and satisfies the condition (9). Further, the non-flexible endoscope according to the present invention can comprise an

image pickup device for picking up the secondary image or an imaging lens system for further relaying the secondary image and an image pickup device for picking up an image I_n formed by the imaging lens system. Each of the non-flexible endoscopes satisfies the condition (5).

Now, description will be made of another type of optical system which is desirable for use in the non-flexible endoscope according to the present invention and comprises a relay lens system performing a single of a plurality of cycles of image relayings.

The optical system of the non-flexible endoscope according to the present invention of the type using the above-mentioned relay lens system consists of: an objective lens system which is disposed in a leading end of a slender insert section to be inserted into cavities of living bodies for observing interiors thereof so as to form a primary image; and a relay lens system which is disposed in the insert section so as to relay the primary image in a single or a plurality of cycles for forming a final image in the vicinity of a near end of the insert section or in a grip section attached to the insert section. This optical system is also configured so as to satisfy the above-mentioned condition (9).

The non-flexible endoscope according to the present invention which uses the optical system described above is similar to the conventional endoscope having the eyepiece section **2** illustrated in FIG. **1**. That is to say, the non-flexible endoscope according to the present invention which uses the optical system described above has a configuration shown in FIG. **31** wherein the endoscope consists of a slender insert section **1** to be inserted into cavities of living bodies and the like, and a grip section **5** which is to be kept outside the cavities even during use of the non-flexible endoscope and has a near end configured as an eyepiece section **2**.

The optical system of the non-flexible endoscope according to the present invention consists, for example, of an objective lens system O disposed in the leading end of the insert section **1**, a relay lens system R for relaying a primary image I_1 formed by the objective lens system O and an eyepiece lens system E disposed in the eyepiece section **2** for forming a nearly parallel light bundle from rays which come from a final image I_n formed by the relay lens system R.

Further, the non-flexible endoscope according to the present invention permits attaching a TV camera system **6** for endoscopes which is configured separately from the grip section **5** to the eyepiece section **2** as shown in FIG. **32**. Disposed in this TV camera system **6** are an imaging lens system IL and a solid-state image pickup device **11**. Though the non-flexible endoscope shown in FIG. **32** uses the TV camera system **6** which is mechanically integrated, this TV camera system may be divided along a dashed line **6***c* shown in FIG. **32** so as to compose an adaptor **6***a* comprising the imaging lens system IL and a TV camera head **6***b* comprising the solid-state image pickup device **11**, and the adaptor **6***b* and the TV camera head **6***b* can be configured so as to be mechanically attachable and detachable to and from each other. When the adaptor **3** and the TV camera head **6***a* are configured so as to be attachable and detachable, it is possible to perform photographing by using various combinations of these members each of which is prepared in a plurality of kinds.

The optical system of the non-flexible endoscope according to the present invention is composed, as shown in FIG. **31** or FIG. **32** for example, of the objective lens system O which is disposed on the side of the leading end in the insert section **1** for forming the primary image I_1 in the insert section **1**, a relay lens system R for relaying the primary image I_1 in a single or a plurality of cycles so as to form a final image I_n in the near end of the insert section **1** or the grip section **5**, and an eyepiece lens system E which is disposed in the eyepiece section **2** of the grip section **5** for allowing rays incident from the final image I_n to emerge in a condition of a nearly parallel light bundle which is observable by naked eyes.

Now, description will be made of the optical system for the non-flexible endoscope which has the composition described above and is configured so as to perform three cycles of image relaying as shown in FIG. **31** or FIG. **32**. The optical system of the non-flexible endoscope according to the present invention is characterized in that the above-mentioned distances D_1 and D_R are nearly equal to each other for enlarging a numerical aperture or obtaining a bright optical system while reserving a length (an effective length) of the insert section required for the non-flexible endoscope.

As in an ordinary case where a final image which must be formed on the object side of an eyepiece lens system E is formed in the vicinity of an insertion section **1**, a quaternary image shown in FIG. **31** or FIG. **32** corresponds to the final image I_n in the optical system of the non-flexible endoscope according to the present invention and is formed, for example, in the grip section **5** as shown in FIG. **31** or FIG. **32**. Accordingly, it is necessary that a distance as measured from the leading end of the insert section to the final image I_n must be equal to or longer than an effective length of the insert section. Though a shorter distance as measured from the leading end of the insert section to the final image permits configuring a brighter optical system, the effective length of the insert section is determined nearly dependently only on a length required for surgical operations and cannot be shorter than this length.

When the optical system of the non-flexible endoscope according to the present invention is configured so as to perform three cycles of image relaying, it forms four images including the final image I_n which is formed at the location determined as described above. Further, a relay lens system R is composed of relay lens unit R_1, R_2, . . . each of which relays an image at a magnification of 1× and the present invention provides a bright optical system by using the relay lens units repeatedly, and adequately selecting an objective lens system and a relay lens system as described below.

When the optical system of the non-flexible endoscope according to the present invention is configured so as to peform three cycles of image relaying as described above, for example, it forms four images including a secondary image, an intermediate image and a final image which are to be formed at locations determined for the reasons described above. Therefore, the present invention selects an adequate location for a primary image so as to obtain a bright optical system.

FIG. **33**A, FIG. **33**B and FIG. **33**C show diagrams illustrating variaitons of numerical apertures to be caused by changing a location of the primary image in a typical optical system of the non-flexible endoscope according to the present invention which is configured to perform three cycles of image relaying.

FIG. **33**A shows a case where the objective lens system O is prolonged so as to have a length D_1 which is equal to a length D_R of each of relay lens units R_1, R_2 and R_3 required for a single cycle of image relaying, FIG. **33**B illustrates a case where the objective lens system is shortened so as to form a primary image I_1 at a location shifted toward the leading end, and FIG. **33**C visualizes a case where the objective lens system O is remarkably prolonged so as to form the primary image I_1 at a location shifted toward an intermediate image I_2. Out of the three cases shown in FIG.

33A, FIG. 33B and FIG. 33C, a refractive power distribution which is most desirable for accomplishing the objects of the present invention is obtained in the case shown in FIG. 33A. The case shown in FIG. 33B corresponds to a composition which is similar to that of the conventional optical system for non-flexible endoscopes using a short objective lens system.

In each of FIG. 33A, FIG. 33B and FIG. 33C, numerical apertures are equal to each other between a side of incidence and a side of emergence at the location of the primary image I_1 formed by the objective lens system O since each of the relay lens untis R_1, R_2 and R_3 of the relay lens system R is set at a magnification of 1× and the primary field lens F_1 is disposed at a location coincident with the primary image I_1. A "numerical aperture" means an angle which is formed between a marginal ray and an optical axis.

Though maximum heights of marginal rays are traced equal in FIG. 33A, FIG. 33B and FIG. 33C, it is apparent that the optical system shown in FIG. 33A has a largest numerical aperture or is brightest since a limit for heights of the marginal rays is not determined only either one of the objective lens system and the relay lens system. In the case shown in FIG. 33B, a limit for heights of the marginal rays is determined by the relay lens system and a numerical aperture is determined dependently only on a length of the relay lens system. In the case shown in FIG. 33C, in contrast, a limit for heights of the marginal rays is determiend by the objective lens system and a numerical aperture is determined dependently on a length of the objective lens system.

In the case shown in FIG. 33A, the limit for heights of the marginal rays is determiend by both the objective lens system and the relay lens system, either of which has a length larger than that of the relay lens system shown in FIG. 33B or that of the objective lens system shown in FIG. 33C, thereby allowing an optical system having a given outside diameter to have a large numerical aperture.

The condition (9) is required for obtaining a large numerical aperture.

D_1/D_R used in the condition (9) is a parameter for varying brightness and brightness is maximum at D_1/D_R=1.0 which corresponds to the condition shown in FIG. 33A. When D_1/D_R is deviated from 1.0, brightness is lowered to values listed below which are expressed taking brightness at D_1/D_R=1.0 as 1:

(When D_1/D_R<1.0) $[\{1+(N-1)\times D_R/D_1\}/N]^2$

(When D_1/D_R>1.0) $[\{1+D_1/(N-1)/D_R\}\times(N-1)/N]^2$

wherein the reference symbol N represents a number of imaging cycles to be performed by the relay lens system.

For the optical system of the non-flexible endoscope according to the present invention which has the typical composition for three cycles of image relaying, or N=4, ratios of brightness at various values of D_1/D_R relative to brightness at D_1/D_R=1 are calculated as listed below:

D_1/D_R	Ratio in brightness
0.01 and 1.42	0.57
0.33 and 1.29	0.69
1.0	1.0

As is seen from the calculation values listed above, D_1/D_R having a value of 0.01 or 1.42 lowers brightness to a half of that at D_1/D_R=1.0 below which brightness is allowed to be lowered. That is to say, if the lower limit or the upper limit of the condition (9) is exceeded, the optical system will be set in the condition shown in FIG. 33B or FIG. 33C, whereby the optical system will have brightness lower than a maximum level which is available with the utmost capability thereof and is not bright enough for practical use. Further, it is desirable, for obtaining at least 70% of the brightness available with the utmost capability of the optical system, to configure it so as to satisfy, instead of the condition (9), the following condition:

$$0.33<D_1/D_R<1.29$$

In the optical system shown in FIG. 31, the primary field lens F_1 which is disposed in the vicinity of the primary image I_1 has a function to relay a pupil of the objective lens system O to the relay lens system R. Since a principal ray emerging from the objective lens system O travels in a direction away from the optical axis, the principal ray cannot pass through the relay lens system R and an image will be eclipsed at a marginal portion of a visual field if the primary field lens F_1 is not disposed in the vicinity of the primary image I_1. It is therefore necessary to dispose the field lens F_1 in the vicinity of the primary image I_1. When an air-contact surface of the primary field lens F_1 is overlapped with the primary image I_1, however, dust or injury on the surface of the primary field lens F_1 will be imaged. It is therefore desirable to dispose the field lens F_1 so as to have air-contact surfaces located slightly apart from the primary image I_1.

The foregoing description which is made of the typical relay lens system configured for three cycles of image relaying (N=4) is applicable also to relay lens systems which are configured for two cycles, three cycles, four cycles, . . . n cycles of image relaying. It is desirable to select values of D_1/D_R within ranges defined below so that the optical system has brightness of at least 70% of that available with the maximum capability thereof when they are configured for numbers of imaging cycles of 2, 3, 4, . . . to 10:

TABLE 3

N (number of imaging cycle)	
2	$0.66 < D_1/D_R < 1.5$
3	$0.56 < D_1/D_R < 1.29$
4	$0.33 < D_1/D_R < 1.29$
5	$0.3 < D_1/D_R < 1.26$
6	$0.3 < D_1/D_R < 1.25$
7	$0.3 < D_1/D_R < 1.25$
8	$0.3 < D_1/D_R < 1.24$
9	$0.3 < D_1/D_R < 1.22$
10	$0.3 < D_1/D_R < 1.2$

By attaching a TV camera system for non-flexible endoscopes to the optical system of the non-flexible endoscope according to the present invention which has the fundamental composition described above, it is possible to carry out observation on a TV monitor indispensable to surgical operations under observation through endoscopes. For such observation on a TV monitor, it is sufficient to attach a TV camera system **6** to a grip section **1** as in the non-flexible endoscope shown in FIG. **31** so that an imaging lens system IL disposed in this TV camera system forms a final image I_n at a location coincident with a light receiving surface of a solid-state image pickup device **5** for picking up the final image I_n.

Now, description will be made below of a composition desirable for the objective lens system which is to be used in the optical system of the non-flexible endoscope according to the present invention. Speaking concretely, it is desirable to compose the objective lens system, in order from the object side, of a first lens component which is disposed in the leading end of an insert section and has a

negative refractive power, and a second lens component which is disposed between the first lens component and a primary field lens F_1, and has a positive refractive power. This refractive power distribution in the objective lens system is desirable for composing the lens system of a reduced number of lens elements while reserving a field angle required for the objective lens system. The negative refractive power of the first lens component has a function to widen a field angle, whereas the positive refractive power of the second lens component has a role to form a real primary image by imaging a virtual image of an object which is formed by the first lens component. Since the first lens component of the objective lens system has the strongest refractive power among those of lens components disposed in an observation optical system which consists of the objective lens system and a relay lens system, the first lens component has a function to correct curvature of field. Further, the second lens component has a role to determine a pupil in the objective lens system. Accordingly, the refractive power distribution described above permits minimizing a number of lens elements required for composing the objective lens system.

The objective lens system of the optical system shown in FIG. **31**, for example, is composed of the first lens component which consists of a single negative lens element and the second lens component which consists of a single positive lens element. In a case where the first lens component which consists of the single negative lens element has a refractive power insufficient for a certain specification item such as a field angle of the objective lens system, it is allowable to dispose an additional lens element having a negative refractive power in the first lens component. Further, it is allowable to dispose a lens element having a positive refractive power or use a cemented lens component for favorably correcting lateral chromatic aberration and astigmatism.

For correcting barrel distortion produced by an objective lens system which is composed only of spherical lens elements, it is sufficient to prevent a principal ray from being refracted excessively by using an aspherical surface in the first lens component on which the principal ray is high. Further, it is necessary for correcting longitudinal chromatic aberration by the second lens component to use a negative lens element having a high dispersing power and it is sufficient for this purpose to compose the second lens component of a combination of a positive lens element and a negative lens element. In such a case, the positive lens element and the negative lens element may be cemented to each other or disposed separately from each other. For the second lens component for which a magnification of approximately $-1\times$ is most desirable, it is sufficient to select a magnification within a range from $-2\times$ to $-0.5\times$. If the second lens component has a magnification outside the range from $-2\times$ to $-0.5\times$, the objective lens system will have a pupil at a location largely deviated from the middle between the leading end and a primary image, whereby marginal rays will undesirably be eclipsed.

Since the objective lens system which is to be used in the optical system of the non-flexible endoscope according to the present invention is configured so as to be long and have a numerical aperture nearly equal to that of a relay lens system, it is necessary to transmit a pupil together with an image. An image cannot be relayed with unchanged brightness unless a diameter of a light bundle which has passed through the pupil Q_2 of the relay lens system R is changed from that of the light bundle at a stage where it has passed through the pupil Q_1 of the objective lens system. Accordingly, it is desirable that a diameter ϕ_1 of the light bundle as measured at the pupil Q_1 of the objective lens system and a diameter ϕ_2 of the light bundle as measured at the pupil Q_2 of the relay lens system satisfy the following condition (10):

$$0.5<\phi_1/\phi_2<1.5 \tag{10}$$

Further, when a distance D_4 as measured from the pupil Q_1 of the objective lens system O to the primary image I_1 is nearly equal to a distance D_5 as measured from the pupil Q_2 of the relay lens system R to the primary image I_1, the pupil Q_1 and the pupil Q_2 are located nearly symmetrical with regard to the primary image I_1, whereby a pupil can be relayed favorably with little loss of light intensity. Further, the primary field lens F_1 may be disposed on the side of the objective lens system O or the side of the relay lens system R of the primary image or can be located so as to comprise the primary field lens F_1 therein. However, intensity of marginal rays will be lowered when the primary field lens F_1 is too far from the primary image I_1. It is therefore desirable to dispose the primary field lens F_1 so as to reserve, between the primary field lens F_1 and the primary image I_1, a distance which is shorter than 10% of D_3. If the distance reserved between the primary field lens F_1 and the primary image I_1 exceeding 10% of D_3, the primary field lens F_1 itself will eclipse the offaxial rays, thereby eclipsing an image at a marginal portion of a visual field or lowering intensity of the marginal rays. The primary field lens F_1 must have a positive refractive power for transmitting a pupil and can be composed of a singel positive lens element so as to have a sufficient function thereof. When the primary field lens F_1 is to be used for correcting lateral chromatic aberration and astigmatism, however, it may be composed of a cemented lens component consisting of a positive lens element and a negative lens element.

Like the conventional non-flexible endoscope which uses a visual field mask disposed at an imaging location for clarifying a range of a visual field to be observed, the non-flexible endoscope according to the present invention may comprise a visual field mask. In such a case, it is most desirable to dispose a visual field mask consisting of a thin black metal sheet or the like at a location of a final intermediate image I_n at which a spatial restriction is minimum. However, a visual field mask may be disposed at a location of the primary image I_1, any one of the other intermediate images I_2, I_3, . . . or in the first lens component of the objective lens system O on which the marginal rays are low and the principal ray is high.

Now, description will be made of an optical system which is to be used in the non-flexible endoscope according to the present invention and of a type comprising an objective lens system and a plurality of relay lens units.

The nineteenth embodiment of the present invention has a configuration illustrated in FIG. **31** which has already been described above. Speaking concretely, the nineteenth embodiment consists of an insert section **1** which is to be inserted into cavities of living bodies and the like, and a grip section **2** which is to be kept outside the cavities and comprises an eyepiece section **2** disposed in the vicinity of a near end thereof. An objective lens system is disposed in the leading end of the insert section **1** of the non-flexible endoscope, a relay lens system R for relaying a primary image I_1 of an object formed by the objective lens system O is disposed in the insert section **1**, and an eyepiece lens system E which converts a light bundle coming from a final image I_n into a nearly parallel light bundle is disposed in the eyepiece section **2**.

The relay lens system R which is used in the optical system of the non-flexible endoscope preferred as the nineteenth embodiment illustrated in FIG. **31** is composed of relay lens units R_1, R_2 and R_3 for relaying an image in three cycles.

The optical system preferred as the nineteenth embodiment is configured so that a ratio between the length D_1 and D_R, i.e., the parameter (D_1/D_R) expressing a ratio between the length D_1 as measured from the leading end of the objective lens system O to the primary image I_1 and the distance as measured from the primary image I_1 to the next image I_2, satisfies the condition (9).

The twentieth embodiment illustrated in FIG. **32** has a configuration which is obtained by connecting a TV camera system **6** to the grip section **5** of the nineteenth embodiment, and uses on objective lens system O, a relay lens system R and an eyepiece lens system E which are the same as those disposed in the nineteenth embodiment. The TV camera system **6** comprisees an imaging lens system IL and a solid-state image pickup device **11** disposed at a location of an image formed by the imaging lens system IL.

When the TV camera system **6** is detachable from the grip section **5** in the twentieth embodiment, it is usable in various modes while exchanging the TV camera system **6** with different types of TV camera systems. Further, when the TV camera system **6** is configured so as to be dividable along a dashed line **6***c*, the twentieth embodiment can be used in a variety of modes by using a large number of combinations of a multiple kinds of adaptors **3***a* comprising imaging lens systems IL and a multiple kinds of TV camera heads **4***b* which are prepared at hand.

Furthermore, the twentieth embodiment can have a focusing fucntion and a vari-focal function which provide convenient adjustments of focusing positions and image surface sizes when lens elements to be disposed in the imaging lens system IL are configured so as to be movable in the adaptor **3***a*.

The twenty-first embodiment of the present invention has a configuration illustrated in FIG. **34**, or consists of an insert section **1**, a grip section **5**, an adaptor **3** connected to the grip section **5** and a TV camera head **4**. An objective lens system O and a relay lens system R are disposed in the insertion sect **1** and the grip section **5**, whereas an imaging lens system IL is disposed in the adaptor **3** for reimaging a final image I_n formed by the relay lens system R onto a light receiving surface of an image pickup device **11** disposed in the TV camera head **4**.

Unlike the nineteenth embodiment or the twentieth embodiment, the twenty-first embodiment uses no eyepice lens system, and therefore permits configuring a non-flexible endoscope and a TV adaptor compacter. Further, when the twenty-first embodiment is configured so as to permit detaching the insert section **1**, the adaptor **3** and the TV camera head **4** from one another, it is usable in a variety of modes by using a large number of combinations of adaptors and TV camera heads which are prepared in a pluralities of kinds.

The twenty-first embodiment can have a focusing function and a vari-focal function for permitting adjustments of focusing locations and image surface sizes when a lens element L_a or L_b which is used for composing the imaging lens system IL disposed in the adaptor **3** is movable.

The twenty-second embodiment of the present invention has a configuration illustrated in FIG. **35**, or consists of an insert section **1** and a grip section **5**. An objective lens system O and a relay lens system R are disposed in the insert section **1** and the grip section **5** respectively. Further, disposed in the grip section **5** is a solid-state image pickup device **11** for reimaging a final image I_n formed in the optical system onto a light receiving surface of the solid-state image pickup device **11**. Accordingly, the twenty-second embodiment permits configuring a TV observation system for the non-flexible endoscope compacter and enhancing operability thereof.

The twenty-second embodiment also permits configuring a TV camera head **4** so as to be detachable from the other sections and exchangeable with another.

FIG. **36** and FIG. **37** exemplify objective lens systems which are composed of long rod-shaped lens components. When an objective lens system having a large total length is composed of a small number of lens components, it requires very long spacing rings for reserving required airspaces among the lens components. An optical system can be brightened by filling these airspaces with a glass material as in the conventional endoscope.

The objective lens systems illustrated in FIG. **36** and FIG. **37**, in which the airspaces filled with air in the embodiment described above are filled with glass materials having high refractive indices, provide an effect equivalent to that available by shortening an effective length by prolonging an optical path length, thereby enabling to obtain optical systems which have enlarged numerical apertures or are brighter.

FIG. **38** and FIG. **39** illustrate oblique viewing optical systems for non-flexible endoscopes. These optical systems are usable also for straight viewing.

FIG. **38** is a sectional view illustrating an objective lens system O for the oblique viewing optical system for non-flexible endoscopes wherein oblique viewing prisms **11***a* and **11***b* are disposed on the side of a first lens component in a section between the first lens component and a second lens component of the objective lens system for configuring the optical system for oblique viewing. A space reserved between the prisms **11***a* and **11***b* is filled with air or an optical cementing agent which has a refractive index lower than a material of the prisms.

In this objective lens system, a light bundle incident thereon from an object passes through the first lens component and the prism **11***a*, transmits through a layer of the medium having the low refractive index, passes into the prism **11***b*, is totally reflected by a bottom surface of the prism **11***b*, reaches a slant surface of the prism **11***b*, and is reflected totally by a boundary between the layer of the medium having the low refractive index and the slant surface so as to travel toward the second lens component. It is desirable to coat the bottom surface of the prism **11***b* with a reflective film of a metal such as aluminium, but such a reflective metal film is unnecessary when a prism having high refractive index is used for total reflection. Though it is desirable to make the prisms **11***a* and **11***b* of a material having a high refractive index, such a material is limited to one of glass materials and can hardly allow manufacturing costs thereof to be reduced. Therefore, it is desirable for obtaining disposable prisms to select an optical plastic material such as an acrylic plastic material for the prisms **11***a* and **11***b*, and manufacture them by injection molding for reduction of manufacturing cost thereof. In this case, the prisms have a low refractive index and it is sufficient for total reflection on the slant surface of the prism **11***b* to reserve a space between the prisms **11***a* and **11***b* so as to form an air layer.

FIG. **39** and FIG. **40** show examples of oblique viewing objective lens systems which are obtained by modifying the objective lens systems illustrated in FIG. **36** and FIG. **37** respectively, and have compositions which can be realized by using oblique viewing prisms (the prisms **17***a* and **17***b* shown in FIG. **38**) in place of the bar-shaped lens component disposed after the first lens component (the concave lens component) out of the bar-shaped lens components in the objective lens system shown in FIG. **36** or FIG. **37** in which spaces are filled with an optical material.

It is rather hard to design oblique viewing prisms for the objective lens system to be used in the optical system of the non-flexible endoscope according to the present invention in which rays are higher in the first lens component than the rays in the first lens component of the conventional objective lens systems which has a small total length. However, the

composition which is described above permits reserving a sufficient effective diameter in prisms and makes it possible to design objective lens systems for oblique viewing non-flexible endoscopes.

As is seen from FIG. **41** (illustraing an objective lens system for endoscopes performing three cycles of image relaying) and FIG. **42** (showing an objective lens system for non-flexible endoscopes performing five cycles of image relaying), the objective lens systems which are to be used in the optical system of the non-flexible endoscope according to the present invention comprise airspaces which are remarkably wider than those reserved in the conventional objective lens system for non-flexible endoscopes. It is therefore undesirable to use metallic spacing rings for holding the lens components at predetermined spacings in the objective lens systems for the non-flexible endoscope according to the present invention since such metallic spacing rings have inside surfaces which allow detrimental rays to be incident due to reflection thereon, thereby producing flare. The objective lens systems for the optical system of the non-flexible endoscope according to the present invention use spacing rings having inside surfaces which are roughened or sand-blasted so as to lower reflection thereon and prevent production of flare. Further, it is possible to obtain spacing rings having roughened inside surfaces by fabricating them with synthetic resin materials and mixing a foreign matter such as glass with the synthetic resin material at molding stages. These spacing rings can prevent produciton of flare.

Though the lens components to be used for composing the optical system of the non-flexible endoscope according to the present invention are ordinarily made of glass materials, a manufacturing cost of the optical system can be lowered by manufacturing the lens components by injection molding of optical plastic materials such a acrylic materials. It is desirable to compose each of the lens components of a single lens element and two lens elements may be disposed separately with a slight airspace reserved therebetween when a cemented lens component is required for composing the optical system.

In the objective lens system shown in FIG. **36** or FIG. **37**, the location of the pupil Q is shifted toward the first lens component (the concave lens component) so that a small virtual image is formed in the vicinity of the first lens component and the principal ray is low on this lens component, thereby preventing a visual field from being eclipsed.

FIG. **44** and FIG. **45** (Embodiemnt 23 and Embodiment 24) show concrete examples of optical systems of the non-flexible endoscopes according to the present invention which are configured so as to perform a single image relaying cycle or a plurality of image relaying cycles, uses relay lens systems having shortened lengths and have numerical data listed below:

Embodiment 23

object distance = −30 mm, F No. = 7.16

Out of the optical system described above, an optical system which performs three cycles of image relaying is illustrated in FIG. **44** and an optical system which performs a single cycle of image relaying is shown in FIG. **45**. These optical systems are configured so as to satisfy the condition (9).

The present invention provide an optical system for non-flexible endoscopes which is bright or has a numerical aperture enlarged by determining a location of a primary image to be formed by an objective lens system so as to shorten a length required for relaying the primary image by one cycle.

We claim:

1. A non-flexible endoscope comprising: an insert section for insertion from a leading end thereof into cavities of an object to be observed for observing interiors thereof, and a grip section which is to be connected to an end of said insert section located on a side opposite to said leading end and always kept outside the cavities during observation, wherein said insert section comprises an objective lens system having a first surface disposed at said leading end for forming a primary image, and a relay lens system for transmitting said primary image so as to form a secondary image in the vicinity of a connecting position between said insert section and said grip section or in said grip section, wherein said grip section comprises an eyepiece lens system for making said secondary image visible, and wherein said insert section satisfies the following condition (5):

$$0.3<D_1/D_2<0.7 \quad (5)$$

wherein the reference symbol D_1 represents a distance as measured from the first surface of said objective lens system to said primary image and the reference symbol D_2 designates a distance as measured from the first surface of said objective lens system to said secondary image.

2. A non-flexible endoscope comprising: an insert section for insertion from a leading end thereof into cavities of an object to be observed for observing interiors thereof, a grip section which is to be connected to an end of said insert section located on a side opposite to said leading end and always kept outside the cavities during observation, and a TV camera system which is to be attached to said grip section, wherein said insert section comprises an objective lens system having a first surface disposed at said leading end for forming a primary image, and a relay lens system for transmitting said primary image so as to form a secondary image in the vicinity of a connecting position between said insert section and said grip section, wherein said grip section comprises an eyepiece lens system for converting rays coming from said secondary image into a nearly parallel light bundle, and wherein said TV camera system comprises an imaging lens system for imaging the nearly parallel light bundle emerging from said eyepiece lens system and an image pickup device for picking up an image formed by said imaging lens system, and wherein said insert section satisfies the following condition (5):

$$0.3<D_1/D_2<0.7 \quad (5)$$

wherein the reference symbol D_1 represents a distance as measured from the first surface of said objective lens system and the reference symbol D_2 designates a distance as measured from the first surface of said objective lens system to said secondary image.

3. A non-flexible endoscope comprising: an insert section for insertion from a leading end thereof into cavities of an object to be observed for observing interiors thereof, wherein said insert section comprises an objective lens system having a first surface disposed at said leading end for forming a primary image, and a relay lens system which is disposed on the image side of said objective lens system for relaying said primary image so as to form a secondary image, and wherein said insert section satisfies the following condition (5):

$$0.3<D_1/D_2<0.7 \quad (5)$$

wherein the reference symbol D_1 represents a distance as measured from the first surface of said objective lens system to the primary image and the reference symbol D_2 designates a distance as measured from the first surface of said objective lens system to the secondary image.

4. A non-flexible endoscope according to claim **3** further comprising an image pickup device disposed at a location of said secondary image.

5. A non-flexible endoscope according to claim **3** further comprising an imaging lens system for reimaging said secondary image and an image pickup device disposed at a location of an image formed by said imaging lens system.

6. A non-flexible endoscope according to claim **2**, **3**, **4** or **5** wherein said objective lens system is composed of a first negative lens component and a second positive lens component, and wherein said second lens component satisfies the following condition (6):

$$0.5<|\beta_2|<2.0 \quad (6)$$

wherein the reference symbol β_2 represents a magnification of said second lens component.

7. A non-flexible endoscope according to claim **6** wherein said first lens component is composed of a single negative lens element and wherein said second lens component is composed of a single positive lens element.

8. A non-flexible endoscope according to claim **6** wherein said first lens component is composed of a single negative lens element and wherein said second lens component is composed of a positive lens element and a negative lens element.

9. A non-flexible endoscope according to claim **1**, **2** or **3** comprising a primary field lens disposed in the vicinity of said primary image.

10. A non-flexible endoscope according to claim **9** satisfying the following condition (7):

$$|D_3/D_2|\leqq 0.1 \quad (7)$$

wherein the reference symbol D_2 represents a distance as measured from a first surface of said objective lens system to said secondary image and the reference symbol D_3 designates a distance as measured from said primary field lens to said primary image.

11. A non-flexible endoscope comprising: an insert section for insertion from a leading end thereof into cavities of an object to be observed for observing interiors thereof, and a grip section which is to be connected to an end of said insert section located on a side opposite to said leading end, wherein said insert section comprises an objective lens system having a first surface disposed in said leading end for forming a primary image and a relay lens system for relaying said primary image in a single cycle or a plurality of cycles so as to form a final image in the vicinity of a connecting position of said insert section or in said grip section, and wherein said insert section satisfies the following condition (9):

$$0.3<D_1/D_R<2.0 \quad (9)$$

wherein the reference symbol D_1 represents a distance as measured from the first surface of said objective lens system to said primary image and the reference symbol D_R designates a distance which is required for relaying said primary image in a single cycle by said relay lens system.

12. A non-flexible endoscope according to claim **11** satisfying the following condition (10):

$$0.5<\phi_1/\phi_2<1.5 \quad (10)$$

wherein the reference symbol ϕ_1 represents a diameter of a light bundle at a location of a pupil of said objective lens system and the reference symbol ϕ_2 designates a diameter of the light bundle at a location of a pupil of said relay lens system.

13. A non-flexible endoscope according to claim **11** wherein said grip section comprises an eyepiece lens system for converting rays coming from the final image formed by said relay lens system into a nearly parallel light bundle which is visible by eyes.

14. A non-flexible endoscope according to claim **13** comprising a TV camera system to be attached to said grip section, wherein said TV camera system comprises an imaging lens system for reimaging said final image and an image pickup device disposed at a location of an image formed by said imaging lens system.

15. A non-flexible endoscope according to claim **13** further comprising a TV camera to be attached to said grip section, wherein said TV camera comprises an imaging lens system for imaging rays emerging from said eyepiece lens system and an image pickup device disposed at a location of an image formed by said imaging lens system.

16. A non-flexible endoscope according to claim **11** comprising an image pickup device disposed at a location of the final image formed by said relay lens system.

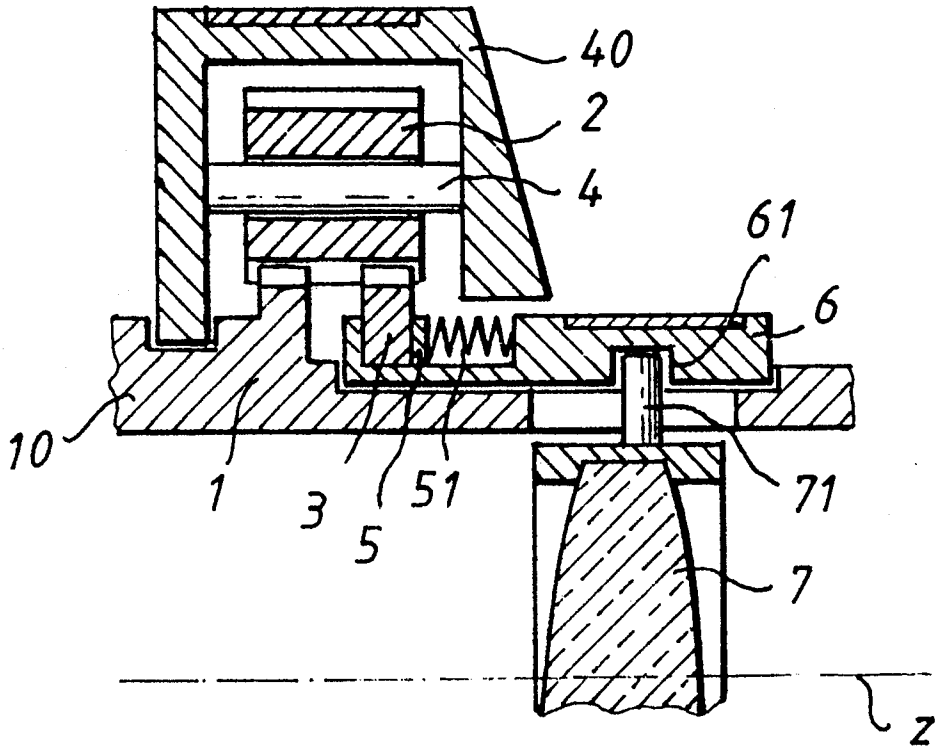
[57] **ABSTRACT**

The invention is directed to an arrangement for displacing the parts of an objective with at least one adjusting ring **6**. A fine adjusting ring **40** is also provided and there is no switchover device which must be actuated by the operator. The fine adjusting ring **40** is at standstill when it is not actively rotated by the operator. A coarse adjusting ring **6** is rotatably journalled in the housing **10** of an objective. A transmission or gearing for suitably fine adjusting this coarse adjusting ring **6** includes a sun gear wheel **1** mounted fixedly on the objective housing **10**, a fine adjusting ring **40** which includes a shaft pin **4** on which planetary gear wheels **2** are journalled and an output gear wheel **3** rotatably mounted on the coarse adjusting ring **6** via a slip clutch **5**.

6 Claims, 1 Drawing Sheet



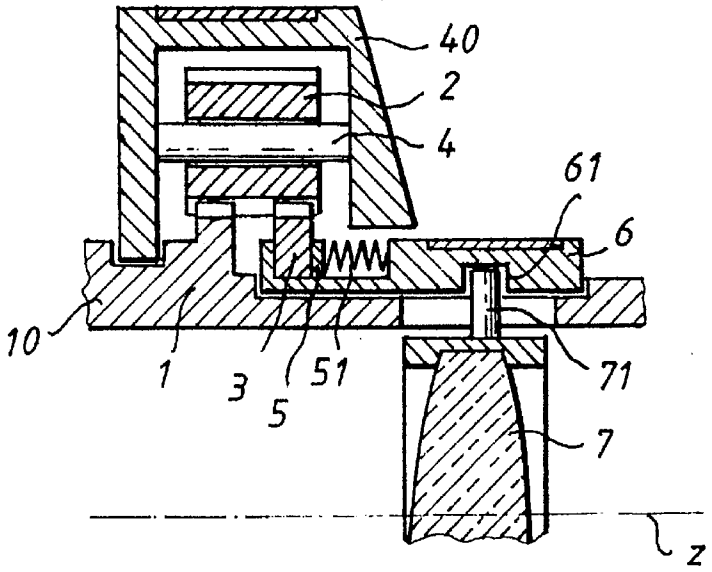


FIG. 1

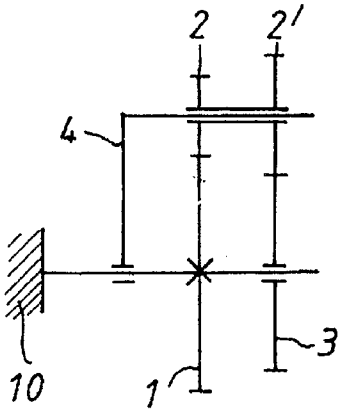

FIG. 2

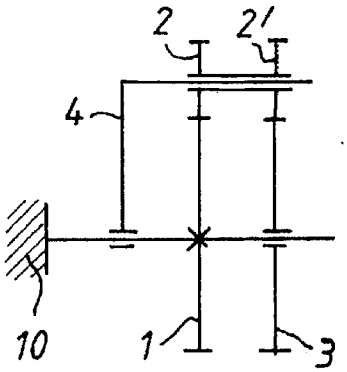

FIG. 3

COARSE AND FINE DRIVES FOR AN OBJECTIVE

FIELD OF THE INVENTION

The invention relates to an arrangement for displacing at least one part of an objective with at least one adjusting ring and also relates to a transmission for the fine displacement of a coarse adjusting ring. The coarse adjusting ring is rotatably journalled in the housing of the objective.

BACKGROUND OF THE INVENTION

It is known to selectively derive a movement of an objective from two different drive sources such as a motor and a manual adjusting ring. U.S. Pat. No. 4,200,377 discloses a focusing mechanism for a camera objective wherein the drives are decoupled via a slip clutch. Published German patent application 4,331,650 discloses a planetary transmission. The inactive drive is brought to standstill by the action of a friction brake.

A manual focusing by adjusting the object spacing (object to lens distance) with two different transmission ratios (coarse and fine drives) is normal for microscopes (that is, very different mechanical conditions); however, this manual focusing is exceptional for photo and film objectives and is only purposeful in a given area of application, namely, for a long focal length telephoto lens for sport (rapid) and nature photography (fine). Photo and film objectives usually have a single distance rotation ring. For rapid focusing, a small rotational angle is advantageous and for sensitive focusing a larger rotational angle is advantageous.

Various manufacturers of objectives offer therefore a range switchover especially for long focal length objectives wherein, with a switch or rotational ring, a distance range can be preselected and thereafter a sharp focusing is made within this range with a distance rotational ring over a larger rotational angle. However, this requires that the photographer must know ab initio in which range the work will be performed.

This is most of all critical at the range boundaries. If the photographer has preselected a range and attempts to sharply focus the object, but cannot attain the point of sharp focus because of the range boundary, the photographer must first change the range and then again search for the point of sharp focus with the distance ring. This is inconvenient and time consuming.

SUMMARY OF THE INVENTION

In view of the foregoing, it is an object of the invention to provide a user-friendly gearing solution for a manual coarse and fine drive for focusing the objective.

The invention provides a user-friendly, rapid and precise focusing. The objective is equipped with two distance adjusting rings which both provide the capability of focusing from the near range to infinity. The first distance adjusting ring (coarse adjusting ring) has a small rotational angle and functions for rapid focusing, for example, to make sport photographs and for coarse prefocusing such as for subjects in nature. The second distance adjusting ring (the fine adjusting ring) can be rotated through a large rotational angle (several rotations of the ring from the near range to infinity) and functions for fine focusing such as when photographing subjects as they are found in nature.

The photographer first attempts to come close to the sharp focusing point with the coarse adjusting ring and then reaches with the hand to the fine adjusting ring in order to precisely adjust the sharp focus.

The coarse adjusting ring directly drives the optical member which is to be displaced linearly. The coarse adjusting ring does this via a thread or a cam (coarse drive). The fine adjusting ring is connected to the coarse adjusting ring via a reduction transmission and a slip clutch. The reduction converts a large rotational angle of the fine adjusting ring into a small rotational angle of the coarse adjusting ring. The distance scale provided on the coarse adjusting ring is therefore also applicable to the indirect drive thereof via the fine adjusting ring.

For higher reductions of the transmission, the fine adjusting ring should not be moved at high rotational speed with the actuation of the coarse adjusting ring. Also, the transmission is self retarding for the translation into the slower rotational speed because the slight frictional torque in the bearing locations of the toothed wheels is sufficient in order to block the transmission. For this reason, a slip clutch is provided between the output wheel of the fine drive and the coarse adjusting ring. The slip clutch is so configured that it transmits the torque of the output wheel of the fine drive to the coarse adjusting ring when the fine adjusting ring is actuated. The transferable torque of the slip clutch must therefore be greater than the drive torque of the coarse drive. The gearing blocks the fine drive when the coarse adjusting ring is actuated and the slip clutch slips. Furthermore, the slip clutch protects the gearing of the fine drive against damage when both coarse and fine adjusting rings are actuated at the same time and when reaching the stops in the end positions with the fine drive.

An especially advantageous embodiment provides for only one planetary gear wheel for transmitting from the sun gear to the output gear wheel. A plurality of such planetary gear wheels can be distributed about the periphery. This is possible when the sun gear wheel and the output gear wheel each have many teeth. The number of teeth differs only slightly and one of the sets of teeth has a profile shift.

In this way, the assembly is facilitated because instead of two pinions, only one pinion is seated on each shaft pin. In the case of two pinions, all planetary gear wheels distributed over the periphery must be precisely adjusted with respect to rotation.

BRIEF DESCRIPTION OF THE DRAWINGS

The invention will now be described with reference to the drawings wherein:

FIG. **1** is a schematic section view taken through a transmission according to the invention;

FIG. **2** is a gearing schematic of a planetary transmission in accordance with an embodiment of the invention; and,

FIG. **3** is a preferred embodiment of the gearing arrangement of the invention.

DESCRIPTION OF THE PREFERRED EMBODIMENTS OF THE INVENTION

In FIG. **1**, the objective housing **10** includes a fixed sun gear wheel **1** formed thereon and having a positive profile shift. A planetary gear wheel **2** is rotatably journalled on the shaft pin **4** which, in turn, is part of a fine adjusting ring **40** and is rotatably journalled on the objective housing **10** for rotation about the main axis Z of the housing. A plurality of planetary gear wheels **2** is distributed about the periphery and there are preferably three in number. The planetary gear wheel **2** furthermore meshes with the output gear wheel **3** (unmodified gear wheel) which is rotatably connected via a slip clutch **5** to the coarse adjusting ring **6**. The slip clutch

5 has a load spring 51. Other varieties of slip clutches 5 can also be used such as those using hydraulic or pneumatic means or media of special or variable viscosity.

The coarse adjusting ring 6 is rotatably journalled on the objective housing 10 to rotate about the main axis Z thereof and has a control cam 61. A cam follower 71 of a slide member 7 engages the control cam 61. A rotational movement of the coarse adjusting ring 6 is converted into a focusing movement along the main axis Z by the cam transmission configured in the manner described above and known per se.

When actuated by the output gear wheel 3, the planetary gear (1, 2, 3, 4) is self-locking as the low friction torques at the fine adjusting ring 40 side of the planetary gear (1, 2, 3, 4) are transformed into a high braking torque because of the high transmission ratio of the planetary gear (1, 2, 3, 4). The slide clutch 5 is suitably adjusted so that the braking torque at the output gear wheel 3 cannot be transmitted from the coarse adjusting ring 6 to the output gear wheel 4. Accordingly, the fine adjusting ring 40 remains stationary when the coarse adjusting ring 6 is actuated.

When the fine adjusting ring 40 is rotated, then the planetary gear wheel 2 rolls on the stationary sun gear 1 and entrains the output gear wheel 3 because of the different tooth number. The output gear wheel 3 is connected to the coarse adjusting ring 6 via the slip clutch 5. The coarse adjusting ring 6 is entrained and effects the displacement of the slide member 7 as described above.

The planetary transmission (1, 2, 3, 4) is again shown in FIG. 2 as a gearing schematic in its normal base form. Two planetary gear wheels (2, 2') are mounted on the shaft pin 4 and are rigidly connected to each other. The planetary gear wheels (2, 2') have the number of revolutions N_4 and have tooth numbers (Z_2, $Z_{2'}$), respectively. The stationary sun gear wheel 1 has the tooth number Z_1. The output wheel 3 has the tooth number Z_3 and the number of revolutions N_3.

The transmission ratio is $N_3/N_4=1-(Z_1 \cdot Z_{2'}/Z_2 \cdot Z_3)$. The output gear wheel 3 (that is, the coarse adjusting ring 6) and the shaft pin 4 (that is, the fine adjusting ring 40) rotate in the same direction when Z_1 is less than Z_3.

The less the difference of the tooth numbers Z_1 and Z_2, the greater is the reduction. By advancing the pinion 2 on the gear wheels 1 and 3, the transmission can be adjusted without play. The planetary gear wheels (2, 2') should be three in number and evenly distributed about the periphery so that no one-sided forces can occur in the transmission. For this reason, the tooth number difference of Z_1 and Z_3 must be a multiple of 3.

The teeth of the planetary gear wheels (2, 2') must be precisely aligned to each other. In order to avoid this and to simplify the assembly of the transmission, a departure in accordance with FIG. 3 is presented which is already considered in FIG. 1. Here, $Z_2=Z_{2'}$, that is, only a single through pinion is provided as the planetary gear wheel 2 and this pinion meshes with the sun gear wheel 1 and the output gear wheel 3. This is possible because: the sun gear wheel 1 and the output gear wheel 3 have many teeth; the respective tooth numbers (Z_1, Z_3) of these wheels differ from each other only slightly; and, the sun gear wheel 1 ($Z_1<Z_3$) has a positive profile shift of the tooth profile (the effective running circle diameter in the first pair (sun gear wheel 1/planet gear wheel 2) differs from the effective running circle diameter of the second pair (output gear wheel 3/planetary gear wheel 2), The transmission ratio is then $N_3/N_4=1-Z_1/Z_3$.

A specific embodiment has the following data for the planetary transmission: number of teeth $Z_1=237$ of the sun gear wheel 1, The number of teeth $Z_3=Z_1+3=240$ for the output gear wheel 3 because three planetary gear wheels 2 are distributed about the periphery for transmitting torque, The number of teeth $Z_2=20$ for the planetary gear wheel 2, Module 0.5. The transmission ratio is then $N_3/N_4=1/80$.

The coarse drive comprising the coarse adjusting ring 6 having the control cam 61, cam follower 71 and displacing member 7 is configured as a screw drive having a rotational angle of 120° and a stroke of 20 mm. A rotation on the coarse adjusting ring 6 of 1° therefore effects a displacement of the displacing member 7 of 0.17 mm.

A rotation on the fine adjusting ring 40 of 1° effects only a displacement of the displacing member 7 of 0.002 mm, that is, 1/80 of the above value.

In lieu of the gear wheel transmission, the planetary transmission (1, 2, 3, 4) of FIG. 2 can be provided with a friction wheel transmission. Here, the two planetary gear wheels (2, 2') can be joined to define a bevel gear.

It is understood that the foregoing description is that of the preferred embodiments of the invention and that various changes and modifications may be made thereto without departing from the spirit and scope of the invention as defined in the appended claims.

What is claimed is:

1. An arrangement displacing at least a part of an objective, the arrangement comprising:

a housing defining a longitudinal axis;

a holding member for holding said one part and being displaceable along said axis;

a coarse adjusting ring rotatably mounted on said housing so as to be rotatable by an operator;

conversion means operatively connecting said coarse adjusting ring to said holding member for converting a rotatable movement of said coarse adjusting ring to a linear displacement of said holder and said part along said axis;

a fine adjusting ring mounted on said housing so as to be rotatable relative thereto by an operator through a first rotational angle;

interface means operatively connecting said fine adjusting ring to said coarse adjusting ring to effect a rotation thereof through a second rotational angle when said fine adjusting ring is rotated by the operator;

said interface means including: means for decoupling said fine adjusting ring from said coarse adjusting ring when said coarse adjusting ring is rotated by the operator whereby said fine adjusting ring remains at standstill; and, rotation reduction means for making said second rotational angle of said coarse adjusting ring a fraction of said first rotational angle whereby a fine adjustment of said linear displacement is obtained when said fine adjusting ring is rotated by the operator.

2. A transmission for adjusting at least a part of an objective mounted in an objective housing defining a longitudinal axis, the transmission comprising:

a coarse adjusting ring rotatably journalled on the housing so as to rotate about said longitudinal axis;

a holding member for holding said one part and being displaceable along said axis;

a coarse adjusting ring rotatably mounted on said housing so as to be movably rotatable by an operator;

conversion means operatively connecting said coarse adjusting ring to said holding member for converting a rotational movement of said coarse adjusting ring to a linear displacement of said holder and said part along said axis;

a sun gear wheel fixedly mounted on said housing;

a fine adjusting ring disposed in surrounding spaced relationship to said housing;

planetary gear means rotatably journalled in said fine adjusting ring for meshing with said sun gear wheel;

an output gear wheel rotatably mounted on said coarse adjusting ring and meshed with said planetary gear means whereby a manual rotation of said fine adjusting ring imparts a rotational movement to said output gear wheel; and,

slip clutch means interposed between said output gear wheel and said coarse adjusting ring for transmitting a torque from said output gear wheel to said coarse adjusting ring when an operator manually rotates said fine adjusting ring and for decoupling said output gear wheel from said coarse adjusting ring when the operator rotates said coarse adjusting ring.

3. The transmission of claim **2**, wherein said planetary gear means comprises a plurality of one-piece pinions uniform throughout and rotatably journalled in said fine adjusting ring so as to mesh with said sun gear wheel and said output gear wheel; and, one of said sun gear wheel and said output gear wheel having a profile shift.

4. An arrangement displacing at least a part of an objective, the arrangement comprising:

a housing defining a longitudinal axis;

a holder for holding said one part and being displaceable along said axis;

a coarse adjusting ring rotatably mounted on said housing so as to be rotatable by an operator;

an angular-to-linear drive operatively connecting said coarse adjusting ring to said holder for converting a rotational movement of said coarse adjusting ring to a linear displacement of said holder and said part along said axis;

a fine adjusting ring mounted on said housing so as to be rotatable relative thereto by an operator through a first rotational angle;

a reduction gear operatively connecting said fine adjusting ring to said coarse adjusting ring to effect a rotation thereof through a second rotational angle when said fine adjusting ring is rotated by the operator;

said reduction gear including: a clutch decoupling said fine adjusting ring from said coarse adjusting ring when said coarse adjusting ring is rotated by the operator whereby said fine adjusting ring remains at standstill; and, rotation reduction gear wheels for making said second rotational angle of said coarse adjusting ring a fraction of said first rotational angle whereby a fine adjustment of said linear displacement is obtained when said fine adjusting ring is rotated by the operator.

5. A transmission for adjusting at least a part of an objective mounted in an objective housing defining a longitudinal axis, the transmission comprising:

a coarse adjusting ring rotatably journalled on the housing so as to rotate about said longitudinal axis;

a holder for holding said one part and being displaceable along said axis;

a coarse adjusting ring rotatably mounted on said housing so as to be movably rotatable by an operator;

an angular-to-linear drive operatively connecting said coarse adjusting ring to said holder for converting a rotational movement of said coarse adjusting ring to a linear displacement of said holder and said part along said axis;

a sun gear wheel fixedly mounted on said housing;

a fine adjusting ring disposed in surrounding spaced relationship to said housing;

planetary gear wheels rotatably journalled in said fine adjusting ring for meshing with said sun gear wheel;

an output gear wheel rotatably mounted on said coarse adjusting ring and meshed with said planetary gear means whereby a manual rotation of said fine adjusting ring imparts a rotational movement to said output gear wheel; and,

a slip clutch interposed between said output gear wheel and said coarse adjusting ring for transmitting a torque from said output gear wheel to said coarse adjusting ring when an operator manually rotates said fine adjusting ring and for decoupling said output gear wheel from said coarse adjusting ring when the operator rotates said coarse adjusting ring.

6. The transmission of claim **5**, wherein said planetary gear wheels are one-piece pinions uniform throughout and rotatably journalled in said fine adjusting ring so as to mesh with said sun gear wheel and said output gear wheel; and, one of said sun gear wheel and said output gear wheel having a profile shift.

[57] **ABSTRACT**

The present invention relates to image-formation on any selected kind of objective body. The characterizing features reside in such that, based upon fed image data, required images are formed on an image-transferable sheet acting for image carry-over service and in reliance on sublimation image transfer technique, and then, by the use of said sheet with said images thus formed thereon, the formed images thereon are transferringly applied on the objective body. By adopting the above measures, the objective body can be formed sharply and clearly with any desired images, irrespective of kind and configuration thereof, with such superior results of highly improved unity and solidability between the formed images and the objective body to be decorated with.

IMAGE FORMATION ON OBJECTIVE BODIES

This is a continuation of application Ser. No. 08/034,186 filed Mar. 18, 1993, now U.S. Pat. No. 5,451,560, which in turn is a continuation of Ser. No. 07/467,415, filed Jan. 19, 1990, now abandoned, which in turn is a divisional of Ser. No. 07/138,384, filed as PCT/JP87/00228, Apr. 10, 1987, now U.S. Pat. No. 4,923,848, issued May 8, 1990.

TECHNICAL FIELD

This invention relates to methods and apparatus for the formation of images as prints on objective bodies through transfer of images preformed by the sublimation transfer technique, and more specifically it relates to such systems as adapted for the formation of images on any selected objective body, such as cards, clothes, papers, and transparent sheets, although these are not limitative to the present invention.

BACKGROUND ART

Reliance is made generally upon the normal printing technique for formation of images on objective bodies. For the execution of the printing technique, provision and use of printing plates (forms or blocks) are requisite. No matter how simple the image-printing is, the plate-making is a very time-consuming the laborious procedure. This is much more so in the printing of various and complexed image combinations, such as those of graphic or portrait images combined with characters, letters or barcodes, as an example, representing extremely complicated and troublesome work.

Further, in the normal printing operation, various operating conditions, including ink selection and the like, must be carefully considered, depending upon the kind and nature of the printing object, thus the best selection thereof is highly delicate and not as simple as expected.

The present invention is proposed upon careful consideration of the foregoing facts, and an object of the invention is to provide a unique process for the formation of sharp and clear images regardless of the kind and nature of the object to be printed upon, and usable and effective materials and apparatuses for carrying out this unique process.

The method of thermal image transfer (sublimation image transfer) on clothes or fabrics with the use of thermal transfer dyestuffs has been practiced for a long time. In this conventional process, a dyestuff picture layer carrying thermal transfer dyestuff is formed on a substrate sheet which is then subjected to heat in an overlapped state on a cloth or fabric, the dyestuff thereby being transferred thermally onto the latter for forming the desired images thereon. By utilizing this technique, and with recent development of the image forming technology concerning fine thermal printers and the like, various fine image forming processes have been proposed to provide fine images which are comparable to photographic images and are transferred onto plastic films from thermal transfer sheets carrying thermal transfer dyestuffs.

According to these recently proposed processes, various images of cameras, or TVs, graphic images of personal computers and the like can be reproduced easily in the form of hard copies on the surface of a transferred material such as a paper or the like sheet carrying thereon a fixedly attached layer of polyester resin, as an example. These images thus reproduced represent an amply high level comparable to those obtained by photography or fine printing arts.

The thermal transfer process so far set forth has an advantage in that it can form any image in a convenient manner yet entails a problem in that it is limited to image-transferred product preferably of polyester and the like materials which must be dyed with thermal transfer dyes. On the other hand, the image-transferred products must be limited to specifically selected shapes, preferably film, sheet or the like configuration, and thus, such materials as wood, metal, glass or ceramics cannot be formed with images in this way. Further, even if the material is plastics such as polyester or the like, and when the image-forming surface is curved or undulated, or physical body other than sheet, even if it represents a plane surface, it is almost impossible to reproduce images precisely thereon, which naturally constitutes a grave problem in the art.

With recent development and enlargement of utilizing fields of various card-style products, such as cash-cards, telephone-cards, prepayment cards; and ID-cards, there are increasing demands for providing these cards with images, symbols and codes, so as to give various other functional and/or decorative effects. Most of these cards are of planar form, but they are frequently not pliable and/or have uneven rough portions due to provision of characters and symbols, resulting in great difficulty in the scheduled image formation relying upon the thermal image transfer process.

There is therefore an urgent demand among those skilled in the art for the provision of a unique technique capable of forming sharp and clear images of desired patterns on the surface of an objective body of any preferred kind of material and having any shape and configuration and surface condition of any kind, and indeed, for combining and unifying image- and decoration effects.

DISCLOSURE OF THE INVENTION

The present invention is basically based on such a principle that a first image transfer pattern is formed on an image transfer material, preferably an image transfer sheet, and in the form of dyestuff images through the sublimation image transfer process executed by first image transfer means, depending upon given image data, preferably including those of letters, characters, symbols, line images, graduated graphic representations, and then the first transfer pattern is transferred to second transfer means for retransferring the images onto an objective body so as to provide a final product.

Based upon the image data fed from various image data input means and at the first image-transfer means, a thermal head is actuated to execute printing operation through a dyestuff film (thermal image-transfer sheet) on an image-transfer material (or more specifically on an image-transferable material which means an image-transferable sheet. This image-printing is carried out according to the sublimation or sublimative image transfer technique. Thus, in this case, the dyestuff on the dyestuff film is transferred or shifted under the influence of heat energy from the thermal head onto the image-transfer material through sublimation, thus providing the first image-transferred means. Since this first image-transferred means has been thus formed with the images by the sublimated dyestuff, they are, then, transferred onto the second image-transferable means which will be brought into tight contact with the object to be decorated and subjected to heat and pressure for execution of further image-transfer operation to provide the final desired product.

In the present invention, the image-transfer material (image-transferable sheet) is, as above referred to, formed

with images by the sublimative image tansfer technique for providing first image-transfer means which has highly sharp and clear images as the operation and results of the characterizing feature of the sublimation image-transfer technique. Therefore, because of the transfer of such sharp and clear images onto the object, it becomes possible to form the images thereon, and indeed, practically irrespective of the kind and nature of the object. In this way, thus, fine image-formation is assured onto practically any objective substance.

And further, by execution of control of the thermal energy applied during the sublimative image-transfer step, the resulting color effect is superior and the image quality is good.

The images sublimatingly applied and formed in the foregoing way are subjected to a further transfer, and onto a substrate product, for providing a final decorative product as desired. In this final product, it should be noted that the underlying layer underneath the images during the sublimative image-transfer stage appears now at the top, acting thus as a kind of protecting layer upon up-and-down positional conversion during execution of the second and final image-transfer stage, resulting in realization of various and numerous effects. As an example, attainment of substantial reduction of contamination, improvement of light resistance, weather resistance and chemical resistance; substantial reduction of color fading; provision of glazing effect; easier and simpler introduction of granular and/or undulated image appearance.

The inventive process is carried into effect basically in such a manner that an image-reception layer provided on one surface of an image-transferable sheet is subjected to an image-forming step with the use of dyestuff capable of depositing therein depending upon the fed image data, so as to form the required images, and then, the image-reception layer of the image-transferable sheet, having been image-fixed and thus now image-carrying, is stuck onto the surface of the object to be decorated upon.

As for the image-transferable sheet adapted for use in the image-transfer during execution of the inventive process, it consists basically of a sheet-like substrate and a reception layer attached, however, in a separable manner, onto one surface thereof. As a modification of the inventive process from the basic mode set forth above, the sheet-like substrate is caused to remain, even after completion of the image-transfer step, as may be occasionally required. In this modified case, it is unnecessary to make the image-reception layer of the image-transfer sheet separable.

Under occasion, the inventive process may be brought into effect in such a way that the image-reception layer of the image-transfer sheet is transferred upon execution of the image-forming step, and indeed, once onto an intermediate image-transfer substrate which is then retransferred, together with the once transferred image-reception layer, onto the surface of an object to be decorated on, and thus, in a retransferring manner.

BRIEF DESCRIPTION OF THE DRAWINGS

In the accompanying drawings:

FIG. **1A** is a block diagram, showing a preferred embodiment of the apparatus according to the present invention;

FIG. **1B** is a schematic view illustrating at (*a*), (*b*) and (*c*), several image-transfer steps for the execution of a process according to the invention;

FIG. **1C** is a schematic view of an image-transfer step, using a platen roll;

FIG. **1D** is a plan view of part of a multi-color dyestuff film adapted for use in an image-forming step;

FIG. **1E** is a schematic view for the illustration of several image-transfer steps;

FIG. **2** is a flow chart of successive operation steps with use of a data-processor, shown in FIG. **1**, functioning as an operating center;

FIG. **3A** is a schematic block diagram, showing a data-processor for the printer;

FIG. **3B** is a block diagram of a sublimative image-transferring printer adopted in the present invention, as a preferred embodiment thereof;

FIG. **4** is a schematic block diagram, showing a color correction unit shown in FIG. **3A**, and several related parts cooperating therewith;

FIG. **5** is a schematic block diagram of a comparator and several related parts cooperating therewith;

FIG. **6** is a circuit block diagram of an image-transfer head shown in FIG. **1B**;

FIG. **7** is a graph showing operational characteristics of a color tone or -gradation corrector unit shown in FIG. **3A**;

FIG. **8** is a table for the illustration, as an example, of picture- or image-elements, as expressed in binary signals;

FIG. **9** is a table showing a conversion operation, as an example, of a parallel/series converter shown in FIG. **3A**;

FIG. **10** is a flow chart, illustrating the operation of the sublimative image transfer printer;

FIG. **11** is a plan view of a final decorative product prepared according to the inventive technique;

FIG. **12** is a sectional view of the product card shown in FIG. **11**, and taken along a section line A—A shown therein;

FIGS. **13** through **31** are a series of sectional views, respectively illustrating several structural examples of image-transferable sheets, suitable for use in the invention; and

FIGS. **32** (*a*), (*b*), and (*c*) are sectional views, indicating final transfer steps.

BEST MODES FOR CARRYING OUT THE INVENTION

Referring now to FIG. **1A** and FIG. **1B**, (*a*), (*b*) and (*c*), a basic schema of the inventive image data processing and image formation .will be illustrated. First, in FIG. **1A**, numeral **101** represents an image input means which is adapted for forming image data based upon optical and the like inputs delivered from a TV-camera, line sensor or the like. Other than those above enlisted only by way of example, video; CD; TV; scanner; personal computer, captain system, capable of providing R.G.B.- and picture image and the like signals may also be utilized in a similar way. The image signal data delivered from the image input means are fed through a data processor **104** to a memory **105** for being stored therein. These stored data can be taken out from the memory and fed through data processor **104** to display means **102** for being displayed thereat.

To the data processer **104**, a mouth/tablet digitizer and/or the like position data processer **103** is electrically connected for introducing position data concerning displayed images appearing at the display **102**. In addition, key board and the like character data input means **106** and font generator **109** are provided for introducing character data. Still further, a barcode generator **110** is provided for introducing barcode when necessary. By the use of these means and units, various additional processing modes can be executed.

The thus processed data are subjected to conversion at a data converter **107** into proper data adapted for operating a sublimation transfer printer and fed forward through a driver **108** to the thermal head.

In this case, by controlling the current duration period to the thermal element of the thermal head, the transfer quantity from the dyestuff film (thermal transfer sheet) is controlled depending upon the thermal energy of the element for realization of the desired gradation degree of concentration on the transfer sheet. There are two different modes of such control of current duration period as follows:

(a) A method for controlling the pulse length corresponding to the picture element in the impressed data to the thermal element of the thermal head or, more specifically, a series data introduced as input to the shift register shown in FIG. **6** and to be described more specifically hereinafter.

(b) A method for controlling the number of pulses of the pulse series corresponding to the picture elements of the data impressed upon the thermal element in the thermal head (in this case, the pulse length being constant).

The degree of gradation of the transfer image can be controlled in the above mentioned way by the regulation of the current-conducting period depending upon the desired gradation degree. On the other hand, the image concentration can be controlled by adjusting the pulse length or the number of pulses contained in the pulse series in correspondence to the picture elements contained in the data as introduced in the shift register and depending upon the driving mode of the thermal head. Further in this case, if the number of gradation of introduced image data is larger than that which can be expressed by the printer unit, a proper conversion operation can be performed by the known strobe control method. As an example, in such case, the conversion of gradation number 256 to 64 may be executed by a ROM, and the thus reduced gradation number can be used as output.

Next, referring to FIG. **1B** at (*a*) and (*b*), reference numeral **121** represents a thermal head which receives signals from the driver **108** shown in FIG. 1A. This thermal head **121** is arranged in opposition to platen roll **122**, forming the printing position therebetween. The dyestuff film (thermal transfer sheet) is fed from a delivery roll **123** to a winding roll **124** through this printing position, these structural and functional features being commonly employed in both the arrangements shown in FIG. **1B** at (*a*) and (*b*).

In the case of FIG. **1B**, (*a*), the mechanism is so arranged that card or sheet style transfer sheets are printed with dyestuff images.

On the other hand, in the case of FIG. **1B**, (b), the mechanism is so arranged that cards are continuously produced with the use of a film style transfer sheet and a dyestuff film in combination.

Now turning back to FIG. **1B**, (a), a number of transfer sheets (cards, sheets or the like) have been stacked and stored within a storage casing **125** and are being thrust upward from below by a spring so that the uppermost sheet is kept in pressure contact with a take-out roll **126**. With the rotation of the roll **126**, the sheets are successively delivered from the casing **125** by conveyer belts **127**, **128** onto a platen roll **122**. Each one of the sheets is fixed on the peripheral surface of the platen roll, now positionally indexed, by means of a gripper or the like mechanical attaching and separating means, static attracting means, or electromagnetic attaching means. Then, the roll **122** is so rotated that the transfer sheet is positioned at the ready-for-printing-position.

Next, the thermal head **121** is brought into pressure contact with the transfer sheet through the intermediary of the dyestuff film, and then the thermal head **121** is energized with electric current while the dyestuff film and platen roll **122** are moved in synchronism for the execution of image transfer (first image transfer).

Upon execution of the image transfer, the platen roll **122** is rotated, the gripper is released and the take-out roll **129** is rotated and brought into pressure contact for taking out the image transfer sheet onto a tray **130**.

The thus taken-out sheet is brought into overlapped state with a new image transfer sheet, not shown, and then, both the sheets are fusingly united together by pressure application of a heated roll, not shown, for execution of a second transfer step job. The whole operation has thus been completed. Before the fusion process, the sheets may be subjected to punching, trimming and/or the like processing, if necessary.

By execution of the foregoing operational steps, a monocolor printing operation has been completed. However, in the case of multicolor printing, use is made of tricolored or quadruple colored dyestuff film and the corresponding printing operations must be repeated. In this case, upon completion of a single monocolor printing procedure, the platen roll is rotated without contact of the take-out roll **129**, until it arrives again at the printing-initiation position, and so on.

In the following, a tricolor printing job will be illustrated with reference to FIG. **1B**, (*b*), and with use of three different series color zones, of cyan, magenta and yellow.

First, a platen roll **122** is positionally indexed, and an image transfer sheet taken out from the roll **131** and a dyestuff film taken out from the roll **123** are brought into pressure contact in an overlapped state. Then a thermal head **121** is pressed against the platen roll **122** through the intermediary of the overlapped sheets. At this stage, the platen roll **122** is rotated counterclockwise while synchronism is kept between the platen roll **122** and the dyestuff film, and the thermal head **121** is kept electrically energized. In this way, the first color printing is executed.

Further, the dyestuff film is fed to the second color zone position, and then, the platen roll **122**, the dyestuff film and the image transfer sheet are fed forward clockwise around the center roll **122**. Thus a second color printing step is executed.

Further, the print-serviced two color sections of the film is fed back counter clockwise around the center of the platen roll **122** for the execution of a third color printing step. Then, each card sheet is taken out from the stack **200** under the action of take-out rolls or the like, not shown, towards and between a pair of thermal transfer rolls **132**, **133**, brought into overlapping state with the image transfer sheet positionally indexed and already subjected to image transfer steps as was described above, and finally subjected to a picture printing operation by pressurizing application of the thermal image transfer rolls **132**, **133** from both sides of each taken-out card, and so on.

The color-printing step with the use of the thermal head is carried into effect in the following manner, as an example.

(First color printing)

Platen roll, image transfer sheet and dyestuff film perform the printing while they are moved in the counterclockwise direction.

(Second color printing)

Platen roll and image transfer sheet are moved in the clockwise direction while the dyestuff film is moved at the same speed and in the counterclockwise direction for performing the color printing under consideration.

(Third color printing)

Platen roll, image transfer sheet and dyestuff film are moved in the counterclockwise direction for execution of the color printing under consideration.

In the modified arrangement shown in FIG. **1**B, (*c*), thermal image transfer rolls **132**, **133** have been replaced by a flat press type image transfer head having up-and-down movable flat printer elements **132'**, **133'**.

It should be noted that in the course of the foregoing first and second image transfer steps, image reversal phenomenon is necessarily brought about upon execution of each image transfer step. In other words and more specifically, when two successive image transfer steps in the foregoing sense are executed, reverse images which have once appeared will return to the original normal images. Therefore, when the printed-out products are to be provided upon execution of the first image transfer step, it is necessary to provide reversed image data in the signal processing system. For this purpose, it is only necessary to reverse the addressing order at the data introduction or readout stage into or from the memory.

In the modified arrangement shown in FIG. **1**C, the foregoing platen roll means has been replaced by a metal block **141** lined with a rubber plate **142** in an overlapped manner. The image transfer sheet and dyestuff film are fed out from respective rolls **131** and **123**. With the use of this modified arrangement, the dyestuff surface layer of the dyestuff film can be brought into tight contact with the image-receiving surface layer of the image transfer sheet, and thermal energy will be transferred evenly form the thermal head **121** to the dyestuff film.

In this case, the image transfer sheet is delivered from the roll **131**, and the desired zone or region of the sheet is set underneath the rubber plate **142** (step **1**).

At the same time, the dyestuff film shown in FIG. **1**D on an enlarged scale is delivered from the roll **123** and a selected one of the different color regions is set underneath the rubber plate **142** (step **2**).

Next, the thermal head **121** is brought into the rear surface of the dyestuff film which is the opposite surface to the dyestuff-coated front layer, and the head **121** is driven while it is being translated in the direction shown by an arrow A, images thereby being formed at the specifically allocated zone(s) or region(s) of the image transfer sheet (step **3**).

Further, the thermal head **121** and rolls **416** and **418** are shifted downwards as shown by arrows B, so as to form an idle gap between the image transfer sheet and the dyestuff film for allowing the latter to shift towards the next following color region (step **4**).

Further, the thermal head **121** and rolls **416** and **418** are returned to their original positions, whereupon the third and further succeeding steps are repeatedly executed until a certain predesired number of color printings are completed.

As shown in FIG. **1**D, the dyestuff film is colored to have several different color regions denoted by Y (yellow), M (magenta), C (cyan) and Bk (black). However, the arrangement order is not limited to that shown: Y; M; C and Bk. In addition, as occasionally required, the Bk-region may be dispensed with. Further, as the color elements to be adopted in the Y, M, C-system may not be limited to the three primary colors provided by the subtractive color mixture. On occasion, a characterizing color which means such a color as preadjusted to provide an objective specifically selected one may be used to form the images concerned. As a further modification, the arrangement shown in FIG. **1**C may be so modified that the traveling direction of the image transfer sheet is selected to be perpendicular to that of the dyestuff film.

FIG. **2** is an operation flow chart for showing schematically operational modes taking the data processor **104** adopted in the embodiment shown in FIG. **1** as the centrum of description. The operational contents of several working parts downstream of the data converter **107** will be set forth separately hereinbelow. Now referring to FIG. **2**, in combination with FIG. **1** and at the step of **S101**, image pickup operation is carried out by means of the image pickup means **101**. For execution of this step, it may be better to pick up the face of a person per se which is to be represented on the card, or alternatively, a photograph, portrait or imagery product thereof will do. Depending upon the nature of the object, a TV camera, line sensor or the like instrument may naturally be selectively utilized.

The data taken by the image pickup means **101** are stored through the data processor **104** at a memory **105** (**S102**). By the use of these stored data, image or images is/are displayed at the display **102** (**S103**). Since this display image is not yet subjected to any processing, it is generally unsuitable for representing on the card. However, under certain circumstances, it may be represented thereon as it is.

Then, the operator observed the displayed image or images on the display unit **102** and adjudges whether additional processing is necessary or not (**S104**). If it is not necessary, he will manipulate the key board **106** to make a certain operation, resulting in the termination of processing at the data processing unit **104**, data being fed out therefrom to the succeeding data converter **107**.

On the contrary, when additional processing is necessary, the operator observes carefully the displayed image or images on the unit **102** and adjudges whether the picture image data, or character data or barcode data should be processed. If the picture image data should be processed, such an operation is made for selecting the proper mass of trimming or layout within the menu range of position-data input means **103**. By the execution of this operation, functions and operations at steps **S105** and **S106** can be executed at one stroke. If trimming is taken as an example, the next step is executed in such a way that position data are fed from the position input means **103** to the data-processer **104** with the use of a carsor. When a tablet digitizer is used as the position data input means, the carsor image displayed in an overlapped manner on the displayed picture image appearing at the display unit **102** by carsor manipulation is positionally specified beforehand in registration with the specified position on the card, for determining the trimming range. Then the operation is carried out in such a way that the picture image data outside the specified trimming range are canceled. By completing these operations, data processing operations relating to step **107** are executed, and, then, the mass for completion of the menu range is selected out. By these measures, steps progress through **S109** to **S102**, and data storing is executed, and further, display representation is brought about through step **S103**. If there is no need for additional processing, an operation termination manipulation is carried out as before at key board **106**, and further operations will be made through data converter **107**.

As for the layout, the operation is carried out with the position data input means **103**, similarly as in the foregoing trimming operation. More specifically, layout is selected out in the menu range of position data input means **103**, and the overall configuration of the card and the display position of picture image are shown at display unit **102**. Then, image inclination correcting operation and the like are carried out so as to realize correspondence thereof with the displayed positional information, the processing operations relating to step **S108** thereby being brought about. After completion of these operations, the mass for the ending in the menu range is selected.

In this way, when selection is made from the menu range by reliance on the position data input means **103**, trimming or layout operation can be brought about. At this stage, when manual operation is carried out at the key board **106**, introduction of character data is executed (S110). As the character data in this sense, in the case of ID card, as an example, the name and/or birthday, month and year of the owner may be used. The data introduced from the key board **106** in accordance with the output character style from the font generator **109** are shown at the display unit **102** in the specified positions on the displaying surface and respectively arranged in accordance with display items. The operator acknowledges these items and detailed displays of the represented images. When he acknowledges them as being true, he will operate the key board **106** for showing the operation ending (S111).

Upon ending the operations as described above, the data are stored in memory **105** (S102) and represented at the display **102**. The operator will acknowledge again this fact, and upon the execution of this, the operations are terminated.

As for the barcode introduction, the data are subjected to inputing at steps S112 and S113, as in a manner similar to the character data introduction as set forth above. The barcodes and the like data may be introduced separately through printing or other mechanical method.

In FIG. 3A, a data processing circuitry usable in the sublimation image transfer printing method is shown only schematically. As shown, the circuitry **107** comprises a picture element density converter **3**; a color corrector **4**; a gradation corrector **10**; a memory **11**; a switch **12**; a buffer **13** and parallel/series converter **14**. The picture element density converter **3** is connected to a picture image input unit **100**.

The unit **100** serves for generation of three primary color data of R.G.B.- or Y.M.C.-mode from original picture images and is connected through the picture element density converter **3** to the color corrector **4**. The converter **3** converts the picture element density of the image data fed from the unit **100** to the desired one, by subtracting or supplementing, as the case may be, image data for each color element. It should be mentioned that for attaining high quality hard copies, conversion of the picture element density to at least 10 lines/mm or so is preferable.

Color corrector **4** consists preferably of a color decoder, level adjuster or color converter, and serves to correct three primary color data converted to those of a predetermined density of picture elements in consideration of characteristics of the image transfer ink in the image transfer sheet and in addition to provide black color data.

The data processing circuitry **107** is connected through a driver **108** to the sublimation image transfer printer.

In FIG. **4**, an example of the color corrector **4** is shown schematically in structure. As shown, it comprises adders **6Y**; **6M** and **6C**, a black color data calculator **7**, and primary and secondary color correction circuits **8** and **9**. Primary color correction circuit **8** serves for making correction of turbidity of the image transfer ink, while secondary color correction circuit **9** provides a capability of arbitrary and selective correction control relative to specifically selected color hue.

The gradation corrector **10** is so arranged as to make correction of the gradation of the data for each color Y, M, C or K (representing black color) fed from the foregoing color corrector **4** when necessary. For this purpose, the corrector **10** includes a gradation circuit (not shown) and the like, whereby a certain mode of highlight stressing or shadow stressing is introduced and realized.

The memory **11** functions to preserve temporarily the data of each color delivered from the gradation corrector **10**, a selection switch **12** being provided at the output side of the memory for selective writing-in of the data of each color to the buffer **13**. The buffer **13** is capable of writing-in the data of one line of the image transfer head **16** and kept in connection with the parallel/series converter **14** adapted for converting parallel data into series data. Additionally, in the simplified machine, black color data series is dispensed with in some instances.

In FIG. **5**, a schematic construction of the parallel/series converter **14** is shown. As shown, parallel data delivered from the buffer **13** are fed to an input side of a comparator **22**, while outputs from a counter **23** are fed to another input side of the comparator **22** which delivers the converted series data to the driver **15** for driving a thermal head **121**.

If necessary, however, the comparator **22** may be replaced by a converter table, not shown, utilizing a parallel/series converting ROM.

In FIG. **6**, a detailed circuit schema of the thermal head **121** is shown. As shown, series data delivered from the comparator **22** are fed into a shift register SR and thence, after being subjected to latching at a latch circuit LT, fed to thermal elements HE through NAND gates NA which are fed at respective one side inlets with strobe signals.

Next, referring to FIG. **3A**, the operation of the data processing circuitry **107** will be described more specifically.

First, when three primary color image data are fed from the picture image inlet circuit **100** to the picture element density converter **3**, the latter converts these three primary color data to those which represent a predetermined picture element density and then are fed to the color correction unit **4**. In this case, it is assumed that the unit **4** is fed with three primary color data expressed in respective concentration signals, which are of yellow: **Y0**; of magenta: **M0** and of cyan: **C0**, respectively, in the present example.

These data: **Y0**; **M0** and **C0** are, as shown in FIG. **4**, fed through respective adders **6Y**; **6M** and **6C** to the black color data calculator **7**, to provide a K-output as expressed mathematically by the following formula:

$$K=\min(Y, M, C)$$

wherein, "min" represents a function which provides a possible minimum value.

These data: **Y0**, **M0** and **C0** are fed from the converter **3** to the primary color correction circuit **8** to provide primarily corrected data **Y1**, **M1** and **C1** which are thence fed to the secondary color correction circuit **9** to provide, through calculation, secondarily corrected data: **Y2**, **M2** and **C2**, respectively. These are then fed to respective adders **6Y**, **6M** and **6C**, which add them to respective data **Y0**, **M0** and **C0**, to provide respectively added output data Y, M, and C to be fed to the gradation correcter circuit **10**, respectively, after being utilized for calculation of the K-output signal value.

The primary color correction circuit **8** serves to calculate primarily corrected data: **Y1**, **M1** and **C1** which are necessarily utilized for correct-out of transfer ink turbit. In this case, the original data: **Y0**, **M0** and **C0** are subjected to matrix calculation to provide the primarily corrected data **Y1**, **M1** and **C1**, as folows:

$$Y1=k_{11}\cdot C0-k_{12}\cdot M0+k_{13}\cdot Y0$$

$$M1=k_{21}\cdot C0+k_{22}\cdot M0-k_{23}\cdot Y0$$

$$C1=k_{31}\cdot C0+k_{32}\cdot M0-k_{33}\cdot Y0$$

where, k_{ij} represents weight coefficients:

i=1–3; and

j=1–3.

The secondary color correction circuit **9** serves to calculate secondary color correction data **Y2**, **M2** and **C2** from primary color correction data **Y1**, **M1** and **C1** by modifying the latter to make certain thereto by performing matrix calculations so as to provide a capability for making an arbitral and selective color control at a certain specifically selected-out color hue, in the following manner:

$$Y2=Y1+l_{11}\cdot\Delta B+l_{12}\cdot\Delta C+l_{13}\cdot\Delta G+l_{14}\cdot\Delta Y+l_{15}\cdot\Delta R+l_{10}\cdot\Delta M$$

$$M2=M1+l_{21}\cdot\Delta B+l_{22}\cdot\Delta C+l_{23}\cdot\Delta G+l_{24}\cdot\Delta Y+l_{25}\cdot\Delta R+l_{26}\cdot\Delta M, \text{ and}$$

$$C2=C1+l_{31}\cdot\Delta B+l_{32}\cdot\Delta C+l_{33}\cdot\Delta G+l_{34}\cdot\Delta Y+l_{35}\cdot\Delta R+l_{36}\cdot\Delta M$$

wherein, l_{ij} represents weight coefficients:

i=1–3;

j=1–6;

ΔB, ΔC, ΔG, ΔY, ΔR, ΔM: characterizing color data.

Thus, when these-secondary correction data **Y2**, **M2** and **C2** are added to the corresponding original data **Y0**, **M0** and **C0** by means of respective adders **6Y**, **6M** and **6C** and under proper selection of weight coefficients k_{ij} for primary color correction circuit **8**, any color discrepancy of the ideal color of the ink appearing on the printed picture images under the action of the sublimation transfer printer can be arbitrarily ammended. In this case, when the weight coefficients l_{ij} for the secondary correction circuit **9** are selected out properly, the color tone of the printing picture images can be modified to an arbitrary degree.

Further, as for the black color data K, correction data **K2** can be calculated by the following formula. With use of these correction data **K2**, which are added to the original black color data K, the desired correction can be executed in a similar manner.

$$K2=K+\mathrm{ml}\cdot\Delta B+m2-\Delta C+m3\cdot\Delta G+m4\cdot\Delta Y+m5\cdot\Delta R+m6\cdot\Delta\mathrm{M}$$

wherein, Mi represents weight coefficients:

i=1–6.

In this way, output data: Y, M, C and K delivered from the color correction circuit **4** are introduced into the gradation corrector **10** as inputs thereof, and each constituent of these data can be subjected to correction as desired.

FIG. **7** shows several characteristic curves illustrating corrections by means of the gradation corrector **10**. More specifically, **f0** represents a standard characteristic curve; **f1** a highlight-stressing operation curve; **f2** a shadow-stressing operation curve; **f3** a highlight-and-shadow stressing operation curve; and **f4** a medium tone stressing operation curve.

As indicated in FIG. **7**, by presetting, as necessary, the tone-reproducing characteristics, which determine the relationship between that concentration of color data and that of the prints printed by means of a sublimation image transferring printer, a color tone similar to that possessed by the original image can be reproduced. More specifically, when no correction is adopted, the curve **f0** is used, while in the case of correction, any selected one of these curves **f1** to **f4** may be utilized depending upon the part of gradation to be stressed. Further, it should be noted that the tone reproducing characteristic curves are not exclusively limited to those which have been specifically shown and described above. As an example, the control of gradation correction by color tone reproducing characteristic mentioned above is executed by a gradation circuit, not shown, and the setting of the color tone reproducing characteristic is brought about by manipulation of any selected one of the control knobs, not shown, which are provided separately for "highlight"; "medium tone" and "shadow".

Y.M.C.K.-data subjected to correction by the gradation corrector **10** are once stored in the memory unit **11**. The thus stored data may be read out from the memory for each color by manipulation of the selection switch **12** and, after provisional storing, per one line of transfer head **16**, at the buffer **13**, introduced into the parallel/series converter **14** for conversion thereby into corresponding series data.

Another example of the data processing circuit for the sublimation transfer printer is shown only schematically in FIG. **3B**. As shown, the processing circuit in **107'** comprises a level regulator **503**; a color converter **504**; an A/D converter **505** and a parallel/series converter **14**.

As the image data introduced into the processing circuit **107'**, those which have been subjected to conversion into R.G.B.-signals in the color decoder **502** from composite video signals delivered from a T.V. camera, VTR or the like are used. On the other hand, R.G.B.-signals delivered from a personal computer, captain system or the like means are introduced as input into the level adjuster **503**.

As the color correction method with the use of the foregoing arrangements, it is possible, more specifically, to adjust the hue saturation and/or brightness in the color decoder **502**, or to adjust the signal level of each color light of R.G.B.-system in the level regulator **503**.

As an example, the color conversion from R.G.B.- to Y.M.C.-system can be executed in the color converter **504**. The simplest possible method in this color conversion is to procure the opposite color to each of the normal colors.

The thus produced color signals of Y.M.C.-system is subjected to A/D conversion and then fed successively through the parallel/series converter **14** and the driver **108** to the thermal head, not shown, to carry out printing in the sublimation transfer principle.

Additionally, in normal cases, with the use of the foregoing system composition, input image data must be of static mode. However, by provision of memory means in front of the color decoder or at an intermediate position between the A/D converter and parallel/series converter, animating images can be processed.

The series data converted in the foregoing manner in the data converter **107** or **107'** are fed to the shift register SR shown in FIG. **6** by n-image elements and then, upon being subjected to latching in the latch circuit LT are further delivered to NAND gate NA as its inputs. When a strobe signal ST is fed as input to the NAND gate NA, the foregoing n-image element data is fed to the thermal element HE.

FIG. **8** is a schematic diagram, showing signals for respective image elements. The gradation has been so selected that the first image element is at the highest gradation level, while the n-th image element corresponds to the lowest gradation level, and that the second to (n–1)th image elements vary linearly in gradation levels, so as to provide representatively a better understandable example of the invention.

Next, the operation of the parallel/series converter **14** will be described.

First, as shown in FIG. **5**, image elements data A, consisting of parallel data, more specifically, comprising parallel eight bit data **A0–A7**, are fed to one-side inputs of comparator **22**, while another side inputs thereof are fed with outputs B, comprising eight bit increment outputs **B0–B7**, of counter **23**. The counter **23** counts clock signals in increments, the outputs **B0–B7** being successively varied.

The comparator **22** performs comparison between the two inputs A and B, so as to deliver successively outputs of binary "1" until the increment output B is brought into coincidence with image elements data A, or more specifically, under the condition of A>B and A=B, while, thereafter, binary "0"-outputs are delivered therefrom. More specifically, comparator **22** will continue to deliver binary "1" until an increment value which corresponds to the weight of concentration of image element data A is given thereto. As an example, if the image element data A has a concentration of gradation 128 of a total 256, output "1" will be repeated to deliver 128 times first and then, output "0" will follow after again 128 times, so as to provide in total a specific series data peculiarly in this case.

These series data are taken out from the comparator **22** in the form of A>B- and A≦B-outputs and of A=B–outputs through an attributed OR-gate **24**, and in the present example, the gradation consists of 256 steps or increments. However, in practice, the gradation may represent a smaller number of steps. As an example, if the incrementing bit is **B1** instead of hitherto employed **B0**, the gradation will have 128 steps; and if **B2** is employed, it will have only 64 steps. In this way, the gradation setting may be varied in a simple manner.

When in the foregoing way, the output B from the counter **23** is stepwise incremented, such series data consisting of a first series of "1" will be delivered until the relationship between the image elements data A and the output B from counter **23** becomes A=B, and of a second series of "0" issued thereafter, as shown in FIG. **8**.

In FIG. **9**, a conversion mode at the parallel/series converter **14**, which, however, is different from that shown in FIG. **8**, as an example, is shown again in the form of a matrix. As-shown, when the image data are of 8-bit parallel kind, as an example, the gradation data are ranged from 0 to 255, providing, therefore, binary series data from "00 . . . 00" to "11 . . . 11".

In this way, the data, per line in the transfer head **16**, kept preserved in the buffer **13** are fed to the parallel/series converter **14** for providing as outputs therefrom into corresponding series data which are then delivered through the driver **15** to the transfer head **16** and thus recorded on a print paper P supported on the transfer drum **17**.

FIG. **10** represents a flow chart illustrating the operation of the sublimate printer as employed in the present invention.

At the first step **S1**, print papers are set in position and the printing ribbon is also set in position ready for performing the required procedure.

At the second step **S2**, printing operation is initiated, and line printings are executed, line by line, accompanying necessary intermittent line shifts, with relation to any selected one of four colors: C (cyan); M (magenta); Y (yellow) and K (black) being carried out. Refer to **S3** and **S4**. When line printings with the selected-out single color have been completed (**S5**), the image transfer sheet is replaced by another color sheet (**S6**) and so on. In this way, line printings are completed in all four colors. In this case, it is naturally most preferable to use a long extended single transfer sheet on which four color ink regions are repeatedly printed in a certain predetermined pattern. The image reception paper is initiated to make print from a certain prescribed position for each of these colors (**S8**). When all of the printing steps have been completed with the four colors, the paper is discharged from position (**S9**) and the printing operation is terminated to be repeated.

In FIG. **11**, a card style sample of the final products according to this invention is shown in front view at **200**. FIG. **12** is a sectional view thereof. Numeral **201** represents the substrate material of the card; **202** a display layer; **203** a surface protecting layer; and **204** a display image as an example. Depending upon the kind of usage and when necessary, the protecting layer **203** may be dispensed with. It should be noted that the display image **204** on the display layer **202** is represented by a sublimative dyestuff, as a characterizing feature of the present invention.

As the main and substantial material of the image transfer sheet, various plain papers, converted papers, plastic resin sheets or the like may be used per se or in combination. When a plastic resin sheet which can be colored directly with a sublimative dye or dyes is used, these image transfer substrates (articles or objects) as at **201** can be united .each with the display layer **202**. Each of these substrate materials, when it is of the card style, may have generally such dimensions: thickness of 0.68 to 0.80 mm and size: 11 to 8×8 to 5 cm.

As the material of the display layer **202**, various known materials which may be colored with sublimative dyestuffs, such as polyethylene, polypropylene, polyester, ABS, AS, polyvinylchloride, polyvinyl/vinyl acetate copolymer, polystyrene, polyacrylate, polyester, polyamide, polyurethane and the like plastic material, may be advantageously utilized. As will be more specifically described hereinafter, this material layer can be united with the substrate material layer **201**. In the case of such unified structure with substrate layer **201**, the thickness and size dimensions may be substantially as the same as before. However, when normal and/or converted papers or metals, which are practically impossible to color with sublimative dyestuffs, are used as the substrate layer **201**, various methods can be utilized for desired coloring. As an example, a solution including at least any selected one of plastic resin materials capable of coloring with sublimative dyestuffs may be coated on the substrate surface, or alternatively used in the form of a film which is laminated thereon. This kind of film preferably has a thickness of about 3 to 50 μm or so. One of main characterizing features represented in and by the final products **200** is that the appearing display image or images as at **204** is/are formed at least partially or wholly with a sublimative dyestuff or dyestuffs. Additionally, the process for formation of such images can be executed in the conventional art.

As an example, the processing method may be executed conventionally as follows.

As an example, a sublimative image transferable sheet, such as a paper sheet, plastic resin film or sheet capable of acting as the carrier is coated on its surface with any suitable binder resin carrier carrying sublimative a dyestuff or dyestuffs under heat, is overlapped on the display layer **202** and then subjected to heat from behind the heat-transferable sheet, preferably in the pattern mode, so as to transfer the dyestuff or dyestuffs into the display layer **202**. It is proper to select the molecular weight of 250 or larger of the dyestuff, for improving the fastness thereof. However, a molecular weight higher than 370 is more favorable. In the

case of provision of the surface protecting layer, there is practically no limitation to the selectability of the dyestuff molecular weight.

The sublimative image transfer may be executed directly on the surface of substrate **201** provided with the display layer **202**. Or alternatively, a carrying, image transferable sheet is prepared separately and, after formation of the image **204** thereof, may be stuck onto or laminated on the substrate **201**.

Image-carrying and image-transferable sheet

In the following, structure, material, usage and application purpose of the image-transferable sheet to be employed in the present invention will be described in detail:

FIG. **13** illustrates only basically and in schematic sectional view the image-transferable sheet adopted in the present invention, while FIGS. **14** through **19** and **22** through **24** illustrate preferable embodiments thereof.

The basic structure of the image transferable sheet **310** is characterized in that, as shown in FIG. **13**, a sheet-like substrate **301** is provided at its one surface with an image-reception layer **302** capable of peel-off from the substrate. By adopting such a structural configuration of the image-transferable sheet, the image-reception layer **302** can be formed with the required image or images with the use of an image transferable sheet having thermally shiftable dyestuff, and then, the image-formed, image-reception layer **302** is peeled off from substrate **301** and attached firmly, preferably as by sticking, on the surface of any selected object or article with use of any suitable means. In this way, various conventional drawbacks inherent in the comparative conventional technique can be basically overcome.

More specifically, as the material of the aforementioned image-reception layer **302**, limitation must be imposed to those which can be colored with thermally shiftable or transferable dyestuff. However, upon formation of necessary images and upon peel-off from the sheet-like substrate **301**, the image-reception layer **302** may be attached fixedly onto the surface of glass-made, metal-made or wooden-made products or plastic-resin made ones which are very difficult to color with thermally shiftable and transferable dyestuffs, indeed, by reliance on conventional sticking techniques as properly adopted in consideration of the specific nature and kind of the material of decorative products to be ornamented. Further, the image-formed and peeled-off, image-reception layer **302** from the sheet substrate **301**, is highly thin and thus sufficiently pliable so that it may be applied even onto any uneven and complicated surface of a product to be decorated or ornamented, having undulations, convexities, concavities, recesses and projections. Therefore, a maximum possible better fitness of the image-reception layer to be ornamented is attained and guaranteed by the present invention. Thus, practically no limitation in the attaching use thereof may be encountered. Further, in sharp contrast to conventional sealing seals and the like, the very thin image-reception layer bearing necessary images can be applied easily to the product per se in a very uniform manner, thus providing no raised and thickened feeling, and giving rise to no foreign feeling upon attachment.

FIG. **14** shows a further example of the image transferable sheet **310**. In this case, there is provided a parting agent layer **303** on the surface of image-reception layer **302**. Between the latter and the sheet substrate **301**, there is provided a parting agent layer **303'**. If necessary, however, any one of the two layers **303**; **303'** may be dispensed with.

The first parting agent layer **303** is provided for prevention of thermal fusion between the image-reception layer **302** and an image transferable sheet, not shown, as may occur during image transfer and formation on the first layer **302** through transfer of thermally transferable dyestuff from the said transferable sheet to the first layer. If there is no risk of such thermal fusion of the above nature, or when the image-transferable sheet has been already provided with such a parting agent layer, the present provision thereof may be unnecessary. As for another parting agent layer **303'**, it is for the purpose of making the latter peel-off operation, to be executed after image-forming step, easier. When the sheet-like substrate **301** is made of polyester or the like material which has, as it is, sufficient separability from image-reception layer **302**, provision of parting agent layer may naturally be dispensed with.

FIG. **15** illustrates a still further example of image transferable sheet **310**. In this case, between the image-reception **302** and the sheet-like substrate **301**, an intermediate layer **304** and/or parting agent layer **303'** is/are provided. The laminating order is optional and thus not binding. The intermediate layer **304** will serve to assist the image formation to be rather firm and beautiful, the image formation being carried out by transferring the thermally shifting and transferring dyestuff from the image transferable sheet to the image-reception layer **302**. For this purpose, the intermediate layer **304** may take, for example, the form of a cushioning layer or heat insulating layer. When a cushioning layer is provided as the intermediate layer **304**, the cohesion between the image transferable sheet and the image reception layer **302** is greatly improved and the thermal shift and transfer of the dyestuff during image formation with the use of a thermal head is evenly executed, the image formation thereby being carried out amply in correspondence with the supplied image signals. Further, when a heat insulating layer consisting of a highly heat-insulative material is used as the intermediate layer **304**, ineffective release of the heat applied during shift and transfer of the dyestuff from the image transferable sheet to the image-reception layer **302** can be reduced to a minimum possible, the effective thermal efficiency thereby being correspondingly improved and ample image formation being accelerated. If necessary, however, these cushioning layer and heat-øinsulating layer can be prepared independently and arranged concurrently in any arranging order.

Additionally, when the intermediate layer **304** is arranged at a higher level than the parting agent layer **303'**, the intermediate layer **304** will be conjointedly peeled off in the case of peel-off of the image-reception layer **302**. On the contrary, when the intermediate layer **304** is arranged at a lower level than the parting agent layer **303'**, the intermediate layer will remain on the sheet-like substrate **301** after execution of the separation of image-reception layer **302**. In this case, therefore, the intermediate layer **304** may be made preferably and at least substantially transparent, when the peeled-off image-reception layer **302** is stuck on a decorative product, while directing the surface of parting agent layer **303** towards the latter.

In the modifications shown in FIGS. **16**, **17**, and **18**, modified from the foregoing embodiment shown in FIG. **15**, a further protecting layer **305** is provided between the image-reception layer **302** and the sheet-like substrate **301**. This protecting layer **305** serves to prevent deterioration of the formed images in the image-reception layer **302** when the latter is stuck on the decorating product while directing the surface (more specifically the image-formed surface) towards the product. For example, this protecting layer **305** is prepared from a superior material which exhibits at least one of desirous properties such as antiwearing, light-fast, weather proofing and anti-chemical qualities. With the use of

the protecting layer **305** having these superior qualities, the images can represent improved fastness in the above various aspects, even after execution of the foregoing sticking procedure.

In the modification shown in FIG. **16**, the protecting layer **305** is arranged between the intermediate layer **304** and the parting agent layer **303'**.

In the further modification shown in FIG. **17**, the protecting layer **305** is arranged between the image-reception layer **302** and the parting agent layer **303'**.

In still another modification shown in FIG. **18**, the intermediate layer **304** takes the role of the protecting layer **305**.

In each of these modifications, the protecting layer **305** is arranged in neighboring relationship with the partition agent layer **303'**, whereby the image-formed and remotely arranged, image-reception layer **302**, kept in its up-and-down reversed state, is capable of adhering securely to the decorative product, so as to be positioned as an uppermost layer, as may be required. In a still further modification shown in FIG. **19**, derived from that shown in FIG. **14**, a sticking layer **306** is further provided between the image-reception layer **302** and the partition agent layer **303**. It should be noted, however, that such a sticking layer as at **306** may be provided in any one of other foregoing examples and modifications, if necessary, in neighboring relationship with the parting agent layer **303'**.

The provision of such a sticking layer as at **306** is highly valuable when the image-formed and peeled-off, image-reception layer is adhering without position reversal onto the decorative product. With this arrangement mode, the protecting layer **305** shown in FIGS. **16**, **17**, and **18** may be dispensed with. If, however, the protecting layer **305** is composed of a material in the form of a sheet-like substrate, the part to be peeled off is thereby strengthed, the peel-off procedure thus being greatly facilitated.

By previous provision of the sticking layer **306**, the image-formed and peeled-off, image-reception sheet **302** can be caused to adhere as it is onto the decorative product without use of a separate sticking agent. As the sticking layer **306**, an ordinary sticking agent which is active at room temperature can be used. Or alternatively, a heat-sensible or light-sensitive sticking agent may be used, if necessary.

In the foregoing, the main structure of the image transferable sheet employed in the present invention has been described in detail. However, other structural modes than those set forth hereinbefore which occur easily to those skilled in the art may be employable in the invention, and thus they may be included within the scope of the invention without departing from the appended claims.

It should be further noted that, in the present invention, the sheet-like substrate may be provided on its one surface with an image-transferable layer capable of peeling off through the intermediary of only one weakly sticking layer.

FIG. **22** shows only schematically in a sectional view a preferred embodiment of such an image-transferable sheet, denoted with same reference numeral **310**.

As shown in FIG. **22**, the image-transferable sheet **310** represents a basic structural characteristic such that any suitable sheet-like substrate **301** is provided on one of the surfaces with an image-reception layer **302** through an only weakly sticking intermediate layer **402**, the layer **302** thus being easily peeled-off when desired. By providing the image-transferable sheet with such a structural characteristic as set forth above, desired positive or negative images are formed by transferring thermally shiftable and transferable dyestuff from the image heat transferable sheet to the image-reception layer **302**, and the thus image-formed layer is peeled off from the sheet-like substrate **301** and then attached onto any suitably selected product with the use of proper means or attached per se thereon without the peeling-off operation, the substrate then being peeled off, whereby an image-formed final product can be obtained.

In the foregoing example, it should be noted that the image reception sheet **302** per se has only a thin thickness and thus represents only poor feedability during the sheet-feeding period within the printer at the time of image formation, insufficient cushioning effect and only insufficient thermal efficiency during the printing operation, and further, it is very difficult to treat in advance of as well as after execution of the image formation. Therefore, the coexistence of the image-reception layer **302** and the sheet-like substrate **301** is absolutely necessary. In addition, it is a requisite requirement that the image reception layer **302** be easily peeled off from the sheet-like substrate **301** upon execution of the image-forming operation, and thus, the layer **302** and the sheet **301** should not be stuck too strongly together. In order to satisfy this requirement, provision is made of weakly stuck layer **402** therebetween. Thus, it should be noted that the term "weakly stuck" employed in this specification and appended claims may be defined as "to be separable by finger's end and the like means from each other without entailing destruction or breakage of the parts originally stuck together". It is worthwhile to say, in considering the relative relationship between the image-reception layer **302** and the sheet-like substrate **301**, there is no necessity to provide the weakly-stuck layer **402** if the aforementioned peeling-off is very easy to bring about.

FIG. **23** illustrates still another modification of the image-transferable sheet **310** denoted by the same reference numeral **310** only for simplicity and convenience, wherein a further parting agent layer **303** is provided on the surface of image-reception layer **302**.

This layer **302** is provided for occasional thermal sticking between the thermal image transferable sheet, not shown, and the image reception layer **302** in the progress of thermal shift and transfer of the dyestuff from the sheet to the layer **302**. This provision of the parting agent layer **303** may be dispensed with if there is no risk of occurrence of such disadvantageous sticking attachment or the sheet under consideration has already been fitted with such a parting agent layer.

A modification shown in FIG. **24** from that shown in FIG. **23** has such a modified structure that a protecting layer **305** is provided between the image-reception layer **302** and the weakly stuck layer **305**. This layer **305** serves to prevent otherwise occurring deterioration of the images at the image-reception layer **302** which has been formed with preferably reversed images and subjected to peeling-off, together with protecting layer **305**, preferably a plastic sheet layer, from the sheet-like substrate **301** and finally stuck onto the decorative product, while directing the image-formed surface of the image-reception layer towards the product. The protecting layer **305** is .made of a material having various excellent physical properties, such as anti-wearing-, light-fastness and antichemical characteristics. Provision of such a protecting layer improves various fastness performances of the formed images after sticking attachment of the image-reception layer **302**.

When necessary, a separate parting agent layer, not shown, may be provided between the protecting layer **305** and the weakly stuck layer **402** for providing easy peel-off capability between these two layers **305** and **402**, as being applicable to the example shown in FIG. **24**. If the surface of the protecting layer **305** should have sufficient peel-off

capability, it is natural to provide such an intermediate parting agent layer as above.

Further, in the case of the image-transferable sheet **310**, it is naturally easy to separate from each other through a peel-off operation, upon the formation of necessary images thereon and before practical use thereof as the image-transfer sheet, and a cut-out slit as at **407** in the sheet-like substrate **301** may be provided for attaining such an easy separation as stated above at a portion of the sheet **310** in proximity to one end thereof. Upon the provision of such a cut-out slit as at **407**, the thus formed flap-like portion can be easily folded out by the operator's finger-tip, thereby affording convenience in a peel-off operation.

The usable materials and composing methods of the foregoing image transferable sheets will now be described.

As a material usable for the sheet-like substrate may be any one or any combination of the following categories:

(1) synthetic paper (polyolefin-series; polystyrene series and the like);

(2) fine quality paper; art paper; coated paper; cast-coated paper, wall paper; back-up paper; backing paper; resin-, emulsion- or synthetic rubber-imprignated paper; resin-admixed paper; paper board; cellulose fiber paper;

(3) polyolefin-, polyvinyl chloride-, polyethylene terephthalate; polystyrene; polymethacrylate; polycarbonate and the like plastic film or sheet.

Use of the synthetic paper belonging to the foregoing category (1) is highly suitable for the purpose of the present invention since the surface thereof generally represents a microvoid layer which provides a low heat conductivity and thus a high heat-insulating peformance. A laminated material representing any combination of the foregoing categories (1), (2) and (3) can be used in the present invention. A representative and recommendable example of such a laminate is that of cellulose fiber paper and synthetic paper or that of cellulose fiber paper and plastic resin film or sheet. Among others, use of the first mentioned kind of laminate will provide an advantage in that the thermal instability such as thermal elongation or shrinkage possessed by the synthetic paper component is compensated for by the cellulose fiber paper, whereby a high thermal sensibility is demonstrated during the printing step due to low thermal conductivity of the synthetic paper component. Further, in the case of the present paper combination, however, a further modified combination of a three-layer laminate: synthetic paper-cellulose fiber paper-synthetic paper may be more advantageously employed for making the frequently appearing lesser by providing a well-balanced structure between both the surfaces of the final laminate.

As the synthetic paper mentioned above, any suitable one usable as a synthetic paper substrate used as a component of the image-transferable sheet layer may be used. As a recommendable example thereof, having a fine porous fine paper structure layer, the synthetic paper called "YUPO", manufactured and sold by Oji Yuka Goseishi Kabushiki Kaisha, Tokyo, may be mentioned. This paper layer having a fine pore structure may be prepared in such a way that a suitable plastic resin material containing a filler of finely divided state is subjected to a mechanical elongation step. When the image-transferable sheet composed of the synthetic paper sheet containing finely divided air as above mentioned is formed with images through a thermal image transfer setp, the concentration of the thus formed images is surprisingly high and no fluctuation of image configuration and concentration is encountered, thanks to the heat insulation effect provided by the very existence of fine air pores, in addition to the improved thermal energy efficiency. Especially, due to the advantageous cushioning effect provided by the air-filled fine pores, the image-receiving layer is supposed to be rather advantageously affected during the image formation step. As an alternative measure, the paper-like layer containing the above-mentioned fine air pores may be, if desired, provided directly with the core material consisting of the cellulose fiber paper or the like.

It is further possible to use plastic film in addition to the cellulose fiber paper in the laminate described above. Still further, a laminate of said cellulose fiber paper and plastic film composed together can be used.

As the method for co-sticking of synthetic paper and cellulose fiber paper, use of a known adhesive agent is naturally adopted, as an example. Or alternatively, the extrusion-laminating, heat-adhesion, or the like process may be relied upon, as the case may be. On the other hand, as the sticking-process between the synthetic paper and the plastic film, the lamination process to be carried out simultaneously with the formation of the film may be adopted. Calendering or the like method may be utilized for the same purpose. Selection of any suitable one of the several foregoing sticking processes depends upon the kind of material or the like condition of the partner member to be stuck together with the synthetic paper. As for the adhesive agent mentioned above, emulsion adhesive such as ethylene-vinyl acetate copolymer, polyvinyl acetate or the like, aqueous solution type adhesive polyester containing carboxyl radicals; or the like may be mentioned. On the other hand, as the laminating use adhesive, organic solvent solution type one such as polyurethane-, acrylic- or the like, may be mentioned.

The material for the image-reception layer must be suitable for reception of heat-transfer dyestuff, such as sublimative disperse dye from the image transfer sheet and holding and maintaining the thus formed images thereon. From the view point of image-holding and blocking prevention, use of such synthetic resin as having glass transition temperature higher than 40° C. may be advantageous. For example, the synthetic resins set forth in the following items (a) through (e) may be used separately or in combination.

(a) Ester bond-bearing resins:

Polyester resin; polyacrylic ester resin; polycarbonate resin; polyvinyl acetate resin; styrene acrylate resin; vinyltoluene acrylate resin and the like.

(b) Urethane bond-bearing resins:

Polyurethane resin and the like.

(c) Amide-bond carrying resins:

Polyamide resins (nylons).

(d) Urea-bond carrying resins:

Urea resins and the like.

(e) Other high polar-bond carrying substances:

Polycaprolacton resin; polystyrene resin; polyvinylchloride resin; polyacrylonitrile resin and the like.

The image-reception layer may be prepared from a resin mixture of saturated polyester and vinyl chloride-vinyl/acetate copolymer. As the saturated polyester, such commercialized products: "Vylon 200"; "Vylon 290"; "Vylon 600"; "Vylon 103" and the like, manufactured and sold by Toyoboseki K.K., Osaka, Japan; "KA-1038C" (manufactured and sold by Arakawa Kagaku K.K., Osaka, Japan; "TP 220"; "TP 235", manufactured and sold by Nippon Gosei K.K., Osaka, Japan; may be advantageously used. The vinyl chloride-vinyl acetate copolymer may have preferably 85–97 wt. % of vinyl chloride component, the polymerization degree being between about 200 and 800. The vinyl chloride-vinyl acetate copolymer may further contain a vinyl alcohol

component, maleic acid component within the purpose of the invention in addition to the main components. According to our experiments, it has been found that these modified copolymers should have rather superior compatibility with polyester resin. The image-reception layer may be, if necessary, composed of polystyrene resin, for example, in this case, styrene monomer, preferably styrene, α-methyl styrene, and vinyl toluene may be used separately or in the form of copolymer or saying in general sense polystyrene resin. Further, such styrene copolymer resin may be used as specifically recommendable material in the above sense, comprising said styrene monomer(s) with other monomer, preferably for example, acrylic acid ester, methacrylic acid ester, acrylonitrile, methacrylonitrile and the acrylic or methacrylic monomer, or further styrene copolymer resin comprising maleic acid anhydride.

It should be noted, however, that among others, polyester series resin is especially superior for the purpose of the present invention.

In any of the foregoing embodiments, however, white pigment is preferably admixed with the material of the image-reception layer for improving the whiteness thereof and further accentuating the sharpness and fineness of the images when transferred thereto and to provide a manually writing-on performance. As the white pigment for this purpose, the following materials may be used separately or in any combination: titanium oxide; zinc oxide; china clay calcium carbonate; finely divided silica and the like.

For further improving the whiteness fluorescent whiteness-increasing agent or -bleaching agent may be added to. Further, for improving the light fastness of transferred images, ultraviolet absorption agent and/or photostabilizing agent may be added to, preferably in a quantity of 0.05 to 10 and 0.5 to 3 weight parts per 100 weight parts of the material resin composing the image-reception layer.

The image-transferable sheet used in the present invention is preferably constituted for improving the separability from the image-transfer sheet in such a way that the surface of the image-reception layer is formed with a partition agent layer, or instead, such agent is admixed to the image-reception layer. As for the partition agent to be used for this purpose, polyethylene wax; Amido Wax, Teflon Powder or the like solid wax; surface active agents such as fluorine-contained agent or phosphoric acid ester series surfactant; silicone oil or the like may be selectively used. Among others, silicone oil may be advantageously utilized.

The silicone oil may be used in oily state, but a hardenable type thereof may be rather advantageous. As the hardenable silicone oil, reaction-hardening one, photo-hardening one, catalytically hardening or the like one may be used selectively according to necessity. However, use of the reaction-hardenable one is most highly recommendable. Silicone oil of this type may be obtained, as example, by reacting amino-modified silicone oil with epoxy-modified silicone oil to obtain a reaction-hardened product. As for the amino-modified silicone oil, "KF-394", "KF-857", "KF-858"; and "X-22-3680"; "X-22-3801C" (manufactured and sold by Shinetsu Kagaku Kogyo K.K., (Tokyo, Japan)) and equivalents thereof may be used. As for the epoxy-modified silicone oil, "KF-100T"; "KF-101"; "KF-60-164"; and "KF-103" (manufactured by Shinetsu, above mentioned) and equivalents thereof may be used. Further, as the catalytically hardenable and photohardenable silicone oils in the above sense, "KS-705F"; "KS-770" of the catalytic hardenable or hardened silicone oils, manufactured by Shinetsu; and "KS-720" and "KS-774" of the photo-hardenable or hardened silicone oils (manufactured equally by Shinetsu) and equivalents thereof may be used. The adding quantity of each of these hardenable or hardened silicone oils may advantageously range from 0.5 to 30 wt. % depending on the material of the resin composing the image-reception layer.

At least a part of the image-reception layer is coated with a solution or dispersion of any of the foregoing partition agents in a suitable solvent and dried and further treated, a suitable parting layer being provided thereon. A particularly suitable partition agent for the formation of this kind of partition layer is the aforementioned reaction type hardenable one obtainable by reacton of an amine-modified silicone oil with an epoxy-modified one. The thickness of the partition layer is 0.01–5 μ, preferably 0.05–2 μ.

It should be noted that when silicone oil is admixed during formation of the image-reception layer, the silicone oil will bleed out after coating and the parting agent layer can be formed by the hardening even after such bleeding. In order to improve the parting ability between the image transferable layer and sheet-like substrate, it is possible to provide a parting layer consisting of a heat-hardenable resin, preferably of the melamine series, and having better affinity for the image transferable layer compositions. For the same purpose as above, however, without special provision of the parting layer, a protecting layer consisting of polymethyl methacrylate resin or cellulose acetate propionate can be provided.

For the formation of the image transferable layer, a solution or dispersion of a material composition suitable for the purpose is applied on the sheet-like substrate through conventional coating or printing. As an alternative way, a separate film or sheet for the image transferable layer **302** is formed preparatorily on a provisional carrier sheet or film and then, as a succeeding step, subjected to an image-transfer onto the substrate.

The intermediate layer is made of either a cushioning or a porous material. In some cases, the intermediate layer may additionally function as the adhesive layer.

The cushioning layer is mainly composed of such a resin which has a value of 100%-modulus as defined at JIS-K-6031 (Japanese Industrial Standard) of less than 100 kg/cm^2. If this value should exceed the above prescribed value, the rigidity will become much higher than that recommended for the intermediate layer. When the layer is formed with such disadvantageous material resin, sufficient adhesion between the heat image-transfer sheet and the image-reception layer cannot be maintained during the printing step. The lower limit of the prescribed 100%-modulus is of the order of 0.5 kg/cm^2 in actual practice.

Preferable kinds of resin to be used for the above purpose, may be enlisted as follows:

polyurethane resin; polyester resin; polybutadine resin; polyacrylic acid ester resin; epoxy resin; polyamide resin; rosin-modified phenol resin; terpene phenol resin; ethylene/vinylacetate copolymer resin; and the like.

These resins can be used independently or in combination of two or more kinds. Since these resins are rather viscous and tend to give rise to manufacturing troubles inorganic additives may be admixed, such as, for example, silica; alumina; clay; calcium carbonate; amide series substance such as amide stearate; and/or the like.

The cushioning layer is preferably formed with the use of one or more of the above specified resins, occasionally with the addition of suitable additive(s); solvent or diluent, prepared into a coating agent or printing ink which is then applied on, according to a known coating or printing process and then subjected to drying to provide a coating. The

thickness of the coating should be between 0.5–50 μm, preferably 2–20 μm or so. With a thickness less than 0.5 μm, the coating will not be able to compensate for the surface irregularities on the substrate, thus being ineffective for the desired purpose. On the other hand, when the thickness exceeds the above specified maximum value or more specifically 50 μm, the overall thickness of the image-transferable layer becomes much too large, so that handling troubles may be encountered during wind-up and overlapping procedures, without attaining further effect as desired. In addition, in this case, a loss of production economy will be inevitably introduced.

The thus obtainable improvement of intimate adhesion between the heat-image transfer sheet and the thermally image-transferable sheet by the provision of the above intermediate layer may .be conceivably attributed to the lower rigidity of the intermediate layer per se, whereby it is liably to be deformed under the influence of the printing pressure, and further to the generally relatively low glass transition temperature and softening temperature of the aforementioned kinds of resin resulting in further lowering of rigidity and tendency to deform than at room temperatures upon reception of heat energy during the image printing step.

The porous layer may be formed generally in the following four ways: 1) through 4).

1) Emulsion of polyurethane or the like resin, methylmethacrylate-butadiene series synthetic rubber latex is foamed by mechanical agitation, coated, and dried on the sheet substrate into a layer.

2) The synthetic resin emulsion or synthetic rubber latex is admixed with a .foaming agent and the liquid mixture is coated and dried on the substrate into a layer.

3) Vinyl chloride-plastisol, polyurethane or the like synthetic resin or styrene-butadiene series or the like synthetic rubber is added with a foaming agent and the liquid mixture is coated on the substrate and subjected to heating to provide a foamed layer formed thereon.

4) A thermoplastic resin or synthetic rubber is dissolved in an organic solvent to provide a solution, and a non-solvent (including that containing aqueous main component), and the latter solution are mixed together to provide a liquid mixture, said nonsolvent being less volatile than the organic solvent and having a considerable mutual solubility with the solvent, and showing, however, non-solubility with the thermoplastic resin or synthetic rubber. The thus prepared liquid mixture is then coated on the sheet-like substrate and dried, to provide a porous membrane upon micro-coagulation of the constituents. The resulting microporous layer can be utilized for the above purpose.

It should be noted that the layers produced by any of the foregoing three processes 1) to 3) have rather large foams contained therein, and thus when the foaming solution for the image-transferable layer is applied thereon and dried, the latter may exhibit excessively coarse surface conditions. Therefore, in order to obtain an optimumly image-transferable smooth surface capable of providing transferred images of high uniformity, provision of the micro-porous layer prepared by the process as set forth in the foregoing item 4) is highly recommendable.

As the thermoplastic resin suitable for the formation of the above porous layer, saturated polyester; polyurethane; vinylchloride-vinylacetate copolymer; cellulose acetopropionate and the like can be used. Further, as the synthetic rubber usable for the same purpose, those of styrene-butadiene series, isoprene series, urethane and the like series may be used. Still further, as the organic solvent and non-solvent liquid used for the formation of the microporous layer, various known substances may be used. Generally speaking, however, methyl ethyl ketone; alcohol and the like are representatively used. On the other hand, as the non-solvent, water is mostly used.

The thickness of the porous layer usable in the present invention is preferably greater than 3 μm, especially preferably in the range of 5 to 20 μm. With the use of a porous layer having a thickness of less than 3 μm, the desired cushioning and heat-insulating effects cannot be attained.

As was referred to hereinbefore in the description stage for the formation of the image-transferable layer, the intermediate layer may act simultaneously as the sticking layer in some cases.

This kind of intermediate layer(s) may be provided on one or both of the surfaces of the thermally image-transferable sheet.

In practice, however, an electrostatic charge may accumulate in the material of the thermally image-transferable sheet during its processing step or during running through the printer. As a countermeasure, a proper antistatic agent may be applied on one surface of the image-transferable layer or on the bottom surface of the thermally image-transferable sheet or it can be included in the material of the image-transferable layer. As the antistatic agent in this sense, a surfactant such as a cation-exchange agent (for example, a quaternary ammonium salt, polyamide derivatives and the like) may be advantageously used. Further, an anion exchange type surfactant, such as alkyl sulfonate may be used. Otherwise, amphoteric ion type surfactants or even, nonionic surfactants may be used for the same purpose.

On the other hand, the antistatic agents may be coated on the surface of image-reception layer by gravure-coating, bar-coating or the like process or alternatively, these agents may be kneaded with the material resin and then subjected to transfer towards the surface during the coating formation and drying step for preparing and providing the image-transferable layer. As the antistatic agents to be admixed with the image-transferable layer material resin, cation-type acrylic polymers may be employed.

The protecting layer is peeled off together with the image-transferred layer, from the sheet-like substrate, and then stuck, in inverted reversed state, onto any desired decorative object, the protecting layer thereby being positioned at the uppermost position, for improving the anti-wearing-light-proofing and anti-chemical performances of the image-bearing layer. As the material adapted for the formation of the protecting layer, for example, alkyd resin; phenol-modified alkyd resin; aminoalkyd resin; phenol resin; urea resin, melamine resin; silicone resin, thermosetting acryl resin, thermosetting polyurethane resin and the like thermosetting resin or normal temperature setting resin; further, ultraviolet hardenable resin; electron ray hardenable and the like activating energy flux hardenable resins or thermoplastic resins such as polyester-; polyurethane-; polyvinyl acetate resin; vinyl chloride-vinyl acetate copolymer resin; polyolefin resin, acryl resin and the like, can be used.

Preparation and use of a protecting layer comprising one or more of the above-mentioned resins are made in such a way that the material resin is dissolved in a properly selected solvent according to the necessity, so as to provide a coating liquid or ink, as the case may be, which is provided between the parting layer and the image transferable layer. The thickness thereof is generally 0.5 to 20 m. It is also possible to form the protecting layer with the use of a resin film which consists of polyester-; acryl-; acrylpolyol-; polyvinyl chloride-; olefin resin or the like resin. It is further possible

advantageously to admix an ultraviolet ray absorbing agent and/or photostabilizer to the material of the protecting layer.

The protecting layers prepared and formed in the foregoing way are thus not made integral with the sheet-like substrate or parting layer and, therefore, the peel-off operation of the sheet-like substrate upon execution of the image transfer is very simple and easy.

It is further recommendable, if necessary, to provide a slip-promoting layer on the bottom surface of the sheet-like substrate, which surface is naturally the one opposite to the image-transferable layer side, so as to properly adjust the friction between the image-transferable sheet and feed roll paper or carrier belt acting during passage through the printer and to improve the running performance of the thermally image-transferable sheet in the printer.

The slip-promoting layer can be formed by adding an organic powder such as polyethylene wax fluorine resin powder or an inorganic powder such as talc, according to necessity, to a resin such as polymethyl methacrylate resin; vinyl chloride-vinylacetate copolymer; vinyl chloride copolymer; cellulose acetate butylate; cellulose acetate propionate; styrene-acryl series or the like resin and kneading the resulting mixture to prepare a composition, applying this composition as a coating on the sheet substrate either directly or after application of a suitable primer treatment, and drying the coating thus applied. A suitable quantity of the slip-promoting layer is 0.5 to 5 g/m^2 after drying.

In the embodiments shown in FIGS. **22**, **23**, and **24**, as the adhesive agent to be used in the slightly weak or weak adhesive layer, it should be noted that those conventionally used adhesives for adhesive tapes and seals can all be used. Preferred examples are polyisoprene rubber; polyisobutyl rubber; styrene butadiene rubber; butadiene acrylonitrile rubber and the like rubber-series resins; (meth)acrylic acid ester-series resins; polyvinyl ether-series resins; polyvinyl acetate-series resins; vinylchloride-acetate copolymer series resins; polystyrene-series resins; polyester-series resins; polyamide-series resins; polychlorinated olefin-series resins; and polyvinyl butyrol-series resins. To the suitably selected adherent may be added a proper quantity of a stickness improver, such as rosin; dammar; polymerized rosin; partially hydrogenated rosin; ester rosin; polyterpene-series resins, terpene-modified substances; petroleum-originated resins; cycropentadiene-series resins; phenol resins; styrene resins; xylene resins; and coumarone-indene resin. Further, when necessary, to the mixture may be added a softening agent, filler; antiaging substance or the like conventional agent(s). As the material for the formation of slightly or weak-adherent layer said above, emulsion type adhesive, preferably of acryl acid ester series can be used. As for the parting function after a long time of preservation, emulsion type adhesives are highly recommendable. These adhesive agents are easily procurable from market.

When necessary, these adhesives are added with proper organic solvent(s) for the adjustment of the viscosity, and then applied by roll coating, die-coating, knife coating, gravure coating or the like conventional technique on the surface of the sheet-like substrate, image-reception layer or protecting layer, so as to provide an adhesive agent layer. The thus formed adhesive layer is preferably of a thickness of 1–50 μm, although this is not limitative.

Formation of Images

In the following, the decorating process according to this invention will be set forth in detail. Utilization of the image-transferable sheet according to this invention constitutes an important main feature thereof.

In FIGS. **20** and **21**, basic practising processes will be described first.

The embodiment shown in FIG. **20** is a result of the use of the transferable sheet shown in FIG. **13**. First, a known transfer sheet **320** is applied onto the image-transferable sheet **310** in an overlapped manner such that the dye-carrying layer **321** is kept in opposition to the image-reception layer **302** of image-transfer sheet **320**, and heat energy is applied, as schematically shown by a plurality of arrows, in accordance with image signals fed at a thermal head, not shown, from the side of image-transferable sheet **310**, or preferably, from the side of the image-transfer sheet **320**, thereby forming the desired images as at **307** in the image-reception layer **302**. Next, the image-reception layer **302** formed therein with the desired images **307** is peeled off from sheet-like substrate **301** and stuck onto the decorative product **306**. Or alternatively, both the sheets **302**; **301** are stuck onto the product **306** without preparatory peeling-off. In the latter case, the peel-off step may be executed after execution of the stickingly attaching step. In the above former case, and in such a case where an adhesive agent layer **306** has preparatorily provided between image-reception layer **302** and sheet-like substrate **301** as was set forth hereinbefore, the sticking attachment is carried into effect in such a way that the adhesive layer **306** is kept in opposing contact with the product **330**, and then the sticking operation is brought about by application of heat and pressure or light and pressure, depending upon the nature and structure of the layer **306**. In this way, the decoration according to the present invention is completed as a preferred one mode thereof.

On the other hand, if there is no preparatory provision of the adhesive layer, either the surface of product **330** or of the peeled-off image reception layer **302**, may be coated with the adhesive agent, and the latter layer **302** per se or otherwise in the up-and-down reversed state may be stickingly attached onto the product **330** (refer to FIG. **21**).

Since the image-reception layer **302** is composed generally of such thermoplastic resin material as is liable to be colored with thermally transferable dyestuff, it can be thermally and fusingly attached to plastic resin-made formlings, clothes or metals even with provision of an adhesive layer, if necessary.

In this case, the image-bearing layer **302**, the image thereof having been formed in the aforementioned way, is stuck on, through the intermediary of the adhesive agent layer **306** as shown in FIG. **25**, while retaining the sheet-like substrate **301** on the surface of the image-reception layer **302**.

A modification of the last-mentioned mode is shown in FIG. **26**. In this case, sheet-like substrate **301** is formed on the surface of the product **330** and the image-reception layer **302** is formed as the outermost layer. Further, in this case, sheet-like substrate **301** and product **330** may be stuck together, and, through the intermediary of a suitable adhesive layer, sticking layer or heat-sealable sheet or the like.

As for the transparent film usable as the said sheet-like substrate, it must be transparent to such a degree as not to conceal the images formed in the image-reception layer, and, in addition, it must have superior surface properties such as, for instance, antiwearing characteristics. As an example, polyolefine; polyvinyl chloride; polyethylene terephthalate; polystyrene; polymethacrylate; polycarbonate and the like plastic resin-made films may be used upon variously surface conditioning. If these transparent films should be too thick, the images will be raised, and the unitary feelings may be lost when these are stuck on respective products to be decorated. Therefore, the film thickness is preferably of the order of 0.5 to 50 μm.

In the case of a further embodiment of the present invention, the image reception layer of image transferable sheet which has been, however, formed with necessary images is subjected to image transfer treatment onto an intermediate image transferable substrate, the latter is then subjected to an image-retransfer with the images, and the thus retransferred images are again transferred onto the surface of the product to be decorated. In the following, this image transfer mode will be set forth in detail.

Embodiments shown in FIGS. **27**, **28** and **29** represent such a process for execution of image transfer operation as by the intermediary of intermediate image transfer sheet **510**. First, as shown in FIG. **27**, a thermally image-transfer sheet **320** having a thermal transferable dyestuff layer **321** is overlapped to image-transfer sheet **510** which is, at this stage, not formed with images **307** and thus consists of a thermal image-transferable sheet, in such a way that .the dyestuff layer **321** or more specifically the parting layer **322** is in opposition to the image-reception layer **302** of the foregoing sheet **510**. In such a case, however, that heat energy is supplied in accordance with image-forming signals delivered from the thermal head, not shown, and, indeed, preferably from the side of the sheet **320** as hinted by a plurality of doubleline arrows for thermal formation of desired images (positive images) as at **307** in the image-reception layer **302**, it is highly recommendable to provide an adhesive layer **402** between the layer **302** and sheet-like substrate **301**.

Then, with the use of the image transfer sheet **510** formed with positive images **307**, the images of layer **302** are transferred, as shown in FIG. **28**, to a separate intermediate substrate **501**, which is, however, fitted with a protecting film layer **305**, thus, the transfer being carried out, in fact, onto the latter, and indeed, with the correspondingly inverted images, attached with same reference numeral only for convenience, from the foregoing layer **302**. In this case, it is preferable to subject the adhesive layer **402** of the image-transfer sheet **510** to the image-transfer operation, together with the image-reception layer **302**. Further, as for the intermediate image-transfer substrate **501**, it is recommendable to provide the protecting film layer **305** through the intermediary of a weak-adhesive layer **402'** as shown. The thus provided intermediate image-transfer sheet **610** represents generally the image-transferable sheet.

FIG. **29** illustrates the step for transfer of the image-reception layer **302** now carrying positive images **307** onto the object **330** to be decorated and under utilization of the previously described intermediate image-transfer sheet **610**.

More specifically, the intermediate image-transfer sheet **610** is overlapped onto the said object **330** in such a way that the adhesive layer **402** of the former in opposition to the surface of the object **330** and pressurized together. Then, the intermediate transfer substrate **501** together with the weak-adhesive layer **402'** is peeled off from the remainder of the thus-pressurized assembly, the now image-carrying layer **302** formed with positive images **307** covered with protecting the film layer **305** thereby remaining in the transferred state on the product **330**. In the case of no provision of the protecting film layer **305** on the intermediate image-transferable sheet **610**, the layer **302** remains in an exposed state. Therefore, an overcoat layer, if necessary, can be provided on the now image-carrying layer **302**.

The previously set forth process carried out by the use of said intermediate image-transferable sheet can be executed by means of the apparatus which is shown schematically in FIG. **1E**.

In this apparatus, more specifically, there is provided a carrier system comprising a series of rolls **411**, **412**, **413** and **414** for conveying the intermediate transfer substrate (sheet), arranged in addition to the apparatus shown in FIG. **1B**. More specifically, the substrate is drawn out from feed roll **414**, conveyed through successive rolls **413**; **412** and retransferred onto one of the products **200**. Other operations are same as set forth hereinbefore with reference to FIG. **1B**. Further, in the case of FIG. **1E**, the final product may take the form of a roll-like substrate which is subjected to an image transfer operation through the intermediate substrate, by transferring its image-carrying, image-transferable layer, for later being punched out properly. Alternatively, under occasion, it may be subjected to half-cut operations downstream of roll **122**.

As was set forth herein above, the preferable method for the formation of desired images on the image-transferable sheet is carried out by use of a heat image-transfer sheet comprising a sheet-like substrate having a layer including a thermally transferable dye (evaporative dye). The heat image-transfer sheet which can be utilized in this method is known per se. And almost every kind of these known sheets can be useful in the practice of the present invention. It should be noted that by employing the foregoing image-transfer method, mono-color or full-color images can be easily formed as occasion may desire.

It should be further noted that details of such heat image-transferable sheet can be easily understood with reference to our U.S. patent application Ser. No. 833039. As for the heat image-transferable sheet usable in the present invention, the coating layer of the sheet (coating film) may include a parting agent. By adopting this measure, the image-reception layer of the image-transferable sheet or the surface thereof, to be subjected to sublimative image-transfer, must not have a separate parting agent layer, the adhesive ability between the image-reception and the surface of object to be decorated can be still further improved upon execution of the sublimative image-transfer and image-formation at the image-reception layer and adherent attachment thereof to the object. As the parting agent to be included in the coating layer of the thermally image-transferable sheet (coating film), silicone oil; silicone resin; phosphoric ester or the like surfactant; and/or chelate- and the like agents, may be selectively utilized. These agents, upon mixed, will ooze out from inside to the outer surface of the coating layer, resulting in providing a better parting quality. However, it is preferable to properly select the kind and nature of the parting agent to be used for this purpose, being such that the agent cannot transfer to the image-reception layer of the image-transferable sheet during the sublimating image-transfer stage. The adding quantity of the parting agent may preferably be 3–25 wt. parts based upon the total amount of resin and coating composing the coating layer taken as 100 wt. %.

In practice, any kind of conventionally known heat transfer sheets is overlapped on the thermally image-transfer sheet employed in the present invention, and then necessary heat energy of 5–100 mJ/mm^2 is applied by use of a conventionally known heat transfer unit, for instance, "Video-printer: VY-100" manufactured and sold by Hitachi Seisakusho, Tokyo, or its equivalent machine, for the formation of necessary images on the image-reception layer of the image-transfer sheet as set forth hereinbefore.

Peel-off operation for removal of the image-reception layer formed with necessary images in the above manner may be carried into effect in a very easy manner, so as to provide it in a thin film carrying the images thereon. In case where the thus-peeled off film carrying the images is provided beforehand with an adhesive layer, composed of a suitable adhesive agent as was referred to, at the opposite

surface to the image-carrying one, the peeled-off film can be, as it is, stuck on the object to be decorated. It is natural that this adhesive attachment procedure can be performed only partially and locally on selected part of the whole surface of the object, or totally thereon, as the case may be. On the contrary, if the peel-off film is provided beforehand with no adhesive layer, the film can be subjected occasionally to a heat fusion onto the surface of the object, if the physical properties or material kind thereof is suitable for such kind of thermal fusion. Or alternatively, a properly selected adhesive agent can be preparatorily applied onto the surface of the film or object, and then, the stick-on job can be executed.

If the image-reception layer is provided preparatorily with a parting layer thereon, as was referred to, the latter layer can be removed off partially or wholly, by grinding or rubbing operation after execution of the sublimating image-transfer job, for avoiding otherwise occurrence of ill effect by the very presence of parting layer in the adhesive attachment of the image-carrying layer film onto the decorative object.

In case of that where the image-transferable sheet is provided with a protecting layer and the latter is composed of a plastic resin film, this film may preferably be cut into pieces or subjected to punch-cuttings.

FIG. **32** illustrates successive die-cutting steps in sectional views, serving for the above purpose. In this case, as shown in FIG. **32** at (a), only image-reception layer **305** of the image-transferable sheet **310**, which has been image-formed through the way of the foregoing image-transfer step, are die-cut by operation of a cutter **801**. Next, as shown in FIG. **32** at (b), a pair of hot stamps **132'**; **133'** are used to execute a pressurizing job under heat from opposite sides, thereby the decorative product **330** being processed into a final product provided tightly with an image-reception layer and a protecting layer, as shown in FIG. **32** at (c).

Further, when occasion desires, the image-carrying film is reversed up-and-down in position after execution of the peel-off job, and, the film is stuck onto the product to be decorated in such a state that the image-carrying surface of the film is kept in direct opposition to the product's decorating surface. In this case, however, it would be rather preferable that in advance of preparatory peel-off of the image-reception layer, the image-carrying transferable sheet is stuck onto the surface of the product to be decorated, and indeed, preferably with use of an adhesive agent, in such a way that the image-carrying layer is kept in direct opposition to the product surface and finally, the sheet-like substrate is peeled off, so as to leave the image-carrying surface on the product's surface.

As in the foregoing, when the images are once reversed and then stuck onto the object to be decorated, the forming images are preferable to reverse in mode (mirror-like relationship) the original to those of reversed mode.

It is further possible that the transfer or sticking-on of the image-carrying layer is carried out through the intermediary of a separate fusing sheet.

In FIG. **30**, use of such fusing sheet **701** for reimage-transfer operation of image-carrying layer **2** already formed with necessary images **307**, however, of reversed mode, and onto the surface of a product.

More specifically, the image-transferable sheet **310** is overlapped onto the product **330** to be decorated in such a way that the image-reception layer **302** carrying the necessary images **307** is kept in opposition to the surface of the product, and indeed, through the intermediary of a fusing seat **701** and then these three components are pressurized together. Further, sheet-like substrate **301**, together with parting layer **303'**, is peeled off, thereby the image-reception layer **302**, now having positive images **307** formed thereon, and protecting the latter, being transferred onto the product **330**. It will be seen in this case, that there is no need for this transfer job, to provide in advance on adhesive layer on the surface of image-reception layer **302** and/or on the surface of the product **330**, and further that a direct heat fusion onto the surface of the product **330** which may be composed of plastic resin, textile fabric, metal or the like common material, however, through the intermediary of a heat-fusible or heat-sealable sheet.

In case where the protecting layer **305** is of plastic resin, similar composing technique as mentioned above may be employed by substituting a weak-sticking layer **402'** for parting layer **303'**.

As the heat-fusible or heat-sealable sheet as at **701** employable in the present invention, it may be composed of one or other material capable of adhering under heat, pressure or both, especially suitable one of those which become soft to be adhesive upon heating. These heat adhering materials in the form of sheets will be, upon softening, charge the pores, meshes or stitches of the product material composed preferably of textiles, woven or non-woven; knits, rough-surface papers or meshed materials, thereby the surface of the product becoming highly smooth for well receiving the image-reception layer **302** for desired image-retransfer with trouble, which effect is superior in the art.

On the contrary, when such heat-fusible or heat adhesive sheet materials which may be called "heat bond sheets" as at **701** are not utilized, it is highly difficult to realize the image-retransfer operation onto certain kind of objects such as rough-surfaced or rough-meshed fabric or the like. Even if the retransfer job could be executed, the obtained images may be blurred and the adhesive may be insufficient, on account of the very thin thickness of the image-reception layer **302**, thus giving rise to technical and commercial troubles.

As for the heat fusible sheet **701** to be used in the foregoing manner, ethylene/vinyl acetate copolymer, nylon copolymer; epoxy/phenol copolymer; epoxy/vinyl copolymer; acrylic resin; polyester resin; or polyolefin resin and the like thermoplastic resins (heat sensible adhesive agents) which are formed into sheets or films may be used. These materials must be softened at 100°–250° C. or so to represent viscous adhesive characteristics. These materials are, when used, capable of being stuck to both the image-transferred product **330** and the image-carrying layer **302**.

These heat bond sheets **701** have generally thickness of 1–200 μm. When the surface of the product **330** to be decorated is relatively smooth, the sheet selected out may be of relatively thin thickness, while, on the contrary, when the surface of the decorative product **330** is relatively rough, as in the case of textile fabrics, unwoven fabrics, meshed fabrics or the like, use of thicker heat bond sheets is rather recommendable.

As set forth above, the use of heat bond sheets is highly recommendable in the decorative image-transfer onto rough surface products, such as those of rough fabrics, woven or non-woven, knitted clothes, meshed one or the like, thereby a better quality image-transfer being executed, in spite of the meshed or highly undulating surface conditions of the objects to be decorated.

Further in the present invention, during the adhering attachment of the image-reception layer already formed with necessary images onto the object or product, an additional processing step is preferably introduced for prevention of occasional interference in the foregoing adhering attachment

step, by rubbing-off or grinding-off part or whole of the parting layer, provided on the surface of the now image-carrying layer, upon completion of the sublimating image-transfer step.

Still further, in such a case that the image-transferable sheet is fitted with a protecting layer which is composed of a plastic resin film, the latter must in advance be subjected to punching or the like cutting step for cutting the film into desirously sized pieces.

FIG. **32** represents such a die-cut (half-cut) process in sectional schema. In this case, at first, as shown at (a) of FIG. **32**, the image-reception layer **302** of an image-transferable sheet **310**, now formed with necessary images through a sublimative image-transfer step, and the protecting layer **305**, are subjected to a die-cutting process by means of a cutter **801** to shape a desired shape. And then, as shown at (b) in FIG. **32**, the cut-out piece is subjected to a pressurizing step under heat by means of a pair of hot stamps **132'**; **133'** to provide a final decorative object, as shown at (c) in FIG. **32**, which is composed of a product **330** to be decorated, however, now attached integrally and jointly with image-carrying layer **302** and protecting layer **305**.

Applied Products

The products applicable with the inventive process for decorating purposes are not limited to occasionally employed kind, shape and nature of the materials. Preferred examples of the usable product may be: cartons; vessels or packages; bags; cassette cases; cassette halves; floppy cases; paper packages and envelopes; stock certificates; personal and bank cheques; bills; bonds; certificates; notifications; car tickets; travel tickets; betting tickets; tax stamps; postage stamps; entrance tickets, money-exchangeable papers and documents; cash-cards, credit cards, orange cards, telephone cards; member's cards; greeting cards; postcards, name cards; driver's certificates; IC-cards; optical cards and the like various cards; accounting cards and documents-envelopes; tags; OHP-sheets; slide films; bookmark slips; calendars; posters; pamphlets; menus; passports; POP-goods and articles; coasters; displays; nameplates; keyboards; cosmetics; personal ornaments (watches; cigarette lighters); stationaries; construction materials; radio-receiving sets; T.V.-sets; speakers; table calculators; automotive gauge boards; emblems; keys; clothes; wearing commodities; footwears; appliances; CA-instruments; sample books; tickets in general; albums; computer graphic and/or medicare graphic image printouts; and the like, where the material kinds, sizes and configurations are regardless for purposes of the invention.

The aforementioned goods and instruments may have printed or the like other images in advance of execution of the process of the invention. Or conversely, the goods and instruments can be formed with necessary images in accordance with the present process, and then, additional images may be formed in conventional printing or the like process.

As an example, when the invention is applied to a card style intermediate product, it is possible to combine image-forming means of the present invention with conventional recording means. As the latter, magnetic recording by use of a magnetic material layer; optical recording by use of an optical recording layer; preferably composed of a membrane having low melting point metal; application of hologram; embossing formation of characters and numerals; application of personal face photograph; engraved formation of personal face or the like; human signatures; recorded information with use of IC-memory; mechanical printing; formation of bar codes; formation of characters and patterns by use of printer, typewriter or pen plotter may be used independently or in any combination.

In the following, the present invention will be more fully described by way of preferred embodiments. In these embodiments, parts or % will be given by weight, not otherwise specifically referred to.

As the image transfer film (dye film) used for sublimating transfer onto the image-transferable sheets, a polyester film, 6 μm thick, subjected to a heat-resisting treatment on one surface thereof only, and bearing color ink composition areas of yellow, magenta and cyan, respectively, was used. The coating rate of the color ink composition was 1.0 g/m^2 when measuring at the dry state.

These color ink compositions were as follows.

Yellow ink composition	
polyvinyl butyral resin ("Eslek-BX-l", manufactured and sold by Sekisui Kagaku K. K., Tokyo)	4.80 parts
dispersion dye ("PTY-52, Disperse Yellow-141", manufactured and sold by Mitsubishi Kasei Kogyo Co., Ltd., Tokyo)	5.50 parts;
methyl ethyl ketone	55.00 parts;
toluene	34.70 parts;
(parting agent	1.03 parts)

Magenta ink composition	
polyvinyl butyral resin (same as above in the case of yellow color ink)	3.92 parts;
dispersion dye ("MS Red G, disperse red 60", manufactured and sold by Mitsui Toatsu K. K.)	2.60 parts;
dispersion dye ("Macrolex Red Violet R, Disperse Violet 26", manufactured and sold by Beyer A. G., West Germany)	1.40 parts;
methyl ethyl ketone	43.34 parts;
toluene	43.34 parts;
(parting agent	0.40 part)

Cyan color ink composition	
polyvinyl butyral resin (same as in said yellow color ink composition)	3.92 parts;
dispersion dye ("Kayaset Blue-714, solvent blue-63", manufactured and sold by Nippon Kayaku K. K., Tokyo)	5.50 parts;
methyl ethyl ketone	68.18 parts;
(parting agent	0.94 parts)

Each of the foregoing color ink compositions was prepared with and without addition of parting agent.

As the parting agent occasionally used in each of the foregoing color ink compositions, any of the following specific agents may be employed:

(a) silicone alkyd parting agent, "KR-5206", manufactured and sold by Shinetsu Kagaku Kogyo K.K., Tokyo;

(b) graft polymer of silicone and acryl, "GS-30", manufactured and sold by Toa Gosei Kagaku K.K.;

(c) silicone graft polymer, "US-3000", manufactured and sold by the above company;

(d) phosphoric acid ester, natrium salt, "RE-410", manufactured and sold by Toho Kagaku Kogyo K.K.;

(e) natural phosphoric acid ester, "Lecytin", manufactured and sold by Ajinomoto Co., Ltd., Tokyo;

(f) silicone oil, "KF 412", manufactured and sold by Shinetsu Kagaku Kogyo K.K., Tokyo;

(g) aluminum chelate agent, "ALM", manufactured and sold by Ajinomoto; and

(h) titanium chelate agent, "TTS", manufactured and sold by Nippon Soda K.K., Tokyo.

Example A-1

As the substrate, a laminate of a synthetic paper, "Yupo FPG 150 μm thick" manufactured and sold by Oji Yuka Co., Ltd., Tokyo, and a polyester film, 6 μm thick, was prepared and coated on the polyester film side surface by a wire bar with a mixture of pull-separating varnish, "Hakurinisu 45" manufactured and sold by Showa Ink Co., Ltd., Tokyo, with an ultra-violet absorbing agent, or more specifically, 2.5-bis (5'-tert-butylbenzoxazolyl (2))-thiofin, 0.5% based on the resin content of the varnish, and dried up to provide a protecting layer of 1 g/m^2, when weighed upon drying.

Then, on the surface of the foregoing protecting layer, an ink composition adapted for the formation of an image-reception layer was coatingly applied and dried up. The applied quantity amounted to 7 g/m^2 when measured upon drying.

Ink composition for the formation of image-reception layer	
polyester resin (manufactured and sold by Toyobo K. K.)	100 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu Kagaku Kogyo K. K., Tokyo)	5 parts;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu Kagaku Kogyo)	5 parts;
solvent (methyl ethyl ketone/toluene/ cyclohexanon 4/2/2)	900 parts.

The ink composition was coated, dried up and cured one day under normal temperature. Then, the layer was kept at 100° C. for 30 minutes under heat, for letting the silicone to bleed up to the surface, to provide an image-transferable layer formed on its surface with a hardened silicone layer.

On the thus-provided image-reception layer, a sublimating image-transfer film was overlapped which is composed of cyan color sublimative dye (molecular weight being higher than 250) carried by a proper binder resin and thermal energy is fed thereon from a thermal head adapted for receiving electric signals representing cyan color components obtained by a color analysis of a portrait photograph, as an example, for providing portrait images corresponding thereto. Then, two successive sublimative image-transfer jobs were executed with use of respective sublimating image-transfer films carrying sublimative magenta and yellow color dyes, each molecular weight being higher than **250**, and substantially in the manner set forth above. In this way, after all, an overall combined display image composed of a full color portrait, in combination with several characters and graphics, was provided.

The image-reception layer of the sheet, now carrying these display images, was overlapped on the card substrate composed of a polyester resin sheet, 100 μm thick, which had been primed to white-opaque state, and pressurized together at 160° C. by means of heated pressure rolls. Then, the polyester film was peeled off at the interface with the protecting layer, thereby providing a final product card transferrd with image-reception layer now carrying the desired image display.

It was found that the overall surface of the product card was generally smooth and showing no raised feeling of the thus-formed and displaying images. Even upon an accelerated testing of the product card for three months held in an atmosphere of 40° C., the images showed no blurrings as well as no interlayer separation. Further, according to an accelerated light-proof test carried out as prescribed in JIS-Standard with use of a carbon arc lamp, the results showed to be classified to JIS-4 or -5 corresponding to an acceptable superior performance. Additionally, a surface scratch test and the like showed also superior durability.

Example A-2

The foregoing image-transferable sheet, now image-carrying, as processed in Example A-1, is then subjected to a peel-off operation for separating the image-carrying layer from the sheet. Then, an adhesive agent of polyester series was coated on the exposed surface of the peeled-off film, and stuck under pressure on a curved surface part of a telephone set. The images could follow up to the stuck curvature into a unitary solid mass, and indeed, without inviting any stuck-on feeling, contrary to the case when a sticky loose-leaf stamp should have been stuck on. In this way, miracle viewing feelings as obtainable with direct-printing operation only, were created and maintained.

Example A-3

A white polyester film, baked on one surface thereof with melamine coating, "E 20", 100 μm thick, manufactured and sold by Toray Co., Ltd. Tokyo, is formed on the opposite surface with a slipping layer, same as in the following Example C-2, through application of polyurethane primer. And an identification mark was provided thereon through the way of regular printing technique. On the melamine resin-baked surface of the white polyester resin film, a layer of peeling varnish (of polymethyl methacrylate-series), manufactured and sold by Showa Inku. Co., Ltd., Tokyo) was applied in dry quantity of 2 g/m^2 and dried up to provide a definite layer.

On the thus-formed protecting layer, the following image-reception layer-forming composition was coated and dried up, so as to form an image-heat transferable sheet. The coated composition was in quantity of 6 g/m^2 by dry weight.

Image-reception layer-forming composition	
polyester resin ("Vylon 600", Tg: 47° C., manufactured and sold by Toyobo, Osaka)	80 parts;
polyester resin ("Vylon 290", Tg: 77° C., manufactured and sold by Toyobo)	20 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu Kagaku Kogyo)	7 parts;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu Kagaku Kogyo)	7 parts;
solvent (methyl ethyl ketone/toluene = 1/1)	800 parts.

On the image-reception layer of the foregoing heat image-transferable sheet, reversed images composed of full color portrait images together with characters and graphics by use of a thermal head, as in the same way with Example A-1, were formed.

Next, the image-reception layer, however, now carrying the reversed images formed in the foregoing manner was brought into contacting and overlapping state with the image displayable surface on a card style substrate made of white

color polyester resin, 125 μm thick, preparatorily primer treated as before, and pressurized together under the action of thermal rolls, and the white polyester film, 100 μm, was peeled off between the protecting layer and the melamine-baked layer, thus providing a final card-style product transferred with the image-reception layer now carrying the necessary images.

The surface of the final card style product represented a smooth and slippery, without fear of interlayer separation and with superior light resistant power.

Example A-4

A white foam polyester resin film, "Merinex", 125 μm thick, manufactured and sold by ICI, was provided with an identification mark on one surface thereof, with regular printing technique.

Then, on the opposite surface of the white foam polyester resin film to the foregoing surface formed with the identification mark, a coating of a polyurethane-series primer was applied and dried up. Further, the following protecting layer-forming composition was applied in dry quantity of 3 g/m^2 and dried up to form a protecting layer.

Protecting layer-forming composition	
acrylic polyole ("Acrit 6416MA", manufactured and sold by Taisei Kako K. K.)	41 parts;
toluene	36 parts;
methyl ethyl ketone	27 parts;
diisocyanate ("Colonate", manufactured and sold by Nippon Polyurethane K. K.)	6 parts.

On the above protecting layer, the following composition was applied in dry quantity of 3 g/m^2 and dried up, to provide an intermediate layer.

Intermediate layer-forming composition	
polyester resin ("Vylon 290", manufactured and sold by Toyo Boseki (Toyobo) K. K., Osaka)	15 parts;
toluene/methyl ethyl ketone = 1/1	85 parts.

On the thus-formed intermediate layer, an image-reception layer which is substantially same with that in the foregoing Example A-3 was provided, so as to form an image-transferable sheet. Then, as same in the foregoing Example A-3, correspondingly inverted images were formed on the image-reception layer and further then, subjected to transfer onto the card substrate by use of thermal rollers. In this way, a final product card, having an image transferable, yet now image-formed layer, was provided.

This card showed favorable results of light-resisting test. Further, it showed a better scratch test result than the foregoing card obtained in Example A-3.

Example A-5

Substrate

A white polyester film, "E-20", 100 μm thick, manufactured and sold by Toray Co., Ltd., Tokyo, was used.

Intermediate layer-forming composition	
Polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki K. K., Osaka)	15 parts;
toluene/methyl ethyl ketone = 1/1 (dry weight: 5 g/m^2)	85 parts.

Protecting layer-forming composition	
"Hakuri-Nisu" (acrylic resin varnish, manufactured and sold by Showa Ink K. K.) (dry weight)	2 g/m^2

Image-reception layer-forming composition	
polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki K. K., Osaka)	10 parts;
polyester resin ("Vylon 200", supplied by Toyo Boseki K. K.)	5 parts;
toluene/methyl ethyl ketone = 1/1	85 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu Kagaku Kogyo)	1 part;
epoxy-modified silicone ("X-22-343", supplied by Shinetsu Kagaku Kogyo)	1 part.
(coated quantity (dry)	5 g/m^2)

With use of the foregoing composition and processed in similar way as in Example A-3, to provide a final card product, having an image-reception layer transferred with necessary images.

Example A-6

Substrate

White polyester resin film, "E-20", 100 μm thick, manufactured and sold by Toray was coated with polyurethane-series primer and dried up.

Parting layer-forming composition	
melamine resin ("Meran 45", manufactured and sold by Hitachi Kasei)	100 parts;
hardener (para-toluenesulfonic acid)	20 parts;
(coating quantity (dry), 2 g/m^2)	

Protecting layer-forming composition	
vinylchloride-vinylacetate ("Vinylite VYHH", manufactured and sold by Union Carbide Corp.)	15 parts;
methyl ethyl ketone = 2/1	85 parts;
(coating quantity (dry): 2 g/m^2)	

Intermediate layer-forming composition	
polyurethane resin ("Takelac T-3350", manufactured and sold by Takeda Pharmaceutical Company, Osaka, of 23%-concentration)	50 parts;
isopropyl alcohol	15 parts;
toluene	25 parts;
methyl ethyl ketone	10 parts.
(coating quantity (dry) 5 g/m^2)	

Image-reception layer composition	
polystyrene resin ("Picolastic D125" (Tg = 53° C.), manufactured and sold by Hercules	15 parts;
toluene/methyl ethyl ketone = 1/1	85 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu Kagaku)	1 part;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu Kagaku)	1 part.
(coating quantity (dry): 6 g/m^2)	

The foregoing composition was prepared and used as in the same manner with Example A-3, to provide a card with the image-reception layer subjected to image-transfer as desired.

Example B-1

As the substrate, a polyester resin film, 6 μm thick, was used and a polyester resin-series primer was coated on one surface thereof and dried up. Further, the following ink composition was applied and dried up. The coating quantity of the composition was set to about 7 g/m^2.

Image-reception layer-forming composition	
polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki K. K.)	100 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu Kagaku)	5 parts;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu Kagaku)	5 parts;
solvent (methyl ethyl ketone/toluene/ cyclohexanone = 4/2/2)	900 parts.

The ink composition was coated, dried up and left standing for a full day, and then subjected to heat treatment at 100° C. for 30 minutes, so as to bleed the silicone towards the film surface for providing thereon an acceptable image-reception layer composing the active surface.

Then, a sublimative image-transferable film, composed of a resin binder evenly mixed with a proper amount of sublimative cyanic dye, the molecular weight being higher than 250, was overlapped on the above image-reception layer and applied with heat energy by means of a thermal head supplied with electric signals corresponding to cyanic color components of a portrait full color photograph as determined by regular color analysis, thus providing cyanic color component images.

Next, as for magenta and yellow color components, similar respective processings were executed and finally, full color display portrait images could be formed.

Then, the exposed surface of image-reception layer of the thus-display image-formed film was overlapped on a card substrate composed of a white opaque, hard vinyl chloride resin sheet, 100 μm thick and pretreated with a conventional primer, and then this assembly was subjected to heat and pressure by means of a pair of heated rolls. In this way, a card product stuck with an image-transferable and now carrying layer was provided.

The surface of this card was generally smooth and slippy, the thus-formed images thereon providing no raised feelings. In an accelerated test of these formed images in hot atmosphere of 40° C. for a continuous period of three months, there were no appreciable image blurring and interlayer separation. Upon execution of a light exposure test in accordance with prescribed conditions in JIS with use of an arc lamp, the results were classified to JIS-4 to 5 Classes which means as acceptable and better image quality. Scratch test results were also superior.

Example B-3

A sticking layer, 1 μm thick, was formed with a polyamide resin sticking agent on the image-carrying surface of the image-transferable sheet, image-formed in the manner as described in foregoing Example B-1, and the thus provided sheet was stuck on the curved surface of a glass tumbler. These images express practically no stuck-on feelings, rather providing such a touch and viewing feeling as if they had been formed by the regular and direct printing technique.

Example C-1

With use of the image-transferable sheet prepared in the foregoing Example A-1, images were formed substantially in accordance with procedures mentioned therein, however, with exception of the formation of reversed images, and then, the image-carrying layer was, without execution of the foregoing peel-off operation, stuck on a portion of curved outer surface of a glass tumbler, whereupon the sheet-like substrate was peeled off, together with the weak-sticking layer. The thus-applied images represent almost no sticking-on grip and viewing feeling, as if they should have been applied through regular and direct-printing technique.

Example C-2

On the surface of a transparent polyester film, 12 μm thick, employed as a protecting film, the following image-reception layer forming composition was applied to form a coated layer (in quantity of 6 g/m^2 when measuring upon drying), dried up and left as it was for full one day. Then, it was held at 100° C. for 30 minutes, to form an image-reception layer. On the surface thereof, a parting surface layer was found to exist, which was composed of a combined hardened product of amino-modified silicone resin and epoxy-modified silicone resin.

Image-reception layer-forming composition	
polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki)	100 parts;
amino-modified silicone resin ("KF-393", manufactured and sold by Shinetsu)	7 parts;
epoxy-modified silicone resin ("X-22-343", manufactured and sold by Shinetsu)	5 parts;
solvent (methyl ethyl ketone/toluene = 1/1)	800 parts.

As the substrate, on the other hand, white polyester resin film, "E-20", 75 μm, manufactured and sold by Toray, was used and coated on one surface thereof with a polyurethane-series primer and dried up. Then, the following composition (in the dried quantity of 1 g/m^2) and dried up, so as to

provide a smooth and stick layer.

Smooth layer-forming composition	
polymethyl methacrylate resin ("Dianal BR-85", manufactured and sold by Mitsubishi Rayon Co., Ltd., Tokyo	12 parts;
polyethylene wax ("MF8F", manufactured and sold by Dulacon Co.)	0.5 part;
toluene/methyl ethyl ketone = 1/1	85 parts.

On the opposite surface of the white-polyester resin sheet to the smoothed surface there, a primer coating of polyurethane-series is applied and dried up, and further coated thereon with the following composition, in quantity of 3 g/m^2, so as to provide a weak-sticky layer.

Weak-sticky layer-forming composition	
weak-sticky adhering agent ("Esdyme AE-206", manufactured and sold by Sekisui Kagaku Kogyo K. K., Tokyo)	50 parts;
water	50 parts.

The weak-sticky adhering layer is brought into contact with the protecting film consisting of a polyester film, 12 μm thick, at the opposite surface to the image-reception layer, and then subjected to heat and pressure, to provide an image-transferable sheet. Upon bringing the image-reception layer of the image-transferable sheet and the dyestuff layer of the heat-image transfer sheet into contact with each other, heat energy was applied from a thermal head, as in the similar manner mentioned in the foregoing Example A-1, and thus heat image-transfer job was executed, so as to provide reversed mode images for expressing a full color portrait as well as characters and graphics.

Next, the image-reception layer formed with the reversed images thereon was overlapped onto the image-displayable surface of a card style substrate, 100 μm thick, made of a white color polyester resin material preparatorily applied with a primer layer by coating a composition, consisting of "Vylon 200", 100 μm thick, manufactured and sold by Toyo Boseki K.K., and then subjected together to heat and pressure by means of at least a heated roll at 160° C. Then, the white polyester film, 75 μm thick, and the weak-sticky adhesive layer were peeled off in unison, for providing a final decorative product card having the image-reception layer transferred with images and carrying dislay images.

This card had a highly smooth surface and was not liable to invite any interlayer separation and showed superior light fastness.

In place of white color polyester-made card substrate preparatorily formed with a primer layer, such a modification was prepared and experimented that the white polyester sheet was formed on its rear surface with a magnetic layer, while, on its front surface there is formed with a write-on layer which consists of proper filler and resin as conventionally, so as to provide a telephone card. This processed telephone card had the write-on layer provided with display images formed by image-transfer.

Example C-3

On the surface of a transparent polyester film, 9 μm thick, used as the protecting layer, an intermediate layer was provided by coating. The coated amount was 5 g/m^2 as measured upon being dried up.

Intermediate layer-forming composition	
polyurethane resin ("Takelack T-3350", solid content 23%, manufactured and sold by Takeda Pharmaceutical Co., Ltd., Osaka)	50 parts;
isopropyl alcohol	15 parts;
toluene	25 parts;
methyl ethyl ketone	10 parts.

Onto the intermediate layer, the following composition was applied for the formation of an image-reception layer. The coated quantity was 5 g/m^2 as measured upon being dried up.

Image-reception layer-forming composition	
polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki)	10 parts;
polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki)	5 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	1 part;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	1 part;
solvent (methyl ethyl ketone/toluene = 1/1)	85 parts.

On the other hand, a white color polyester film, which was similar to that employed in the foregoing Example C-2 was formed with a slidingly smooth layer, as well as a weak-sticking adhesive layer, the latter being brought into intimate contact with a transparent polyester film, 9 μm thick, at the opposite surface to the image-reception layer and then, subjected to heat and pressure, for providing a heat image-transferable sheet. As further processed in the similar manner in the foregoing Example C-2, full-color photographic images (reversed images) were thus formed on the image-reception surface. In this way, a final product card, having its image-reception layer transferringly formed with display images.

Example C-4

Substrate

White color polyester sheet, "E-20", 100 μm thick, manufactured and sold by Toray was formed thereon with a polyurethane-series primer coating. Then, a weak-sticking layer was applied thereon with use of the following composition.

Weak-sticking layer-forming composition	
weak-sticking agent ("Esdyne AE-206", manufactured and sold by Sekisui Kagaku Kogyo K. K., Tokyo)	50 parts;
water	50 parts.

Protecting layer-forming composition	
polyester resin ("Vylon-200", manufactured and sold by Toyo Boseki)	15 parts;
diisocyanate ("Colonate L", manufactured and sold by Nippon Polyurethane Co., Ltd.)	1 part;
toluene/methyl ethyl ketone = 1/1	84 parts.

Image-reception layer-forming composition	
polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki K. K.)	10 parts;
vinyl chloride-vinyl acetate copolymer resin ("Vinylite VAGH" (Tg = 79° C.), manufactured and sold by Union Carbide Corp)	5 parts;
toluene/methyl ethyl ketone = 1/1	85 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	1 part;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	1 part.

With use of the above composition and processed substantially same as in the foregoing Example C-2, a final card product was obtained.

Example D-1

An image-transferable sheet was prepared as in the foregoing Example A-1 and thermally image-transferred with reversed mode images of a full color portrait photograph, to provide an intermediate image-transfer medium. The latter is overlapped by its image-reception layer onto the surface of a sheet of rough-textured cotton cloth, however, through the intermediary of an acrylic acid ester-vinyl acetate copolymer sheet, 100 μm thick. Then, the assembly was subjected to heat and pressure. Then, the substrate sheet and weak-sticky adhesive layer, together, were peeled off. The thus transfered images have sufficient surface smoothness, showing superior surface conditions.

Without use of the bond-attaching sheet in the above process and when similar image-transfer job as above was performed, the resulted images followed the surface undulations appearing disadvantageously on the material product of the rough fabrics and thus were highly uneven, and further, on account of insufficient adhering performance acting between the image-receiving layer and the woven fabrics serving as product material, easy and frequent separations took place therebetween.

Example D-2

In the similar way as was disclosed in the foregoing Example D-1, an intermediate image-transfer medium carrying reversed images was prepared and overlapped on a polymethacrylate board preparatorily subjected to surface-roughening operation through a conventional sand-blasting step, and through the intermediary of a bond-adhering sheet pressurized together under heat, as was employed in Example D-1. Then, the sheet-like substrate was peeled off, together with the weak adhesive layer. The thus-provided images were highly smooth and even in spite of the highly rough and undulating conditions at the surface to be image-transferred. In addition, the image-carrying surface showed superior results in various resisting tests.

Without use of the foregoing bond-sticking layer, the similarly transferred images showed considerable undulations and distortions. Further, on account of insufficient adhering performance, easy and frequent peel-offs of applied images were feared.

Example D-3

On the surface of a polyester resin film, 25 μm thick, the following composition adapted for the formation of bond-sticking layer was coated and dried up, in dried quantity of 5 g/m^2, to provide a film formed thereon a bond sticking sheet.

Bond-sticking sheet-forming composition	
polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki)	15 parts;
methyl ethyl ketone/toluene = 1/1	84 parts.

The bond-sticking sheet surface, together the polyester resin film proper, was brought into contact with the image-representing surface of a white color polyester made-card substrate, 25 μm thick, and then, subjected to heat and pressure by means of at least a heat roll kept at 200° C., arranged to supply heat energy from the side of the polyester resin surface, thereby heat bonding the bond-sticking sheet onto the card surface, whereupon the polyester resin film being forcedly peeled off.

Further then, as in the similar way as adopted in foregoing Examples C-2; A-3; A-4 and C-3, use is made of the image-reception layers representing reversed images thereon, the respective image-reception layers were whereupon brought into contact with the card's bond-sticking surface of the card and subjected to heat and pressure by use of at least a heat roll kept at 200° C. Then, the white color polyester resin substrate was peeled off, together with the weak-sticky adhering layer. In this way, a final product card displaying the portrait photograph was obtained.

Example D-4

Substrate

A white color polyester resin sheet, "E-20" 100 μm thick, manufactured and sold by Toray Co. Ltd., was coated with a polyurethane-series primer. On the surface of the thus precoated sheet, the following composition was coated to form a weak-sticking adhesive layer.

Weak-sticking adhesive component	
weak-sticking adhesive agent, ("Esdyne AE-206", manufactured and sold by Sekisui Kagaku)	50 parts.

Image-reception layer-forming composition	
polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki)	7.5 parts;
polyester resin ("Vylon 290", manufactured and sold by Toyo Boseki)	7.5 parts;
toluene/methyl ketone = 1/1	85 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	1 part;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	1 part.

The foregoing compositions were prepared. On the other hand, a polyester resin film, 25 μm thick, was coated on one

surface thereof with a 15%-solution of polyester resin, "Vylon 200", manufactured and sold by Toyo Boseki, in toluene/methyl ethyl ketone=1/1 and dried up. The coating quantity was adjusted to 5 g/m^2 when measuring in dried state. In this way, a bond-sticking sheet was provided.

Then, the coated surface of the thus prepared bond-sticking sheet was brought into contact with the image display surface of a card style substrate of white color hard vinyl chloride or the like resin material preparatorily subjected to a primer coating treatment in overlapping state and then, the whole assembly was subjected to heat and pressure with use of at least a heated roll to 130° C., thus the bond-sticking layer being stuck on the card surface. Under this condition, the polyester resin film, 25 μm thick, was peeled off.

Then, the image-reception layer, now carrying thereon reversed images, was brought into contact with the bond-sticking sheet and the resulted whole was subjected to heat and pressure by use of at least a heated roll and the white color polyester resin substrate, together with the weak-sticking adhesive layer, was peeled off. In this way, the card, now displaying the portrait images, was provided.

Example D-5

Substrate

Same as in the foregoing Example D-4.

Weak-sticking adhesive layer

Same as in the foregoing Example D-4.

Protecting layer-forming composition	
polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki)	15 parts;
diisocyanate ("Colonate L", manufactured and sold by Nippon Polyurethane)	1 part;
toluene/methyl ethyl ketone = 1/1	84 parts.

Image-reception layer-forming composition	
polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki)	10 parts;
toluene/methyl ethyl ketone = 1/1	85 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	1 part;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	1 part.

With use of the foregoing materials and compositions, the processings were carried out as in the foregoing Example D-4, to provide a final product card displaying portrait images as was desired.

Example D-6

Substrate

Same as in the foregoing Example D-4.

Weak-sticking adhesive layer

Same as in the foregoing Example D-4.

Image-reception layer-forming composition	
polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki)	10 parts;
vinyl chloride-vinyl acetate copolymer resin ("Vinylite VAGH", manufactured and sold by Union Carbide Corp.)	5 parts;
toluene/methyl ethyl ketone = 1/1	85 parts.

The foregoing materials and compositions were prepared and processed in the similar way as in the foregoing Example D-4, to provide a final product card, displaying the desired portrait images as were desired.

Example E-1

On a polyethylene terephthalate film, 9 μm thick, a solution of saturated polyester resin, "Vylon 600", manufactured and sold by Toyo Boseki, in toluene/methyl ethyl ketone=1/1, was coated by reliance of the known reverse roll-coating process, and dried up. The coated quantity was 7 g/m^2 when measuring in dry condition. In this way, a weak-sticking adhesive layer could be formed.

On the weak-sticking adhesive layer, the following composition, 3 g/m^2 (dry), was coated by means of an oblique-lined gravure roll for solid and full printing use and in the reverse roll-coating process, and then dried up, to provide an image-reception layer.

Image-reception layer-forming composition	
polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki)	70 parts;
polyester resin, ("Vylon 290", manufactured and sold by Toyo Boseki)	30 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	5 parts;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	5 parts;
methyl ethyl ketone (wt. ratio 1/1)	700 parts.

On the opposite surface to the image-reception layer of the thus-prepared image-transferable sheet, a synthetic paper substrate, "Yupo FPG 110", 110 μm thick, manufactured and sold by Oji Yuka K.K., coated with "Vylon 600" as the adhesive agent in quantity of 10 g/m^2 (dry) was stuck intimately together.

On the other hand, a polyethylene terephthalate film substrate, 6 μm thick, preparatorily provided on one surface thereof with a heat-resisting layer was used and the following composition was applied on the opposite surface of the substrate with use of a wire bar and dried up, in the quantity of 1 g/m^2 (dry), so as to provide a dyestuff layer. In this way, a heat image-transferable sheet was prepared and provided.

Dyestuff layer-forming composition	
dispersion dye ("Kayaseo Blue-136", manufactured and sold by Nippon Kayaku K. K.)	4 parts;
ethylhydroxyethyl cellulose	6 parts;
methylethylketone/toluene (wt. ratio: 1/1)	90 parts.

The dyestuff layer of the foregoing heat image-transfer sheet was brought into contact with the image-reception layer of the image-transferable sheet in overlapping manner, then, heat energy was applied from a thermal head from the side of heat-resisting layer of the heat image-transfer sheet, thereby dyestuff being transferred to the image-reception layer of image-transferable sheet, and indeed, for the formation of positive images.

Then, the image-transferable sheet, now carrying the required positive images was stuck together under heat and pressure at 140° C. for 5 seconds on the intermediate image-transfer substrate prepared in the following manner, in mutually opposed manner. Then, the synthetic paper "Yupo" was peeled off at the intersurface between the polyester resin film and the "Vylon 600" layer. In thus way, the inventive image-transfer sheet (intermediate image-transfer medium) carrying the corresponding reverse images was provided.

Method for the preparation of intermediate image-transfer substrate

A sheet of fine quality or stick paper, unit weight: 82 g/m^2 was applied with a coating, about 20 μm thick, of polyethylene resin through conventional extrusion coating process. Thereon, further, a catalyst-added toluene solution of a parting agent silicone, "KS-707", manufactured and sold by Shinetsu was applied and dried up in quantity of about 2 g/m^2 (dry), for the purpose of curing. Thereon, still further, the following coating liquid composition was applied by means of a conventional coating bar and dried up, to provide an intermediate image transfer substrate. The thus coated and dried resin quantity was measured to 7 g/m^2.

Coating liquid composition	
polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki)	100 parts;
methyl ethyl ketone/toluene (mixing ratio by weight: 1/1)	700 parts.

A sheet of coated paper, pretreated for pore-filling, was coated, in the similar manner as above, with the foregoing liquid composition, to provide an image-transferable medium. On and with the presently coated surface, the image carrying surface of the foregoing intermediate image-transfer medium is brought into opposing contact and stuck together under heat and pressure at 140° C. for 7 seconds. Finally, the laminate of fine-quality paper and polyethylene was peeled off, to provide a final decorative product now displaying the positive images as required.

It will thus be seen that by adopting the above processing steps, the positive images formed under the action of the thermal head are transferred, through the intermediary of intermediate image transfer medium, onto the final object to be decorated, and indeed, in the form of positive mode. It will be further seen that, since the dyestuff is well distributed within the image-reception layer, the transferred positive images are highly sharp and fresh, in addition to much profundities.

Since a resin layer was overlappingly applied on the thus-formed images, weather fastness, frictional durability and light-fastness of the finally formed images could be highly and amazingly improved. When suitable ultraviolet absorbing agent, antioxydant, quenching agent and/or radical scavenger is added to, further improvement of the light-fastness can be attained.

Example E-2

The substrate of image-transferable medium adopted in the foregoing Example E-1 was replaced by a hard polyvinyl chloride card, 100 μm thick, and other processing modes were same as in Example E-1. In this way, a high quality, positive-image transferred, decorative final product was successfully provided. When the image include human portrait photograph, the final product was highly useful for ID-card.

Example E-3

The substrate of image-transferable medium adopted in the foregoing Example E-1 was replaced by a transparent polyester film, and other processing modes were same as employed therein. In this way, a transparent film formed with the wanted positive images of better quality as before was obtained. This film was highly useful in OHP-services.

Example E-4

A sheet of high quality paper, unit weight: 104 g/m^2, was coated with a layer of polypropylene resin, thickness: about 20 μm, through the way of conventional extrusion coating technique, then the coating was further coated with a silicone solution for use in parting service and hardenable under electron rays and dried up. The quantity of the coating silicone was about 1 g/m^2 upon drying. In this way, an electron-hardened, provisional substrate was provided. On this substrate, the following, image-reception layer-forming composition was applied as a layer by use of a coating bar, and then dried up, for providing an image-reception layer. The coated resin quantity in the above last step amounted about 5 g/m^2.

Image-reception layer-forming composition	
polystyrene ("Picolastic D 150" (Tg = 69° C.), manufactured and sold by Rika-Hercules Co., Ltd.	100 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	7 parts;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	7 parts.

Further processing was carried out as was set forth in the foregoing Example E-2, for providing a final product card, carrying thereon the wanted positive images of same superior quality, as was in Example E-2.

Example E-5

On the image transferable medium used in the foregoing Example E-4, however, in the present Example, a thermoplastic resin, adhesive, polyolefine-series film, "Adwin

500", manufactured and sold by Showa Denko K.K., Tokyo, was applied as a layer. Other materials were used and processed as set forth therein. In this way, a decorative final product formed with necessary positive was obtained with superior results.

Industrial Availabilities

As will be well understood from the foregoing detailed description of the invention, it is possible according to the present inventive system, to form highly easily and evenly the desired images sharply and attractingly on any product and object to be decorated or graphically ornamented, substantially irrespective of material kind and configuration thereof, and indeed, with a surprising unitary touch and feeling with the substrate. Therefore, the invention can be utilized broadly and conveniently in such various industrial fields, where unitary formation of various images, characters, symbols, numerals and graphics, on and to the articles, objects and substrate products to a sufficiently miracle and attracting degree.

We claim:

1. A sublimatingly image transferred product comprising:

a plastic card; and

an image-reception layer containing a releasing agent provided on said plastic card,

said image-reception layer being directly formed on said plastic card by thermal fusion, and said image-reception layer having a transferred image formed by sublimation transfer, said transferred image being formed on the plastic card surface side.

2. The sublimatingly image transferred product of claim **1**, further comprising a protective layer formed on said image-reception layer.

3. The sublimatingly image transferred product of claim **2**, wherein said protective layer contains an ultraviolet absorbing agent and/or a photostabilizer.

4. The sublimatingly image transferred product of claim **2**, wherein said protective layer comprises a resin selected from the group consisting of an alkyd resin, a phenol-modified alkyd resin, an aminoalkyd resin, a phenol resin, a urea resin, a melamine resin, a silicone resin, a thermosetting resin, a cold setting resin, an actinic lay hardenable resin, and a thermoplastic resin.

5. The sublimatingly image transferred product of claim **4**, wherein said thermoplastic resin comprises a resin selected from the group consisting of a polyester resin, a polyurethane resin, a polyvinyl acetate resin, a vinyl chloride-vinyl acetate copolymer, a polyolefin resin, and an acrylic resin.

6. The sublimatingly image transferred product of claim **1**, wherein said image-reception layer comprises a resin selected from the group consisting of a polyester resin, a polyacrylic ester resin, a polycarbonate resin, a polyvinyl acetate resin, a styrene-acrylate resin, a vinyltoluene-acrylate resin, a polyurethane resin, a polyamide resin, a polycaprolactone resin, a polystyrene resin, a polyvinylchloride resin, and a polyacrylonitrile resin.

[57] **ABSTRACT**

A compact objective lens with a diaphragm arranged behind the lens system suitable for use in very compact photographic cameras. The objective lens comprises a plurality of components arranged in a triplet or a triplet type configuration and is capable of covering at least a 55 degree field of view.

COMPACT OBJECTIVE LENS SYSTEM

CROSS-REFERENCE TO RELATED APPLICATION(S)

This application is related to U.S. patent application Ser. No. 08/084,380, filed Jun. 29, 1993, and entitled A TRIPLET-TYPE LENS FOR USE IN A COMPACT PHOTOGRAPHIC CAMERA, filed in the names of Lee R. Estelle and William T. Goosey, Jr.

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to a lens system suitable for use as an objective or taking lens for compact photographic cameras and providing a field coverage of at least 55 degrees and preferably 60 degrees or higher.

2. Description of the Prior Art

With the increasing demand for manufacturing smaller, more compact photographic cameras at a lower cost, there is an increased need for use of smaller and less costly lens systems. Triplet or a Tessar-type lens systems are good candidates for such use because these systems have relatively few lens elements.

Triplet-type or triplet derivatives such as Tessar-type lenses have been used in photographic apparatus for many years. Moreover, the objectives having a triplet-type lens system with the diaphragm arranged either in front of the first lens element or behind the last lens element are also well known, and such lens systems are disclosed in U.S. Pat. Nos. 3,910,685, 4,886,342, 4,892,398, 4,676,607, 3,967,884, 3,895,857 and 3,784,287. Such objectives have an advantage of being compact, having relatively few lens elements and eliminating the costs of "split" barrels.

However, many of these lens systems are assembled in their optical barrels with spacers such as spacer rings or shims placed between the optical components. This is disadvantageous because the spacers may cause tolerance build-up on thicknesses as well as tolerance build-ups due to spacer wedge. In addition, there is an increased cost due to extra parts.

The need for the spacers or shims can be eliminated when the elements are made of plastic and mounted as shown in U.S. Pat. Nos. 4,886,342 and 3,784,287, but this severely limits the choice of the optical materials of which the lens elements are made. For example, certain index ranges and V number materials may be required by the photographic lens system, in order to enhance its performance, but such materials are available in optical grade are glass and not in plastic.

Finally, there is a problem if the edge contact is established too far from the clear aperture, the lens element diameter will increase, the lens elements thickness will increase and the compactness of the overall optical system will be compromised.

Thus, there is a growing demand for more compact photographic cameras and correspondingly, there exists a need to further improve and simplify the lens system for use in such cameras, and to lower the cost of making such lens systems by making them less expensive to assemble while maintaining or improving their imaging quality.

SUMMARY OF THE INVENTION

An object of the present invention is to produce a photographic lens device of high quality which includes a lens system which is uniquely suited for use in compact photographic cameras and which is relatively inexpensive to produce and to assemble.

Yet, another object of the present invention is to provide a lens system that is easy to assemble and the configuration of which promotes lens elements to self-center and also eliminates the need of spacers while maintaining the lens system's compactness.

These and other objects of the invention have been attained by a lens system comprising from the object side: a first positive meniscus lens component having foremost lens surface convex to the object side; a second bi-concave lens component; a third bi-convex lens component; and a diaphragm arranged behind the rear-most lens element of the the lens system, wherein the lens system fulfills the following conditions:

$$N_3 - N_1 \leqq 0.1$$

$$\frac{N_1}{N_2} \geqq 0.9$$

$$0.25f < \Sigma d < 0.35f$$

where f is the composite focal length of the lens system; Σd is the distance from the vertex of the foremost lens surface to the vertex of the last lens surface; N_1 represents the refractive index of the positive lens element forming the first lens component; N_2 represents the refractive index of the negative lens element forming the second lens component; N_3 represents the refractive index of the positive lens element forming the third lens component. These relationships help maintain the aberration's balance while maintaining the compactness of the optical system.

According to another aspect of the present invention, a lens system comprises: a first outer lens component, the first outer lens component being a positive lens component; a negative lens component located between and airspaced from the first outer lens component and a second outer lens component; a positive power second outer lens component; and an aperture stop, said aperture stop located on the outer side of one of said outer lens components, wherein the airspaces between said components are so arranged that there exists an edge contact between the lens components at less than 3 mm and preferably less than 2 mm beyond clear aperture.

According to yet another aspect of the present invention, a compact lens system for use in a compact photographic camera comprises: a plurality of optical elements spaced in a close proximity to one another, the plurality of lens elements having sufficient powers and spacings to enable said lens system to cover a field of view of at least 55 degrees, said plurality of lens elements including at least one positive lens element and one negative lens element wherein the airspace between said positive lens element and said negative lens element is smaller than the thickness of said positive lens element; and the lens system in order to be suitable for use in a compact camera satisfies the following parameters:

$$20 \leqq f \leqq 30$$

$$5 \leqq BF \leqq 24.85$$

$$2 \times f/No.|_{min.} \leqq 5.6,$$

where f is the focal length of the lens system, BF is the back focus of the lens system. $f/No.|_{min}$ is the f/No. that the system is intended to perform at without being stopped down.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a simplified cross-sectional view of a lens system corresponding to a first embodiment of the invention.

FIG. **2** is a simplified cross-sectional view of a lens system corresponding to a second embodiment of the invention.

FIGS. **3***a*–**3***d* represent the aberration curves of the lens system corresponding to the first embodiment.

FIGS. **4***a*–**4***d* represent the aberration curves of the lens system corresponding to the second embodiment.

FIGS. **5** and **6** are cross-sectional views in schematic of a photographic device showing the objective lens systems of FIGS. **1** and **2** and their respective mounting structure.

FIG. **7** illustrates the requirements of the edge contact as they apply to the rear surface of a negative lens element.

FIG. **8** illustrates formation and propagation of unwanted light if the edge contact points are located at the clear aperture of the surface.

FIG. **9** illustrates how rays of stray light propagate in an optical system that does not form an embodiment of this invention.

FIG. **10** illustrates a lens system of FIG. **2** and how it substantially eliminates light flare or stray light problems.

FIG. **11** is a cross-sectional view of the lens system of FIG. **2** and showing a mounted objective lens system in a barrel utilizing a heat-seal ring retainer.

FIGS. **12***a* and **12***b* illustrate steps in the formation of a heat-seal retainer for an optical mount such as one illustrated in FIG. **11**.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENT

Referring to FIGS. **1** and **5**, a photographic device, such as a compact photographic camera **55**, includes a barrel **4** and a three-component lens system **100** retained on the lens barrel **4** and including, in order from an object side, a first, second and third lens elements **L1**, **L2** and **L3**, respectively, in appropriately spaced axial alignment and forming a taking lens system for focusing light onto a photographic film F located by suitable means (not shown) at the focal plane of the camera. An aperture stop ST is located behind the rear lens element **L3**. The f/No. of the lens system may be determined by the opening in the diaphragm ST. As the opening is reduced, the f/No. increases. The particular lens mount **4** is shown for illustrative purposes only and this is but one type of mount which may be used with the lens system disclosed. Since the lens system is primarily intended for use in connection with very compact photographic cameras which are fabricated on a high volume production basis, it is preferred that the lens mount be compact and also be constructed so that its manufacture is adapted to the assembly of the lens components therein for mass production. In this particular embodiment, the first lens component is positive and is in the form of a single lens element **L1** which has a meniscus shape and has a convex first surface **S1** and a concave second surface **S2**. The second lens component is in the form of a bi-concave lens element having a front surface **S3** and a rear surface **S4**. A third lens component is in the form of a bi-convex single lens element and it has a front surface **S5** and a rear surface **S6**. The focal lengths of the first, second and third lens components are 19.86,–8.31 and 10.04 respectively. The absolute value of the ratio of the focal length of the middle component to the total lens system focal length is 0.325. It is important in order to fill the film plane, that the compact lens system according to this invention is capable of covering at least a 55 degree field of view and preferably a field of view of 60 degrees or more and most preferably, a field of 65 degrees or greater. In particular, the lens system of this embodiment is capable of maintaining an excellent performance over a 67 or 68 degree field of view. The lens system satisfies the following conditions and definitions:

$$N_3 - N_1 \leqq 0.1;$$

$$\frac{N_1}{N_2} \geqq 0.9;$$

and more preferably $0.9<N_2/N_1<1.0$;

$$0.22f<\Sigma d<0.38f$$

where f is the composite focal length of the lens system; Σd is the distance from the vertex of the foremost lens surface to the vertex of the last lens surface; N_1 represents the refractive index of a positive lens element forming the first lens component; N_2 represents the refractive index of a negative lens element forming the second lens component; and N_3 represents the refractive index of a positive lens element forming the third lens component.

The significance of the above-mentioned conditions is as follows: It is advantageous to have high index glasses in the positive lens elements, because it helps to keep the Petzval sum low. Also, with the higher index of refraction, the lens element may be made with weaker radii of curvature, thus, the lens system can be made more compact. In addition, in order to correct the Petzval sum, it is advantageous to have the index N_2 of the negative lens element as low as possible. However, typically in flint glasses, the lower the index of refraction is, the higher the V number; and, in order to correct color aberrations, we need a low V number. Thus, the first two requirements help us balance the Petzval sum and color correction in the lens system. The last condition helps to keep the lens compact and is also a condition for well-corrected coma aberration for a wide angle system as ours. The performance of the lens system of the first embodiment is illustrated in FIGS. **3***a*–**3***d*.

FIG. **3***a* is a graph of longitudinal spherical aberration (in mm) with respect to aperture is in three wavelengths. The graph shows well corrected spherical aberration and the axial color which is corrected at approximately the 0.9 aperture.

FIG. **3***b* is a graph of the tangential and sagittal coddington field curvature (in mm). It can be seen that there is a node beyond the 0.6 field and the astigmatism is well balanced.

FIG. **3***c* is a graph that plots the percent distortion with respect to relative image height. It can be seen that the distortion is not greater than 2% at any point in the field.

FIG. **3***d* shows a plot of lateral color (in mm) as a function of relative field. It shows that the lateral color is well balanced and does not vary by more than 5 microns through most of the field.

Although in principal the lens elements can be made of plastic, the lens elements of this embodiment are all made from glass. This eliminates some of the distortion problems referred to in U.S. Pat. No. 4,886,342. The lens elements powers, shapes and the airspaces between the lens elements of lens system **100** are arranged so that there exists an edge or other contact between mutually contacting lens elements at less than Δ=3 mm and preferably at less than Δ=2 mm beyond the clear aperture CA. (See FIG. **7** for illustration of

Δ.) The "clear aperture" of a surface of a lens element in the lens system is basically a minimum size aperture of the lens element that allows all of the desired bundles of light rays to go through the lens system to the image plane. These desired bundles of rays are often determined by other surfaces of the lens system. The clear aperture of a surface of a lens element in the lens system is defined as the necessary minimum size openings on the lens surfaces of the lens system that must satisfy both of the following conditions: a) it must be large enough to satisfy the minimum f/No. required; and b) it must be large enough to transmit the required amount of light in the comers of the field at the maximum field coverage. If the clear apertures are too small, then there will be unacceptable vignetting; and if they are too large, poorly corrected light could reach the image plane. Also, if they are too large, the lens system will not be compact as desired, and may exhibit stray light problems. The section outside the clear aperture may be masked off or otherwise treated so that light striking outside of the clear aperture would be prevented from propagating through the lens system.

The pairs of mutually contacting surfaces are S2*a* and S3*a*; S4*a* and S5*a*. These surfaces do not have to be flat, vertical surfaces and they do not need to be cemented together. Surfaces S2*a*, S3*a*, S4*a* and S5*a* are segments of the surfaces S2, S3, S4 and S5, respectively.

Having an edge contact allows all of the elements to be placed next to each other so they physically touch each other as in glass-to-glass contact thus eliminating the costly need for superfluous spacers. No adhesive is usually necessary. However, where a thin layer of adhesive is used, this may still be considered to be edge contact in accordance with the invention. This edge contact also eliminates tolerance build-up on the thickness of spacers as well as tolerance build-up on spacer wedge. The manufacturing errors on spacer thickness and spacer wedge angle also cause misalignment of the lens components with respect to each other. This results in the degredation in the performance of the lens system. As stated above, by maintaining the contact between the lens elements, the need for spacers is eliminated which also results in improved performance of the optical system. As an additional benefit of the edge contact, the lens components tend to self align or self center, thus, eliminating a need for complex alignment procedures. The importance of achieving an edge contact at points P on a circle of diameter (CA+Δ), where Δ is in the range of or less than 3 mm, and more preferably 2 mm or less beyond the clear aperture CA (FIG. 7), is that the lens diameter will be held at a minimum. This requirement also tends to minimize the thicknesses of the lens elements and the airspaces between them and thus produces the overall lens system which is very compact and also less expensive to manufacture. On the other hand, it is preferable not to have an edge contact exactly at the clear aperture (i.e. Δ≈0.0 mm beyond the clear apeture) because digs and chips from beveling operation can cause unwanted sparkling. That is, the digs, scratches, bubbles, and chips, etc. at the resulting edge contact cause the impinging light A to disperse (FIG. 8). The (unwanted) dispersed light B then may propagate through the lens system and impinge on the imaging medium such as film. With the stop outside the lens system, the cost of "split" barrels is also eliminated.

The requirement that the airspace d_1 between the first and the second elements L1 and L2 be smaller than the first element's thickness T_1 and that the airspace d_2 between the second lens element L2 and the third lens element L3 be smaller than the thickness T_3 of the third lens element L3 facilitates the compactness of the lens system and helps maintain the edge contact between the lens elements. It is preferable that the following relationship be maintained, $T_1 \geqq 2d_1$ and $T_3 \geqq 2d_2$ and more preferably that $T_1 \geqq 2d_1$ and $T_3 \geqq 3d_2$. In this first embodiment,

$$\frac{T_1}{d_1} = 2.9 \text{ and } \frac{T_3}{d_2} = 3.5.$$

The dimensions d_1, d_2, T_1 and T_3 are taken along the optical axis A. In addition, in order to facilitate lens system compactness, one may specify that at least one airspace between the positive lens element and the second or middle lens element be smaller than the thickness of said second lens element. It should be also noted, the requirements that

$$0.275 \leqq \frac{|f_2|}{f} \leqq 0.375$$

and that

$$1.5 \leqq \frac{f_1}{f_3}$$

(where f_1, f_2 and f_3 are the focal length of the first, second and third lens components respectfully, and f is the focal length of the lens system) help to maintain a nice aberration balance while keeping the lens system compact.

Finally, by placing the aperture stop (or diapragm) at the rear of the lens system, it is protected from dust and dirt. Placement of the aperture stop (i.e. diapragm) in front of the optical system, requires that a cover glass be placed in front of the aperture stop to keep dust and dirt out. Therefore, by placing the aperture stop at the rear of the optical system (i.e. towards the image plane), eliminates the need for the cover glass.

This design is extremely compact as can be determined by a vertex-to-film plane distance which is short—i.e. only 27.26 mm when the focal length is 25.6 mm. The size of the front clear aperture is 9.9 mm and the system f/No. is 4.5. In designing the lens system for the compact camera, it has been determined that the focal length range needs to be between 20 and 30 mm in order to make the lens system more compact and that the focal range should preferably be between 22 and 28 mm and more preferably between 25 and 27 mm. We determined that a short focal length (i.e. f<20 mm) tends to require more elements because the field angle has to increase to cover the same image size, and this causes the aberration correction to become increasingly difficult. In particular, such aberrations as distortion and astigmatism become predominant. On the other hand, a lens system having the same f/No., but a longer focal length (i.e. f>30) will tend to make all elements larger and the front vertex to image plane longer thus producing a more bulky lens. The advantages provided by edge contact would also be jeopardized. In addition, the back focal length BF, (back focal length is the distance as measured from the rear vertex of the rear surface of the last lens element to the image plane) needs to be between 5 mm and 24.85 mm . Placing a lens element closer than approximately 5 mm to the image plane when stopping the lens down to f/16 or greater results in small artifacts on the lens surface near the image plane to be visible at the image plane. Thus, it is found that a lens system satisfying the following parameters or requirements is particularly suited for use in very compact cameras:

$$20 \leqq f \leqq 30, \quad (1)$$

$$5 \leqq BF \leqq 24.85 \quad (2)$$

and

$2 \leqq f/No.|_{min.} \leqq 5.6,$ (3)

where f is the focal length of the lens system, BF is the back focus of the lens system. $f/No.|_{min}$ is the f/No. that the system is intended to perform at without being stepped down. Alternatively, in the lens system which can be used in lower cost cameras, the f/No. may be slower, thus, the third requirement can be altered to 3<f/No.<16 where f/No. is the lens system's F-number.

FIG. **5** illustrates the lens elements **L1**, **L2** and **L3** of lens system **100** are freely placed in the lens barrel **4**. Their optical axes are aligned without a need to cement these elements to each other. All of the lens components are pressed against the lens barrel. In this embodiment, the three lens components are mounted in the cylindrical recess surface of the lens barrel and have outer annual barrel contacting surfaces **1***b*, **2***b* and **3***b* respectively which fit within hollow cylindrical surfaces **4***a*, **4***b* and **4***c* forming the inner surfaces of the barrel **4**. The lens elements have just enough clearance to move within the barrel so as to be positioned within the barrel. Finally, the lens system **100** is securely retained within the lens barrel **4** by a pressing member **10** for pressing the first lens element **L1** against the second lens element **L2**, and by a pressing member **20** for pressing the third lens element **L3** against the second lens element **L2**.

In the photographic lens devices, the lens components can be readily slipped inside the lens barrel **4**. Once the edge contact is established between the lens elements, the lens elements align themselves with a high degree of accuracy and are then retained in the barrel in that alignment by the pressing members **10** and **20** which are adjacent to lens elements **1** and **3** respectively.

Finally, it is preferred that high index materials be used for outer elements in a design of this lens system. Some of the reasons are reduced field curvature and spherical aberration correction. In addition, the edge contact properties are closely related to a best choice of high index glass. (This is all related to f/No., field coverage and focal length range requirements discussed above.) If low indices are used, the powers and radii of the outer elements are redefined in such a way that it becomes more difficult to achieve edge conditions.

Constructional values for the first preferred embodiment of the invention is shown in Table 1 below, in which the lens elements are numbered from front to rear, N is the index of refraction for the d line of the spectrum, V is the Abbe number, R is the radius of curvature of the lens surface, T is the axial thickness of the lens element, and d is the axial separation between the lens elements.

TABLE 1

f = 25.57; BF = 20.68; semifield angle = 33.58°.
Maximum aperture with no vignetting corresponds to f/4.5.

Lens		Clear			Material	
Element	Surface	Aper.	Radius	Thickness	N_d	V
L1	S1	9.90	R_1 = 7.4251	T_1 = 2.852	1.713	53.8
	S2	7.90	R_2 = 13.046	d_1 = 0.974

		4.40	DIAPHRAGM			

The second embodiment of the present invention is shown in FIGS. **2**, **6** and **11**. Referring to FIGS. **2**, **6** and **11**, a photographic device includes a barrel (**4**A, **4**B) and a three component lens system **200** retained on the lens barrel. The lens system **200** parameters are provided in Table 2.

The second embodiment is similar to the first embodiment in that it is also a behind-stop type lens system for photographic cameras and in that it also comprises three lens components (arranged in positive-negative-positive configuration). Thus, this lens constitutes a triplet derivative. However, unlike the first embodiment, this embodiment comprises four lens elements. They are, in succession from the object side, a first lens component that is in the form of a first lens element **L1'** which is a positive meniscus lens element having its convex surface facing the object side, a second lens component that is in the form of a second lens element **L2'** which is biconcave, a third lens component that is in the form of a third lens element **L3***a*' which is biconvex and a fourth lens element **L3***b*' which is a negative meniscus lens element having its convex surface facing the image side. The third and the fourth lens elements **L3***a*' and **L3***b*' are joined together to form a positive cemented doublet lens component. The lens system **200** has a stop ST in position most adjacent to the rear surface **S7'** of the fourth or rear-most lens element **L3***b*'. It is important that the lens system has a field of view of at least 55 degrees, preferably over 60 degrees and most preferably 65 or more degrees. Accordingly, the lens system of this embodiment has a full field of over 67 degrees. The lens system **200** was found, as in the previous embodiment, that having

$$0.275 \leqq \frac{|f_2|}{f} \leqq 0.375 \text{ and } 1.5 \leqq \frac{f_1}{f_3}$$

helped maintain the aberration balance while keeping the lens system compact. The lens system of the second embodiment also satisfies the following conditions:

$$20 \leqq f \leqq 30$$

$$5 \leqq BF \leqq 24.85$$

$$3 \leqq f/No. \leqq 16,$$

more specifically, the parameters of the lens system are provided in the following table.

TABLE 2

f' = 25.56; BF = 20.31; semifield angle = 33.58°; f/No. = 3.5.

Lens		Clear			Material	
Element	Surface	Aper.	Radius	Thickness	N_d	V
L1'	S1'	10.53	R_1 = 8.02940	T_1 = 2.500	1.734	51.8
	S2'	8.80	R_2 = 15.8029	d_1 = 1.102		
L2'	S3'	8.23	R_3 = −31.7598	T_2 = 0.668	1.689	31.2
	S4'	6.76	R_4 = 8.18380	d_2 = 0.577		
L3a'	S5'	6.60	R_5 = 15.8680	T_3 = 2.565	1.788	47.5

	S7'	5.91	R_7 = −31.4600	d_3 = 1.000		
		6.14[1]	DIAPHRAGM[1]			

[1]THE DIAPHRAM ACTS AS A BAFFLE WHEN THE LENS OPERATES AT f/3.5 AND APERTURE HOLD ON SURFACE S7' BECOMES THE STOP.

All of the above dimentions, for radii, thickness and clear apertures are in millimeters.

The performance of this lens system **200** is illustrated in FIGS. *4a–4d*.

FIG. *4a* is the graph of longitudinal spherical aberration (in mm) with respect to aperture in three wavelengths. The graph shows well corrected spherical aberration and the axial color is corrected at approximately the 0.9 aperture.

FIG. *4b* is a graph of the tangential and sagittal coddington field curvature (in mm). It can be seen that there is a node beyond the 0.6 field and the astigmatism is well balanced.

FIG. *4c* is a graph that plots the percent distortion with respect to relative image height. The distortion is less than approximately 0.5% at any point in the field.

FIG. *4d* shows a plot of lateral color (in mm) as a function of relative field. It shows that the lateral color is well balanced and does not vary by more than 5 microns through most of the field.

FIGS. **6** and **11** illustrate that the lens elements L1, L2, L3 and L4 of lens system **200** are freely placed in the camera's lens barrels. Their optical axes A' are aligned without a need to cement these elements to each other. All of the lens components are pressed against the respective lens barrel inner walls. In each embodiment, the three lens components are mounted in cylindrical recess surfaces of the lens barrel and have outer annual barrel contacting surfaces *1b'*, *2b'* and *3b'* respectively. The lens elements have just enough clearance to move within the barrel so as to be positioned within the barrel. Finally, the lens system **200** is securely retained within the lens barrel by a pressing member **10** for pressing the first lens element L1 against the second lens element L2, and by a pressing member **20** for pressing the third lens element L3 against the second lens element L2.

In the photographic lens devices, the lens components can be readily slipped inside the lens barrel **4**. Once the edge contact is established between the lens elements, the lens elements align themselves, i.e. self-center, with a high degree of accuracy and are then retained in the barrel in that alignment by pressure means such as the pressing members **10'** and **20'** or the barrel surfaces **30** and **40** which are adjacent to lens elements L1 and L4 respectively.

Finally, it is preferred that high index materials be used for outer elements in a design of this lens system. Some of the masons are reduced field curvature and spherical aberration correction. In addition, the edge contact properties are closely related to a best choice of high index glass. (This is all related to f/No., field coverage and focal length range requirements discussed above.) If low indices are used, the powers and radii of the outer elements are redefined in such a way that it becomes more difficult to achieve edge conditions.

The lens system assembly is done in the following fashion. At first, the rear component is dropped into the lens barrel where it is retained by front and rear pressing members **20** or **40** and the barrel walls. The second component is dropped in second. It contacts physically with the rear lens component establishing the edge contact. Once the edge contact is established, the airspace d_2 between the second and the rear lens component is automatically set with the required precision without any further involvement on the part of the assembly personnel. Lastly, the front component corresponding to the lens element **L1** is dropped into the lens barrel. Once the edge contact between the front component and the second component is established, the distance between these components is accurately set. Finally, with all lens components nested against each other in a barrel, pressure means is applied to the front lens element to permanently keep the lens system elements in an optical, axially aligned relationship with each other and to prevent lens elements from movement. This may be done by use of a pressure member **10'** (FIG. **6**), or alternatively by use of a heat seal retainer **30** (FIG. **11**). The heat seal retainer **30** may be formed (FIG. **12**) by applying sufficient sonic energy to create heat which softens a plastic lip **31** which forms a ring **32** and extends round the edge of a lens element. A metal tool then presses the ring over and down upon the upper surface of the lens element, permanently retaining it in the barrel.

As in the previous embodiment, the airspaces between the lens elements are arranged so that there exists an edge contact between the lens elements at Δ equal to about 2 mm, or Δ less than 2 mm beyond the clear aperture CA. This insures that the lens elements can be placed next to each other in glass-to-glass (i.e. lens element-to-lens element) contact thus eliminating the costly need for superfluous spacers while having a compact lens system which can be used in a compact photographic camera. With the stop outside the lens system and this combination of lens elements, the cost of "split" barrels is eliminated. When two lens elements are to be edge contacted to eliminate the need for a spacer, it is advantageous to have both lens elements have a finished diameter that extends beyond the edge contact points and then precision bevel one of the elements (usually the element with the concave surface). The bevel is placed at the precise distance from the lens element's center so that its sag, when edge contacted with another lens element (as done during the assembly of lens elements into the barrel), will accurately define the desired airspace between the two elements. In addition, manufacturing the precision bevel in this manner reduces the amount of edge chips and hence reduces the effects of unwanted stray light.

The requirement that the airspace d **1** between the first and the second lens elements **L1'** and **L2'** be smaller than the first lens element's thickness T_1 and that the airspace d_2 between the second lens element **L2** and the third lens element **L3*a***' be smaller than the thickness T_3 of the third lens element **L3*a***' facilitates the compactness of the lens system and helps maintain the edge contact between the lens elements. It is preferable that the following relationship be maintained, $T_1 \leqq 2d_1$ and $T_3 \leqq 2d_2$ and more preferably that $T_1 \leqq 2d_1$ and $T_3 > 3d_2$. In this first embodiment,

$$\frac{T_1}{d_1} = 2.2 \text{ and } \frac{T_3}{d_2} = 4.4.$$

In addition, in order to facilitate lens system compactness, one may specify that at least one airspace between the positive lens element and the second or middle lens element be smaller than the thickness of said second lens element.

This arrangement also enhances the unique method of utilizing the rear surface of which lens of the lens system to act as the stop when the lens system is operating in a wide open or fast mode (i.e. low f/No.) and enabling the "true" diaphragm; i.e. the aperture stop, to act as a baffle to control the upper rays at the f/3.5 opening (see FIG. **6**). For f/Nos. slower than f/3.5, the diaphragm acts as the true stop.

Furthermore, by placing a limiting clear aperture at surface **S5** controls upper rays at the mid obliquities thus improving their image quality.

An important consideration is the reduction of light coming from overhead and through multiple reflections eventually exposing the film. This condition is illustrated in FIG. **9**. FIG. **9** shows that a double reflection condition for a light source at 72 degree azimuth angle allowing bundles of light striking high in the aperture to easily bounce twice within the front lens and then make it through a lens system to the image plane, resulting in an unacceptable picture quality.

Therefore, the first and the second lens components corresponding to lens elements **L1** and **L2'** are configured so as to minimize the upward slope of the stray rays after the reflection from the front surface of the front lens element **L1'** (i.e. the 2nd reflection within the first lens element). This change results in fewer stray light rays passing through the aperture stop opening. The diaphragm walls of the aperture stop will thus block the rest of the unwanted or stray light. The shape of the second component also permits the shape of the first lens component **L1** to be configured to minimize the angle of incidence of the rays for controlling internal reflections, with the result that the high incident overhead light (ray C in FIG. **10**) that enters the front surface of **S1'** above the optical axis does not propagate towards the opening in the diaphragm and instead will be limited by the diaphragm wall. Thus, total internal reflections that will send light rays towards the image plane is minimized.

The lens system **200** of the second preferred embodiment illustrates the result of designing for stray light minimization. The stray bundles of light D do not make it through the lens system unless they strike the front most lens surface of the lens system below the optical axis resulting in near grazing incidence thus reducing the intensity of the light that is refracted. The refracted bundle is then vignetted before it reaches the image.

Thus, in this second embodiment, the shape of the second element **L2'** is configured to eliminate double and triple reflections that results in undesirable light flare at the image plane from a bright overhead object, such as the sun, when it is subtending an angle from 55 to 75 degrees. When the sun is lower in the horizon (i.e. when it subtends an angle less than 55 degrees) it would be seen in the viewfinder and the camera sensor would be eliminated as a potential camera shot. If the sun is higher than 75 degrees, then them is no chance of double reflection due to high grazing angles of the light. FIG. **9** shows the stray ray bundles and illustrates this effect. FIG. **10** shows how this effect has been controlled.

Finally, the lens systems described herein are particularly advantageous when used in the focal length range 24 mm to 27 mm and for covering half fields of at least 34 degrees.

The invention has been described in detail with particular reference to preferred embodiments thereof, but it will be understood that variations and modifications can be effected within the spirit and scope of the invention.

I claim:

1. A lens system comprising from an object side:

a first positive power meniscus lens component having a foremost lens surface convex to the object side;

a second bi-concave lens component engaging said first lens component and defining with said first lens component an airspace separating said second lens component from said first component;

a third bi-convex lens component engaging said second lens component and defining with said second lens component an airspace between said third lens component from said second lens component; and

a diaphragm arranged behind the rear-most lens element of the lens system, wherein all of the airspaces between said lens components are so arranged that there exists between all of adjacent lens components an edge contact located only at points located within the region from over 0.0 mm at a position to sufficiently eliminate stray light to about 2 mm beyond clear aperture diameter, and wherein the lens system fulfills the following conditions:

$$N_3 - N_1 \leqq 0.1$$

$$\frac{N_1}{N_2} \geqq 0.9$$

$$0.25f < \Sigma d < 0.35f$$

where:

f is the composite focal length of the lens system;

Σd is the distance from the vertex of the foremost lens surface to the vertex of the last lens surface;

N_1 represents the refractive index of a positive lens element forming the first lens component;

N_2 represents the refractive index of a negative lens element forming the second lens component; and

N_3 represents the refractive index of a positive lens element forming the third lens component.

2. A lens system as claimed in claim **1**, wherein:

$$T_1 \geqq 2d_1$$

and

$$T_3 \geqq 3d_2.$$

where:

d_1 is an airspace between the first and the second lens component;

d_2 is an airspace between the second and the third lens component;

T_1 is the thickness of said first positive lens element forming the first lens component; and

T_3 is the thickness of said positive lens element forming the third lens component.

3. A lens system according to claim 1 wherein:

$$0.275 \leqq \frac{|f_2|}{f} < 0.375\ 1.5 \leqq \frac{f_1}{f_3}$$

where:

f_1 represents the focal length of the first lens component;

f_2 represents the focal length of the second lens component; and

f_3 represents the focal length of the third lens component.

4. A lens according to claim 1, wherein:

$$0.3 \leqq \frac{|f_2|}{f} \leqq 0.36$$

and

$$1.6 \leqq \frac{f_1}{|f_2|} \leqq 2.0.$$

5. A photographic device according to claim 1, wherein said first lens component is a singlet lens element, said second lens component is a single lens element; and said third lens component is a cemented doublet.

6. A photographic device according to claim 5, wherein said cemented doublet comprises a front biconvex positive lens element and a rear meniscus negative lens element.

7. A lens system comprising a plurality lens of components arranged in order from an object side:

a first positive power meniscus lens component having an object type surface convex to the object side;

a second bi-concave lens component engaging said first lens component and having an airspace separating said second lens component from said first component;

a third bi-convex lens component engaging said second lens component and having an airspace separating said third lens component from said second lens component, said plurality of lens components having radii of curvature, thicknesses and airspaces to enable the lens to cover at least 55 degree field of view, wherein all of the airspaces between said lens components are so arranged that there exists between all of adjacent lens components an edge contact located only at points located within the region from over 0.0 mm at a position to sufficiently eliminate stray light to about 2 mm beyond clear aperture diameter; and

a diaphragm arranged behind a rear-most lens element of a lens system, and wherein said lens system fulfills the following conditions:

$$T_1 \geqq 2d_1$$

and

$$T_3 \geqq 2d_2.$$

where:

d_1 is an airspace between a first and a second lens element;

d_2 is an airspace between the second and a third lens element;

T_1 is the thickness of the first lens element; and

T_3 is the thickness of the third lens element.

8. A lens system according to claim 7, wherein all of the lens elements are glass lens elements.

9. A lens system according to claim 7, wherein:

$$0.275 \leqq \frac{|f_2|}{f} < 0.375\ 1.5 \leqq \frac{f_1}{f_3}$$

where:

f_2 represents the focal length of the second lens component;

f_1 represents the focal length of the first lens component; and

f is the focal length of the lens system.

10. A photographic device according to claim 7, wherein two of said lens components each consist of a single lens element; and one of said lens components is a cemented doublet.

11. A lens system comprising in order from an object side:

a first positive power lens component;

a negative power lens component located between and airspaced from said first positive power lens component and a second positive power lens component;

the second positive power lens component located behind said negative power lens component;

an aperture stop, said aperture stop located on an outer side of one of said positive power lens components; and

wherein all of airspaces between said lens components are so arranged that there exists an edge contact between all of the adjacent lens components so that there are contacting lens surfaces and said edge contact exists only at points located within the region from 0.0 mm at a position to sufficiently eliminate stray light to less than 3 mm beyond a clear aperture diameter of each of said contacting lens surfaces.

12. A lens system according to claim 11, wherein said edge contact is at less than 2 mm beyond said clear aperture.

13. A lens system according to claims 12, wherein:

$$0.275 \leqq \frac{|f_2|}{f} \leqq 0.375,$$

where f_2 represents the focal length of the negative power lens component and f is the focal length of the lens system.

14. A lens according to claim 12, wherein:

$$0.3 \leqq \frac{|f_2|}{f} \leqq 0.36,$$

where f_2 represents the focal length of the negative power lens component and f is the focal length of the lens system.

15. A compact lens system according to claim 11, wherein said aperture stop being arranged behind a rearmost lens element from an object side.

16. A compact lens system according to claim 11 having the following parameters:

$$22 \leqq f \leqq 28$$

$$5 \leqq BF \leqq 23$$

$$2 \leqq f/No._{min.} \leqq 5.6,$$

where f is the focal length of the lens system, BF is the back focus of the lens system and $f/No._{min.}$ is the F-number that the lens system performs at without being stepped down.

17. A compact lens system according to claim 11, wherein the rear lens of positive power component is a cemented doublet.

18. A compact lens system according to claim **16**, wherein there is an edge contact between all of the lens components at more than 0.0 mm so as to sufficiently eliminate stray light to less than 3 mm beyond clear aperture, and

$$0.275 \leqq \frac{|f_2|}{f} \leqq 0.375,$$

where f_2 represents the focal length of the negative power lens component and f is the focal length of the lens system.

19. A photographic device according to claim **11**, wherein two of said lens components each consist of a single lens element; and one of said lens components is a cemented doublet.

20. A compact lens system for use in a compact photographic camera comprising:

a plurality of lens elements forming lens components and spaced in a close proximity to one another, said plurality of lens elements having sufficient powers and spacings to enable said lens system to cover a field of view of at least 55 degrees, said plurality of lens elements including at least one positive power lens element and one negative power lens element wherein an airspace between said positive power lens element and said negative power lens element is smaller than a thickness of said positive lens element, wherein all of airspaces between the lens components are so arranged that there exists between all adjacent lens components an edge contact located only at points located within the region from over 0.0 mm at a position to sufficiently eliminate stray light to about 2 mm beyond clear aperture diameter; and

the lens system being suited for use in a compact camera and satisfying the following parameters:

$20 \leqq f \leqq 30$

$5 \leqq BF \leqq 24.85$

$2 \leqq f/No.|_{min.} \leqq 5.6,$

where f is the focal length of the lens system, BF is the back focus of the lens system and $f/No.|_{min.}$ is the F-number that the lens system performs at without being stopped down.

21. A compact lens system according to claim **20**, wherein said plurality of lens elements are only three lens components arranged in order from an object side, a first positive power lens component that includes said one positive power lens element, a second negative power lens component that includes said negative power lens element, and a third positive power lens component.

22. A compact lens system according to claim **20** further comprising an aperture stop arranged behind a rearmost lens element from an object side.

23. A compact lens system according to claim **21** further comprising an aperture stop arranged behind a rearmost lens element from the object side.

24. A photographic device according to claim **20**, wherein said first lens component is a singlet lens element, said second lens component is a single lens element; and said third lens component is a cemented doublet.

25. A compact lens system for use as a taking lens in a compact camera, the lens system comprising no more than four lens elements centered on an optical axis and grouped together in a 3 lens component lens group with an aperture stop arranged outside of the lens group; said lens elements arranged so that there is edge contact among all of the adjacent and uncemented lens elements and the lens elements have cooperating edge surfaces to self-center said lens elements, wherein all of airspaces between said adjacent and uncemented lens elements are so arranged that said edge contact exits only at points located within a region from over 0.0 mm at a position to eliminate stray light to about 2 mm beyond clear aperture diameter, said lens components being a front positive power lens component, a negative power lens component and a rear positive power lens component wherein said rear positive power lens component is a cemented doublet comprising one positive lens element and one negative lens element.

26. A compact lens system according to claim **25** further having the following parameters:

f' = 25.56; BF = 20.31; semifield angle = 33.58°; f/No. = 3.5.

Lens		Clear			Material	
Element	Surface	Aper.	Radius	Thickness	N_d	V

Where f' is the composite focal length of the lens system: BF is the back focal length of the lens system: F/No. is the F-number of the lens system: Li' is the lens element number i: and Si' is the lens surface number i.

28. A compact lens system for use in a compact camera comprising:

a plurality of optical elements spaced in close proximity to one another, said plurality of lens elements having sufficient powers and spacings to enable said lens system to cover a field of view of at least 55 degrees, said plurality of lens elements including at least one positive lens element and one negative lens element wherein an airspace between said positive lens element and said negative lens element is smaller than a thickness of said positive lens element, wherein all of airspaces between all of adjacent lens elements are so arranged that there exists an edge contact located only at points located within the region from over 0.0 mm at a position to sufficiently eliminate stray light to about 2 mm beyond clear aperture diameter; and

the lens system being suited for use in a compact camera and satisfying the following parameters:

$$2 \leqq f/No.|_{min.} \leqq 5.6$$

$$20 \leqq f \leqq 30,$$

where:

f is the focal length of the lens system; and

$f/No.|_{min.}$ is the F-number that the lens system performs at without being stopped down.

29. A compact lens system for use in a compact photographic camera comprising:

a plurality of lens elements forming a plurality of lens components and spaced in a close proximity to one another, said plurality of lens elements having sufficient powers and spacings to enable said lens system to cover a field of view of at least 50 degrees, said plurality of lens elements including at least one positive power lens element and one negative power lens element wherein an airspace between said positive power lens element and said negative power lens element is smaller than a thickness of said positive lens element, wherein all of airspaces between the lens components are so arranged that there exists between all adjacent lens components an edge contact located only at points located within the region from over 0.0 mm at a position to sufficiently eliminate stray light to about 2 mm beyond clear aperture diameter; and

the lens system being suited for use in a compact camera and satisfying the following parameters:

$$20 \leqq f \leqq 30$$

$$5 \leqq BF \leqq 24.25$$

$$3 \leqq f/No.|_{min.} \leqq 16,$$

where f is the focal length of the lens system, BF is the back focus of the lens system, all distances are in mm, and the f/No. is the f number of the lens system.

30. A compact lens system according to claim **29**, wherein said plurality of lens elements are only three lens components arranged in order from an object side, a first positive power lens component that includes said one positive power lens element, a second negative power lens component that includes said negative power lens element, and a third positive power lens component.

31. A compact lens system according to claim **29** further comprising an aperture stop arranged behind a rearmost lens element from an object side.

32. A compact lens system according to claim **30** further comprising an aperture stop arranged behind a rearmost lens element from the object side.

33. A lens system according to claim **29**, wherein all of airspaces between said lens components are so arranged that there exists an edge contact between all of the lens components at less than 2 mm beyond a clear aperture of any contacting surface.

34. A lens system according to claim **30**, wherein all of airspaces between said lens components are so arranged that there exists an edge contact between all of the lens components at less than 2 mm beyond a clear aperture of any contacting surface.

[57] **ABSTRACT**

In a Faraday microscope for examining specimens with stray magnetic fields in a reflected light beam path with a magnetic indicator film arranged in front of the specimen, the influence of the specimen on the indicator film is evaluated with the indicator film arranged as the termination of the microscope objective, the indicator film advantageously being arranged on an optically transparent substrate. The indicator film and substrate are taken into account in the optical calculation of the microscope objective.

FIG. 4

FARADAY MICROSCOPE WITH MAGNETO-OPTICAL INDICATOR AS TERMINATING ELEMENT OF OBJECTIVE LENS

BACKGROUND OF THE INVENTION

1. Field of the Invention

The invention is directed to a Faraday microscope for examining specimens with stray magnetic fields in a reflected light beam path, wherein a magneto-optical film is arranged in front of the specimen and the influence of the specimen on the indicator film is evaluated with respect to optical polarization, and to a process for adjusting the Faraday microscope.

2. Background of the Invention

Arrangements of this type are known from (1) B. Ludescher, et al., "Faraday Low-Temperature Microscope for Observing Dynamic Magnetization Processes in Superconductors [Faraday-Tieftemperatur-Mikroskop zur Beobachtung dynamischer Magnetisierungsvorgänge in Supraleitern]", *Laser und Optoelektronik* 23 (1991), pages 54–58; (2) L. A. Dorosinskii, et al., *Physica C* 203 (1992) , page 149; (3) M. V. Indenbohm, et al., *Physica C* 209 (1993), page 295.

A device for detecting magneto-optical anisotropism, particularly of magnetic recording media, is described in U.S. Pat. No. 4,410,227.

A laser polarizing microscope for observing magnetic domains is known from JP 3-185338 (A).

A Kerr microscope for examining current paths utilizing the polar Kerr effect is known from DE 4027049.

The magneto-optical Faraday effect causes a rotation of the polarization plane of polarized light at angle w as it passes through a magneto-optical material of thickness d according to the equation

$$w=RM(x)d,$$

where R represents a material constant of the magneto-optical material and M(x) represents the magnetization component at point x parallel to the light path.

The rotation of the plane of polarization is visible by observing the light at the polarizer-analyzer intersection. For example, with the aid of the Faraday effect, dynamic processes in superconductors and magnetic structures in magnetic storage media can be examined. In general, the constant R is so small that the Faraday effect is observed only in special materials.

A "Faraday microscope" in which a magneto-optically active film is vacuum-deposited on the superconductor to be examined is known (see 1 above). Since the Faraday rotation which can be achieved is very small, the interference between the light beams reflected at the surface of the magneto-optical film and those reflected in regions at the surface of the superconductor which are free of magnetic fields is used for evaluation. It is disadvantageous that every specimen to be analyzed must first be vacuum-deposited.

It is known (see 2, 3 above) to place thin magneto-optical indicator plates on the specimen to be analyzed, since the lateral resolution and sensitivity of the indicator decreases sharply with increasing distance from the specimen. In so doing, there is a risk that the specimen will be scratched. Moreover, a large indicator plate must be used when analyzing specimens extending over a surface area in order to avoid repeated placement. However, large indicator plates

are expensive and difficult to produce. The indicator plate is formed by a substrate (garnet) on which the actual magneto-optical indicator film has been deposited. The substrate has a high index of refraction (n=approximately 2) so that the optical imaging is impaired when observing the magneto-optical indicator film.

OBJECT AND SUMMARY OF THE INVENTION

The primary object of the present invention is to realize an improved Faraday microscope for examining specimens with stray magnetic fields. In particular, damage to the surface of specimens is substantially prevented and different specimens may be examined. Further, the invention makes it possible to bring the indicator film as close as possible to the analyzed region of the surface of the specimen which is generally not perfectly planar.

According to the invention, this object is met in a Faraday microscope for examining specimens with stray magnetic fields in a reflected-light beam path, wherein a magneto-optical indicator film is arranged in front of the specimen and the influence of the specimen on the indicator film is evaluated with respect to optical polarization, the improvement comprising that the indicator film is arranged at the end of a microscope objective. Preferred further embodiments and an adjustment process for the microscope objective are within the scope of the invention. A preferred embodiment of a microscope objective is also within the scope of the invention.

A strain-free, (reflected-light) microscope objective suitable for polarization and having a magneto-optical indictor plate as its terminating element is particularly advantageous. The indicator plate is taken into account in the optical calculation for the microscope objective. Further, the objective has an arrangement for protecting the specimen and objective.

Operation of this objective is further facilitated by the use of automatic focussing. In so doing, focussing on the specimen is first effected automatically by a different objective with a reduced depth of field, the location on the object to be examined is selected, whereupon the objective with the indicator plate is switched to. The focussing device now automatically moves the objective with the indicator plate to a minimum distance from the specimen. For this purpose, it is necessary to determine and store the difference between the balanced length of the objective with the reduced depth of field and that of the objective with the indicator plate in an adjustment process following assembly of the microscope.

The indicator plate normally has a reflective layer. A transparent indicator plate without a reflective layer can also be used in an advantageous manner with favorably reflecting, optically isotropic specimens. The specimen can be observed first without a polarizer so that a bright-field image is achieved. When the polarizer/analyzer is switched on, an imaging of the magnetic properties of the specimen is achieved. In this way, a correlation between the surface structure of the specimen and magnetic field contrast is made possible without the use of an additional objective.

When highly reflective optically isotropic specimens are used, the indicator plate can also advantageously have a semi-transparent reflective layer. The semi-transparent reflective layer can be used in the bright field without polarizers for interferometric adjustment of the distance between the indicator plate and the surface of the specimen. The interference can also be used to detect the correlation

between surface topology and magnetic contrast when a polarizer/analyzer is used.

Further, the objective according to the invention is advantageously surrounded by a current coil or Helmholtz coil. A magnetic field (along the optical axis) can be generated and modulated with the current coil, which can be used to improve contrast (e.g., elimination of earth field) and to influence the specimen in situ. A magnetic field can be produced vertically to the optical axis with a Helmholtz coil to homogenize the indicator plate.

Further, the microscope is advantageously outfitted with a monochromator (e.g., exchangeable interference filters) to make use of the dispersion of the Faraday rotation.

Further, the microscope advantageously has an aperture stop which is adjustable vertically to the optical axis so that in-plane magnetization components of the specimen can also be detected by oblique incidence of light with eccentric aperture stop.

The invention is explained more fully in the following with reference to the schematic drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

In the drawings:

FIG. **1** illustrates a schematic construction of a microscope according to the invention;

FIG. **2** illustrates a diagram of the objective according to the invention;

FIG. **3** illustrates a variant of an indicator plate in accordance with the invention; and

FIG. **4** illustrates an example of a microscope with integrated indicator plate.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

The general construction of the microscope according to the invention is shown schematically in FIG. **1**. The light from a light source **1** with associated illuminating optics **2** is linearly polarized in a polarizer **3**. A deflecting element or beam splitter **4** deflects the light into the objective **5** according to the invention. A Berek prism is advantageously provided as beam splitter, since this ensures a homogeneous polarization field with high-intensity illumination and, accordingly, optimal contrast can be achieved at light intensities which are frequently low.

Due to its magnetic field components, the magnetic specimen **6** causes a rotation of the plane of polarization of light in the indicator plate **51**. The light is reflected at the reflective layer of the indicator plate **51**, passes through the objective and reaches the analyzer **7** via the beam splitter. If the analyzer **7** is crossed with the polarizer **3**, light only enters through the analyzer when a Faraday rotation has taken place. Accordingly, the light which reaches the video camera **8** or is observed visually via imaging optics contains an image of the magnetic characteristics of the specimen.

One or both of the polars are advantageously constructed so as to be rotatable so as to enable variation in contrast.

The construction of the objective according to the invention is shown schematically in FIG. **2**. The objective contains the indicator plate **51** as terminating element. The entire lens system **54** including the indicator plate **51** is arranged in a sliding tube **52**. The sliding tube **52** is guided in a stationary tube **53** and is pressed against a stop **56** by a spring **55**. This arrangement protects the specimen and objective and ensures contact between the indicator plate and specimen. The front barrel or mount **57** can be produced from a softer material, e.g., Teflon.

A variant of the construction of the indicator plate **51** is shown schematically in FIG. **3**. The magneto-optical film **512** is deposited on a suitable, often monocrystalline, substrate **511** followed by a reflective layer **513** which is protected by a protective layer **514**. Another advantage of the reflective layer consists in that the light passes twice through the magneto-optical indicator film so that the rotation of the plane of polarization is doubled. The objective **5** is so dimensioned in the optics calculation that the object plane lies in the reflective layer.

The indicator plate advantageously supports an anti-reflection coating **515** because the substrate often has a high refractive index and accordingly high inherent reflection. The anti-reflection coating **515** improves contrast.

When highly reflective, optically isotropic specimens are used, the indicator plate can also advantageously have a semi-transparent reflective layer **513**. The semi-transparent reflective layer can be used in the bright field without polarizer **2** for interferometric adjustment of the distance between the indicator plate and the surface of the specimen. The interference can also be used to detect the correlation between surface topology and magnetic contrast when the polarizer/analyzer is switched on.

Further, the objective **5** according to the invention is advantageously surrounded by a small current coil **13**. A magnetic field can be generated along the optical axis and modulated with the current coil, which can be used to improve contrast (e.g., elimination of earth field) and to influence the specimen in situ. A magnetic field can be produced vertically to the optical axis, i.e., parallel to the surface of the specimen, with a Helmholtz coil **16** which can be used to homogenize the indicator plate. If the microscope is equipped with automatic focussing acting on the objective focussing arrangement **11** or stage focussing arrangement **12**, the difference between the balanced length of the objective **10** with reduced depth of field and that of the objective **5** with the indicator plate is first determined and stored in an adjustment process following assembly of the microscope. Then, focussing on the specimen is first effected automatically by the objective **10** with reduced depth of field, the location on the object to be examined is selected, and the objective turret **9** is switched to the objective **5** with indicator plate. The focussing device now automatically moves the objective **5** with indicator plate to the minimum optimum distance from the specimen.

The microscope is advantageously outfitted with a monochromator **14** (e.g., exchangeable interference filters) to make use of the dispersion of the Faraday rotation. Accordingly, the wavelength at which the magneto-optical film **512** has its maximum Faraday rotation can be used.

Further, the microscope advantageously has an aperture stop **15** which is adjustable vertically to the optical axis so that in-plane magnetization components of the specimen can also be detected by oblique incident light with eccentric aperture stop.

FIG. **4** shows an advantageous example of a microscope objective with integrated indicator plate with surfaces F1, F2 and lens surfaces F3–F15 with distances d1–d14 and radii of curvature r1–r15. The optical parameters are:

within a tolerance of 20%.

While the foregoing description and drawings represent the preferred embodiments of the present invention, it will be obvious to those skilled in the art that various changes and modifications may be made therein without departing from the true spirit and scope of the present invention.

What is claimed is:

1. In a Faraday microscope for examining specimens with stray magnetic fields in a reflected-light beam path, wherein a magneto-optical indicator film is arranged in front of the specimen and the influence of the specimen on the indicator film is evaluated with respect to optical polarization, the improvement comprising that the indicator film is arranged at the end of a microscope objective as a terminating element of said objective.

2. The Faraday microscope according to claim **1**, wherein the indicator film is arranged on an optically transparent supporting substrate, the indicator film and substrate being taken into account in the optical calculation of the microscope objective.

3. The Faraday microscope according to claim **2**, wherein the indicator film is a component part of an indicator plate which is arranged along with the optical elements of the microscope objective in a common housing.

4. The Faraday microscope according to claim **3**, wherein the indicator plate is provided with a protective layer in the direction of the specimen.

5. The Faraday microscope according to claim **2**, wherein an anti-reflection coating is provided in front of the supporting substrate in the direction of light.

6. The Faraday microscope according to claim **1**, wherein an anti-reflection coating is provided subsequent to the indicator film in the direction of light.

7. The Faraday microscope according to claim **4**, wherein the protective layer is formed as an anti-reflection coating.

8. The Faraday microscope according to claim **2**, wherein the supporting substrate is a monocrystalline substrate.

9. The Faraday microscope according to claim **1**, wherein a reflective layer is arranged subsequent to the indicator film in the direction of light.

10. The Faraday microscope according to claim **9**, wherein the reflective layer is arranged between the indicator film and the protective layer.

11. The Faraday microscope according to claim **9**, wherein the reflective layer is semi-transparent.

12. The Faraday microscope according to claim **1**, wherein the microscope objective with the indicator film is arranged in a sliding tube which is guided in an outer tube so as to be displaceable.

13. The Faraday microscope according to claim **12**, wherein the sliding tube is supported in a springing manner and its displacement is limited by a stop.

14. The Faraday microscope according to claim **3**, wherein a crossed polarizer/analyzer arrangement is provided for detecting rotation of the polarization plane by the indicator plate, at least one of the polars being rotatable for the purpose of variation in contrast.

15. The Faraday microscope according to claim **3**, wherein the indicator plate is arranged in the immediate vicinity of the specimen.

16. The Faraday microscope according to claim **3**, wherein the indicator plate is placed on the specimen.

17. The Faraday microscope according to claim **1**, including means for providing a magnetic field in the vicinity of the microscope objective to influence the magnetic properties of the specimen.

18. The Faraday microscope according to claim **17**, wherein the microscope objective is surrounded by said means which includes a current-conducting coil for generating a magnetic field parallel to the optical axis.

19. The Faraday microscope according to claim **17**, said means for providing a magnetic field includes a Helmholtz coil, said field being generated vertically to the optical axis.

20. The Faraday microscope according to claim **19**, wherein a monochromator with adjustable wavelength is provided in the optical path of the microscope.

21. The Faraday microscope according to claim **1**, wherein an adjustable aperture stop is provided in the beam path.

22. The Faraday microscope according to claim **1**, wherein the illuminating beam path and the analysis beam path are united via a beam splitter.

23. The Faraday microscope according to claim **22**, wherein the beam splitter is a Berek prism.

24. The Faraday microscope according to claim **1**, wherein said microscope objective has the following optical parameters with lens surfaces with surface numbers **3–15** and distances **d1–d14** and wherein an indicator plate is arranged in front of the objective with surface numbers **1** and **2**:

Surface no.	Radius (mm)	Distance d (mm)	Glass type	Refractive index
1	infinite			1.0000
		0.50000	garnet	1.9740

25. A process for adjusting a Faraday microscope objective with integrated indicator plate relative to the surface of a superconducting specimen, comprising the steps of: focusing a different objective with reduced depth of field on the specimen surface in a first step, and placing the microscope objective with integrated indicator plate in the beam path and adjusting the objective to a minimum distance from the specimen in a second step.

26. The process according to claim **25**, including the step of determining the difference between the balanced length of the objective with reduced depth of field and that of the objective with integrated indicator plate during adjustment and taking said differences into account when setting the minimum distance from the specimen.

[57] **ABSTRACT**

A detecting apparatus which detects an inclination of an objective lens relative to a reference surface is provided. The objective lens is part of an optical data recording and reproducing apparatus in which data is optically recorded on and reproduced from a recording medium which is placed parallel to the reference surface. The apparatus includes a transparent parallel plate which is opposite the objective lens, parallel to the reference surface, and made of a material that is substantially optically equivalent to a transparent material of the recording medium. The apparatus further includes a reflecting mechanism for reflecting coherent light which has passed through the objective lens and the transparent parallel plate back towards the transparent parallel plate and the objective lens, and a beam splitting mechanism for splitting the coherent light into a first beam and a second beam. The apparatus further includes a wavefront rotating mechanism for rotating the first beam and the second beam about an optical axis in a manner such that the first beam and the second beam are rotated through 180 degrees with respect to one another, and a mechanism for superposing the first beam and the second beam to produce an optical interference.

INCLINATION OF AN OBJECTIVE LENS IN AN OPTICAL INFORMATION SYSTEM

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to an apparatus and method for adjusting an optical system.

2. Description of Related Art

In a conventional optical data recording and reproducing apparatus in which a laser beam is used to record data onto a recording medium, such as a photo magnetic disc (magneto-optical disc), and to read and reproduce the recorded data from the recording medium, it is necessary to converge the laser beam onto the recording medium so as to form a beam spot. The beam spot is made as small as possible to thereby correctly write data onto and read data from the recording medium. However, if the optical axis of the objective lens is not normal to the recording medium, coma occurs. The coma makes it impossible to correctly converge the laser beam onto the recording medium to form a small beam spot, resulting in a restriction of the amplitude of reading signals or an increase of jitters, and thus leading to a failure to correctly reproduce the recorded data.

To this end, it is necessary to precisely adjust the posture of the objective lens so that the optical axis thereof is normal to the recording medium, in the course of the manufacturing process of the optical data recording and reproducing apparatus. The allowable inclination of the optical axis of the objective lens with respect to the recording medium decreases as the numerical aperture (NA) of the objective lens increases. The objective lens used in recent optical data recording and reproducing apparatuses has a large numerical aperture to enhance the data recording density.

The U.S. Pat. No. 5,157,459 has disclosed an inclination adjusting device of an objective lens for adjusting an inclination of the objective lens relative to a recording medium. The adjusting device can be attached to the optical data recording and reproducing apparatus. The device is positioned opposite to the objective lens of the data recording and reproducing apparatus. In other words, adjustment can be performed with a master glass, which corresponds to an optical disc (i.e., the recording medium), positioned opposite to the objective lens. This inclination adjusting device takes in coherent light that is emitted from a laser light source in the optical data recording and reproducing apparatus, and enables the adjustment of the objective lens inclination relative to the master glass in accordance with the interference fringes of the coherent light.

The device, however, cannot adjust the inclination of the objective lens while monitoring the inclination from the recording medium side because a comatic aberration detecting system having a plurality of optical elements is positioned opposite and close to the objective lens. In other words, since there is little space between the comatic aberration detecting system and the objective lens, the comatic aberration detecting system prevents the device from being capable of adjusting the inclination of the objective lens while monitoring the inclination of the objective lens. Due to this inconvenience in prior art, after the inclination of the objective lens is detected in accordance with the interference fringes, the inclination adjusting device has to be removed from the optical data recording and reproducing apparatus to actually adjust the objective lens. This means that it was impossible to adjust the inclination of the objective lens while monitoring the inclination of the objective lens, i.e., whenever an inclination adjustment was carried out, the adjusting device is first attached to the optical data recording and reproducing apparatus, and then removed after the inclination data is obtained to carry out the actual adjustment of the inclination of the objective lens.

The optical system in the optical data recording and reproducing apparatus is usually comprised of various optical elements. It is necessary for the optical system to have an extremely high performance with respect to the diffraction limit (resolution limit). Accordingly, the optical elements which constitute the optical system must be extremely precisely machined or produced. For instance, a single aspherical objective lens, which is provided on opposite sides thereof with aspherical lens surfaces and which has a numerical aperture NA of about 0.55, the wavefront aberration (coma) of the objective lens caused by the deviation of the optical system, etc., would amount to around 0.9 λ (λ=wavelength of light) which is represented by the PV value (difference between the maximum value and the minimum value), assuming that the parallel or transverse deviation (decentering) of one of the aspherical lens surfaces is 10 μm.

To prevent such a large wavefront aberration from occurring, not only must high precision machines be employed to produce or machine the optical elements, but the optical system also must be very carefully assembled. This increases the manufacturing cost of the optical system in the optical data recording and reproducing apparatus. Moreover, the assembling and adjustment of the optical system require a long time and a highly skilled artisan.

SUMMARY OF THE INVENTION

The primary object of the present invention is to provide a detecting apparatus which detects an inclination of an objective lens to adjust the same. In particular, the present invention is directed to a detecting apparatus in which an inclination adjustment of the objective lens can be easily performed from a position opposite the objective lens.

To achieve the object mentioned above, according to the present invention, there is provided a detecting apparatus which detects an inclination of an objective lens relative to a reference surface, the objective lens being part of an optical data recording and reproducing apparatus in which data is optically recorded on and reproduced from a recording medium which is placed parallel to the reference surface. The apparatus includes a transparent parallel plate which is opposite the objective lens, parallel to the reference surface, and made of a material that is substantially optically equivalent to a transparent material of the recording medium; a reflecting mechanism for reflecting coherent light which has passed through the objective lens and the transparent parallel plate back towards the transparent parallel plate and the objective lens; a beam splitting mechanism for splitting the coherent light into a first beam and a second beam; a wavefront rotating mechanism for rotating the first beam and the second beam about an optical axis in a manner such that the first beam and the second beam are rotated through 180 degrees with respect to one another; and, a mechanism for superposing the first beam and the second beam to produce an optical interference.

Another object of the present invention is to provide a lens supporting apparatus which makes it possible to reduce the number of components of an optical pickup to thereby reduce the weight of the same and enable a fast tracking operation (i.e., high-speed tracking).

To achieve the object mentioned above, there is provided a lens supporting apparatus which supports an objective lens of an optical data recording and reproducing apparatus, in which data is optically recorded on and reproduced from a recording medium placed parallel to a reference surface. The apparatus includes an oblique annular lens supporting surface which is inclined relative to a peripheral edge of the objective lens. The annular lens supporting surface supports the objective lens in a manner such that the inclination of the objective lens can be adjusted with respect to the reference surface. The apparatus further includes a mechanism for moving the lens supporting surface to bring a peripheral edge of the objective lens into contact with an external object to thereby move the objective lens along the lens supporting surface in order to vary an inclination of the objective lens relative to the reference surface.

Still another object of the present invention is to provide a lens adjusting method for adjusting the inclination of a lens with respect to a lens holder.

To achieve the object mentioned above, there is provided an inclination adjusting method for adjusting an inclination, relative to a reference surface, of an objective lens of an optical data recording and reproducing apparatus in which data is optically recorded on and reproduced from a recording medium which is positioned parallel to the reference surface. The inclination adjusting method includes the steps of positioning a lens supporting member which supports the objective lens at a predetermined position; placing the objective lens on the lens supporting member; adjusting the inclination of the objective lens while observing interference fringes to reduce a coma, the interference fringes being caused by an inclination of the objective lens relative to a transparent plate, and the transparent plate being positioned parallel to the reference surface and made of a material that is substantially optically equivalent to the recording medium; and, fixing the objective lens to the lens supporting member.

Yet another object of the present invention is to provide a lens positioning apparatus, a lens adjusting apparatus and a method for smoothly adjusting the inclination of a lens supported on a lens holder.

To achieve the object mentioned above, a positioning apparatus, which positions a lens relative to a lens supporting member, is provided. The position apparatus includes a sucking tube which holds the lens by a vacuum force, and a guide portion which has a circular hole. An inner surface of the circular hole guides the lens in a radial direction of the sucking tube so as to position the lens in the radial direction when the sucking tube is inserted into the circular hole. The circular hole is formed in a manner such that a diameter of the circular hole is larger than a diameter of the sucking tube and substantially corresponds to a diameter of the lens.

According to still another aspect of the present invention, an inclination adjusting apparatus is provided with a body, and an oblique annular lens supporting surface which is inclined relative to a peripheral edge of the objective lens and which supports the objective lens in a manner such that the objective lens can be inclined with respect to the lens supporting surface. The inclination adjusting apparatus includes a rotational portion which is rotatably supported by the body in a manner such that a rotational center of the rotational portion is positioned in the vicinity of a rotational center of the lens when the lens is inclined with respect to the lens supporting surface. An adjusting pawl, which is supported by the rotational portion for engaging with a peripheral edge of the lens, is also provided.

According to yet another aspect of the present invention, there is provided an inclination adjusting method for adjusting an inclination of a lens which is supported on ah oblique annular lens supporting surface inclined relative to a peripheral edge of the lens. The lens is displaced by an inclination adjusting member on the oblique annular lens supporting surface thereby inclining the lens at a predetermined angle. The inclination adjusting method includes a first step of determining an angle at which the lens is to be inclined; a second step of inclining the inclination adjusting member at the angle; a third step of bringing the inclination adjusting member into contact with the lens; and, a fourth step of moving the oblique annular lens supporting surface toward the inclination adjusting member to abut the lens against the inclination adjusting member.

According to yet another aspect of the present invention, there is provided an inclination adjusting apparatus which adjusts an inclination of a lens. The inclination adjusting apparatus includes a lens supporting member having an oblique annular supporting surface which supports the lens in a manner such that the lens can be inclined with respect to the supporting surface. The inclination adjusting apparatus further includes an inclination adjusting member which comes into contact with a surface of the lens, the surface being located opposite to the lens supporting member. An inclination defining member for defining an inclination of the inclination adjusting member, and a biasing mechanism for biasing the lens supporting member towards the inclination adjusting member while bringing a part of the inclination adjusting member into contact with the lens to thereby abut the lens against the inclination adjusting member.

Another object of the present invention is to provide a coma compensating method in which imprecise optical elements, such as a lens which has been incorrectly manufactured, can be used, and in which assembling operation of the optical system can be simplified.

To achieve the object mentioned above, a lens adjusting method, in an optical apparatus in which coherent light emitted from a light source is made incident upon a recording medium through an optical system including an objective lens and a plurality of optical elements so as to reproduce data recorded on the recording medium based upon light reflected by the recording medium, is provided. The lens adjusting method includes a first step of adjusting a relative inclination between the objective lens and the recording medium on a lens supporting member which supports the objective lens to compensate a coma occurring in the optical system; and, a second step of securing the objective lens to the lens supporting member by an adhesive applied between the objective lens and the lens supporting member.

The present disclosure relates to subject matter contained in Japanese patent application Nos. 5-66009, 5-66010, 5-66011, 5-66012 (all filed on Mar. 2, 1993), 5-85637 (filed on Mar. 19, 1993), and No. 5-111103 (filed on Apr. 14, 1993) which are expressly incorporated herein by reference in their entirety.

BRIEF DESCRIPTION OF THE DRAWINGS

The invention will be described below in detail with reference to the accompanying drawings, in which;

FIG. **1** is a conceptual view of a first embodiment of a lens inclination detecting apparatus according to the present invention;

FIG. **2** is a conceptual view of an optical path of an optical system including an objective lens, a glass cover, and a hemispherical lens;

FIG. **3** is a schematic view of interference fringes indicated in a monitor of an interference fringe viewing portion;

FIG. **4** is a schematic view of image points indicated in a monitor of a image point viewing portion;

FIG. **5** is a conceptual view of a second embodiment of a lens inclination detecting apparatus according to the present invention;

FIG. **6** is a conceptual view of a third embodiment of a lens inclination detecting apparatus according to the present invention;

FIG. **7** is a conceptual view of a fourth embodiment of a lens inclination detecting apparatus according to the present invention;

FIG. **8** is a conceptual view of an optical path of an optical system including an objective lens, a glass cover, and a concave mirror;

FIG. **9** is a conceptual view of a fifth embodiment of a lens inclination detecting apparatus according to the present invention;

FIG. **10** is a conceptual view of a sixth embodiment of a lens inclination detecting apparatus according to the present invention;

FIG. **11** is an explanatory view of an occurrence of a deviated image point when an objective lens is inclined on a lens holder;

FIG. **12** is a schematic view of a mounting portion of an objective lens to a tracking mechanism;

FIG. **13** is a sectional view of a tracking mechanism;

FIG. **14** is a perspective view of a lens holder;

FIG. **15** is a schematic plan view of an optical disc apparatus mounting device;

FIG. **16** is a sectional view of a positioning device;

FIG. **17** is a sectional view of a lens feeding device;

FIG. **18** is a schematic view of a guide mechanism having an oblique guide surface for an objective lens;

FIG. **19** is an explanatory view of an adhesive reservoir in which an adhesive is introduced by an adhesive application member;

FIGS. **20** and **21** are flow charts of an inclination adjusting operation;

FIGS. **22** and **23** are flow charts of another inclination adjusting operation;

FIG. **24** is a plan view of an inserting member;

FIG. **25** is a sectional view of an inserting member;

FIG. **26** is a sectional view of an inclination adjusting apparatus in an initial position;

FIG. **27** is a sectional view of an inclination adjusting apparatus in an operative position in which the inclination of an objective lens is adjusted;

FIG. **28** is a sectional view taken along the line P—P in FIG. **27**;

FIG. **29** is a plan view of an inclination adjusting apparatus;

FIG. **30** is a sectional view of another embodiment of an inclination adjusting apparatus;

FIG. **31** is a view of another example of inclination adjusting pawls;

FIGS. **32, 33** and **34** are schematic views of three different examples of an objective lens;

FIG. **35** is a schematic view of an objective lens and glass cover used in a simulation;

FIG. **36** shows diagrams of optical characteristics of an objective lens shown in FIG. **35**;

FIG. **37** is a diagram of a wavefront aberration on an optical axis, that is represented by the PV value when there is no inclination of an objective lens with respect to a glass cover;

FIG. **38** is a diagram of a wavefront aberration that is varied by the change in the angle of incident light with respect to the optical axis when there is no inclination of an objective lens with respect to a glass cover;

FIG. **39** is a diagram similar to FIG. **37**, when a first lens surface of an objective lens is decentered from the optical axis;

FIG. **40** is a diagram similar to FIG. **38**, when a first lens surface of an objective lens is decentered from the optical axis;

FIG. **41** is a diagram similar to FIG. **37**, when a first lens surface of an objective lens is inclined;

FIG. **42** is a diagram similar to FIG. **38**, when a first lens surface of an objective lens is inclined;

FIG. **43** is a diagram similar to FIG. **37**, when an objective lens is inclined at 25 minutes (') with respect to a glass cover;

FIG. **44** is a diagram similar to FIG. **38**, when an objective lens is inclined at 25 minutes (') with respect to a glass cover;

FIG. **45** is a diagram similar to FIG. **37**, when an objective lens is inclined with respect to a glass cover to compensate a wavefront aberration which is caused when a first lens surface of an objective lens is decentered from the optical axis; and,

FIG. **46** is a diagram similar to FIG. **38**, when an objective lens is inclined with respect to a glass cover to compensate a wavefront aberration which is caused when a first lens surface of an objective lens is decentered from the optical axis.

DESCRIPTION OF THE PREFERRED EMBODIMENT

FIG. **1** shows a first embodiment of a lens inclination detecting apparatus **200** which detects an inclination of an objective lens **150** in a photo magnetic disc apparatus **100**.

The photo magnetic disc apparatus **100** constitutes an optical data recording and reproducing apparatus which records (or writes) data onto a recording medium which is in the form of a photo magnetic disc(magneto-optical disc), and reads and reproduces the recorded data from the photo magnetic disc. The optical system of the optical data recording and reproducing apparatus will be discussed below.

A divergent laser beam (i.e., coherent light) emitted from a light source **101**, such as a semiconductor laser or laser diode (LD), is collimated by a collimating lens **102**. The cross sectional shape of the collimated light is converted to a circular shape by a beam shaping prism (i.e., anamorphic prism) **103**. The beam shaping prism **103** is provided with beam splitting prisms **104** and **105** secured thereto. The laser beam transmitted through the beam shaping prism **103** and reflected by a beam splitter **106**, which is defined between the beam splitting prisms **104** and **105**, is made incident upon a light sensor **107** which detects the quantity of light outputted from the LD **101**, so that the adjustment is carried out until the quantity of light received by the light sensor **107** is a predetermined value.

The laser beam transmitted through the beam splitter **106** is reflected by a mirror **110**; transmitted through an insertion prism **201** (beam splitting means) of the inclination detecting apparatus **200**; reflected by a mirror **112**; and made incident upon an objective lens **150**.

The objective lens **150** is opposite a glass cover (i.e., transparent parallel plate) "A". The glass cover "A" is made of a material which is optically equivalent to that of a transparent plate K1 of the photo magnetic disc K shown in FIG. **12**. When the inclination of the objective lens **150** is adjusted, the cover glass "A" is disposed at a position that is substantially equivalent to the location where transparent plate K1 of the photo magnetic disc K is disposed during normal use of the photo magnetic disc apparatus **100**. In normal use, the photo magnetic disc K is set when the recording and reproducing operation are performed by the photo magnetic disc apparatus **100**. When the photo magnetic disc K is set in during normal use, the disc K is disposed parallel to a reference plane of the photo magnetic disc apparatus **100**. Accordingly, when the cover glass "A" is disposed during the adjustment of the objective lens **150**, the cover glass "A" is oriented parallel to the reference plane.

The signal detecting system of the photo magnetic disc apparatus **100** will be explained hereinafter in the state in which the glass cover "A", instead of a magnetic disc, is positioned opposite the objective lens **150**.

The laser beam reflected by the photo magnetic disc is transmitted through the objective lens **150**; reflected by the mirror **112** and the mirror **110**; and made incident upon the beam splitting prisms **104** and **105**. The laser beam reflected by the beam splitter **106** provided between the beam splitting prisms **104** and **105** is transmitted through a ½ wave plate **113** where the direction of polarization thereof is rotated by 45 degrees. Thereafter, the light is incident upon a polarization beam splitter which is comprised of a prism **114** and a wedge prism **115**. The light incident upon the polarization beam splitter is split into P-polarized and S-polarized light components that are transmitted through a condenser lens **116** and converged onto a signal detector **117** having two data sensors for obtaining photo magnetic signals, etc.

The light transmitted through the beam splitter **106** is reflected by a beam splitter **108** located between the beam shaping prism **103** and the beam splitting prism **104** and is received by a condenser lens **121**. The light is then reflected by a prism **122**; transmitted through a cylindrical lens **123**; and received by an error detector **124**. Namely, the light has an astigmatic difference caused by the condenser lens **121** and the cylindrical lens **123** and is converged onto the error detector **124** where tracking error signals and focusing error signals are obtained by a push-pull method and an astigmatism correction method, respectively.

The following discussion will be directed to the optical system of the lens inclination detecting apparatus **200**.

The hemispherical lens **202** is located next to the glass cover "A" on the side opposite;to the objective lens **150** with respect to the glass cover "A". The insertion prism **201** is inserted between the mirrors **110** and **112** of the photo magnetic disc apparatus, i.e., within the optical path of the collimated light. The insertion prism **201** includes a polarization beam splitter (PBS) **201***a* which is precisely machined so as not to produce a wavefront aberration, and a ¼ wave plate **201***b* which is located on the side of the PBS **201***a* next to the objective lens **150**. Of the linearly polarized light incident upon the insertion prism **201**, light that is linearly polarized in the same plane as the P polarized light is converted to circularly polarized light by the ¼ wave plate **201***b*. The circularly polarized light is reflected by the hemispherical lens **202** and is transformed back into linearly polarized light when the circularly polarized light again passes through the ¼ wave plate **201***b*. This change of circularly polarized light to linearly polarized light causes a total internal reflection of the linearly polarized light at the insertion prism **201** towards the lens inclination detecting apparatus **200** because the phases of the circularly polarized light and the linearly polarized light differ by 180 degrees. This is a result of the light passing through the ¼ wave plate **201***b* twice. Therefore, there is no return light towards the LD **101** from the insertion prism **201**, and no occurrence of noise due to the return light.

It is possible to provide a ½ wave plate **201***c* on the side of the polarization beam splitter **201***a* nearest the LD **101**. Since the polarization direction of light from the LD **101** can be optionally selected by properly selecting the mounting state of the ½ wave plate **201***c* to the PBS **201***a*, the light reflected from the hemispherical lens **202** can be appropriately received by the detecting apparatus **200** regardless of the location of the detecting apparatus **200**, even if the direction of the incident polarized light lies on a plane which includes the optical axis and the line normal to the reflecting surface of the insertion prism.

The light reflected by the insertion prism **201** is partly transmitted through a half mirror **203** and is made incident upon an interference fringe viewing portion **205** through an imaging lens **204**. The interference fringe viewing portion **205** is provided with, for example, a CCD camera and a monitor (not shown). In the interference fringe viewing portion **205**, interference fringes B which are caused by an interference of the beam transmitted through the objective lens **150** and the glass cover "A" and reflected by the flat surface **202***a* of the hemispherical lens **202**, and the beam transmitted through the objective lens **150** and the glass cover "A" and reflected by the spherical surface **202***b* of the hemispherical lens **202** are viewed. A reflecting mechanism includes the flat surface **202***a* and the spherical surface **202***b*. A beam splitting mechanism includes the flat surface **202***a* and the spherical surface **202***b*. An superposing mechanism includes the flat surface **202***a* and the spherical surface **202***b*. A wavefront rotating mechanism includes the flat surface **202***a*. The distortion of the interference fringes B is due to a coma which is in turn caused by the inclination of the objective lens **150** with respect to the glass cover "A".

The light reflected by the half mirror **203** is made incident upon a condenser lens **211**. The light transmitted through the condenser lens **211** is split into two beams by a beam splitter **212**. One of the beams is received by a image point viewing portion **214** through a magnifying lens **213**, and the other beam is received by an alignment detector **215**. The image point viewing portion **214** and the alignment detector **215** are each provided with, for example, a CCD camera and a monitor (not shown).

In the image point viewing portion **214**, the magnified image (point image) of light reflected by the flat surface **202***a* of the hemispherical lens **202** and the magnified image (point image) C of light reflected by the spherical surface **202***b* of the hemispherical lens **202** are viewed. The image point formed by the flat surface **202***a* does not contain a coma component which is asymmetrical in 180 degree directions with respect to the optical axis. However, the image point C formed by the spherical surface **202***b* contains the coma component.

The alignment detector **215** is provided to adjust the relative positional relationship among the convergence point

of the beam incident upon the objective lens **150**, the flat surface **202***a* of the hemispherical lens **202**, and the center of curvature of the spherical surface **202***b* of the hemispherical lens **202**, the center being located on the flat surface **202***a* so as to effectively view the interference fringes and the image points. As will be discussed hereinafter, the alignment detector **215** is used, for example, upon commencement of the adjustment of the inclination of the objective lens **150**, upon setting the relative position between the hemispherical lens **202** and the photo magnetic disc apparatus **100**, or upon the adjustment of the inclination of the objective lens **150**, etc.

The detection sensitivity of the coma component of the wavefront aberration (referred to as coma) will be discussed below with reference to FIG. **2**.

In FIG. **2**, the light L1 transmitted through the objective lens **150** and the glass cover "A" is partly reflected by the flat surface **202***a* of the hemispherical lens **202** in a direction symmetrical thereto with respect to the optical axis of the objective lens **150**. The reflected light is indicated at L2. Of the coherent light which has passed through the objective lens **150** and the glass cover "A" once, all the rays which are reflected by the flat surface **202***a* are reflected back through the glass cover "A", the objective lens **150**, and along a path that is symmetrical to the incoming path with respect to the optical axis. Due to this reflection, if the flat surface **202***a* is viewed from the objective lens **150** along the light path, the wavefront of the reflected coherent light is observed as being turned by 180 degrees.

The light transmitted through the flat surface **202***a* is partly reflected by the spherical surface **202***b* of the hemispherical lens **202**, as indicated at L3. The reflected light L3 is transmitted along the same optical path as the incident light and emitted from the objective lens **150**. Of the coherent light having passed once through the objective lens **150** and the glass cover "A", the rays that are reflected by the spherical surface **202***b* are reflected by the spherical surface **202***b* back through the glass cover "A", the objective lens **150**, and along the same light path as the incoming light path. As a result of this reflection by the spherical surface **202***b*, the wavefront of the reflected coherent light is observed from the objective lens **150** along the light path as being returned to the objective lens **150** without being rotated. The two wavefronts of reflected light at the flat surface **202***a* and at the spherical surface **202***b* are rotated relative to one another through 180 degrees around the optical axis of the objective lens **150**. Accordingly, the only aberration that is observed is the comatic aberration.

A coma, which is rotationally symmetrical with respect to the optical axis, does not appear in the wavefront which has been transmitted through the. objective lens **150** and the glass cover "A", and reflected by the flat surface **202***a* back towards and through the glass cover "A" and the objective lens **150**. On the other hand, the wavefront reflected by the spherical surface **202***b* of the hemispherical lens **202** and transmitted again through the objective lens **150** contains a coma that is double that of the coma of the wavefront that passes the objective lens **150** and the glass cover "A" once, since the first-mentioned wavefront passes the objective lens **150** and the glass cover "A" twice. The interference fringes are caused by the interference of the two kinds of wavefront mentioned above. Thus, the coma caused by the passage through the objective lens **150** and the glass cover "A" can be viewed with double sensitivity in the interference fringe viewing portion **205**. In other words, one interference fringe appears in the interference fringe viewing portion **205** when the coma, which is caused due to the inclination of the objective lens **150** with respect to the glass cover "A", is $\lambda/2$ (λ=wavelength of light transmitted through the objective lens).

The following discussion will be addressed to the adjustment of the inclination of the objective lens, with reference to FIGS. **1**, **3** and **4**, according to the present invention. The objective lens **150** is disposed on a lens holder (not shown), and the glass cover "A" is disposed at an appropriate position with reference to a contacting surface **131***b* (FIG. **25**) of the spindle motor **131**.

Thereafter, the relative position of the hemispherical lens **202** and the objective lens **150** in the optical axis direction is adjusted so as to obtain a clear image point of light condensed by the objective lens **150** and reflected by the flat surface **202***a* of the hemispherical lens **202**, while observing the image point viewed in the alignment detector **215** and the image point viewing portion **214**. After that, the relative position of the hemispherical lens **202** and the objective lens **150** in the direction perpendicular to the optical axis is adjusted so that the image point of light condensed by the objective lens **150** and reflected by the spherical surface **202***b* of the hemispherical lens **202** is located at the position of the image point formed by the flat surface **202***a* of the hemispherical lens **202**, while observing the image point in the alignment detector **215**. When the glass cover "A" is arranged adjacent to the flat surface **202***a*, the positional relationship between the glass cover "A" and the flat surface **202***a* becomes similar to the relationship between the transparent plate K1 and the data recording surface K2 (see FIG. **12**) of an actual photo magnetic disc. If the glass cover "A" is brought into contact with the flat surface **202***a*, additional light reflection may occur other than the reflection at the flat surface **202***a* and the flat surface **202***b*. This additional reflection at the contacting surface may bring about an adverse effect on the interference fringe observation. To prevent such from occurring, in the present embodiment, the glass cover "A" and the flat surface **202***a* are disposed with a predetermined distance therebetween.

The interference fringes B, as shown in FIG. **3**, are displayed in the monitor of the interference fringe viewing portion **205**. The image points C and D, as shown in FIG. **4**, are indicated in the monitors of the alignment detector **215** and the image point viewing portion **214**. The distortion of the interference fringes B is caused by the coma and increases as the inclination of the objective lens **150** relative to the glass cover "A" increases. The image point C is formed by light reflected by the spherical surface **202***b* of the hemispherical lens **202** and has an outstanding coma. The image point D is formed by light reflected by the flat surface **202***a* of the hemispherical lens **202** and has no coma. There is a difference in magnification of the image to be viewed between the alignment detector **215** and the image point viewing portion **214**. Both the image points C and D are magnified at a large magnification rate in the image point viewing portion **214** and can be clearly viewed.

If the distortion of the interference fringes B is above a predetermined value (e.g., $\lambda/4$, in other words ½ fringe), the inclination of the objective lens **150** is adjusted to substantially eliminate the distortion, so that the interference fringes are linear. If the adjustment of the objective lens **150** causes the convergence point of light by the objective lens **150** to be considerably deviated from the center of curvature of the spherical surface **202***b* of the hemispherical lens **202**, there will be too many tilt fringes, making it difficult to determine the degree of the distortion of the interference fringes B. In such case, the objective lens **150** (or the whole photo magnetic disc apparatus **100**) or the hemispherical lens **202**

is displaced in a direction perpendicular to the optical axis of the objective lens **150** to reduce the number of the tilt fringes B to an appropriate number (for example, 3 or 4 fringes). Thereafter, coma caused by the relative inclination of the objective lens with respect to the glass cover is observed. Consequently, the inclination of the objective lens **150** is adjusted so that the interference fringes B become linear again. The above-mentioned operations are repeated to correctly adjust the inclination of the objective lens **150**.

In the above-mentioned embodiment, the hemispherical lens **202** is provided on the side opposite to the objective lens **150** with respect to the glass cover "A", so that the relative inclination between the objective lens **150** and the glass cover "A" is detected in accordance with the interference fringes B caused by the light reflected by the hemispherical lens **202**. Accordingly, it is substantially only the hemispherical lens **202** which serves as the optical system to obtain the interference fringes B on the right side of the glass cover "A" in FIG. **5**. Consequently, the portion of the detecting apparatus **200** containing the hemispherical lens **202** is made small. This makes it possible to adjust the objective lens **150** from the side of the hemispherical lens **202**. Accordingly, there is no restriction to the mounting mechanism of the objective lens **150** to a lens holder or support (not shown). Namely, if a mounting structure of the objective lens **150** to the focusing and tracking mechanism, as shown in FIGS. **11** through **14** is used to lighten the whole focusing and tracking device in the photo magnetic disc apparatus, it is possible to easily adjust the inclination of the objective lens **150**.

In the above-mentioned embodiment, the light transmitted through the objective lens **150** is reflected and split by the hemispherical lens **202**, so that the light is separated into the above-noted two bundles of rays. The wavefronts of the two bundles of rays which are rotated through 180 degrees around the optical axis in a relative manner are superposed to thereby produce the interference fringes. Namely, the reflection, separation, rotation and superimposition of beams are effected by the single member. Consequently, no harmful external light tends to enter the above-noted superimposed bundles of rays. Accordingly, stable interference fringes B are obtained, resulting in an easy adjustment of the inclination, in comparison with an arrangement in which a concave mirror and a Dove prism are used in combination, as will be discussed hereinafter.

Also, in this embodiment, since the hemispherical lens **202** is used, the adjustment of the relative position between the hemispherical lens **202** and the objective lens **150** (i.e., the alignment adjustment) can be easily effected. Namely, since the center of curvature of the spherical surface portion **202*b*** of the hemispherical lens **202** is located on the flat surface portion **202*a***, the adjustment of the hemispherical lens **202** in the axial direction can be completed only by making the convergence point of the objective lens **150** coincidental with the flat surface portion **202*a***. Thereafter, the adjustment of the hemispherical lens **202** or the objective lens **150** (or, the photo magnetic disc apparatus **100**) with respect to the optical axis in the vertical direction (i.e., perpendicular to the optical axis) is carried out by making the convergence point of the objective lens **150** coincidental with the center of curvature of the spherical surface **202*b***.

In the first embodiment, the coma produced in the optical system of the photo magnetic disc apparatus **100** and the lens inclination detecting apparatus **200** can be substantially eliminated only by adjusting the relative inclination of the objective lens **150** and the glass cover "A" provided in the terminal stage of the optical system. Namely, in this embodiment, the coma produced in the optical system can be eliminated by adjusting the relative inclination of the objective lens **150** and the glass cover "A" without increasing the assembly accuracy of the optical elements of the optical system, according to the first embodiment.

When the adjustment of the inclination of the objective lens **150** is completed, as mentioned above, the photo magnetic disc apparatus is moved to a subsequent assembling or checking station.

FIG. **5** shows a second embodiment of a lens inclination detecting apparatus **200**, according to the present invention.

In the second embodiment, the insertion prism of the first embodiment is not provided, so that the light reflected from the hemispherical lens **202** is detected by the signal detecting system of the photo magnetic disc apparatus **100**. Namely, the light reflected from the hemispherical lens **202** is reflected by the prism **114** and introduced into the inclination detecting apparatus **200**. The light is split into two beams by the beam splitter **221** in the lens inclination detecting apparatus **200**. One of the split beams is made incident upon the interference fringe viewing portion **205** through the image forming lens **222** and the other split beam is transmitted through the condenser lens **223** and is made incident upon the beam splitter **224**. One of the beams split by the beam splitter **224** is introduced into the image point viewing portion **214** through the magnifying lens **225**, and the other split beam is made incident upon the alignment detecting portion **215**.

The remaining structure of the optical arrangement shown in FIG. **5** is same as the first embodiment.

In the second embodiment, the absence of the insertion prism between the mirrors **110** and **112** attenuates the disturbance of the wavefront of light towards the hemispherical lens **202**. Consequently, the inclination of the objective lens **150** can be more accurately detected in the second embodiment than the first embodiment.

FIG. **6** shows a third embodiment of a lens inclination detecting apparatus **200**, according to the present invention.

In the third embodiment, the interference fringes B, which are employed to detect the inclination of the objective lens **150**, are formed by the laser beam emitted from the He-Ne (helium-neon) laser source **230** provided in the lens inclination detecting apparatus **200**, unlike the first embodiment. Namely, the laser beam emitted from the He-Ne laser source **230** is converted to divergent light by a beam expander **231** and collimated by the collimating lens **232**, and is then made incident upon the insertion prism **201** (which has the same function as a mirror in this embodiment) through the beam splitter **233**.

The remaining structure of the third embodiment is the same as the first embodiment. Namely, the light incident upon the lens inclination detecting apparatus **200** through the insertion prism **201** is partly transmitted through the half mirror **203** to reach the interference fringe viewing portion **205** through the image forming lens **204**, and is partly reflected by the half mirror **203** to be made incident upon the condenser lens **211**. The light emitted from the condenser lens **211** is split into two bundles of rays by the beam splitter **212**. One of the split beams is made incident upon the image point viewing portion **214** through the magnifying lens **213** and the other split beam is made incident upon the alignment detector **215**. The thickness of the glass cover "A" in the third embodiment is determined in accordance with the wavelength of the laser beam emitted by the He-Ne laser source **230**.

According to the third embodiment, since the visible light is emitted from the laser source **230**, the interference fringes

B and the image points C and D can be directly viewed by a viewer without relying upon the CCD camera. Consequently, the adjustment of the inclination of the objective lens **150** can be much more simplified. Moreover, in comparison with the arrangement in which the semiconductor laser source **101** within the photo magnetic disc apparatus **100** is employed, no aberration is caused in the light path between the LD source **101** and the insertion prism **201**. Accordingly, a higher detection accuracy of the inclination of the objective lens **150** is obtained.

FIG. **7** shows a fourth embodiment of a lens inclination detecting apparatus **200**, according to the present invention.

In the fourth embodiment, there is provided a concave mirror **240** instead of the hemispherical lens. The light reflected by the concave mirror **240** is transmitted through the glass cover "A" and the objective lens **150** and is made incident upon the mirror **112**.

The light reflected by the beam splitter of the insertion prism **201** is partly transmitted through the half mirror **203** where the light is split. A half mirror (i.e., a reflecting means) **241** is provided for partially transmitting and partially reflecting light. A beam splitting means includes the half mirror **241**. The light transmitted through the half mirror **241** is incident upon the first Dove prism **242** which is per se known. Namely, when the light passes through the Dove prism **242**, the beam is inverted with respect to the first axis normal to the sheet of the drawings. The beam is then reflected by the mirror **243** and made incident upon the half mirror (i.e., a superposing means) **244**. The first Dove prism **242** and the second Dove prism **246** together constitute a wavefront rotating means. Light reflected by the half mirror **241** is reflected by the mirror **245** and is transmitted through the second Dove prism **246**, so that the beam is inverted with respect to the vertical axis (i.e., a second axis perpendicular to the first axis of the first Dove prism **242**) in FIG. **7** to reach the half mirror **244**.

The two beams are rotated by approximately 180 degrees about the optical axis by the first and second Dove prisms **242** and **246**, so that the two bundles are superimposed. Consequently, the interference fringes B are produced due to the coma which is the asymmetric aberration in 180 degrees directions with respect to the optical axis. The interference fringes B are converged as an image in the interference fringe viewing portion (not shown).

The remaining structure of the fourth embodiment is the same as the first embodiment.

The detection sensitivity of the coma in the fourth embodiment will be discussed below with reference to FIG. **8**.

In FIG. **8**, the light rays L4 and L5 transmitted through the objective lens **150** and the glass cover "A" are reflected by the concave mirror **240** and are returned along the same optical paths and emitted from the objective lens **150**.

The degree of coma contained in the wavefront reflected by the concave mirror **240** and transmitted through the objective lens **150** is twice that of the wavefront transmitted once through the objective lens **150** and the glass cover "A", since the return light passes twice through the objective lens **150** and the glass cover "A". The wavefront containing the "double" coma is split into two wavefronts which are relatively turned by 180 degrees with respect to the optical axis by the Dove prisms to be superimposed. Consequently, the coma caused by the transmission of the wavefront through the objective lens **150** and the glass cover "A" can be viewed at a fourfold sensitivity. Namely, one interference fringe is viewed when the coma caused by the inclination of the objective lens **150** with respect to the glass cover "A" is $\lambda/4$. Thus, the coma can be detected at very high sensitivity.

FIG. **9** shows a fifth embodiment of a lens inclination detecting apparatus **200**, according to the present invention.

The fifth embodiment is different from the fourth embodiment in that light transmitted through the half mirror **203** is split into two bundles or rays by the beam splitter **252**. The two types of bundle of rays are made incident upon the reflecting mirror **250** and the corner-cube prism **251**, respectively.

The bundle of rays reflected by the reflecting mirror **250** has the same direction as the light reflected by the concave mirror **240** with respect to the optical axis and is transmitted through the beam splitter **252** (i.e., a beam splitting means and a beam superposing means) to be made incident upon the image forming lens **253**. The bundle of rays reflected by the corner-cube prism (i.e., a wavefront rotating means) **251** corresponds to light reflected by the concave mirror **240** and the wavefront of the bundle of rays is rotated by 180 degrees with respect to the optical axis and is reflected by the beam splitter **252** to be made incident upon the image forming lens **253**. Consequently, the interference fringes B caused by the coma can be viewed in the interference fringe viewing portion **205**. The coma can be detected at high sensitivity similar to the fourth embodiment.

FIG. **10** shows a sixth embodiment of a lens inclination detecting apparatus **200**, according to the present invention.

In the sixth embodiment, the corner-cube prism **251** in the fifth embodiment is replaced with the condenser lens **254** and the reflecting mirror **255**. Namely, the condenser lens **254** and the reflecting mirror **255** has the same function as the corner-cube prism **251** in the fifth embodiment.

Consequently, one of the bundles of rays obtained by splitting light incident upon the beam splitter **252** is rotated through 180 degrees about the optical axis by the condenser lens **254** and the reflecting mirror **255**. This bundle of rays is superposed with another bundle of rays which is reflected by the reflecting mirror **250** at the beam splitter **252**. The superposition of the bundles of rays produces interference fringes. The condenser lens **254** and reflecting mirror **255** together constitute a wavefront rotating means. The other structure and operation of the sixth embodiment are the same as those in the fifth embodiment. Namely, the coma can be detected at high sensitivity similar to the fifth embodiment.

FIGS. **11** through **14** show the mounting structure of the objective lens **150** to the focusing and tracking mechanism of the photo magnetic disc apparatus **100**.

As shown in FIG. **11**, the objective lens **150** is supported by the lens supporting surface **152** of the lens supporting member (lens holder) **151**. The supporting surface **152** is a conically oblique surface. The objective lens **150** is, for example, a single glass mold lens with opposite aspherical lens surfaces. The single objective lens **150** is provided on the outer peripheral surface thereof with a peripheral or annular flange **153** which comes into contact with the supporting surface **152**. The lens supporting surface **152** may be spherical.

It is now assumed that the center line CL of the supporting surface **152** is identical to the optical axis of the objective lens **150** and that the objective lens **150** is parallel with the glass cover "A". If the objective lens **150** is displaced by the lateral force applied thereto through a displacement δ, the displacement of the flange **153** of the lens **150** takes place along the supporting surface **152**, so that the objective lens **150** is rotated about the intersecting point C1 of the straight

line M normal to the supporting surface **152** and the center axis CL in a cross section, as indicated at two-dotted and dashed line in FIG. **11**. Namely, there is an inclination angle θ of the optical axis of the objective lens **150**, and the convergence point C2 of the objective lens is moved, so that the deviation ϵ of the image point occurs. The inclination θ causes the coma, so that the distortion of the interference fringes B (FIG. **1**) increases.

Furthermore, the number of the tilt fringes (interference fringes B) is increased by the deviation ϵ of the image point. This makes it difficult for an operator to observe the magnitude of the distortion of the interference fringes. To prevent this, it is desirable that only the inclination θ occurs without causing the deviation ϵ of the image point, upon the adjustment of the inclination of the objective lens **150**.

No deviation ϵ of the image point occurs due to the inclination of the objective lens **150**, when the objective lens **150** is rotated about the rear principal point (i.e., principal point adjacent to the image) N2 thereof, provided that the incident light is collimated light. However, in case where the objective lens **150** is displaced with respect to the supporting surface **152**, as mentioned above, the intersecting point C1 of the optical axis and the straight line which passes through the contacting point of the supporting surface **152** and the flange **153** and which is perpendicular to the supporting surface **152** must coincide with the center line CL which contains the rear principal point N2, in order that the objective lens **150** rotates about the rear principal point N2. It is however difficult to support the objective lens in such an arrangement. Therefore, in the first through sixth embodiments, if the number of the interference fringes increases due to the occurrence of the deviation ϵ of the image point during the adjustment of the inclination of the lens, so that it is difficult to measure or detect the magnitude or degree of the coma, the whole lens inclination detecting apparatus **200** or the hemispherical lens **202** (or the concave mirror **240**) is displaced in the direction perpendicular to the optical axis of the objective lens to attenuate the deviation ϵ of the image point or reduce the number of the interference fringes to thereby measure the coma. The adjustment of the inclination of the objective lens **150** will be discussed hereinafter.

FIG. **12** schematically shows the mounting structure of the objective lens **150** to the focusing and tracking mechanism **160**.

The focusing and tracking mechanism (i.e., coarse actuator) **160** is provided below the photo magnetic disc K, so that the objective lens **150** emits the laser beam S towards the photo magnetic disc K from the lower side thereof. The lens holder (fine actuator) **151** is connected to the securing member **155** through the springs **154**. The securing member **155** is secured to the movable member **157** by the screw **156**. Consequently, the lens holder **151** is displaced with respect to the securing member **155** when an elastic deformation of the springs **154** takes place. As mentioned above, since the inclination of the objective lens **150** is adjustable with respect to the lens holder **151** and the securing member **155** is integrally connected to the movable member **157**, it is not necessary to provide a mechanism which relatively inclines the securing member **155** or the movable member **157**, unlike prior art in which such a mechanism is indispensable. Thanks to this, it is not necessary to provide any component which provides for inclinable movement of the securing member **155** with respect to the movable member **157**. Consequently, not only can the focusing and tracking mechanism **160** be considerably lightened, but also the speed of the tracking operation for the photo magnetic disc can be increased.

FIG. **13** shows the internal structure of the split type focusing and tracking mechanism **160** of photo magnetic disc apparatus.

The movable member **157** is movably supported on rails **161**, for example, through a ball bearing (not shown), so that the movable member **157** is moved along the rail **161** to a position corresponding to a predetermined track of the photo magnetic disc apparatus. The movable member **157** is provided with the mirror **112** (FIG. **1**) through which the laser beam is made incident upon the objective lens **150** and the laser beam emitted from the objective lens **150** is made incident upon the detecting system (not shown). The securing member **155** is secured to the movable member **157** through the connecting member **158**. Note that the connecting member **158** is not shown in FIG. **12**.

The springs **154** extend in the direction perpendicular to the sheet of the drawings in FIG. **13**. The lens holder **151** is spaced from the securing member **155** and the connecting member **158**, and is supported only by the springs **154**. The lens holder **151** is provided with a hole **162** which extends in the vertical direction under the objective lens **150**. There are a plurality of solenoid coils **163** surrounding the hole **162**. The connecting member **158** is provided with magnets **169** (FIG. **14**) corresponding to the solenoid coils **163**. As is well known, to record or reproduce data on or from the photo magnetic disc K, the solenoid coils **163** are selectively activated or energized in accordance with the tracking error signals or focusing error signals, so that a slight displacement of the lens holder **151** occurs to adjust the relative positional relationship between the objective lens **150** and the focus position and the track position of the photo magnetic disc K.

The mounting mechanism of the objective lens **150** is not limited to that shown in FIGS. **12** and **13**, and the present invention can be applied to any type of adjusting apparatuses which adjust the relative inclination of the objective lens and the photo magnetic disc.

FIG. **14** shows the lens holder **151**, in which the supporting surface **152** on which the objective lens **150** is supported and the surroundings thereof are exaggerated.

The conical lens supporting surface **152** is made of a part of a cone whose apex is located on the center axis of the hole **162**. The diameter of the conical supporting surface **152** decreases towards the lower end (inner end) thereof. There are four projections **164** which project upward from the outer peripheral edge (upper edge) of the supporting surface **152**. The projections **164** are spaced at an equi-angular distance and are provided on inner surfaces thereof with recessed portions **165** which form adhesive reservoirs. The adhesive reservoirs **165** receive an excess amount of adhesive between the objective lens **150** and the supporting surface **152**. Namely, if the adhesive expands when it sets, the excess adhesive can be absorbed by the adhesive reservoirs **165**, so that no adhesive is discharged onto the lens surface of the objective lens **150**.

The following discussion will be directed to the adjusting operation of the inclination of the objective lens **150** that is disposed on the lens holder **151**, with reference to FIGS. **15** through **29**.

FIG. **15** shows a plan view of the mounting apparatus **500** of the photo magnetic disc apparatus. The mounting apparatus **500** includes a pair of parallel guide members **501** and **502** on which a pallet **503** is slidably supported. The photo magnetic disc apparatus **100** is disposed on the pallet **503** at a first stage ST1.

Thereafter, the pallet **503** is transferred in the right direction in FIG. **15** and stopped at a second stage ST2 at which

a positioning apparatus **300** is provided, as shown in FIG. **16**. The positioning apparatus **300** is adapted to determine the position of the lens holder **151** with respect to the rails **161** (FIG. **13**). The rails **161** extend in the left and right directions in FIG. **13**. A stop **301** is provided on the mounting apparatus **500** to restrict the movement of the lens holder **151** with respect to the rails **161**, so that the connecting member **158** abuts against the stop **301** to carry out the substantial positioning of the lens holder **151**. Thereafter, a lock mechanism (not shown) is actuated to lock the focusing and tracking mechanism **160** to the rails **161**, and the stop **301** is rotated upward to disconnect the same from the connecting member **158**.

To confirm the positioning state, there is a microscopic objective lens **302** above the front end of the stop **301**. The microscopic objective lens **302** is secured to the lower end of the cylindrical holder **304** mounted to a securing plate **303**. The holder **304** is provided on the upper end thereof with a CCD camera **305** to which the monitor **306** is connected. If the image of the lens holder **151** does not concur with a mark which represents a predetermined position (i.e., reference position) of the lens holder in the monitor, the fine adjustment of the position of the photo magnetic disc apparatus **100** is carried out to adjust the lens holder **151** by a horizontal position adjusting mechanism **505** (FIG. **15**) so as to make the image coincidental with the reference mark.

The horizontal position adjusting mechanism **505** is provided on the lower surface of the pallet **503** so as to move the photo magnetic disc apparatus **100** with respect to the pallet **503** in the X-axis direction parallel with the guide members **501** and **502** and the Y-axis directions perpendicular to the X-axis direction. Namely, when an X-axis adjusting knob **506** is rotated about the axis thereof, the fine adjustment of the photo magnetic disc apparatus **100** in the X-axis direction is effected, and when a Y-axis adjusting knob **507** is rotated about the axis thereof, the fine adjustment of the photo magnetic disc apparatus **100** in the Y-axis direction is effected, respectively.

Thereafter, the pallet **503** and, accordingly, the photo magnetic disc apparatus **100** is moved to the left (with respect to FIG. **15**) along the guide members **501** and **502**, and is stopped at a third stage ST3. At the third stage ST3, the objective lens **150** is disposed on the lens holder **151** by the lens feeding apparatus **310** which will be discussed below, and the adhesive is supplied between the lens holder **151** and the objective lens **150**.

FIG. **17** shows the lens feeder **310** provided at the third stage ST3.

A cylindrical bearing member **312** is secured to the securing plate **311** to project therefrom. The projecting end of the bearing member **312** from the securing plate **311** is fitted in the hollow conical guide member **313**. The guide member **313** is provided with a inner conical surface **314**. The guide member **313** is provided on the outer periphery thereof with four adhesive applying members **315** which are spaced at an equi-angular distance about the center axis of the guide member **313**. Each of the adhesive applying members **315** is made of an elongated tube which is connected to an adhesive supplier **317** through a flexible tube **316**. The adhesive supplier **317** is controlled to supply a predetermined amount of adhesive.

An insertion tube **321** having a sucking tube **322** at the front end thereof is slidably fitted in the inner wall surface **318** of the bearing member **312**. The insertion tube **321** is connected to a vacuum source **325**, so that the objective lens **150** can be held at and by the front end of the sucking tube **322** with the help of the vacuum. The base end **321***a* of the insertion tube **321** is slidably supported by and in a supporting pipe **323** which is provided with a guide groove **323***a* in which a bolt **324** secured to the base end **321***a* is engaged. Namely, the bolt **324** is guided in the guide groove **323***a* so that the insertion tube **321** is relatively movable with respect to the supporting tube **323** in the axial direction.

The supporting tube **323**, the insertion tube **321**, and the sucking tube **322** are originally detached from the bearing member **312**. In this state, the objective lens **150** is picked up at the front end of the sucking tube **322**. When the objective lens **150** is held by the front end of the sucking tube **322**, the insertion tube **321** and the sucking tube **322** are inserted in the bearing member **312** and the guide member **313**. During the insertion, the outer peripheral surface **154** of the objective lens **150** is guided by the tapered surface **314** of the guide member **313** and the circular hole **319** at the front end thereof, as shown in FIG. **18**. Consequently, the positioning of the objective lens **150** relative to the circular hole **319** in the radial direction, i.e., the centering of the objective lens **150** is executed. Further insertion of the insertion tube **321** and the sucking tube **322** causes the lower end of the supporting pipe **323** to come into contact with the upper end of the bearing member **312**. Consequently, the front end of the sucking tube **322**, and accordingly, the objective lens **150** project downward from the circular hole **319** of the guide member **313**, as shown in FIG. **17**.

Thereafter, the insertion tube **321** and the sucking tube **322** are moved downward with respect to the supporting pipe **323**, the bearing member **312** and the guide member **313**, so that the objective lens **150** is disposed on the supporting surface **152** of the lens holder **151**. As soon as the vacuum supply to the insertion tube **321** and the sucking tube **322** is stopped, the sucking tube **322** is slightly separated from the objective lens **150**. In this state, the front ends of the four adhesive applying members **315** are opposed to the center portions of the upper surfaces of the corresponding projections **164** of the lens holder **151**. A predetermined amount of adhesive G is fed from the adhesive applying members **315** into the respective adhesive reservoirs **165** that are spaced at an equi-angular distance. It should be appreciated here that since the adhesive G is introduced in the adhesive reservoirs **165**, the adhesive G can be uniformly applied to the outer peripheral edge of the objective lens **150** supported on the supporting surface **152** of the lens holder **151**. In the illustrated embodiment, the adhesive G is an ultra violet setting type adhesive.

After the adhesive G has been applied, the insertion tube **321** and the sucking tube **322** are moved upward to come away from the objective lens **150** by a return spring (not shown) and are stopped at a position away from the objective lens **150**.

Thereafter, at a fourth stage ST4, the inclination of the objective lens **150** is adjusted, and the adhesive G is set to secure the objective lens **150** to the lens holder **151**. The adjustment of the inclination of the objective lens **150** will be discussed below with reference to FIGS. **20** and **21** which show flow charts of the adjusting operation.

At step S10, an insertion member **330**, as shown in FIGS. **24** and **25** is attached to the photo magnetic disc apparatus **100** which has been transferred again to the first stage ST1 after the operation at the third stage ST3 has been completed (FIGS. **26** and **27**).

The insertion member **330** has a cylindrical body **331** which is provided on the center portion thereof with a center

hole **333** in which an output shaft **131***a* of a spindle motor **131** is fitted. A first arm **334** projects from the cylindrical body **331** in the radial direction. The glass cover "A" is attached to the front end of the first arm **334**. In the insertion member **330**, a contacting surface **331***a* of the cylindrical body **331** abuts a contacting surface **131***b* of the spindle motor **131** to make the glass cover "A" parallel to a reference surface (i.e., the contacting surface **131***b*). The contacting surface **131***b* is arranged parallel to the photo magnetic disc K.

A second arm **335** which is in the form of a rectangle to surround the first arm **334** as viewed from above is provided on the front end thereof with a supporting portion **336** which extends downward therefrom. The insertion prism **201** is attached to the supporting portion **336**. Namely, the insertion prism **201** is located below the glass cover "A". Note that the front end of the second arm **335** and the supporting portion **336** have holes **337** and **338** through which light reflected by the insertion prism **201** passes, respectively. The first arm **334** is provided with an opening **339** through which the inclination adjusting pawl **401** can extend.

At step **S11**, the photo magnetic disc apparatus **100** is conveyed to the fourth stage ST4 where the inclination adjusting apparatus **400** is provided. The inclination adjusting apparatus **400** which is adapted to adjust the inclination of the objective lens **150** with respect to the glass cover "A" includes the hemispherical lens **202** and the inclination adjusting pawls **401**. In the state shown in FIG. **27**, the flat surface portion **202***a* of the hemispherical lens **202** is parallel with the glass cover "A". Note that the inclination adjusting apparatus **400** will be discussed hereinafter.

The photo magnetic disc apparatus **100** is secured at a predetermined position underneath the inclination adjusting apparatus **400**. The inclination adjusting apparatus **400** which has been originally located above and away from the objective lens **150**, as shown in FIG. **26**, is moved down at step **S12** to a position close to the objective lens **150**, as shown in FIG. **27**. In this state, the positioning of the hemispherical lens **202** in the axis direction is executed, and the inclination adjusting pawls **401** are located close to the objective lens **150**.

At step **S13**, the fine adjustment of the objective lens **150** in the optical axis direction (Z-axis direction) thereof is effected so that the image point (FIG. **4**) indicated in the alignment detector **215** (FIG. **1**) and the image point D indicated in the image point viewing portion **214** are clear spot images, i.e., the convergence point of the objective lens **150** is located on the flat surface portion **202***a* of the hemispherical lens **202**. This fine adjustment is carried out by controlling the activation of the solenoid coils **163** (FIG. **14**) to move the objective lens **150** only or moving the whole photo magnetic disc apparatus **100** by a driver (not shown), while observing the monitors of the alignment detector **215** and the image point viewing portion **214**. The fine adjustment of the objective lens **150** can be replaced with the fine adjustment of the hemispherical lens **202** in the optical axis direction.

At step **S14**, the fine adjustment of the objective lens **150** in the direction normal to the optical axis is carried out so that the convergence point of the objective lens **150** concurs with the center of curvature of the spherical surface portion **202***b* of the hemispherical lens **202**, while observing the interference fringes B and the image points C and D (FIG. **3**) displayed in the monitors of the interference fringe viewing portion **205**, the image point viewing portion **214**, and the alignment detector **215**, respectively. Namely, the fine adjustment causes the image point C to move close to the image point D. This fine adjustment is effected by the slight displacement of the photo magnetic disc apparatus **100** in the X-axis direction and the Y-axis direction by the horizontal position adjusting mechanism **505**. As a result, an appropriate number of tilt fringes (for example, three tilt fringes) and the coma are added to the interference fringes B, so that the distortion of the interference fringes, i.e., the coma can be easily and clearly viewed. It is alternatively possible to execute a fine adjustment of the hemispherical lens **202** in the X-axis direction and Y-axis direction, instead of the fine adjustment of the objective lens **150**.

At step **S15**, the tilt fringe(s) of an optional direction indicated in the monitor of the interference fringe viewing portion **205** is (or are) selected and observed to measure the degree of the coma contained in the light emitted from the objective lens **150**. If the degree of the coma is not within an allowable limit, i.e., if the magnitude of the distortion of the interference fringes B is above a predetermined value, it is determined that the inclination of the objective lens **150** with respect to the glass cover "A" is too large. Consequently, the inclination of the objective lens **150** is adjusted by the inclination adjusting apparatus **400** in steps subsequent to step **S20**. Conversely, if the coma is within the allowable limit, no adjustment of the inclination of the objective lens **150** is carried out, and the control proceeds to step **S26**.

The structure of the inclination adjusting apparatus **400** will be described below, referring to FIGS. **27** through **29**.

There is a hemispherical lens holder **404** provided on the lower surface of the body **402** of the inclination adjusting apparatus **400**. The hemispherical lens holder **404** is provided on the front end thereof with the vertically extending hole **403**. The hemispherical lens **202** is secured to the lower end of the hole **403**.

As can be seen in FIG. **28**, the four adjusting pawls **401** are formed by cutting the center portion of the circular disc plate **409** into a predetermined shape. The adjusting pawls **401** extend in the radial directions. The circular disc plate **409** is attached to the lower surface of a hemispherical rotatable member **410**. The center of the circular disc **409** is located within the hemispherical lens **202**. The adjusting pawls **401** are spaced at an equi-angular distance of 90 degrees, and are bent at the front ends thereof to project below the level of the hemispherical lens **202**. The front ends of the adjusting pawls **401** extend to the vicinity of the center of curvature of the hemispherical outer peripheral surface of the rotatable member **410**, so that the front ends are located below the level of the lower surface of the glass cover "A" upon adjustment of the inclination of the objective lens **150**, as shown in FIG. **27**.

One of the four adjusting pawls **401** is located within the opening **339** of the first arm **334**. The rotatable member **410** is provided with a cut-away portion **419** which prevents the hemispherical lens holder **404** from interfering with the rotatable member **410**.

The hemispherical outer peripheral surface **411** of the rotatable member **410** is slidably supported in and by the hemispherical recess **412** formed on the lower surface of the body **402**. The center of curvature of the hemispherical outer peripheral surface **411** and the corresponding hemispherical recess **412** is located on the optical axis of the objective lens **150** in the vicinity of the center of rotation C1 of the objective lens **150** (FIG. **11**). Namely, the center of rotation of the rotatable member **410** is located in the vicinity of the center of rotation C1 (FIG. **11**) of the objective lens **150**, the center of rotation C1 being located on the optical axis of the objective lens **150**.

The rotatable member **410** is provided with a vertically extending connecting hole **413** in which a hollow cylindrical operation shaft **414** is fitted. The operation shaft **414** is provided on the lower end thereof with a flange **417** whose diameter is larger than the diameter of the connecting hole **413**, so that the flange **417** comes into surface contact with the lower surface of the rotatable member **410**. The operation shaft **414** projects upward from the connecting hole **413** and extends through a passage **430** formed on the body **402**. An annular pressing member **415** is fitted to the upper end of the operation shaft **414**. Between the pressing member **415** and the body **402** is provided a spring **416** which continuously biases the rotatable member **410** upwardly through the pressing member **415**.

The operation shaft **414** is provided therein with a parallel plate (transparent glass) **431** which is in parallel with a reference surface of the adjusting pawls **401**. The parallel plate **431** is adapted to confirm an initial position of the inclination of the adjusting pawls **401** at step **S12** in the inclination adjusting operation of the objective lens **150**.

There are four microadjusters **421** screwed in the cylindrical wall **418** provided on the upper end of the body **411** to surround the pressing member **415**. A spindle **422** of each microadjuster **421** extends inward through a cylindrical wall **418** to abut against the outer peripheral surface of the pressing member **415**. The rotation of the microadjusters **421** about the respective axes causes the handles to move in the respective axial directions to vary the length of the inward projection of the microadjusters **421** from the cylindrical wall **418**. Consequently, the pressing member **415** can be displaced in the horizontal direction by decreasing the length of projection of two of the microadjusters **421** and increasing the length of projection of the remaining two microadjusters **421**, so that the operation shaft **414** is inclined to rotate the rotatable member **410**. The rotation of the rotatable member **410** varies the inclination of the adjusting pawls **401** to adjust the inclination of the objective lens **150**, as will be discussed hereinafter.

The distance between the center of rotation of the rotatable member **410** and the contact portions T of the microadjusters **421** and the pressing member **415** is larger than (for example, about ten times) the distance between the center of rotation **C1** of the objective lens **150** and the supporting surface **152** (FIG. **11**). Consequently, when the axial displacement of the microadjusters **421** caused by the rotation thereof takes place, the displacement of the objective lens **150** is about one-tenth (1/10) the displacement of the handles **421**. Thus, the fine adjustment of the inclination of the objective lens **150** can be accurately effected by the microadjusters **421**.

As may be seen in FIG. **29**, there are springs **423** within the body **402** to correspond to the microadjusters **421**. The springs **423** abut at one end thereof, for example, against the outer peripheral surface of the circular disc **409**, and abut at the other ends thereof against the upper portion of the body **402**, respectively. The rotatable member **410** is continuously biased upwards by the springs **423**, so that the rotatable member **410** can be stably held in the inclined state.

Turning back to FIGS. **20** and **21**, the inclination of the objective lens **150** is carried out as follows.

At step **S20**, the inclination adjusting apparatus **400** slightly descends until the adjusting pawls **401** come into contact with the outer peripheral edge of the objective lens **150**. At step **S21**, the microadjusters **421** are rotated to rotate the rotatable member **410** to thereby incline the adjusting pawls **401**. The direction and degree of the inclination of the adjusting pawls **401** are determined in accordance with the interference fringes B viewed at step **S20**. Namely, if it is detected from the interference fringes B that the coma appears inclined, for example, at 45 degrees from the X-axis direction in the horizontal plane, the adjusting pawls **401** are inclined in that direction. As a result, the objective lens **150** is displaced along the supporting surface **152** to vary the contact portion of the objective lens **150** with the supporting surface **152** to thereby adjust the inclination of the objective lens **150**. At step **S22**, a slight upward movement of the inclination adjusting apparatus **400** takes place to move the adjusting pawls **401** away from the objective lens **150**.

At step **S21**, the convergence point **C2** of the objective lens **150** is displaced as a result of the inclination of the objective lens **150**, as mentioned above with reference to FIG. **11**. Consequently, the number of the tilt fringes of the interference fringes B is increased. The increase in the number of the tilt fringes may make it difficult for an operator to determine the degree of coma. Thereafter, at step **S22.5**, the number of the tilt fringes of the interference fringes B is checked to see if the number is too large to measure the coma. If the number is too large, the photo magnetic disc apparatus **100**, and accordingly, the objective lens **150** are moved in the direction to reduce the number of the tilt fringes (step **S23**), i.e., in the direction opposite to the direction of the inclination of the adjusting pawls **401** at step **S21** by actuating the horizontal position adjusting mechanism **505**. Alternatively, it is possible to move the hemispherical lens **202**. If the number is not too large, the operation proceeds directly to step **S24**. At step **S24**, the direction of the maximum coma is detected by the fine adjustment of the horizontal position adjusting mechanism **505** to check whether or not the coma is still present.

At step **S25**, whether or not the coma is within the allowable limit is checked, similar to step **S15**. If the coma is not within the allowable limit, the operations at steps **S20** through **S24** are performed again.

Consequently, if the coma is attenuated to be within the allowable limit, the control proceeds to step **S26** at which the periphery of the objective lens **150** is illuminated with the ultra violet radiation to set the adhesive G. As a result, the objective lens **150** is secured to the supporting surface **152** of the lens holder **151**.

At step **S27**, the inclination adjusting apparatus **400** and the hemispherical lens holder **404** are moved upward to retract the inclination adjusting pawls **401** from the objective lens **150**. Namely, the inclination adjusting apparatus **400** is returned to the initial position shown in FIG. **26**. At step **S28**, the four handles **421** are rotated to adjust the adjusting pawls **401** whose inclination is returned to the reference position, i.e., the position in which reference plate **401*a***, which is integral with adjusting pawls **401**, is parallel to the contacting surface **131*b*** of the spindle motor **131** (FIG. **25**). In the course of the adjustment of the reference plate **401*a***, the laser beam is emitted towards the parallel plate **431**, so that the laser beam reflected by the parallel plate **431** is made coincident with the reference mark provided in the monitor. In this state, the parallel plate **431** and the adjusting pawl reference plate **401*a*** are parallel with the contacting surface **131*b*** and the glass cover "A".

Thereafter, at step **S29**, the photo magnetic disc apparatus **100** is returned to the initial position, i.e., the first stage **ST1**. At step **S30**, the insertion member **330**, and accordingly, the glass cover "A" and the insertion prism **201** are removed from the photo magnetic disc apparatus **100**. Thereafter, at step **S31**, the photo magnetic disc apparatus **100** is removed

from the optical disc apparatus mounting apparatus **500**. Thus, the adjustment of the inclination of the objective lens **150** of the photo magnetic disc apparatus **100** is completed.

As can be understood from the foregoing, according to the inclination adjusting method as shown in FIGS. **20** and **21**, the inclination of the objective lens **150** with respect to the lens holder **151** can be easily and accurately adjusted since the adjustment of **150** is carried out on a real-time basis while the variation of the coma is being observed. Moreover, although the inclination detecting apparatus **200** (FIG. **1**) according to the first embodiment is used to effect the inclination method, the adjusting method can be equally applied also to the inclination detecting apparatuses shown in the second through sixth embodiments.

FIG. **30** shows another embodiment of the inclination adjusting apparatus **400**.

In this embodiment, the microadjusters **421** shown in FIG. **27** are replaced with sticks **440** which extend in the radial directions of the rotatable member **410**. The sticks **440** are secured at the lower ends thereof to corresponding holes **441** formed in the hemispherical outer surface **411** of the rotatable member **410**. The body **402** is provided with openings **442** through which the sticks **440** extend. The sticks **440** project outward from the openings **442** of the body **402**. The diameter of the openings **442** is larger than the diameter of the sticks **440**, so that the sticks **442** are movable (swingable) within the respective openings **440** about the center of curvature of the rotatable member **410**. The remaining structure of the apparatus shown in FIG. **30** is the same as that shown in FIG. **27**.

In the embodiment illustrated in FIG. **27**, the rotatable member **410** is rotated when the microadjusters **421** are selectively rotated to vary the projection length of the spindle **422** thereof, as mentioned above. Consequently, if the direction in which the objective lens **150** is to be inclined to eliminate the coma is identical to the axial direction of none of the four microadjusters **421**, it is necessary to actuate all the microadjusters **421** in combination to thereby incline the rotatable member **410** in the desired direction.

In the embodiment illustrated in FIG. **30**, the sticks **440** are selectively inclined in the direction in which the rotatable member **410** is to be rotated. Namely, the sticks **440** allow for a more precise and easier adjustment than the microadjusters **421**, since the rotatable member **410** is directly rotated.

FIG. **31** shows another embodiment of the adjusting pawls **401** whose front ends are different in shape from those in FIGS. **26** and **27**.

In the arrangement shown in FIG. **31**, the adjusting pawls **401** are provided on the front ends thereof with recesses (notches) **451** in which the upper corner or edge portion **159** of the objective lens **150** is engaged. When the objective lens **150** is pressed by the adjusting pawls **401** to move the lens holder **151** downward, the objective lens **150** tends to laterally slide. However, the engagement of the upper corner edge **159** in the recesses **451** prevents the objective lens **150** from moving in the transverse direction. Consequently, it is ensured that a smooth inclination of the objective lens **150** takes place and the lens holder **151** is returned to the initial position by the restoring force of the spring **154**.

FIGS. **32** through **34** show different examples of the objective lens **150** and the lens holders **151**.

As mentioned above, in the embodiment shown in FIG. **11**, the objective lens **150** is supported on the tapered supporting surface **152** of the lens holder **151**. Consequently, the center of rotation of the objective lens **150** is located at a level higher than the objective lens **150** during the adjustment of the inclination of the objective lens **150**. Therefore, the inclination of the objective lens **150** causes the convergence point C2 to move, thus resulting in the occurrence of the deviation ϵ of the image point. This results in an increase in the number of the interference fringes B. One of the solutions to such a deviation of the image point is to provide a conical supporting surface **152** which expands downward (i.e., in the direction opposite to the convergence point of the objective lens **150**), as shown in FIG. **32**. Namely, the diameter of the conical supporting surface **152** increases towards the lower end thereof. In the arrangement shown in FIG. **32**, the center of rotation of the objective lens **150** is located in the vicinity of the rear principal point N2 of the objective lens **150**. Note that, in the modification shown in FIG. **32**, it is necessary to always suck the objective lens **150** from the upper side thereof, for example, by the use of vacuum in the course of the inclination adjustment of the objective lens.

Also, in another solution shown in FIG. **33**, the center of rotation of the objective lens **150** is located in the vicinity of the rear principal point N2 of the objective lens **150**. Namely, in FIG. **33**, the supporting surface **152** of the lens holder **151** is defined by a conical surface which expands towards the upper end thereof (i.e., towards the convergence point of the objective lens), similar to the supporting surface shown in FIG. **11**. The difference between the arrangements shown in FIG. **11** and FIG. **33** resides in the annular or cylindrical holding ring **150*a*** provided on the peripheral edge of the objective lens **150** and having a center located on the optical axis of the objective lens **150** in FIG. **33**. The lower end of the holding ring **150*a*** is supported on and by the supporting surface **152** of the lens holder **151**. The objective lens **150** with the holding ring **150*a*** is integrally made of a plastic lens which is molded, for example, in an injection molding process.

FIG. **34** shows a modified embodiment of the objective lens **150**. The objective lens **150** shown in FIG. **34** has a lower surface **150*b*** which is supported on and by a tapered inner peripheral edge **151*a*** of the lens holder **151**. In this arrangement, it is impossible to incline (or rotate) the objective lens **150** about the rear principal point N2 of the objective lens **150**, but the center of rotation C3 of the objective lens is located closer to the rear principal point N2 than the embodiment shown in FIG. **11**.

FIGS. **22** and **23** show flow charts of the inclination adjusting operations of the objective lens **150** different from those shown in FIGS. **20** and **21**. The operations up to steps **S15** are the same as those in FIGS. **20** and **21**, and accordingly, no explanation therefor will be given herein below. Accordingly, the following explanation will begin with step **S20**. Note that in the flow charts shown in FIGS. **22** and **23**, although the inclination detecting apparatus **200** of the objective lens shown in FIG. **1**, according to the first embodiment mentioned above is used, it goes without saying that the inclination detecting apparatus according to any one of the second through sixth embodiments can be also equally used.

At step **S20**, the inclination adjusting apparatus **400** is slightly moved downward until the inclination adjusting pawls **401** come into contact with the peripheral edge of the objective lens **150**. Thereafter, at step **S21**, the solenoid coils **163** are activated to bias the lens holder **151** upward. As a result, the upward movement of the lens holder **151** takes place, so that the objective lens **150** is pressed against the adjusting pawls **401**. Namely, the objective lens **150** is held between the adjusting pawls **401** and the lens holder **151**

(FIG. 27), so that the objective lens **150** can be smoothly displaced on the supporting surface **152** to be inclined at an inclination angle identical to the inclination angle of the adjusting pawls **401**. At step S22, the slight upward movement of the inclination adjusting apparatus **400** occurs to move the adjusting pawls **401** away from the objective lens **150**.

As a result of the inclination of the objective lens **150** at step S21', the convergence point C2 of the objective lens **150** is displaced, as mentioned above with reference to FIGS. **11**, and consequently, an operator may have difficulty in measuring the degree of coma, due to the increase in the number of the tilt fringes of the interference fringes B. To prevent this, at step S22.5, whether or not the there are too many tilt fringes to measure the coma is checked. If the number of the tilt fringes is above a predetermined value, the photo magnetic disc apparatus **100**, and accordingly, the objective lens **150** are moved by the operation of the horizontal position adjusting mechanism **505** in the direction to reduce the number of the tilt fringes (step S23), i.e., in the direction opposite to the direction of the inclination of the objective lens obtained at step S21'. Alternatively, it is possible to move the hemispherical lens **202**. If the number of the tilt fringes is not above a predetermined value, the operation proceeds directly to step S24.

At step S24, the fine adjustment of the horizontal position adjusting mechanism **505** varies the direction of the tilt fringes of the interference fringes B to find the direction of the maximum coma to check whether or not the coma is still present.

At step S25, the magnitude of the coma is determined, similar to step S15. If the coma is not within a predetermined limit, the control proceeds to step S32 to incline the adjusting pawls **401** by a predetermined angle. The angle by which the adjusting pawls **401** are to be inclined, corresponding to the inclination angle of the objective lens **150**, is determined in accordance with the distortion of the interference fringes B measured at step S23. The relationship between the variation of the inclination angle of the objective lens **150** and the variation of the coma (distortion of the interference fringes B) is obtained in advance by experiments or calculation. Namely, one variation of the inclination angle of the objective lens **150** corresponds to one variation of the coma (i.e., 1:1). For example, in case of the objective lens **150** whose NA is 0.55 (NA=0.55), it is necessary to incline the objective lens **150** by about 34' (minutes) in order to vary one interference fringe. This value is arrived at by dividing the magnitude of the curvature or inclination of the interference fringes B by the distance or pitch of the interference fringes B. Note that the calculation of the variation of the inclination angle of the objective lens **150** and the variation of the coma is per se known. Also, note that the direction of the adjusting pawls **401** has been already obtained at step S24.

The following discussion will be addressed to the adjusting operation of the inclination of the adjusting pawls **401** at step S32 in more detail.

The laser beam is emitted from the upper side of the parallel plate **431** (FIG. **27**) and a image point of the light reflected therefrom is observed in the monitor (not shown). The image point is displaced in the monitor in accordance with the inclination angle of the adjusting pawls. The reference mark provided in the monitor is adapted to detect or measure the displacement of the image point, i.e., the inclination angle of the adjusting pawls **401**. Namely, the inclination of the adjusting pawls **401** is carried out by rotating the rotatable member **410** which is in turn rotated by the rotation of the microadjusters **421**, while observing the image point in the monitor.

The inclination angle of the adjusting pawls **401** can be detected by a special angle detector which is additionally provided, instead of the measurement of the image point of the light reflected from the parallel plate **431**.

After the operation at step S32 is completed, the control is returned to step S20 in which the adjusting pawls **401** are brought into contact again with the objective lens **150**, and then, the lens holder **151** is biased upward at step S21. Consequently, the objective lens **150** is held between the adjusting pawls **401** and the lens holder **151**, and is displaced along the supporting surface **152** of the lens holder **151** to be inclined at an inclination angle identical to that of the adjusting pawls **401**. As a result of the inclination of the objective lens **150**, the image point of the light reflected from the spherical surface portion **202***b* of the hemispherical lens **202** is displaced in the monitor of the alignment detector **215** (FIG. **1**). Also, in the monitor of the interference fringe viewing portion **205**, the number of the tilt fringes of the interference fringes B is increased owing to the occurrence of the deviation ϵ of the image point (FIG. **11**). If there are too many tilt fringes to measure the coma, the control proceeds to step S23 to reduce the number of the tilt fringes, and thereafter, whether or not the coma is within the allowable limit is checked at step S25. If the displacement of the image point caused by the change of the inclination angle of the objective lens **150** at step S21 is small in the monitor of the alignment detector **215**, it is possible to measure the displacement of the image point in the monitor of the image point viewing portion **214**.

If the coma is within the allowable limit, the control proceeds to step S26 where the peripheral edge of the objective lens **150** is illuminated with the ultra violet radiation through the parallel plate **431** to set the adhesive G. Consequently, the objective lens **150** is secured to the supporting surface **152** of the lens holder **151**.

Thereafter, at step S27, the inclination adjusting apparatus **400** and the hemispherical lens holder **404** are moved upward to retract the adjusting pawls **401** from the objective lens **150**. Namely, the inclination adjusting apparatus **400** is returned to the initial position as shown in FIG. **26**. Thereafter, at step S28, the adjusting pawls **401** are returned to the initial position (horizontal position) by rotating the four microadjusters **421**. During the return operation, the adjustment is effected such that the image point of the light reflected from the parallel plate **431** comes to a predetermined position in the monitor. Thereafter, at step S29, the photo magnetic disc apparatus **100** is returned to the initial position, i.e., the first stage ST1. At step S30, the insertion member **330**, i.e., the glass cover "A" and the insertion prism **201** are removed from the photo magnetic disc apparatus **100**. Thereafter, at step S31, the photo magnetic disc apparatus **100** is removed from the optical disc apparatus mounting apparatus **500**. Thus, the adjustment of the inclination of the objective lens **150** of the photo magnetic disc apparatus **100** is completed.

As can be understood from the foregoing, according to the inclination adjusting method as shown in FIGS. **22** and **23**, the inclination angle of the objective lens **150** is determined in accordance with the distortion of the interference fringes B to incline the objective lens **150** by the inclination angle thus determined, without changing the inclination angle of the adjusting pawls **401** while observing the distortion of the interference fringes B. The inclination angle can be detected

by the displacement of the image point in the monitor. In the case that the inclination of the objective lens **150** which is made of a single glass mold lens with opposite aspheric lens surfaces as used in the illustrated embodiments is adjusted by an inclined supporting surface, the deviation ϵ of the image point corresponding to the value of the inclination to be adjusted to eliminate the coma is large, thus resulting in an increased displacement of the image point in the monitor. Namely, there is a relatively large displacement of the image point with respect to the magnitude of the coma to be eliminated, so that the adjustment of the inclination angle can be easily effected.

In this embodiment, the objective lens **150** is held between the lens holder **151** which is biased towards the adjusting pawls **401** whose inclination angle has been adjusted and the adjusting pawls **401**, so that the objective lens **150** is rotated and displaced on the supporting surface **152** of the lens holder **151**. Accordingly, the objective lens **150** can be smoothly inclined in accordance with the inclination of the adjusting pawls **401**, against the spring **154** provided between the lens holder **151** and the securing member **155**.

The inclination adjusting apparatus and method according to the present invention are not limited to those for the photo magnetic disc apparatus and can be applied to adjust the inclination of a lens in other optical instruments.

As can be seen from the foregoing, according to the lens inclination detecting apparatuses of the above first, second, forth, fifth, and sixth embodiments of the present invention, the coherent light which is emitted from the semi-conductor laser beam source **101** and transmitted through the objective lens **150** and the cover glass "A" can be introduced, at a point far from the objective lens **150** within the optical system of the optical data recording and reproducing apparatus **100**, to the optical system of the lens inclination detecting apparatus **200** by reflecting the coherent light at the hemispherical lens **202** or the concave mirror **240** to return the same to the optical system of the optical data recording and reproducing apparatus.

Moreover, according to the lens inclination detecting apparatus of the third embodiment of the present invention, the coherent light which is emitted from the He-Ne laser beam source **230** and transmitted through the objective lens **150** and the cover glass "A" can be introduced, at point far from the objective lens **150** within the optical system of the optical data recording and reproducing apparatus **100**, to the optical system of the lens inclination detecting apparatus **200** by reflecting the coherent light at the hemispherical lens **202** to return the same to the optical system of the optical data recording and reproducing apparatus.

In the lens inclination detecting apparatus **200**, as is above explained, the cover glass "A" and the hemispherical lens **202** (or the concave mirror **240**), both of which can be made small in size, are placed opposite the objective lens **150**, while an interference fringe optical system including the interference fringe observing portion **205** is located far from the position opposite to the objective lens **150**. This arrangement results in a large space opposite the objective lens **150** outside of the optical data recording and reproducing apparatus **150**. Accordingly, the inclination adjusting apparatus **400** can be positioned in the large space. Furthermore, the inclination of the objective lens **150** can be adjusted from a position at which the optical magnetic disc K is normally placed when the optical recording and reproducing apparatus **100** is used. In this adjustment operation, the adjusting pawls **401** of the inclination adjusting apparatus **400** are inserted between the cover glass "A" and the objective lens **150**. As a result, adjustment of the inclination of the objective lens **150** can be effectively carried out while observing interference fringes.

The elimination of coma by the adjustment of the inclination of the objective lens **150** will be discussed below, with reference to simulation results.

FIG. **35** shows the shape of the objective lens **150** which is in the form of a single lens having opposite aspheric surfaces and the glass cover "A" used in the simulations.

Numerical data of the objective lens **150** used in the simulations is as follows:

NA (numerical aperture)=0.55; focal length=3.3 mm; ω (angle of view)=1.7°; paraxial radius of curvature of the first lens surface=2.124 mm; paraxial radius of curvature of the second lens surface=−6.837 mm; lens thickness=2.180 mm; and, refractive index=1.53677.

Data for the glass cover "A" used in the simulation is as follows:

thickness=1.200 mm and refractive index=1.57346.

The aspheric surface of the objective lens **150** is defined by the following equation:

$$X=CxY^2/(1+(1-(1+K)\times C^2\times Y^2)^{1/2})+A_4\times Y^4+A_6\times Y^6+A_8\times Y^8\times A_{10}\times Y^{10}$$

wherein "X" designates the distance from the tangential plane W; "Y" the distance from the optical axis OX; and, "C" the curvature of the aspherical apex; respectively. The constant of cone K and the constants of the aspheric surface A_4, A_6, A_8, and A_{10} are as follows;

for the first lens surface,

$K=-0.4377$; $A_4=-0.7167\times10^{-3}$; $A_6=-0.6080\times10^{-4}$; $A_8=-0.1060\times10^{-4}$; and, $A_{10}=-0.2730\times10^{-5}$

and for the second lens surface,

$K=0.0000$; $A_4=0.1665\times10^{-1}$; $A_6=-0.3180\times10^{-2}$; $A_8=0.5060\times10^{-3}$; and, $A_{10}=-0.3960\times10^{-4}$

FIG. **36** shows the optical characteristics of the objective lens **150**, i.e., the spherical aberration, the sine condition, and the astigmatism. As can be seen from FIG. **36**, the objective lens **150** has the corrected sine condition, etc., and accordingly has little or no aberration.

FIG. **37** shows the wave aberration on the optical axis, that is represented by PV value (difference between the maximum value and the minimum value) when the inclination of the objective lens **150** with respect to the glass cover "A" is zero.

FIG. **38** shows the variation of the wave aberration which is represented by rms (root mean square) when the inclination of incident light with respect to the optical axis changes. As can be seen in FIGS. **37** and **38**, the objective lens **150** is an aplanatic lens having a corrected sine condition. If the incident light is inclined at about 1.5 degrees with respect to the optical axis, the wave aberration is smaller than ¼ of λ.

FIGS. **39** and **40** show the wave aberration when there is a manufacturing error in the objective lens **150**, i.e., when the first lens surface thereof is decentered from the optical axis by 10 μm in the vertical direction. FIGS. **39** and **40** correspond to FIGS. **37** and **38**, respectively. Namely, in FIGS. **39** and **40**, the wave aberration is represented by PV value and rms, respectively. As may be seen in FIGS. **39** and **40**, the manufacturing error of the objective lens **150** has a considerable influence on the wave aberration. In FIG. **39**, the wave aberration is 0.9 λ (PV value) .

FIGS. **41** and **42** show the wave aberration when the first lens surface is inclined at 4 minutes, as a manufacturing error of the objective lens **150**. In FIGS. **41** and **42**, the wave

aberration is represented by PV value and rms, respectively. As may be seen in FIGS. **41** and **42**, if the first lens surface of the objective lens **150** is inclined, there is a large wave aberration, similar to the case where the first lens surface is decentered. The tendency of the wave aberration in FIGS. **41** and **42** is similar to that in FIGS. **39** and **40**. Such a tendency occurs in a lens having a corrected sine condition.

FIGS. **43** and **44** show the wave aberration when the objective lens **15** fails to be located at a correct position. Namely, the objective lens **150** is inclined at an angle of 25 minutes with respect to the glass cover "A". In FIGS. **43** and **44**, the wave aberration is represented by PV value and rms, respectively. As can be seen in FIG. **43**, a coma occurs when the objective lens **150** is inclined with respect to the glass cover "A". The wave aberration in FIG. **43** is identical in magnitude to that in FIG. **39** or **41** and is symmetrical with respect to the optical axis. Moreover, since the incident light upon the objective lens **150** is inclined with respect thereto, the wave aberration by rms value with respect to the incident angle is not symmetrical with respect to the optical axis, as shown in FIG. **44**.

FIGS. **45** and **46** show the wave aberration which is caused when the first lens surface of the objective lens **150** is decentered by 10 μm from the optical axis in the vertical direction and which is corrected by inclining the objective lens **150** at an angle of 24.6 minutes with respect to the glass cover "A". In FIGS. **45** and **46**, the wave aberration is represented by PV value and rms, respectively. As can be seen in FIGS. **45** and **46**, the wave aberration due to the manufacturing error (assembly error) of the objective lens **150** can be substantially eliminated by inclining the objective lens **150** with respect to the glass cover. In FIG. **45**, although a slight wave aberration remains, since the slight wave aberration arises mainly due to the defocus (out of focus) component, substantially no deterioration of the image occurs.

In FIG. **46**, the minimum wave aberration occurs approximately at −0.5 degrees, and the wave aberration by rms is asymmetric with respect to the ordinate. This is because the light incident upon the objective lens **150** is inclined relative to the optical axis by the inclination of the objective lens **150**. In the adjustment to eliminate the wave aberration, since the adjustment is effected such that the wave aberration on the optical axis is reduced to be a predetermined value, there is no problem with the asymmetrical wave aberration with respect to the ordinate.

It can be understood from the simulations mentioned above that the wave aberration can be varied by the inclination of the objective lens **150** with respect to the glass cover "A" (FIGS. **43** and **44**). Therefore, even if there is a wave aberration caused by the first lens surface of the objective lens **150** decentered from the optical axis due to a manufacturing error as seen in FIGS. **39** and **40**, the wave aberration can be eliminated by inclining the objective lens **150** (FIGS. **45** and **46**).

If the first lens surface is inclined by the manufacturing error (FIGS. **41** and **42**), the wave aberration due to the inclination of the first lens surface can be compensated by varying the inclination of the objective lens **150**. The same would be true for the second lens surface of the objective lens **150**. Furthermore, a wave aberration caused by a manufacturing error of an optical element (for example, collimating lens) other than the objective lens **150** or by a positioning error of any optical elements, etc., can also be corrected.

Namely, the coma (wave aberration) which is produced in the optical system can be cancelled by the coma (wave aberration) that is identical in magnitude and opposite in direction to the first-mentioned coma and that is positively produced in the optical system by the adjustment of the relative inclination of the objective lens and the glass cover.

Consequently, the wave aberration (coma) produced in the optical system can be eliminated merely by adjusting the inclination angle of the objective lens which is located at the terminal stage of the optical system **150** without increasing the tolerance of the optical elements of the optical system. Furthermore, since it is only necessary to adjust the inclination angle of the objective lens in order to eliminate the aberration, the assembling operation and the adjusting operation of the optical system are simplified and require less time.

As can be understood from the above discussion, according to the present invention, not only can the adjustment of the inclination of the objective lens with respect to the recording medium be performed from the side of the objective lens opposite to the recording medium, but also there is no restriction to the mounting mechanism of the objective lens. Moreover, in the supporting apparatus of the objective lens according to the present invention, the number of the elements of the optical pick-up can be reduced, thus resulting in a light-weight pick-up and a fast tracking operation.

In the optical data recording and reproducing apparatus of the present invention, the fine adjustment of the objective lens relative to the recording medium can be executed to eliminate the tracking error and focusing error which would be otherwise caused upon recording and reproducing data on and from the recording medium. Namely, the supporting member (lens holder) of the objective lens is elastically connected to the securing member through an elastic means, such as a spring. Accordingly, the objective lens is slightly displaceable through the elastic deformation of the elastic means, for example, when the electromagnetic force is applied. In the optical data recording and reproducing apparatus, if the objective lens is disposed on the movable lens holder and is engaged at the upper surface thereof by the adjusting member to adjust the inclination of the objective lens with respect to the lens holder, it is impossible to smoothly move the objective lens with respect to the lens holder since the lens holder is displaced by the deformation of the spring which is caused when the lens holder is pressed. However, in the positioning apparatus of the present invention, the inclination of the objective lens can be easily and smoothly adjusted with respect to the lens holder.

Furthermore, in the adjusting method to correct the coma according to the present invention, not only can the optical elements having less manufacturing accuracy than the prior art be used, but also the assembling operation of the optical elements can be simplified.

Although the invention has been described with reference to particular means, materials and embodiments, it is to be understood that the invention is not limited to the particulars disclosed and extends to all equivalents within the scope of the claims.

We claim:

1. A detecting apparatus for detecting an inclination of an objective lens relative to a reference surface, said objective lens being part of an optical data recording and reproducing apparatus in which data is optically recorded on and reproduced from a recording medium which is placed parallel to said reference surface, comprising;

a transparent parallel plate which is opposite said objective lens, parallel to said reference surface, and made of a material that is substantially optically equivalent to a transparent material of said recording medium;

reflecting means for reflecting a coherent light which has passed through said objective lens and said transparent parallel plate back towards said transparent parallel plate and said objective lens;

beam splitting means for splitting said coherent light into a first beam and a second beam;

wavefront rotating means for rotating said first beam and said second beam about an optical axis in a manner such that said first beam and said second beam are rotated through 180 degrees with respect to one another; and,

means for superposing said first beam and said second beam to produce an optical interference.

2. The detecting apparatus of claim **1**, wherein said reflecting means, said beam splitting means, said wavefront rotating means, and said superposing means comprise a single hemispherical lens positioned adjacent to said transparent parallel plate on the opposite side of said objective lens.

3. The detecting apparatus of claim **2**, wherein said hemispherical lens comprises a flat reflecting surface and a spherical reflecting surface whose center of curvature is located on said flat reflecting surface, and wherein said hemispherical lens splits said coherent light by reflecting segments of said coherent light at said flat reflecting surface and said spherical reflecting surface, thereby creating said first beam and said second beam, respectively.

4. The detecting apparatus of claim **3**, further comprising:

an interference fringe observing portion for observing interference fringes which are produced by said superposing means, and a prism for introducing said first beam and said second beam, which have been reflected by said hemispherical lens toward said objective lens and superposed with each other by said hemispherical lens, to said interference fringe observing portion from an optical path of an optical system of said optical data recording and reproducing apparatus, wherein said prism is an insertion prism which is inserted into said optical path so as to split said first and said second beams from said optical path.

5. The detecting apparatus of claim **3**, further comprising:

an interference fringe observing portion for observing interference fringes which are produced by said superposing means, and a beam splitter for introducing said first beam and said second beam, which have been reflected by said hemispherical lens toward said objective lens and superposed with each other by said hemispherical lens, to said interference fringe observing portion from an optical path of an optical system of said optical data recording and reproducing apparatus, wherein said beam splitter introduces said first and second beams, which have been split from said optical path to be emitted to the outside of said optical data recording and reproducing apparatus, to said interference fringe observing portion.

6. The detecting apparatus of claim **3**, wherein said recording medium is a photo magnetic disc, and wherein said flat reflecting surface corresponds to a data recording surface of said photo magnetic disc, and further wherein said objective lens is adjusted in a manner such that a converging point of said objective lens is coincident with said center of curvature of said spherical reflecting surface.

7. The detecting apparatus of claim **3**, further comprising:

an alignment detector for detecting a positional relationship between a convergence point of light converged by said objective lens and said flat reflecting surface.

8. The detecting apparatus of claim **7**, wherein said coherent light reflected by said reflecting means and transmitted through a signal detecting system of said optical data recording and reproducing apparatus is introduced to said alignment detector from said optical data recording and reproducing apparatus.

9. The detecting apparatus of claim **8**, further comprising:

an image point observing portion for observing a coma component contained in said coherent light reflected by said reflecting means, wherein said coherent light reflected by said reflecting means and transmitted through said signal detecting system is introduced into said alignment detector.

10. The detecting apparatus of claim **1**, wherein said reflecting means is a concave mirror for reflecting said coherent light back towards said transparent parallel plate.

11. The detecting apparatus of claim **10**, wherein said beam splitting means is a half mirror for splitting coherent light, which has been reflected by said reflecting means and has passed through said objective lens and said transparent parallel plate twice, into said first beam and said second beam.

12. The detecting apparatus of claim **11**, wherein said wavefront rotating means comprises two Dove prisms positioned in such a manner that, when said first beam and said second beam split by said half mirror pass through said two Dove prisms, said beams are rotated through 180 degrees with respect to one another.

13. The detecting apparatus of claim **11**, wherein said wavefront rotating means includes a corner-cube prism for rotating a wavefront of one of said first beam or of said second beam about said optical axis by 180 degrees.

14. The detecting apparatus of claim **11**, wherein said wavefront rotating means includes a condenser lens and a reflecting mirror for rotating said first beam or said second beam about said optical axis by 180 degrees, wherein said reflecting mirror is positioned at a converging point of said condenser lens.

15. The detecting apparatus of claim **1**, further comprising:

an interference fringe observing portion for observing interference fringes which are produced by said superposing means.

16. The detecting apparatus of claim **15**, wherein said coherent light, which has passed through said superposing means said optical system of said optical data recording and reproducing apparatus, and has proceeded outside of said optical data recording and reproducing apparatus, is introduced to said interference fringe observing portion.

17. The detecting apparatus of claim **15**, wherein said optical data recording and reproducing apparatus includes a semiconductor laser light source which emits said coherent light.

18. The detecting apparatus of claim **17**, wherein said detecting apparatus further includes a He-Ne lapser source for introducing a visible light portion of a spectrum of said coherent light to said objective lens.

19. The detecting apparatus of claim **17**, further comprising means for introducing said coherent light emitted by said semiconductor laser light source into said objective lens, for reflecting said coherent light by a half-mirror within an optical path of an optical system of said optical data recording and reproducing apparatus, said coherent light having been reflected by said reflecting means and having twice passed through said objective lens and said transparent parallel plate, and for introducing said coherent light reflected by said half-mirror into said interference fringe observing portion.

20. The detecting apparatus of claim 19, wherein said second beam splitting means is a prism, which is positioned within a parallel bundle of rays of said optical system, for preventing said coherent light from returning to said semiconductor laser light source.

21. The detecting apparatus of claim 19, wherein said second beam splitting means comprises a wave plate for enabling selecting a polarization direction of said coherent light emitted from said semiconductor laser light source.

22. A lens supporting apparatus which supports an objective lens of an optical data recording and reproducing apparatus in which data is optically recorded on and reproduced from a recording medium, which is placed parallel to a reference surface, comprising:

an oblique annular lens supporting surface inclined relative to a peripheral edge of said objective lens for supporting said objective lens in a manner such that an inclination of said objective lens can be adjusted with respect to said reference surface;

means for moving said lens supporting surface to bring a peripheral edge of said objective lens into contact with an adjusting device to thereby move said objective lens along said lens supporting surface in order to vary an inclination of said objective lens relative to said reference surface.

23. The lens supporting apparatus of claim 22, further comprising:

a lens supporting member connected to a securing portion of said optical data recording and reproducing apparatus, said lens supporting surface formed on said lens supporting member.

24. The lens supporting apparatus of claim 23, said moving means comprises a solenoid coil provided on said lens supporting member, and a magnet provided on said securing portion, and wherein said lens supporting member is moved by energizing said solenoid coil.

25. The lens supporting apparatus of claim 23, wherein said objective lens is provided on a peripheral edge thereof with a flange supported by said lens supporting surface.

26. The lens supporting apparatus of claim 25, wherein said peripheral edge of said objective lens is integrally provided with a plurality of cylindrical portions extending parallel to said optical axis, said cylindrical portions being supported at one of ends thereof by said lens supporting surface.

27. The lens supporting apparatus of claim 26, wherein a rotational center of said objective lens with respect to said lens supporting surface is positioned by said plurality of said cylindrical portions to make said rotational center substantially coincident with a rear principal point of said objective lens.

28. The lens supporting apparatus of claim 22, wherein said lens supporting surface is tapered in a direction away from a position at which said recording medium is placed.

29. The lens supporting apparatus of claim 22, wherein said lens supporting surface is tapered in a direction towards a position at which said recording medium is placed, and wherein said tapered lens supporting surface is formed in a manner such that said objective lens can be rotated about a center which is substantially coincident with a rear principal point of said objective lens.

30. The lens supporting apparatus of claim 22, wherein said lens supporting surface is a conical section.

31. The lens supporting apparatus of claim 22, wherein said lens supporting surface is a spherical section.

32. The lens supporting apparatus of claim 22, wherein said objective lens is rotatable about a rotational center thereof, said rotational center being substantially coincident with a rear principal point of said objective lens.

33. A lens supporting apparatus for supporting an objective lens of an optical data recording and reproducing apparatus in which data is optically recorded on and reproduced from a recording medium placed parallel to a reference surface, comprising:

an annular supporting portion for supporting said objective lens;

a supported surface formed on said objective lens and supported on said annular supporting portion in a manner such that said supported surface can be moved on said annular supporting portion to be inclined relative to said reference surface; and

means for moving said annular supporting portion to bring a peripheral edge of said objective lens into contact with an adjusting device to thereby move said objective lens along said annular supporting portion in order to vary an inclination of said objective lens relative to said reference surface.

34. An inclination adjusting method for adjusting an inclination, relative to a reference surface, of an objective lens of an optical data recording and reproducing apparatus in which data is optically recorded on and reproduced from a recording medium which is positioned parallel to said reference surface, comprising:

a first step of positioning a lens supporting member which supports said objective lens at a predetermined position;

a second step of placing said objective lens on said lens supporting member;

a third step of adjusting said inclination of said objective lens while observing interference fringes to reduce a coma, said interference fringes being caused by an inclination of said objective lens relative to a transparent plate, said transparent plate being positioned parallel to said reference surface and made of a material that is substantially optically equivalent to said recording medium; and,

a fourth step of fixing said objective lens to said lens supporting member.

35. The inclination adjusting method of claim 34, wherein said second step further includes a step of introducing an adhesive, which solidifies when ultraviolet rays are applied thereto, between said objective lens and said lens supporting member, and wherein, in said fourth step, said objective lens is fixed to said lens supporting member by applying ultraviolet rays to said adhesive so as to solidify said adhesive.

36. The adjusting method of claim 34, wherein said lens placing step comprises positioning said objective lens relative to a sucking tube which holds said objective lens by a vacuum force and which places said objective lens on said lens supporting member by releasing the vacuum force.

37. A positioning apparatus which positions a lens relative to a lens supporting member, comprising:

a sucking tube which holds said lens by a vacuum force; and,

a guide portion which has a circular hole, an inner surface of said circular hole guiding said lens in a radial direction of said sucking tube so as to position said lens in said radial direction when said sucking tube is inserted into said circular hole, wherein said circular hole is formed in a manner such that a diameter of said circular hole is larger than a diameter of said sucking tube and substantially corresponds to a diameter of said lens.

38. The positioning apparatus of claim 37, wherein said guide portion further includes a tapered portion having a conical shape for introducing said sucking tube into said circular hole, and an adhesive applying member provided in an outer circumferential portion of said guide portion for applying an adhesive to secure said lens, whose position relative to said lens supporting member has been adjusted, to said lens supporting member.

39. The positioning apparatus of claim 38, further comprising a plurality of said adhesive applying member, said plurality of said adhesive applying members being provided at equal intervals around a center axis of said guiding portion.

40. An inclination adjusting apparatus, comprising:

a body;

an oblique annular lens supporting surface which is inclined relative to a peripheral edge of an objective lens and which supports said objective lens in a manner such that said objective lens can be inclined with respect to said lens supporting surface;

a rotational portion which is rotatably supported by said body in a manner such that a rotational center of said rotational portion is positioned in the vicinity of a rotational center of said lens when said lens is inclined with respect to said lens supporting surface; and

an adjusting pawl which is supported by said rotational portion for engaging with a peripheral edge of said lens;

wherein said rotational portion comprises a rotatable member having a spherical surface to which said adjusting pawl is secured, and a recess having a spherical surface formed in said body to slidably support said rotatable member having a spherical surface.

41. The inclination adjusting apparatus of claim 40, wherein said adjusting pawl is provided with a recess with which an upper corner of said peripheral edge of said lens can be engaged.

42. The inclination adjusting apparatus of claim 40, wherein said rotational portion comprises a passage formed on said recess having a spherical surface; a pressed member which passes through said passage to be connected to said rotatable member having a spherical surface; and, a microadjuster which abuts against said pressed member in a plurality of directions to move said pressed member, wherein said rotatable member having a spherical surface is rotated when said pressed member is moved by operating said microadjuster.

43. The inclination adjusting apparatus of claim 42, wherein a distance between a rotational center of said rotatable member having a spherical surface and a contacting portion of said microadjuster which abuts against said pressed member is set larger than a distance between a peripheral edge of said lens and a rotational center of said lens.

44. The inclination adjusting apparatus of claim 40, wherein said rotational portion comprises a passage formed on said recess having a spherical surface, and a rod which passes through said passage and is connected to said rotatable member having a spherical surface, and wherein said rotatable member having a spherical surface is rotated by moving said rod.

45. The inclination adjusting apparatus of claim 40, further comprising a detecting means for detecting state in which said adjusting pawl is located at a reference position.

46. The inclination adjusting apparatus of claim 45, wherein said detecting means comprises a transparent glass sheet that is parallel with a reference plate of said adjusting pawl, and wherein said adjusting pawl is initially positioned with respect to said lens based upon a bundle of rays reflected on said transparent glass sheet.

47. An inclination adjusting method for adjusting an inclination of a lens which is supported on an oblique annular lens supporting surface that is inclined relative to a peripheral edge of said lens, wherein said lens is positioned by an inclination adjusting member on said oblique annular lens supporting surface to incline said lens at a predetermined angle, comprising:

determining an angle at which said lens is to be inclined;

inclining said inclination adjusting member at said angle;

contacting said inclination adjusting member with said lens; and

displacing said oblique annular lens supporting surface in a direction toward said inclination adjusting member to abut said lens against said inclination adjusting member.

48. An inclination adjusting apparatus which adjusts an inclination of a lens, comprising:

a lens supporting member having an oblique annular supporting surface which supports said lens in a manner such that said lens can be inclined with respect to said supporting surface;

an inclination adjusting member which comes into contact with a surface of said lens, the surface being located opposite to said lens supporting member;

alignment detector for defining an inclination of said inclination adjusting member; and,

biasing means for biasing said lens supporting member towards said inclination adjusting member while bringing a part of said inclination adjusting member into contact with said lens to thereby abut said lens against said inclination adjusting member.

49. The inclination adjusting apparatus of claim 48, wherein said lens supporting member is connected to a securing portion of an optical data recording and reproducing apparatus through a biasing means in a manner such that said lens supporting member can be moved with respect to said securing portion.

50. The inclination adjusting apparatus of claim 49, wherein said biasing means comprises a solenoid coil provided on said lens supporting member, and a magnet provided on said securing portion, so that when said solenoid coil is energized, said lens supporting member is moved to incline said lens to thereby abut said lens against said inclination adjusting member.

[57] **ABSTRACT**

A wide-angle objective lens is comprised, from the object side, of a first lens component which is a negative meniscus lens having its convex surface facing the object side, a second lens component which is a meniscus lens having its convex surface facing the object side and having positive refractive power, a third lens component which is a cemented meniscus lens comprising a positive lens and a negative lens cemented together and having its convex surface facing the object side and having positive refractive power, a fourth lens component which is a positive meniscus lens having its concave surface facing the object side, and a fifth lens component which is a negative meniscus lens having its concave surface facing the object side. The wide-angle objective lens has a stop disposed between the second lens component and third lens component, and satisfies predetermined conditions.

COMPACT WIDE-ANGLE OBJECTIVE LENS

This is a continuation-in-part of application Ser. No. 080,971 filed Jun. 24, 1993, which is a continuation of application Ser. No. 973,614 filed Nov. 9, 1992, both now abandoned.

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to a wide-angle objective lens for cameras, and particularly to a compact, large aperture, wide-angle objective lens suitable for use in a 35 mm format lens shutter camera or a 35 mm format camera with a range finder.

2. Related Background Art

Biogon type, abiogon type, etc. are known as symmetrical type wide-angle lenses having a negative, positive, negative refractive power distribution. The biogon type wide-angle lens can cover a wide angle of view and can make distortion small. Also, its refractive power distribution is a negative, positive, negative refractive power distribution and therefore, as compared with a symmetrical type wide-angle lens of a positive, negative, positive refractive power distribution such as a topogon type wide-angle lens, the biogon type wide-angle lens has an advantage that the quantity of marginal light is great and moreover the diameters of fore and rear lenses can be made small.

Various wide-angle lenses of negative, positive, negative construction are known as the developed types of the biogon type wide-angle lens. They are known, for example, from Japanese Utility Model Publication No. 43-30782, U.S. Pat. No. 3,829,198, U.S. Pat. No. 4,211,472, Japanese Laid-Open Patent Application No. 56-140311, etc.

Examples in which the F-number is made small are shown in Japanese Utility Model Publication No. 43-30782 and U.S. Pat. No. 4,211,472 and examples which comprise a small number of lens components are shown in U.S. Pat. No. 3,829,198 and Japanese Laid-Open Patent Application No. 56-140311.

However, the biogon type wide-angle lens generally suffers from the disadvantages that the total thickness of the lens system (the thickness from that surface of the lens which is most adjacent (nearest) to the object side to that surface of the lens which is most adjacent to the image side) is great and that the F-number is large.

In the lens systems shown in U.S. Pat. No. 3,829,198 and Japanese Laid-Open Patent Application No. 56-140311, the number of lens components is small but the correction of spherical aberration is deficient and therefore, the F-number cannot provide a large aperture. They also have suffered from the disadvantages that the total thickness of the lens system is very great and that the spacing between the front unit and the rear unit of the lens system in which a diaphragm is placed is too narrow and therefore great limitations must be imposed upon the structure of an aperture stop, a shutter unit, a lens barrel, etc.

In the lens system shown in Japanese Utility Model Publication No. 43-30782, the total thickness of the lens system is very great. Moreover the diameters of the fore and rear lenses are great. This is against the desire to make the lens system compact. In the lens system shown in U.S. Pat. No. 4,211,472, the F-number provides a large aperture but the total thickness of the lens system is great, and this is against the desire to make the lens compact. Also, the shape of coma is bad and therefore, if the lens system is left in its original condition, it is necessary to apply a limitation to the light beam and the quantity of marginal light becomes very small, and this has not been preferable.

Further, in the lens system of Japanese Laid-Open Patent Application No. 54-70826, the symmetry of the refractive power distributions on both sides of a stop is destroyed, the air space between a negative lens component disposed on the object side and a positive lens component and the air space between the positive lens component and a negative lens component disposed on the image side are both are widened, and a wide-angle of view and a large aperture can be obtained. However, this lens system has the disadvantages that the great air spaces result in a great total thickness of the lens system and that the height of a ray of light passing through the lens component remote from the stop becomes far from the optical axis and therefore the effective diameter of each lens becomes large.

Further, Gaussian type, Topogon type, etc. are known as symmetrical type lenses having positive, negative, positive refractive power distribution.

The positive, negative, positive symmetrical type lens is advantageous for large aperture, but cannot cover a wide-angle of view, and conversely, the aforedescribed negative, positive, negative symmetrical lens can cover a wide-angle of view, but has the disadvantage for large aperture.

In the positive, negative, positive symmetrical type lens, the off-axis light beam passing through the lens component remote from the stop passes a location remote from the optical axis and therefore, when an attempt is made to achieve a wide-angle, the effective diameters of the front and rear lenses become large, and this results in the bulkiness of the optical system. Accordingly, when an attempt is made to achieve a wide-angle, a negative, positive, negative symmetrical type lens is desirable.

Thus, it has been difficult to provide an optical system which satisfies the condition that a wide-angle can be achieved by a symmetrical type lens and the optical system is compact with a large aperture. The positive, negative, positive symmetrical type lens and the negative, positive, negative symmetrical type lens are generally of a construction advantageous in the correction of distortion and chromatic aberration. When in such symmetrical type lenses, the whole lens system is axially moved to effect focusing (so-called whole axial movement system), the fluctuation of off-axis aberration can be suppressed to a certain degree.

However, where the whole axial movement system is used in the optical system as disclosed in Japanese Laid-Open Patent Application No. 54-170826 wherein the symmetry of the refractive power arrangement of the negative, positive, negative symmetrical type lens is greatly destroyed in order to make the optical system bright, there has been a problem that the fluctuation of off-axis aberration becomes great.

SUMMARY OF THE INVENTION

Accordingly, it is an object of the present invention to solve the above-noted problems peculiar to the prior art and to provide a symmetrical type wide-angle lens which realizes the small total thickness and great aperture of the lens system and which is compact and bright as well as small in distortion.

To achieve the above object, a wide-angle objective lens according to the present invention comprises, in succession from the object side, a first lens component comprising a

negative meniscus single lens having its convex surface facing the object side, a meniscus-shaped second lens component having its convex surface facing the object side and having positive refractive power, a stop, a third lens component comprising a cemented meniscus lens comprising a positive lens and a negative lens cemented together and having its convex surface facing the object side and having positive refractive power, a fourth lens component comprising a positive meniscus single lens having its concave surface facing the object side, and a fifth lens component comprising a negative meniscus single lens having its concave surface facing the object side, and is constructed into a negative, positive, negative refractive power arrangement as a whole, and when the focal length of said first lens component is f_1 and the focal length of said fifth lens component is f_5 and the radius of curvature of that surface of said third lens component which is most adjacent to the image side is r_{32} and the radius of curvature of that surface of said fourth lens component which is most adjacent to the object side is r_{41}, said wide-angle objective lens is designed to satisfy at least one of the following conditions:

$$0\ 02 \leqq |t_1/f_1| \leqq 0.1$$

$$0.01 \leqq |t_4/f_5| \leqq 0.08$$

$$-0.85 \leqq (r_{32}+r_{41})/(r_{32}-r_{41}) \leqq 0.90,$$

where

t_1: the air space on the optical axis from that surface of the first lens component which is most adjacent to the image side to that surface of the second lens component which is most adjacent to the object side,

t_4: the air space on the optical axis from that surface of the fourth lens component which is most adjacent to the image side to that surface of the fifth lens component which is most adjacent to the object side.

By constructing the objective lens as described above, it becomes possible to correct, in particular curvature of image field, astigmatism and coma, and a wide-angle lens which is compact, large aperture and high in performance can be realized.

It is a further object of the present invention to provide a wide-angle lens which suffers little from the fluctuation of off-axis aberration caused by focusing and which is compact with a large aperture and covers a wide-angle of view.

To achieve the above object, the present invention has a stop, and a first lens unit and a second lens unit that are disposed on the object side of the stop and on the image side of the stop respectively. The first lens unit and the second lens unit are designed such that, during focusing, the first and second lens units are moved on the optical axis toward the object side and the amounts of movement of the lens units on the optical axis differ from each other.

Other objects, features and effects of the present invention will become fully apparent from the following detailed description of the invention taken in conjunction with the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** shows the lens construction of a first embodiment of the present invention.

FIG. **2** shows the lens construction of a second embodiment of the present invention.

FIG. **3** shows the lens construction of a third embodiment of the present invention.

FIG. **4** shows the lens construction of a fourth embodiment of the present invention.

FIG. **5** shows the lens construction of a fifth embodiment of the present invention.

FIG. **6** shows the lens construction of a sixth embodiment of the present invention.

FIG. **7** shows the lens construction of a seventh embodiment of the present invention.

FIG. **8** shows the lens construction of an eighth embodiment of the present invention.

FIGS. **9**A and **9**B are schematic views schematically showing the refractive power arrangements in ninth to thirteenth embodiments of the present invention and in which objects are at infinity and a near distance, respectively.

FIG. **10** shows the lens construction of the ninth to twelfth embodiments of the present invention.

FIG. **11** shows the lens construction of the thirteenth embodiment of the present invention.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

Some embodiments of the present invention will hereinafter be described in detail with reference to the accompanying drawings.

FIGS. **1** to **8** show the lens constructions of first to eighth embodiments, respectively, of the present invention. The wide-angle lenses according to the present invention, as shown in FIGS. **1** to **8**, comprise, in succession from the object side, a first lens component **L1** comprising a negative meniscus single lens having its convex surface facing the object side, a meniscus-shaped second lens component **L2** having its convex surface facing the object side and having positive refractive power, a third lens component **L3** comprising a cemented meniscus lens comprising a positive lens and a negative lens cemented together and having its convex surface facing the object side and having positive refractive power, a fourth lens component **L4** comprising a positive meniscus single lens having its concave surface facing the object side, a fifth lens component **L5** comprising a negative meniscus single lens having its concave surface facing the object side, and a stop between the second lens component **L2** and the third lens component **L3**, is constructed into a negative, positive, negative refractive power arrangement as a whole, and is designed to satisfy at least one of the following conditions:

$$0.02 \leqq |t_1/f_1| \leqq 0.1 \quad (1)$$

$$0.01 \leqq |t_4/f_5| \leqq 0.08 \quad (2)$$

$$-0.85 \leqq (r_{32}+r_{41})/(r_{32}-r_{41}) \leqq 0.90, \quad (3)$$

where

t_1: the air space on the optical axis from that surface of the first lens component **L1** which is most adjacent to the image side to that surface of the second lens component **L2** which is most adjacent to the object side,

t_4: the air space on the optical axis from that surface of the fourth lens component **L4** which is most adjacent to the image side to that surface of the fifth lens component **L5** which is most adjacent to the object side,

f_1: the focal length of the first lens component **L1**,

f_5: the focal length of the fifth lens component **L5**,

r_{32}: the radius of curvature of that surface of the third lens component L3 which is most adjacent to the image side,

r_{41}: the radius of curvature of that surface of the fourth lens component L4 which is most adjacent to the object side.

As described above, the lens construction of the present invention is comprised of the first lens component L1 and the fifth lens component L5 each having negative refractive power, and the second lens component L2, the third lens component L3 and the fourth lens component L4 each having positive refractive power, and is a negative, positive, negative refractive power arrangement as a whole.

The first lens component L1 and the fifth lens component L5 each are a negative meniscus lens having its concave surface facing the stop S to sufficiently correct curvature of image field and astigmatism. By the negative meniscus lenses being thus used, it becomes possible to make the angle of view greater and increase the quantity of marginal light.

In a lens having a great angle of view, the correction of astigmatism and curvature of image field is important and it is necessary that the Petzval sum be an appropriate value.

Generally, in case of a lens of a negative, positive, negative refractive power arrangement having symmetry with respect to the stop S, as the air space between a lens unit adjacent to the object side and a positive lens unit and between a negative lens unit adjacent to the image side and the positive lens unit become wider, the degree of freedom of aberration correction increases more, and the Petzval sum can be made into an appropriate value.

However, where these air spaces are made great, the Petzval sum can be made into an appropriate value and this is advantageous for aberration correction, but the diameters of the fore and rear lenses become large and this is not preferable. Conversely, where these air spaces are made small, the Petzval sum increases to the positive and the correction of negative astigmastism and curvature of image field becomes difficult. So, where the refractive power of the first lens component L1 and of the fifth lens component L5 is made great to alleviate the Petzval sum, it will adversely affect coma, and this is not preferable.

The Petzval sum which is the cause of these problems can be improved to a certain degree by setting the refractive indices of the positive lens and the negative lens to appropriate values.

According to the present invention, in the symmetrical type wide-angle lens as disclosed in Japanese Utility Model Publication No. 43-30782, it becomes possible to divide the cemented positive lens disposed rearwardly of the stop into two lens components L3 and L4, effect the correction of spherical aberration by that surface r_{32} of the third lens component L3 which is most adjacent to the image side and that surface r_{41} of the fourth lens component L4 which is most adjacent to the object side, and make the F-number small. Further, since the cemented positive lens is divided into two lens components, the degree of freedom of aberration correction increases and it is possible to correct curvature of image field and astigmatism better.

The aforementioned conditional expressions of the present invention will hereinafter be described in detail.

Conditional expressions (1) and (2) are conditions regarding the correction of astigmatism and curvature of image field and compactness.

If the lower limit of conditional expression (1) is exceeded, the following two cases ① and ② are conceivable.

① A case where the air space t_1 between the first lens component L1 and the second lens component L2 is small; and

② A case where the focal length f_1 of the first lens component L1 is great.

In case ①, positive distortion increases and the correction of spherical aberration becomes impossible, and the F-number cannot be made small. In case ②, the Petzval sum increases to the positive and therefore, the correction of negative astigmastism and curvature of image field becomes impossible.

On the other hand, if the upper limit of conditional expression (1) is exceeded, the following two cases ③ and ④ are conceivable.

③ A case where the air space t_1 between the first lens component L1 and the second lens component L2 is great; and

④ A case where the focal length f_1 of the first lens component L1 is small.

In case ③, there is an advantage in aberration correction, but the diameter of the fore lens and the total thickness of the lens system become great and this is against the desire for compactness, and thus is not preferable. In case ④, Petzval sum decreases, but the coma under the principal ray increases to the negative in a portion which is great in the angle of view, and this is not preferable.

If the lower limit of conditional expression (2) is exceeded, the following two cases ⑤ and ⑥ are conceivable.

⑤ A case where the air space t_4 between the fourth lens component L4 and the fifth lens component L5 is small; and

⑥ A case where the focal length f_5 of the fifth lens component L5 is great.

In case ⑤, the correction of spherical aberration becomes impossible and the F-number cannot be made small. In case ⑥, the Petzval sum increases to the positive and the correction of negative astigmatism and curvature of image field becomes impossible, and a good image plane cannot be obtained.

On the other hand, if the upper limit of conditional expression (2) is exceeded, the following two cases ⑦ and ⑧ are conceivable.

⑦ A case where the air space t_4 between the fourth lens component L4 and the fifth lens component L5 is great; and

⑧ A case where the focal length f_5 of the fifth lens component L5 is small.

In case ⑦, the degree of freedom with which the Petzval sum is made into an appropriate value increases and this is advantageous in correcting astigmatism and curvature of image field, but the total thickness of the lens system becomes great and this is against the desire for compactness, and thus is not preferable. In case ⑧, the correction of spherical aberration becomes impossible and further, the fluctuation of the coma above the principal ray by the angle of view becomes great and this is not preferable.

Conditional expression (3) is a condition regarding the shape of the air space between the third lens component L3 and the fourth lens component L4, and is concerned with coma, curvature of image field and astigmatism.

If the upper limit of conditional expression (3) is exceeded, the Petzval sum will increase to the positive and cannot be made into an appropriate value and the correction of astigmatism and curvature of image field will become difficult, and a good image plane cannot be obtained. Also, the shape of coma will exhibit a sharp tendency toward inner coma, and this is not preferable.

If conversely, the lower limit of conditional expression (3) is exceeded, a good Petzval sum will be obtained, but

aberrations of high orders will occur in a portion which is great in the angle of view and astigmatism will become great. Also, the shape of coma will exhibit a great tendency toward outer coma, and this is not preferable.

It is desirable that in order to correct spherical aberration, curvature of image field and astigmatism and to form the lens compactly, the wide-angle lens according to the present invention be designed to further satisfy the following conditions:

$$0.20 \leqq |r_{42}/f| \leqq 0.55 \quad (4)$$

$$0.40 \leqq D/f \leqq 1.00, \quad (5)$$

where

f: the focal length of the entire lens system,

r_{42}: the radius of curvature of that surface of the fourth lens component L4 which is most adjacent to the image side,

D: total thickness of the lens system. Conditional expression (4) is concerned with the correction of spherical aberration.

If the upper limit value of conditional expression (4) is exceeded, it will become impossible to correct positive spherical aberration, and this is not preferable.

If conversely, the lower limit value of conditional expression (4) is exceeded, it will become impossible to correct negative spherical aberration, and this is not preferable.

Now, the wide-angle lens of the present invention is characterized in that, as compared with popular symmetrical type wide-angle lenses, its back focal length differs little, but the total thickness of the lens is very small. This makes it possible to make the lens barrel into the sunk barrel type to thereby contain it compactly when the lens of the present invention is used in a compact lens shutter camera or a camera with a range finder, and it is more realistic and effective to make the total thickness of the lens system small than to shorten the back focal length.

So, conditional expression (5) sets a condition for prescribing the total thickness of the lens system, i.e., the length from that surface of the first lens component L1 which is most adjacent to the object side to that surface of the fifth lens component L5 which is not adjacent to the image side.

If the lower limit value of conditional expression (5) is exceeded, the difference in height between the on-axis ray and the off-axis ray will become small in the lens far from the stop S and the degree of freedom will be deficient and thus, it will become impossible to correct the on-axis aberration and the off-axis aberration independently of each other.

If conversely, the upper limit value of conditional expression (5) is exceeded, the Petzval sum can be made into an appropriate value and a better image plane performance will be obtained, but this is against the desire for compactness and is therefore against an object of the present invention.

Also, it is desirable that in order to correct curvature of image field and astigmatism better, the first lens component L1, the third lens component L3 and the fifth lens component L5 be designed to satisfy the following conditions:

$$0.04 < N_{31} - N_{32} < 0.25 \quad (6)$$

$$N_1 < 1.70 \quad (7)$$

$$N_5 < 1.70, \quad (8)$$

where

N_{31}: the refractive index of the positive lens L3 disposed on the object side in the third lens component L3 for d-line, the refractive index of the negative

N_{32}: the refractive index of the negative lens disposed on the image side in the third lens component L3 for d-line,

N_1: the refractive index of the first lens component L1 for d-line,

N_5: the refractive index of the fifth lens component L5 for d-line.

Conditional expression (6) represents the difference between the refractive indices of the position lens disposed on the object side in the third lens component L3 and the negative lens disposed on the image side in the third lens component L3 for d-line.

If the lower limit value of conditional expression (6) is exceeded, the Petzval sum will increase to the positive and therefore, it will become impossible to correct negative curvature of image field and astigmatism.

If conversely, the upper limit value of conditional expression (6) is exceeded, a better Petzval sum will be obtained, but aberrations of high orders will occur in a portion which is great in the angle of view and astigmatic difference will be created, and this is not preferable.

Conditional expressions (7) and (8) are concerned with curvature of image field and astigmatism.

If the upper limit values of these conditional expressions are exceeded, the Petzval sum will increase to the positive and therefore, the correction of curvature of image field and negative astigmatism will become impossible and a good image plane will not be obtained.

Another embodiment of the present invention has a first lens unit and a second lens unit disposed with a stop interposed therebetween, on the object side of the stop and on the image side of the stop, respectively, said first lens unit comprising, in succession from the object side, a first lens component of negative refractive power and a second lens component of positive refractive power, said second lens unit comprising a third lens component of positive refractive power and a fourth lens component of negative refractive power, said first lens unit and said second lens unit being designed such that during focusing, they are moved on the optical axis toward the object side and the amounts of movement of said lens units on the optical axis differ from each other.

The present invention as a whole is of a negative, positive, negative refractive power arrangement. The first lens component of negative refractive power in the first lens unit disposed at a location remote from the stop and the fourth lens component of negative refractive power in the second lens unit are negative meniscus lenses having their concave surfaces facing the stop in order to sufficiently correct curvature of image field and astigmatism. The use of the negative meniscus lenses leads to the achievement of a wider angle and the provision of the action of increasing the quantity of marginal light.

The present invention makes the first lens unit and the second lens unit take their share of the correction of on-axis aberration and the correction of off-axis aberration. Specifically, there are the following two kinds of sharing:

(a) To achieve a wide-angle and yet make the refractive power of the first lens unit small in the positive, thereby correcting the off-axis aberration well with the first lens unit, and make the refractive power of the second lens unit great in the positive and divide the positive lens component in the second lens unit into two lens components, thereby correcting the on-axis aberration well with the second lens unit and making the optical system bright.

(b) To achieve a wide-angle and yet make the refractive power of the second lens unit small in the positive,

thereby correcting the off-axis aberration well with the second lens unit, and make the refractive power of the first lens unit great in the positive and divide the positive lens component in the first lens unit into two lens components, thereby correcting the on-axis aberration well with the first lens unit and making the optical system bright.

In the present invention, as described in items (a) and (b) above, the lens units forward and rearward of the stop S are made to take their share of the correction of the on-axis aberration and the correction of the off-axis correction to thereby enable the optical system to be bright, but correspondingly thereto, the symmetry of the refractive power on both sides of the stop is destroyed. Therefore, when focusing is effected by the use of the whole axial movement system, it becomes impossible to suppress the fluctuation of the off-axis aberration well.

So, the fluctuation of the off-axis aberration, when focusing is effected by the use of the whole axial movement system, will hereinafter be considered with respect to the following two types of optical systems in which the refractive power distribution on both sides of the stop is asymmetrical,

(I) Petrofocus Type; and

(II) Telephoto Type.

In the case of (I) above, the refractive power arrangement on both sides of the stop is negative and positive and the pupil magnification exceeds **1**. Therefore, when the object position moves from the infinity state to a short distance, positive astigmatism occurs.

In the case of (II) above, the refractive power arrangement on both sides of the stop is positive and negative and the pupil magnification is smaller than **1**. Therefore, when the object position moves from the infinity state to a short distance, negative astigmatism occurs.

In the present embodiment, when focusing by the whole axial movement is effected, the construction of item (a) above corresponds to (I) above, and when the object position moves from the infinity state to a short distance, positive astigmatism occurs. According to the definition of the third-order aberration coefficient in Lens Designing Method by Yoshiya Matsui, the third-order aberration coefficient III of the second lens unit exhibits the positive (+). Therefore, if the amount of axial movement of the second lens unit is made small relative to the amount of axial movement of the first lens unit, positive astigmatism could be suppressed well and the fluctuation of off-axis aberration caused during focusing could be suppressed.

Conversely, the construction of item (b) above corresponds to (II) above, and when the object position moves from the infinity state to a short distance, negative astigmatism occurs. At this time, the third-order aberration coefficient III of the second lens unit exhibits the negative (–). Therefore, if the amount of axial movement of the second lens unit is made great relative to the amount of axial movement of the first lens unit, the fluctuation of off-axis aberration caused during focusing could be alleviated.

As described above, the present invention effects focusing by the use of the so-called floating system that makes the amounts of axial movement of the first lens unit and the second lens unit different from each other during focusing, thereby enabling the fluctuation of off-axis aberration caused by focusing to be suppressed well.

In the present invention, it is desirable that with the above-described construction, the following conditional expression (9) or (10) be satisfied.

$$0<\Delta\cdot\phi/(\phi_a-\phi_b)<0.2 \quad (9)$$

$$0.3<|\phi 1/\phi|<0.95 \quad (10)$$

where

ϕ_a: the refractive power of the first lens unit,

ϕ_b: the refractive power of the second lens unit,

ϕ: the refractive power of the whole lens system,

Δ: an amount defined by the following equation:

$$\Delta=(\delta 1-\delta 2)/\delta 2$$

when the amount of movement of the first lens unit during focusing is $\delta 1$ and the amount of movement of the second lens unit is $\delta 2$,

$\phi 1$: the refractive power of the first lens component.

Conditional expression (9) is a condition for suppressing the fluctuation of aberration in short distance focusing very well.

If the upper limit value of conditional expression (9) is exceeded, the correction of the fluctuation of off-axis aberration caused by focusing will become excessive. If conversely, the lower limit value of conditional expression (9) is exceeded, the correction of the fluctuation of off-axis aberration caused by focusing will become deficient. Accordingly, it is preferable that the range of this condition be satisfied.

Conditional expression (10) is a condition for achieving the balance of the shortening of the full length and the effective diameter of the front lens.

If the upper limit value of conditional expression (10) is exceeded, the refractive power of the first lens component will become great to the negative and therefore, the diverging action will become strong and the back focal length will become too great. If conversely, the lower limit value of conditional expression (10) is exceeded, the refractive power of the first lens component will become small to the negative and the height of the ray of off-axis light passing through the first lens component will become far from the optical axis, and if an attempt is made to obtain the amount of marginal light, the effective diameter of the front lens will become great, which will lead to the bulkiness of the optical system, and this is not preferable.

The lens constructions of the embodiments of the present invention will hereinafter be described in greater detail.

All of Embodiments 1 to 7, as shown in FIGS. **1** to **7**, are lens systems of two groups **G1** and **G2** constituting is a lens of five-unit seven-component construction comprising, in succession from the object side, a first lens component **L1** which is a negative meniscus lens having its convex surface facing the object side, a second lens component **L2** which is a cemented positive meniscus lens comprising a biconvex lens and a biconcave lens, a stop S, a third lens component **L3** which is a cemented positive meniscus lens comprised of a biconvex lens and a biconcave lens, a fourth lens component **L4** which is a positive meniscus lens having its concave surface facing the object side, and a fifth lens component **L5** which is a negative meniscus lens having its concave surface facing the object side.

Also, Embodiment 8, as shown in FIG. **8**, is a lens of five-unit six-component construction comprising, in succession from the object side, a first lens component **L1** which is a negative meniscus lens having its convex surface facing the object side, a second lens component **L2** which is a positive meniscus lens having its convex surface facing the object side, a stop S, a third lens component **L3** which is a cemented positive meniscus lens comprised of a biconvex lens and a biconcave lens, a fourth lens component **L4** which is a positive meniscus lens having its concave surface facing

the object side, and a fifth lens component L5 which is a negative meniscus lens having its concave surface facing the object side.

The numerical data of the respective embodiments of the present invention will be shown in Tables 1 to 8 below. In these tables, f represents the focal length, F_{NO} represents F-number and 2ω represents the angle of view. The numbers at the left end represent the order from the object side, r represents the radius of curvature of each lens surface, d represents the spacing between adjacent lens surfaces, and the refractive index n and Abbe number ν are values for d-line (λ=587.6 nm).

By using popular aspherical lenses, it is of course possible to introduce an aspherical surface into the first lens component **L1** or the fifth lens component **L5** of the present invention to thereby correct astigmatism and curvature of image field better and achieve a wide-angle, and to introduce an aspherical surface into the second lens component **L2**, the third lens component **L3** or the fourth lens component **L4** to

thereby further correct spherical aberration and achieve a great relative aperture.

FIGS. **9**A and **9**B schematically show the refractive power arrangements of ninth to thirteenth embodiment of the present invention. FIG. **9**A shows the refractive power arrangement when the object position is in the infinity state, and FIG. **9**B shows the refractive power arrangement when the object position is in a short distance state. It is shown in FIGS. **9**A and **9**B that as the object position moves from the infinity to the short distance, the first lens unit **G1** and the second lens unit **G2** move toward the object side.

Each of the ninth to twelfth embodiments, as shown in FIG. **10**, is of a construction which comprises, in succession from the object side, a first lens component **L1** which is a negative meniscus lens having its convex surface facing the object side, a second lens component **L2** which is a cemented lens of positive refractive power comprising a biconvex lens and a biconcave lens cemented together and having its convex surface facing the object side as a whole, a third lens component **L3** comprising a cemented lens component of positive refractive power comprising a biconvex lens having its convex surface of sharper curvature facing the image side and a biconcave lens cemented thereto and having its convex surface facing the object side as a whole, a fourth lens component **L4** which is a positive lens component having its concave surface facing the object side, and a fifth lens component **L5** which is a negative meniscus lens having its convex surface facing the image side, a stop **S** being disposed between the second lens component **L2** and the third lens component **L3**.

The numerical data of the ninth to twelfth embodiments of the present invention are given below. In the data Tables below, the numbers at the left end represents the order from the object side, r represents the radius of curvature of each lens surface, d represents the spacing between adjacent lens surface, and the refractive index n and Abbe number ν are values for d-line (λ=587.6 nm).

The condition-corresponding values of the above data are shown below.

$\Delta\cdot(\phi_a-\phi_b)/\phi=0.046$ (1)

$|\phi 1/\phi|=0.726$ (2)

The thirteenth embodiment, as shown in FIG. **11**, is of a construction which comprises, in succession from the object side, a first lens component **L1** which is a negative meniscus lens having its convex surface facing the object side, a second lens component **L2** which is a positive meniscus lens having its convex surface of sharp curvature facing the object side, a third lens component **L3** which is a positive lens component comprising a biconcave lens having its concave surface of sharper curvature facing the image side and a biconvex lens having its convex surface of sharper curvature facing the object side, said biconcave lens and said biconvex lens being cemented together, a fourth lens component **L4** of positive refractive power comprising a biconcave lens and a biconvex lens cemented together and having its convex surface facing the image side as a whole, and a fifth lens component **L5** which is a negative meniscus lens having its convex surface facing the image side, a stop S being disposed between the third lens component **L3** and the fourth lens component **L4**.

The numerical data of the thirteenth embodiment of the present invention are given below. In the data Table below, the numbers at the left end represents the order from the object side, r represents the radius of curvature of each lens surface, d represents the spacing between adjacent lens surfaces, and the refractive index n and Abbe number ν are values for d-line (λ=587.6 nm).

13	−18.9952	(Bf)		

Variations in the spacing when the photographing distance is infinity (∞) and a short distance (300 mm) are shown below.

TABLE 18

Photographing Distance	Infinity	300 mm
d7	1.350	1.492
Bf	18.460	21.287

The condition-corresponding values of the above data are shown below.

$\Delta\cdot(\phi_a-\phi_b)/\phi=0.012$ (1)

$|\phi 1/\phi|=0.489$ (2)

By using popular aspherical lenses in the ninth to thirteenth embodiments of the present invention, introducing an aspherical surface into the first lens component **L1** or the fifth lens component **L5**, it is possible to correct astigmatism and curvature of image field better and achieve a wider angle. By introducing an aspherical surface also into the second lens component **L2**, the third lens component **L3**, or the fourth lens component **L4**, it is of course possible to correct spherical aberration further and achieve a greater aperture.

According to the present invention, there can be achieved a wide-angle lens which is compact and high in performance and as small as the order of F 2.8. The present invention can be used not only in 35 mm format cameras, but also in large format cameras. Further, when focusing is effected by general axial movement, the fluctuations of aberrations are very small and a good performance can be obtained.

What is claimed is:

1. A wide-angle objective lens system comprising, in order from an object side:

a first lens component including a negative meniscus single lens having a convex surface facing the object side;

a meniscus-shaped second lens component having positive refractive power and having a convex surface facing the object side;

a stop;

a third lens component including a cemented meniscus lens having positive refractive power, having a positive lens and a negative lens cemented together, and having a convex surface facing the object side;

a fourth lens component including a positive meniscus single lens having a concave surface facing the object side; and

a fifth lens component including a negative meniscus single lens having a concave surface facing the object side,

said lens system satisfying at least one of the following conditions:

$$0.02 \leqq |t_1/f_1| \leqq 0.1$$

$$0.01 \leqq |t_4/f_5| \leqq 0.08$$

$$-0.85 \leqq (r_{32}+r_{41})/(r_{32}-r_{41}) \leqq 0.90$$

where

t_1: an air space on an optical axis of the lens system between a surface of the first lens component which is nearest to an image side and a surface of the second lens component which is nearest to the object side,

f_1: the focal length of the first lens component,

t_4: an air space on said optical axis between a surface of the fourth lens component which is nearest to the image side and a surface of the fifth lens component which is nearest to the object side,

f_5: the focal length of the fifth lens component,

r_{32}: the radius of curvature of a surface of the third lens component which is nearest to the image side,

r_{41}: the radius of curvature of a surface of the fourth lens component which is nearest to the object side.

2. A wide-angle objective lens system according to claim **1**, wherein said fourth lens component and the total thickness of the lens system satisfy the following conditions:

$$0.20 \leqq |r_{42}/f| \leqq 0.55$$

$$0.40 \leqq D/f \leqq 1.00$$

where

f: the focal length of the entire lens system,

r_{42}: the radius of curvature of a surface of the fourth lens component which is nearest to the image side,

D: the total thickness of the lens system.

3. A wide-angle objective lens system according to claim **1**, wherein said first lens component, said third lens component and said fifth lens component satisfy the following conditions:

$$0.04 < N_{31} - N = 21\ 0.25$$

$$N_1 < 1.70$$

$$N_5 < 1.70$$

where

N_{31}: the refractive index of the positive lens of the third lens component for d-line,

N_{32}: the refractive index of the negative lens of third lens component for d-line,

N_1: the refractive index of the first lens component for d-line,

N_5: the refractive index of the fifth lens component for d-line.

4. A wide-angle objective lens system according to claim **1**, wherein said second lens component and said third lens component each include a cemented meniscus lens having a biconvex lens and a biconcave lens cemented together and having a convex surface facing the object side, said stop being disposed in the air space between said biconcave lens in said second lens component and said biconvex lens in said third lens component.

5. A wide-angle objective lens system according to claim **1**, wherein said second lens component includes a positive meniscus single lens having a convex surface facing the object side, said third lens component includes a cemented meniscus lens having a biconvex lens and a biconcave lens cemented together and having a convex surface facing the object side, and said stop is disposed in the air space between said positive meniscus single lens in said second lens component and said biconvex lens in said third lens component.

6. A wide-angle objective lens system according to claim **1**, which is designed in accordance with the following data:

F = 28.9
F_{NO} = 2.88
2ω = 73.8°

	r	d	n	υ
1	17.100	1.50	1.54739	53.5
2	9.282	2.70		
3	12.910	3.90	1.84042	43.3
4	−60.183	1.10	1.62588	35.7
5	14.650	5.00		
6	50.105	3.30	1.79668	45.4
7	−10.659	1.00	1.67270	32.2
8	43.956	1.40		
9	−36.842	3.00	1.79668	45.4
10	13.025	1.50		
11	−9.805	1.50	1.58144	40.8
12	−14.846	20.83		

(1) $|t_1/f_1| = 0.068$
(2) $|t_4/f_5| = 0.027$
(3) $(r_{32} + r_{41})/(r_{32} - r_{41}) = 0.088$
(4) $|r_{42}/f| = 0.451$
(5) $D/f = 0.897$
(6) $N_{31} - N_{32} = 0.123$
(7) $N_1 = 1.547$
(8) $N_5 = 1.581$

where f represents the focal length, F_{NO} represents the F-number, 2ω represents the angle of view, the numbers at the left end represent the order from the object side, r represents the radius of curvature of each lens surface, d represents the spacing between adjacent lens surfaces, and n and ν represent the refractive index and Abbe number, respectively, for d-line (λ=587.6 nm),

r_{42}: the radius of curvature of a surface of the fourth lens component which is nearest to the image side,

D: the total thickness of the lens system,

N_{31}: the refractive index of the positive lens of the third lens component for d-line,

N_{32}: the refractive index of the negative lens of the third lens component for d-line,

N_1: the refractive index of the first lens component for d-line,

N_5: the refractive index of the fifth lens component for d-line.

7. A wide-angle objective lens system according to claim **1**, which is designed in accordance with the following data:

f = 28.9
F_{NO} = 2.87
2ω = 73.0°

	r	d	n	υ
1	12.475	1.50	1.57501	41.6
2	8.882	3.10

11	−8.993	1.50	1.58144	40.8
12	−17.685	20.51		

(1) $|t_1 / f_1| = 0.051$
(2) $|t_4 / f_5| = 0.024$
(3) $(r_{32} + r_{41}) / (r_{32} - r_{41}) = 0.506$
(4) $|r_{42} / f| = 0.369$
(5) $D / f = 0.824$
(6) $N_{31} - N_{32} = 0.056$
(7) $N_1 = 1.532$
(8) $N_5 = 1.581$

where f represents the focal length, F_{NO} represents the F-number, 2ω represents the angle of view, the numbers at the left end represent the order from the object side, r represents the radius of curvature of each lens surface, d represents the spacing between adjacent lens surfaces, and n and ν represent the refractive index and Abbe number, respectively, for d-line (λ=587.6 nm),

r_{42}: the radius of curvature of a surface of the fourth lens component which is nearest to the image side,

D: the total thickness of the lens system,

N_{31}: the refractive index of the positive lens of the third lens component for d-line,

N_{32}: the refractive index of the negative lens of the third lens component for d-line,

N_1: the refractive index of the first lens component for d-line,

N_5: the refractive index of the fifth lens component for d-line.

8. A wide-angle objective lens system according to claim **1**, which is designed in accordance with the following data:

f = 28.9
F_{NO} = 2.87
2ω = 74.0°

	r	d	n	υ

(8) $N_5 = 1.581$

where f represents the focal length, F_{NO} represents the F-number, 2ω represents the angle of view, the numbers at the left end represent the order from the object side, r represents the radius of curvature of each lens surface, d represents the spacing between adjacent lens surfaces, and n and ν represent the refractive index and Abbe number, respectively, for d-line (λ=587.6 nm),

r_{42}: the radius of curvature of a surface of the fourth lens component which is nearest to the image side,

D: the total thickness of the lens system,

N_{31}: the refractive index of the positive lens of the third lens component for d-line,

N_{32}: the refractive index of the negative lens of the third lens component for d-line,

N_1: the refractive index of the first lens component for d-line,

N_5: the refractive index of the fifth lens component for d-line.

14. A wide-angle objective lens comprising, in order from an object side:

a first lens component including a negative meniscus lens having a convex surface facing the object side;

a second lens component having a convex surface facing the object side and having positive refractive power;

a third lens component which is a cemented lens having positive refractive power, the cemented lens consisting of, in order from the object side, a positive lens and a negative lens;

a fourth lens component having a convex surface facing an image side and having positive refractive power; and

a fifth lens component including a negative meniscus lens having a convex surface facing the image side,

said wide-angle objective lens system satisfying the following condition:

$$0.04<N_{31}-N_{32}<0.25$$

where

N_{31}: the refractive index of the positive lens of the third lens component for d-line;

N_{32}: the refractive index of the negative lens of the third lens component for d-line.

15. A wide-angle objective lens system according to claim **14**, wherein a stop is disposed between said second lens component and said third lens component, and said wide-angle objective lens satisfies the following condition:

$$-0.85\leqq(r_{32}+r_{41})/(r_{32}-r_{41})\leqq0.90$$

where

r_{32}: the radius of curvature of a surface of the third lens component which is nearest to the image side;

r_{41}: the radius of curvature of a surface of the fourth lens component which is nearest to the object side.

16. A wide-angle objective lens system according to claim **14**, wherein, when the total thickness of the lens system is D and the focal length of the whole lens system is f, said wide-angle objective lens satisfies the following condition:

$$0.4<D/f\leqq1.0.$$

17. A wide-angle objective lens system according to claim **14**, wherein a stop is disposed between said second lens component and said third lens component and, when focusing is performed, a lens unit disposed on the object side of the stop and a lens unit disposed on the image side of the stop are designed so as to move different distances on the optical axis.

18. A wide-angle objective lens system comprising, in order from an object side:

a first lens unit including, in order from the object side, a first lens component having negative refractive power and a second lens component having positive refractive power;

a stop; and

a second lens unit having positive refractive power,

said first lens unit and said second lens unit moving different distances on an optical axis of the lens system when moved toward the object side during focusing.

19. A wide-angle objective lens system according to claim **18**, satisfying the following condition:

$$0<\Delta\cdot\phi/(\phi_a-\phi_b)<0.2$$

where

ϕ_a: the refractive power of said first lens unit,

ϕ_b: the refractive power of said second lens unit,

ϕ: the refractive power of the whole lens system,

Δ: an amount defined by the following equation:

$$\Delta=(\delta1-\delta2)/\delta2$$

when the amount of movement of the first lens unit during focusing is $\delta 1$ and the amount of movement of the second lens unit during focusing is $\delta 2$.

20. A wide-angle objective lens system according to claim **19**, wherein, when the refractive power of said first lens component is $\phi 1$ and the refractive power of the whole lens system is ϕ, said wide-angle objective lens satisfies the following condition:

$$0.3<|\phi 1/\phi|<0.95.$$

21. A wide-angle objective lens system according to claim **18**, wherein said second lens unit has a negative lens component nearest to the image side.

22. A wide-angle objective lens system according to claim **18**, wherein, when the total thickness of the lens system is D and the focal length of the whole lens system is f, said wide-angle objective lens system satisfies the following condition:

$$0.4<D/f\leqq 1.0.$$

[57] **ABSTRACT**

A real image mode finder optical system includes an objective lens, an image inverting optical member for erecting an object image formed by the objective lens, and an eyepiece for observing the object image. The objective lens has a reflecting surface and satisfies a condition:

$$0.1<D/f<0.4$$

where D is the distance between the exit surface of the objective lens and the entrance surface of the image inverting optical member and f is the focal length of the objective lens. Thus, the real image mode finder optical system are constructed with a small number of parts and compact design.

REAL IMAGE MODE FINDER OPTICAL SYSTEM HAVING AN OBJECTIVE LENS INTEGRATED AS A PRISM WITH A REFLECTIVE SURFACE

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to a real image mode finder optical system which is suitable for compact cameras such as photographic cameras and video cameras.

2. Description of the Related Art

In general, finder optical systems are available in virtual image modes, such as Albada and inverse Galilean types, and real image modes, such as Keplerjan types. The finder optical systems of conventional compact cameras has found many uses for virtual image modes. It is for this reason that the virtual image mode finder optical system brings about a wide field angle with comparative ease, has a smaller number of parts because it dispenses with an image erecting means, and allows its length along the optical axis to be reduced. Recently, on the other hand, the real image mode finder optical system has undergone many improvements such that an indicating member, like a field frame, is made easy to see, the effective diameters of lenses can be reduced, and an image inverting optical member, like a Porro prism, can be integrally molded of plastic. Consequently, real image mode finder optical systems (such as those set forth, for example, in Japanese Patent Preliminary Publication Nos. Sho 63-44616 and Sho 61-156018) have come into prominent use.

With the conventional real image mode finder optical systems as mentioned above, however, when an attempt is made to secure a relatively wide field angle, the height of an object image formed by an objective system will inevitably increase. Thus, for compactness of the optical system, the refracting power of the objective system need be increased. This causes the degradation of aberration. Hence, in order to improve the performance of the optical system, it is indispensable to increase the number of lenses of the objective system and lessen the refracting power of each lens. As a consequence of this, the problem is raised that the number of parts used in the optical system increases and its arrangement is complicated. Moreover, the position of the object image formed by the objective system is located in front of the image inverting optical member, and an eyepiece is located behind it.

FIG. **1** show the arrangement of the conventional real image mode finder optical system. This optical system includes an objective lens having lens surfaces R_1 and R_2; an image inverting optical member having lens surfaces R_3 and R_4 and reflecting surfaces M_1, M_2, M_3, and M_4; and an eyepiece having lens surfaces R_5 and R_6. Thus, when the finder optical system is actually disposed in a camera body, the objective lens and the eyepiece, as shown in FIG. **1**, are situated in front of and behind the Porto prism of the image inverting optical member, no matter how the arrangement of the optical system is simplified. Hence, the corresponding thickness of the optical system is imperatively needed, and there is a limit to the reduction of the length along the optical axis.

In order to solve such a problem, optical systems, such as those disclosed in Japanese Patent Preliminary Publication Nos. Sho 63-226616 and Hei 1-255825, are available. These optical systems are designed so that the position of an object image formed by an objective lens is located inside an image inverting optical member to thereby intend the reduction of the overall length. Such prior art, however, develops the defect that because an optical member, such as a field frame, is disposed at the imaging position, the image inverting optical member, such as the Porto prism which can be integrally molded originally, must be divided into two, with a resulting increase in the number of parts.

SUMMARY OF THE INVENTION

It is, therefore, an object of the present invention to provide a real image mode finder optical system in which compactness can be realized by a simple arrangement, without increasing the number of parts, the field angle covers a wide range, and the overall length can be reduced.

In order to achieve this object, the real image mode finder optical system according to the present invention includes an objective lens, an image inverting optical member for erecting an object image formed by the objective lens, and an eyepiece for observing the object image. The objective lens has a reflecting surface and satisfies the condition:

$$0.1<D/f<0.4 \quad (1)$$

where D is the distance between the exit surface of the objective lens and the entrance surface of the image inverting optical member and f is the focal length of the objective lens. The objective lens is constructed so that the conventional objective lens and the first refleeting surface of the conventional image inverting optical member are integrally configured as a prism.

FIG. **2** shows a state where the finder optical system of the present invention is incorporated in a camera. The finder optical system comprises an objective lens **4** shaped into a prism form, having an entrance surface **1**, a reflecting surface **2**, and an exit surface **3**; an image inverting prism **8** having three reflecting surfaces **5**, **6**, and **7**; and an eyepiece **9**. Each of the entrance surface **1** and the exit surface **3** of the objective lens **4**, followed by the entrance surface **10** of the image inverting prism **8**, is configured as a curved surface with a positive power.

In the finder optical system, an image of an object is formed by the combined refracting power of the objective lens **4** and the entrance surface of the image inverting prism **8**, and is observed through the eyepiece **9**. Further, the reflecting surface **2** of the objective lens **4** and the three reflecting surfaces of the image inverting prism **8** have the same configuration as those of the Porro prism, and these four reflecting surfaces invert the image to form an erect image.

Apart from the finder optical system, a photographic lens **11** is disposed nearly parallel to the optical axis of the finder optical system. Reference numeral **12** represents film. These components are arranged, together with others, inside a camera body **13**.

In this way, the real image mode tinder optical system according to the present invention, as shown in FIG. **2**, is compactly incorporated in the camera body, and thus it does away with the corresponding thickness required for the objective lens of the conventional finder optical system such as shown in FIG. **1**. The arrangement of the finder optical system can thus be simplified to reduce the overall length.

In the real image mode finder optical system of the present invention, the distance D between the exit surface of the objective lens and the entrance surface of the image inverting optical member needs some degree of space to correct

for aberration. For its limit, it is desirable to satisfy Eq. (1). This is because if the value of Eq. (1) exceeds the lower limit, the ability to correct for aberration will decrease at the surface on the image side of the objective lens, and in particular the degradation of astigmatism will be caused, while if the value of Eq. (1) passes the upper limit, a compact arrangement of the entire finder optical system becomes impossible.

Further, it is desirable that the finder optical system of the present invention provides the entrance and exit surfaces of the objective lens with curvatures, satisfying conditions:

$$f/r1>0.9 \quad (2)$$

$$f/r2>-0.7 \quad (3)$$

where r_1 and r_2 are radii of curvature of surfaces on the objective and image sides of the objective lens, respectively. If the value of each of Eqs. (2) and (3) exceeds the lower limit of f/**r1** or the upper limit of f/**r2**, the refracting power of the objective lens will decline. This makes it difficult to bring about the finder optical system which has a simple arrangement and a wide field angle as in the present invention. Hence, by providing curvatures within the limits of the values satisfying Eqs. (2) and (3), the objective lens can hold a positive power of moderate strength, with a wide field angle.

If, however, the refracting power of the objective lens is extremely high, it is difficult to secure a finder optical system of high performance. Thus, in the above-mentioned finder optical system, if either the entrance or exit surface of the objective lens, or both, are made aspherical, aberrations can be favorably corrected and a finder optical system of high performance can also be realized. Additionally, if the entrance surface of the image inverting optical member is provided with curvature, an entrance pupil can be situated adjacent to the lens system. In this way, the height of a ray through the objective lens can be held low, which situation is effective for compactness of the objective lens.

This and other objects as well as the features and advantages of the present invention will become apparent from the following detailed description of the preferred embodiments when taken in conjunction with the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a sectional view showing the arrangement of a real image mode finder optical system of prior art;

FIG. **2** is a view showing a state where a real image mode finder optical system according to the present invention is incorporated in a camera;

FIG. **3** is a sectional view showing a fundamental arrangement of the optical system of the present invention:

FIG. **4** is a developed view of the optical system in a first embodiment of the present invention;

FIGS. **5**A, **5**B, and **5**C are aberration curve diagrams in the first embodiment;

FIG. **6** is a developed view of the optical system in a second embodiment of the present invention;

FIGS. **7**A, **7**B, and **7**C are aberration curve diagrams in the second embodiment;

FIG. **8** is a developed view of the optical system in a third embodiment of the present invention; and

FIGS. **9**A, **9**B, and **9**C are aberration curve diagrams in the third embodiment.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

In accordance with the embodiments shown, the present invention will be explained in detail below. FIG. **3** shows the fundamental arrangement of the present invention, and FIG. **4** is a developed view in the first embodiment of the present invention. The optical system of one first embodiment includes an objective lens having a first lens surface **r1**, a first reflecting surface M_1, and a second lens surface r_2; an image inverting optical member having a third lens surface r_3, a second reflecting surface face M_2, a third reflecting surface M_3, a fourth reflecting surface M_4, and a fourth lens surface r_4; and an eyepiece having a fifth lens surface r_5 and a sixth lens surface r_6. Of these surfaces, the third lens surface r_3 constituting the image inverting optical member is provided with curvature to transmit a pupil and assumes the role of a field lens. FIGS. **5**A, **5**B, and **5**C are the aberration curve diagrams of the first embodiment.

The numerical data of the first embodiment are shown below.

Finder magnification = 0.4x
Half field angle of incidence $\omega = 30.2°$
$r_1 = 6.1989$ (aspherical)
$d_1 = 12.4315$ $n_1 = 1.4924$ $\nu_1 = 57.7$
$r_2 = -4.9467$ (aspherical)
$d_2 = 2.991$
$r_3 = 21.5324$
$d_3 = 28.7940$ $n_3 = 1.4924$ $\nu_3 = 57.7$
$r_4 = \infty$
$d_4 = 1.4830$
$r_5 = 17.4342$ (aspherical)
$d_5 = 2.4950$ $n_5 = 1.4924$ $\nu_5 = 57.7$
$r_6 = -26.5239$
$d_6 = 15.0000$
r_7 = (pupil)

Aspherical coefficients

First surface

$P = 0.076$
$E = -0.23077 \times 10^{-2}$, $F = 0.36733 \times 10^{-3}$,
$G = -0.30451 \times 10^{-4}$, $H = 0.94683 \times 10^{-6}$

Second surface

$P = 0.9521$
$E = 0.16652 \times 10^{-2}$, $F = 0.14210 \times 10^{-4}$,
$G = -0.11044 \times 10^{-4}$, $H = 0.33959 \times 10^{-6}$

Fifth surface

$P = 3.6453$
$E = -0.17402 \times 10^{-3}$, $F = 0.21924 \times 10^{-6}$,
$G = -0.10042 \times 10^{-7}$, $H = 0.94956 \times 10^{-10}$

The values of Eqs. (1), (2), and (3) in the first embodiment are as follows:

D/f=0.338

f/**r1**=1.428

f/**r2**=−1.783

FIG. **6** and FIGS. **7**A, **73**, and **7**C are the developed view and aberration curve diagrams of the second embodiment, respectively. The numerical data of this embodiment are shown below.

Finder magnification = 0.36x
Half field angle of incidence $\omega = 27.4°$
$r_1 = 4.6532$ (aspherical)
$d_1 = 10.954$ $n_1 = 1.4924$ $\nu_1 = 57.7$
$r_2 = -5.1387$ (aspherical)
$d_2 = 2.252$
$r_3 = 14.4746$
$d_3 = 24.535$ $n_3 = 1.4924$ $\nu_3 = 57.7$
$r_4 = \infty$
$d_4 = 4.495$
$r_5 = 12.6655$ (aspherical)
$d_5 = 2.495$ $n_5 = 1.4924$ $\nu_5 = 57.7$
$r_6 = -70.549$
$d_6 = 15.000$
r_7 = (pupil)

Aspherical coefficients

First surface

$P = 0.3235$
$E = -0.20256 \times 10^{-2}$, $F = 0.11492 \times 10^{-3}$,
$G = -0.35607 \times 10^{-5}$, $H = 0.43666 \times 10^{-7}$

Second surface

$P = 1.4247$
$E = 0.12102 \times 10^{-2}$, $F = 0.12589 \times 10^{-2}$,
$G = -0.13793 \times 10^{-3}$, $H = 0.47637 \times 10^{-5}$

Fifth surface

$P = 3.0260$
$E = -0.28238 \times 10^{-3}$, $F = 0.38424 \times 10^{-5}$,
$G = -0.30426 \times 10^{-6}$, $H = 0.45719 \times 10^{-8}$

The values of Eqs. (1), (2), and (3) in the second embodiment are as follows:

D/f=0.286

f/r1=1.689

f/r2=−1.530

FIG. **8** and FIGS. **9**A, **9**B, and **9**C are the developed view and aberration curve diagrams of the third embodiment, respectively. The numerical data of this embodiment are shown below.

Finder magnification = 0.45x
Half field angle of incidence $\omega = 28.1°$
$r_1 = 5.4622$ (aspherical)
$d_1 = 12.446$ $n_1 = 1.4924$ $\nu_1 = 57.7$
$r_2 = -9.8755$ (aspherical)
$d_2 = 2.601$
$r_3 = 21.5326$
$d_3 = 28.500$ $n_3 = 1.4924$ $\nu_3 = 57.7$
$r_4 = \infty$
$d_4 = 1.500$
$r_5 = 17.4342$ (aspherical)
$d_5 = 2.4950$ $n_5 = 1.4924$ $\nu_5 = 57.7$
$r_6 = -26.5239$
$d_6 = 15.000$
r_7 = (pupil)

Aspherical coefficients

First surface

$P = 0.2243$
$E = -0.11644 \times 10^{-2}$, $F = 0.53422 \times 10^{-4}$,
$G = -0.11963 \times 10^{-5}$, $H = 0.99294 \times 10^{-8}$

Second surface

$P = 1.9306$
$E = 0.11786 \times 10^{-2}$, $F = 0.90395 \times 10^{-4}$,
$G = -0.10352 \times 10^{-4}$, $H = 0.32060 \times 10^{-6}$

Fifth surface

$P = 0.9985$
$E = -0.57527 \times 10^{-3}$, $F = 0.1924 \times 10^{-6}$,
$G = -0.10042 \times 10^{-7}$, $H = 0.94956 \times 10^{-10}$

The values of Eqs. (1), (2), and (3) the third embodiment are as follows:

D/f=0.267

f/r1=1.786

f/r2=−0.980

In each embodiment mentioned above, r1, r2, . . . represent radii of curvature of individual lens surfaces; d1, d2, . . . are the thicknesses of individual lenses or spaces therebetween; n1, n3, . . . are the refractive indices of individual lenses; and ν1, ν3, . . . , represent Abbe's numbers of individual lenses.

Also, the configurations of aspherical surfaces in each embodiment are expressed by the following equation using the aspherical coefficients:

$$X = \frac{CS^2}{1+\sqrt{1-PC^2S^2}} + ES^4 + FS^6 + GS^8 + HS^{10}$$

where X represents the coordinates in the direction of the optical axis, S the coordinates in the direction normal to the optical axis, C the curvature (=1/r) at the vertex of the aspherical surface, and P the conic constant.

What is claimed:

1. A real image mode finder optical system comprising, in order from an object side thereof:

an objective lens;

an image inverting optical member for erecting an object image formed by said objective lens; and

an eyepiece for observing said object image;

wherein said objective lens has a reflecting surface and satisfies a condition:

$0.1 < D/f < 0.4$

where D is a distance between an exit surface of said objective lens and an entrance surface of said image inverting optical member and f is a focal length of said objective lens.

2. A real image mode finder optical system comprising, in order from an object side thereof:

an objective lens;

an image inverting optical member having a plurality of reflecting surfaces for erecting an image, by reflections caused at said plurality of reflecting surfaces;

an eyepiece disposed after said image inerting optical member;

wherein at least one of the reflecting surfaces of said image inverting optical member is disposed inside said objective lens;

wherein the reflecting surfaces, exclusive of said at least one reflecting surface disposed within said objective lens, are integrally configured as a prism, and disposed after said objective lens; and

wherein said objective lens satisfies a condition:

$0.1 < D/f < 0.4$

where D is a distance between an exit surface of said objective lens and an entrance surface of said prism and f is a focal length of said objective lens.

3. A real image mode finder optical system according to claim **2**, wherein said objective lens comprises a lens having an entrance surface, a reflecting surface, and an exit surface, and satisfies conditions:

$$f/r1>0.9$$

$$f/r2>-0.7$$

where **r1** and **r2** are radii of curvature of the entrance surface and the exit surface of said lens, respectively.

4. A real image mode finder optical system according to claim **3**, wherein the entrance surface of said prism is a curved surface.

5. A real image mode finder optical system according to claim **3**, wherein one of the entrance surface and the exit surface of said objective lens is aspherical.

6. A real image mode finder optical system according to claim **3**, wherein both the entrance surface and the exit surface of said objective lens are aspherical.

[57] **ABSTRACT**

The present invention relates to image-formation on any selected kind of objective body. The characterizing features reside in such that, based upon fed image data, required images are formed on an image-transferable sheet acting for image carry-over service and in reliance on sublimation image transfer technique, and then, by the use of said sheet with said images thus formed thereon, the formed images thereon are transferringly applied on the objective body. By adopting the above measures, the objective body can be formed sharply and clearly with any desired images, irrespective of kind and configuration thereof, with such superior results of highly improved unity and solidability between the formed images and the objective body to be decorated with.

IMAGE FORMATION ON OBJECTIVE BODIES

This is a Continuation of application Ser. No. 07/467,415 filed Jan. 19,1990, now abandoned, which, in turn, is a division of application Ser. No. 07/138,384 filed Dec. 8, 1987, now U.S. Pat. No. 4,923,848 issued May 8, 1990.

TECHNICAL FIELD

This invention relates to methods and apparatus for the formation of images as prints on objective bodies through transfer of images preformed by the sublimation transfer technique, and more specifically it relates to such systems as adapted for the formation of images on any selected objective body, such as cards, clothes, papers, and transparent sheets, although these are not limitative to the present invention.

BACKGROUND ART

Reliance is made generally upon the normal printing technique for formation of images on objective bodies. For the execution of the printing technique, provision and use of printing plates (forms or blocks) are requisite. No matter how simple the image-printing is, the plate-making is a very time-consuming and laborious procedure. This is much more so in the printing of various and complexed image combinations, such as those of graphic or portrait images combined with characters, letters or barcodes, as an example, representing extremely complicated and troublesome work.

Further, in the normal printing operation, various operating conditions, including ink selection and the like, must be carefully considered, depending upon the kind and nature of the printing object, thus the best selection thereof is highly delicate and not as simple as expected.

The present invention is proposed upon careful consideration of the foregoing facts, and an object of the invention is to provide a unique process for the formation of sharp and clear images regardless of the kind and nature of the object to be printed upon, and usable and effective materials and apparatuses for carrying out this unique process.

The method of thermal image transfer (sublimation image transfer) on clothes or fabrics with the use of thermal transfer dyestuffs has been practiced for a long time. In this conventional process, a dyestuff picture layer carrying thermal transfer dyestuff is formed on a substrate sheet which is then subjected to heat in an overlapped state on a cloth or fabric, the dyestuff thereby being transferred thermally onto the latter for forming the desired images thereon. By utilizing this technique, and with recent development of the image forming technology concerning fine thermal printers and the like, various fine image forming processes have been proposed to provide fine images which are comparable to photographic images and are transferred onto plastic films from thermal transfer sheets carrying thermal transfer dyestuffs.

According to these recently proposed processes, various images of cameras, or TVs, graphic images of personal computers and the like can be reproduced easily in the form of hard copies on the surface of a transferred material such as a paper or the like sheet carrying thereon a fixedly attached layer of polyester resin, as an example. These images thus reproduced represent an amply high level comparable to those obtained by photography or fine printing arts.

The thermal transfer process so far set forth has an advantage in that it can form any image in a convenient manner yet entails a problem in that it is limited to image-transferred products preferably of polyester and the like materials which must be dyed with thermal transfer dyes. On the other hand, the image-transferred products must be limited to specifically selected shapes, preferably film, sheet or the like configuration, and thus, such materials as wood, metal, glass or ceramics cannot be formed with images in this way. Further, even if the material is plastics such as polyester or the like, and when the image-forming surface is curved or undulated, or physical body other than sheet, even if it represents a plane surface, it is almost impossible to reproduce images precisely thereon, which naturally constitutes a grave problem in the art.

With recent development and enlargement of utilizing fields of various card-style products, such as cash-cards, telephone-cards, prepayment cards; and ID-cards, there are increasing demands for providing these cards with images, symbols and codes, so as to give various other functional and/or decorative effects. Most of these cards are of planar form, but they are frequently not pliable and/or have uneven rough portions due to provision of characters and symbols, resulting in great difficulty in the scheduled image formation relying upon the thermal image transfer process.

There is therefore an urgent demand among those skilled in the art for the provision of a unique technique capable of forming sharp and clear images of desired patterns on the surface of an objective body of any preferred kind of material and having any shape and configuration and surface condition of any kind, and indeed, for combining and unifying image- and decoration effects.

DISCLOSURE OF THE INVENTION

The present invention is basically based on such a principle that a first image transfer pattern is formed on an image transfer material, preferably an image transfer sheet, and in the form of dyestuff images through the sublimation image transfer process executed by first image transfer means, depending upon given image data, preferably including those of letters, characters, symbols, line images, graduated graphic representations, and then the first transfer pattern is transferred to second transfer means for retransferring the images onto an objective body so as to provide a final product.

Based upon the image data fed from various image data input means and at the first image-transfer means, a thermal head is actuated to execute printing operation through a dyestuff film (thermal image-transfer sheet) on an image-transfer material (or more specifically on an image-transferable material which means an image-transferable sheet). This image-printing is carried out according to the sublimation or sublimative image transfer technique. Thus, in this case, the dyestuff on the dyestuff film is transferred or shifted under the influence of heat energy from the thermal head onto the image-transfer material through sublimation, thus providing the first image-transferred means. Since this first image-transferred means has been thus formed with the images by the sublimated dyestuff, they are, then, transferred onto the second image-transferable means which will be brought into tight contact with the object to be decorated and subjected to heat and pressure for execu-

tion of further image-transfer operation to provide the final desired product.

In the present invention, the image-transfer material (image-transferable sheet) is, as above referred to, formed with images by the sublimative image transfer technique for providing first image-transfer means which has highly sharp and clear images as the operation and results of the characterizing feature of the sublimation image-transfer technique. Therefore, because of the transfer of such sharp and clear images onto the object, it becomes possible to form the images thereon, and indeed, practically irrespective of the kind and nature of the object. In this way, thus, fine image-formation is assured onto practically any objective substance.

And further, by execution of control of the thermal energy applied during the sublimative image-transfer step, the resulting color effect is superior and the image quality is good.

The images sublimatingly applied and formed in the foregoing way are subjected to a further transfer, and onto a substrate product, for providing a final decorative product as desired. In this final product, it should be noted that the underlying layer underneath the images during the sublimative image-transfer stage appears now at the top, acting thus as a kind of protecting layer upon up-and-down positional conversion during execution of the second and final image-transfer stage, resulting in realization of various and numerous effects. As an example, attainment of substantial reduction of contamination, improvement of light resistance, weather resistance and chemical resistance; substantial reduction of color fading; provision of glazing effect; easier and simpler introduction of granular and/or undulated image appearance.

The inventive process is carried into effect basically in such a manner that an image-reception layer provided on one surface of an image-transferable sheet is subjected to an image-forming step with the use of dyestuff capable of depositing therein depending upon the fed image data, so as to form the required images, and then, the image-reception layer of the image-transferable sheet, having been image-fixed and thus now image-carrying, is stuck onto the surface of the object to be decorated upon.

As for the image-transferable sheet adapted for use in the image-transfer during execution of the inventive process, it consists basically of a sheet-like substrate and a reception layer attached, however, in a separable manner, onto one surface thereof. As a modification of the inventive process from the basic mode set forth above, the sheet-like substrate is caused to remain, even after completion of the image-transfer step, as may be occasionally required. In this modified case, it is unnecessary to make the image-reception layer of the image-transfer sheet separable.

Under occasion, the inventive process may be brought into effect in such a way that the image-reception layer of the image-transfer sheet is transferred upon execution of the image-forming step, and indeed, once onto an intermediate image-transfer substrate which is then retransferred, together with the once transferred image-reception layer, onto the surface of an object to be decorated on, and thus, in a retransferring manner.

BRIEF DESCRIPTION OF THE DRAWINGS

In the accompanying drawings:

FIG. **1A** is a block diagram, showing a preferred embodiment of the apparatus according to the present invention;

FIG. **1B** is a schematic view illustrating at B-1, B-2 and B-3, several image-transfer steps for the execution of a process according to the invention;

FIG. **1C** is a schematic view of an image-transfer step, using a platen roll;

FIG. **1D** is a plan view of part of a multi-color dyestuff film adapted for use in an image-forming step;

FIG. **1E** is a schematic view for the illustration of several image-transfer steps;

FIG. **2** is a flow chart of successive operation steps with use of a data-processor, shown in FIG. **1**, functioning as an operating center;

FIG. **3A** is a schematic block diagram, showing a data-processor for the printer;

FIG. **3B** is a block diagram of a sublimative image-transferring printer adopted in the present invention, as a preferred embodiment thereof;

FIG. **4** is a schematic block diagram, showing a color correction unit shown in FIG. **3A**, and several related parts cooperating therewith;

FIG. **5** is a schematic block diagram of a comparator and several related parts cooperating therewith;

FIG. **6** is a circuit block diagram of an image-transfer head shown in FIG. **1B**;

FIG. **7** is a graph showing operational characteristics of a color tone or -gradation corrector unit shown in FIG. **3A**;

FIG. **8** is a table for the illustration, as an example, of picture- or image-elements, as expressed in binary signals;

FIG. **9** is a table showing a conversion operation, as an example, of a parallel/series converter shown in FIG. **3A**;

FIG. **10** is a flow chart, illustrating the operation of the sublimative image transfer printer;

FIG. **11** is a plan view of a final decorative product prepared according to the inventive technique;

FIG. **12** is a sectional view of the product card shown in FIG. **11**, and taken along a section line A—A shown therein;

FIGS. **13** through **31** are a series of sectional views, respectively illustrating several structural examples of image-transferable sheets, suitable for use in the invention; and

FIGS. **32** (*a*), (*b*), and (*c*) are sectional views, indicating final transfer steps.

BEST MODES FOR CARRYING OUT THE INVENTION

Referring now to FIG. **1A** and FIG. **1B**, **1B-1**, **1B-2** and **1B-3**, a basic scheme of the inventive image data processing and image formation will be illustrated. First, in FIG. **1A**, numeral **101** represents an image input means which is adapted for forming image data based upon optical and the like inputs delivered from a TV-camera, line sensor or the like. Other than those above enlisted only by way of example, video; CD; TV; scanner;-personal computer, captain system, capable of providing R.G.B.- and picture image and the like signals may also be utilized in a similar way. The image signal data delivered from the image input means are fed through a data processor **104** to a memory **105** for being stored therein. These stored data can be taken out from the memory and fed through data processor **104** to display means **102** for being displayed thereat.

To the data processer **104**, a mouth/tablet digitizer and/or the like position data processer **103** is electrically connected for introducing position data concerning displayed images appearing at the display **102**. In addition, key board and the like character data input means **106** and font generator **109** are provided for introducing character data. Still further, a barcode generator **110** is provided for introducing barcode when necessary. By the use of these means and units, various additional processing modes can be executed.

The thus processed data are subjected to conversion at a data converter **107** into proper data adapted for operating a sublimation transfer printer and fed forward through a driver **108** to the thermal head.

In this case, by controlling the current duration period to the thermal element of the thermal head, the transfer quantity from the dyestuff film (thermal transfer sheet) is controlled depending upon the thermal energy of the element for realization of the desired gradation degree of concentration on the transfer sheet. There are two different modes of such control of current duration period as follows:

(a) A method for controlling the pulse length corresponding to the picture element in the impressed data to the thermal element of the thermal head or, more specifically, a series data introduced as input to the shift register shown in FIG. **6** and to be described more specifically hereinafter.

(b) A method for controlling the number of pulses of the pulse series corresponding to the picture elements of the data impressed upon the thermal element in the thermal head (in this case, the pulse length being constant).

The degree of gradation of the transfer image can be controlled in the above mentioned way by the regulation of the current-conducting period depending upon the desired gradation degree. On the other hand, the image concentration can be controlled by adjusting the pulse length or the number of pulses contained in the pulse series in correspondence to the picture elements contained in the data as introduced in the shift register and depending upon the driving mode of the thermal head. Further in this case, if the number of gradation of introduced image data is larger than that which can be expressed by the printer unit, a proper conversion operation can be performed by the known strobe control method. As an example, in such case, the conversion of gradation number **256** to **64** may be executed by a ROM, and the thus reduced gradation number can be used as output.

Next, referring to FIG. **1B** at **1B-1** and **1B-2**, reference numeral **121** represents a thermal head which receives signals from the driver **108** shown in FIG. **1A**. This thermal head **121** is arranged in opposition to platen roll **122**, forming the printing position therebetween. The dyestuff film (thermal transfer sheet) is fed from a delivery roll **123** to a winding roll **124** through this printing position, these structural and functional features being commonly employed in both the arrangements shown in FIG. **1B** at **1B-1** and **1B-2**.

In the case of FIG. **1B-1**, the mechanism is so arranged that card or sheet style transfer sheets are printed with dyestuff images.

On the other hand, in the case of FIG. **1B-2**, the mechanism is so arranged that cards are continuously produced with the use of a film style transfer sheet and a dyestuff film in combination.

Now turning back to FIG. **1B-1**, a number of transfer sheets (cards, sheets or the like) have been stacked and stored within a storage casing **125** and are being thrust upward from below by a spring so that the uppermost sheet is kept in pressure contact with a take-out roll **126**. With the rotation of the roll **126**, the sheets are successively delivered from the casing **125** by conveyer belts **127, 128** onto a platen roll **122**. Each one of the sheets is fixed on the peripheral surface of the platen roll, now positionally indexed, by means of a gripper or the like mechanical attaching and separating means, static attracting means, or electromagnetic attaching means. Then, the roll **122** is so rotated that the transfer sheet is positioned at the ready-for-printing-position.

Next, the thermal head **121** is brought into pressure contact with the transfer sheet through the intermediary of the dyestuff film, and then the thermal head **121** is energized with electric current while the dyestuff film and platen roll **122** are moved in synchronism for the execution of image transfer (first image transfer).

Upon execution of the image transfer, the platen roll **122** is rotated, the gripper is released and the take-out roll **129** is rotated and brought into pressure contact for taking out the image transfer sheet onto a tray **130**.

The thus taken-out sheet is brought into overlapped state with a new image transfer sheet, not shown, and then, both the sheets are fusingly united together by pressure application of a heated roll, not shown, for execution of a second transfer step job. The whole operation has thus been completed. Before the fusion process, the sheets may be subjected to punching, trimming and/or the like processing, if necessary.

By execution of the foregoing operational steps, a monocolor printing operation has been completed. However, in the case of multicolor printing, use is made of tricolored or quadruple colored dyestuff film and the corresponding printing operations must be repeated. In this case, upon completion of a single monocolor printing procedure, the platen roll is rotated without contact of the take-out roll **129**, until it arrives again at the printing-initiation position, and so on.

In the following, a tricolor printing job will be illustrated with reference to FIG. **1B-2**, and with use of three different series color zones, of cyan, magenta and yellow.

First, a platen roll **122** is positionally indexed, and an image transfer sheet taken out from the roll **131** and a dyestuff film taken out from the roll **123** are brought into pressure contact in an overlapped state. Then a thermal head **121** is pressed against the platen roll **122** through the intermediary of the overlapped sheets. At this stage, the platen roll **122** is rotated counterclockwise while synchronism is kept between the platen roll **122** and the dyestuff film, and the thermal head **121** is kept electrically energized. In this way, the first color printing is executed.

Further, the dyestuff film is fed to the second color zone position, and then, the platen roll **122**, the dyestuff film and the image transfer sheet are fed forward clockwise around the center roll **122**. Thus a second color printing step is executed.

Further, the print-serviced two color sections of the film is fed back counter clockwise around the center of the platen roll **122** for the execution of a third color printing step. Then, each card sheet is taken out from the stack **200** under the action of take-out rolls or the like, not shown, towards and between a pair of thermal transfer rolls **132, 133**, brought into overlapping state

with the image transfer sheet positionally indexed and already subjected to image transfer steps as was described above, and finally subjected to a picture printing operation by pressurizing application of the thermal image transfer rolls **132, 133** from both sides of each taken-out card, and so on.

The color-printing step with the use of the thermal head is carried into effect in the following manner, as an example.

(First color printing)

Platen roll, image transfer sheet and dyestuff film perform the printing while they are moved in the counterclockwise direction.

(Second color printing)

Platen roll and image transfer sheet are moved in the clockwise direction while the dyestuff film is moved at the same speed and in the counterclockwise direction for performing the color printing under consideration.

(Third color printing)

Platen roll, image transfer sheet and dyestuff film are moved in the counterclockwise direction for execution of the color printing under consideration.

In the modified arrangement shown in FIG. **1B-3**, thermal image transfer rolls **132, 133** have been replaced by a flat press type image transfer head having up-and-down movable flat printer elements **132'**, **133'**.

It should be noted that in the course of the foregoing first and second image transfer steps, image reversal phenomenon is necessarily brought about upon execution of each image transfer step. In other words and more specifically, when two successive image transfer steps in the foregoing sense are executed, reverse images which have once appeared will return to the original normal images. Therefore, when the printed-out products are to be provided upon execution of the first image transfer step, it is necessary to provide reversed image data in the signal processing system. For this purpose, it is only necessary to reverse the addressing order at the data introduction or readout stage into or from the memory.

In the modified arrangement shown in FIG. **1C**, the foregoing platen roll means has been replaced by a metal block **141** lined with a rubber plate **142** in an overlapped manner. The image transfer sheet and dyestuff film are fed out from respective rolls **131** and **123**. With the use of this modified arrangement, the dyestuff surface layer of the dyestuff film can be brought into tight contact with the image-receiving surface layer of the image transfer sheet, and thermal energy will be transferred evenly form the thermal head **121** to the dyestuff film.

In this case, the image transfer sheet is delivered from the roll **131**, and the desired zone or region of the sheet is set underneath the rubber plate **142** (step **1**).

At the same time, the dyestuff film shown in FIG. **1D** on an enlarged scale is delivered from the roll **123** and a selected one of the different color regions is set underneath the rubber plate **142** (step **2**).

Next, the thermal head **121** is brought into the rear surface of the dyestuff film which is the opposite surface to the dyestuff-coated front layer, and the head **121** is driven while it is being translated in the direction shown by an arrow A, images thereby being formed at the specifically allocated zone(s) or region(s) of the image transfer sheet (step **3**).

Further, the thermal head **121** and rolls **416** and **418** are shifted downwards as shown by arrows B, so as to form an idle gap between the image transfer sheet and the dyestuff film for allowing the latter to shift towards the next following color region (step **4**).

Further, the thermal head **121** and rolls **416** and **418** are returned to their original positions, whereupon the third and further succeeding steps are repeatedly executed until a certain predesired number of color printings are completed.

As shown in FIG. **1D**, the dyestuff film is colored to have several different color regions denoted by Y (yellow), M (magenta), C (cyan) and Bk (black). However, the arrangement order is not limited to that shown: Y; M; C and Bk. In addition, as occasionally required, the Bk-region may be dispensed with. Further, as the color elements to be adopted in the Y, M, C-system may not be limited to the three primary colors provided by the subtractive color mixture. On occasion, a characterizing color which means such a color as preadjusted to provide an objective specifically selected one may be used to form the images concerned. As a further modification, the arrangement shown in FIG. **1C** may be so modified that the traveling direction of the image transfer sheet is selected to be perpendicular to that of the dyestuff film.

FIG. **2** is an operation flow chart for showing schematically operational modes taking the data processor **104** adopted in the embodiment shown in FIG. **1** as the centrum of description. The operational contents of several working parts downstream of the data converter **107** will be set forth separately hereinbelow. Now referring to FIG. **2**, in combination with FIG. **1** and at the step of **S101**, image pickup operation is carried out by means of the image pickup means **101**. For execution of this step, it may be better to pick up the face of a person per se which is to be represented on the card, or alternatively, a photograph, portrait or imagery product thereof will do. Depending upon the nature of the object, a TV camera, line sensor or the like instrument may naturally be selectively utilized.

The data taken by the image pickup means **101** are stored through the data processor **104** at a memory **105** (**S102**). By the use of these stored data, image or images is/are displayed at the display **102** (**S103**). Since this display image is not yet subjected to any processing, it is generally unsuitable for representing on the card. However, under certain circumstances, it may be represented thereon as it is.

Then, the operator observed the displayed image or images on the display unit **102** and adjudges whether additional processing is necessary or not (**S104**). If it is not necessary, he will manipulate the key board **106** to make a certain operation, resulting in the termination of processing at the data processing unit **104**, data being fed out therefrom to the succeeding data converter **107**.

On the contrary, when additional processing is necessary, the operator observes carefully the displayed image or images on the unit **102** and adjudges whether the picture image data, or character data or barcode data should be processed. If the picture image data should be processed, such an operation is made for selecting the proper mass of trimming or layout within the menu range of position-data input means **103**. By the execution of this operation, functions and operations at steps **S105** and **S106** can be executed at one stroke. If trimming is taken as an example, the next step is executed in such a way that position data are fed from the position input means **103** to the data-processer **104** with the use of a carsor. When a tablet digitizer is used as the position data input means, the carsor image displayed in

an overlapped manner on the displayed picture image appearing at the display unit **102** by carsor manipulation is positionally specified beforehand in registration with the specified position on the card, for determining the trimming range. Then the operation is carried out in such a way that the picture image data outside the specified trimming range are canceled. By completing these operations, data processing operations relating to step **107** are executed, and, then, the mass for completion of the menu range is selected out. By these measures, steps progress through **S109** to **S102**, and data storing is executed, and further, display representation is brought about through step **S103**. If there is no need for additional processing, an operation termination manipulation is carried out as before at key board **106**, and further operations will be made through data converter **107**.

As for the layout, the operation is carried out with the position data input means **103**, similarly as in the foregoing trimming operation. More specifically, layout is selected out in the menu range of position data input means **103**, and the overall configuration of the card and the display position of picture image are shown at display unit **102**. Then, image inclination correcting operation and the like are carried out so as to realize correspondence thereof with the displayed positional information, the processing operations relating to step **S108** thereby being brought about. After completion of these operations, the mass for the ending in the menu range is selected.

In this way, when selection is made from the menu range by reliance on the position data input means **103**, trimming or layout operation can be brought about. At this stage, when manual operation is carried out at the key board **106**, introduction of character data is executed (**S110**). As the character data in this sense, in the case of ID card, as an example, the name and/or birthday, month and year of the owner may be used. The data introduced from the key board **106** in accordance with the output character style from the font generator **109** are shown at the display unit **102** in the specified positions on the displaying surface and respectively arranged in accordance with display items. The operator acknowledges these items and detailed displays of the represented images. When he acknowledges them as being true, he will operate the key board **106** for showing the operation ending (**S111**).

Upon ending the operations as described above, the data are stored in memory **105** (**S102**) and represented at the display **102**. The operator will acknowledge again this fact, and upon the execution of this, the operations are terminated.

As for the barcode introduction, the data are subjected to inputing at steps **S112** and **S113**, as in a manner similar to the character data introduction as set forth above. The barcodes and the like data may be introduced separately through printing or other mechanical method.

In FIG. **3A**, a data processing circuitry usable in the sublimation image transfer printing method is shown only schematically. As shown, the circuitry **107** comprises a picture element density converter **3**; a color corrector **4**; a gradation corrector **10**; a memory **11**; a switch **12**; a buffer **13** and parallel/series converter **14**. The picture element density converter **3** is connected to a picture image input unit **100**.

The unit **100** serves for generation of three primary color data of R.G.B.- or Y.M.C.-mode from original picture images and is connected through the picture element density converter **3** to the color corrector **4**. The converter **3** converts the picture element density of the image data fed from the unit **100** to the desired one, by subtracting or supplementing, as the case may be, image data for each color element. It should be mentioned that for attaining high quality hard copies, conversion of the picture element density to at least **10** lines/mm or so is preferable.

Color corrector **4** consists preferably of a color decoder, level adjuster or color converter, and serves to correct three primary color data converted to those of a predetermined density of picture elements in consideration of characteristics of the image transfer ink in the image transfer sheet and in addition to provide black color data.

The data processing circuitry **107** is connected through a driver **108** to the sublimation image transfer printer.

In FIG. **4**, an example of the color corrector **4** is shown schematically in structure. As shown, it comprises adders **6Y**; **6M** and **6C**, a black color data calculator **7**, and primary and secondary color correction circuits **8** and **9**. Primary color correction circuit **8** serves for making correction of turbidity of the image transfer ink, while secondary color correction circuit **9** provides a capability of arbitrary and selective correction control relative to specifically selected color hue.

The gradation corrector **10** is so arranged as to make correction of the gradation of the data for each color Y, M, C or K (representing black color) fed from the foregoing color corrector **4** when necessary. For this purpose, the corrector **10** includes a gradation circuit (not shown) and the like, whereby a certain mode of highlight stressing or shadow stressing is introduced and realized.

The memory **11** functions to preserve temporarily the data of each color delivered from the gradation corrector **10**, a selection switch **12** being provided at the output side of the memory for selective writing-in of the data of each color to the buffer **13**. The buffer **13** is capable of writing-in the data of one line of the image transfer head **16** and kept in connection with the parallel/series converter **14** adapted for converting parallel data into series data. Additionally, in the simplified machine, black color data series is dispensed with in some instances.

In FIG. **5**, a schematic construction of the parallel/series converter **14** is shown. As shown, parallel data delivered from the buffer **13** are fed to an input side of a comparator **22**, while outputs from a counter **23** are fed to another input side of the comparator **22** which delivers the converted series data to the driver **15** for driving a thermal head **121**.

If necessary, however, the comparator **22** may be replaced by a converter table, not shown, utilizing a parallel/series converting ROM.

In FIG. **6**, a detailed circuit scheme of the thermal head **121** is shown. As shown, series data delivered from the comparator **22** are fed into a shift register SR and thence, after being subjected to latching at a latch circuit LT, fed to thermal elements HE through NAND gates NA which are fed at respective one side inlets with strobe signals.

Next, referring to FIG. **3A**, the operation of the data processing circuitry **107** will be described more specifically.

First, when three primary color image data are fed from the picture image inlet circuit **100** to the picture element density converter **3**, the latter converts these three primary color data to those which represent a predetermined picture element density and then are fed to the color correction unit **4**. In this case, it is assumed that the unit **4** is fed with three primary color data expressed in respective concentration signals, which are of yellow: **Y0**; of magenta: **M0** and of cyan: **C0**, respectively, in the present example.

These data: **Y0**; **M0** and **C0** are, as shown in FIG. **4**, fed through respective adders **6Y**; **6M** and **6C** to the black color data calculator **7**, to provide a K-output as expressed mathematically by the following formula:

$$K=\min(Y, M, C)$$

wherein, "min" represents a function which provides a possible minimum value.

These data: **Y0**, **M0** and **C0** are fed from the converter **3** to the primary color correction circuit **8** to provide primarily corrected data **Y1**, **M1** and **C1** which are thence fed to the secondary color correction circuit **9** to provide, through calculation, secondarily corrected data: **Y2**, **M2** and **C2**, respectively. These are then fed to respective adders **6Y**, **6M** and **6C**, which add them to respective data **Y0**, **M0** and **C0**, to provide respectively added output data Y, M, and C to be fed to the gradation correcter circuit **10**, respectively, after being utilized for calculation of the K-output signal value.

The primary color correction circuit **8** serves to calculate primarily corrected data: **Y1**, **M1** and **C1** which are necessarily utilized for correct-out of transfer ink turbit. In this case, the original data: **Y0**, **M0** and **C0** are subjected to matrix calculation to provide the primarily corrected data **Y1**, **M1** and **C1**, as folows:

$$Y1=k_{11}\cdot C0-k_{12}\cdot M0+k_{13}\cdot Y0$$

$$M1=k_{21}\cdot C0+k_{22}\cdot M0-k_{23}\cdot Y0$$

$$C1=k_{31}\cdot C0+k_{32}\cdot M0-k_{33}\cdot Y0$$

where,

k_{ij} represents weight coefficients:

i=1–3; and

j=1–3.

The secondary color correction circuit **9** serves to calculate secondary color correction data **Y2**, **M2** and **C2** from primary color correction data **Y1**, **M1** and **C1** by modifying the latter to make certain thereto by performing matrix calculations so as to provide a capability for making an arbitral and selective color control at a certain specifically selected-out color hue, in the following manner:

$$Y2=Y1+l_{11}\cdot\Delta B+l_{12}\cdot\Delta C+l_{13}\cdot\Delta G+l_{14}\cdot\Delta Y+l_{15}l_{15}\cdot\Delta+\cdot\Delta M$$

$$M2=M1+l_{21}\cdot\Delta B+l_{22}\cdot\Delta C+l_{23}\cdot\Delta G+l_{24}\cdot\Delta Y+l_{25}\cdot\Delta R+l_{26}\cdot\Delta M,$$

and

$$c2=C1+l_{31}\cdot\Delta B+l_{32}\cdot\Delta C+l_{33}\cdot\Delta G+l_{34}\cdot\Delta Y+l_{35}\cdot\Delta R+l_{36}\cdot\Delta M$$

wherein,

l_{ij} represents weight coefficients:

i=**1–3**;

j=**1–6**;

ΔB, ΔC, ΔG, ΔY, ΔR, ΔM:

characterizing color data.

Thus, when these secondary correction data **Y2**, **M2** and **C2** are added to the corresponding original data **Y0**, **M0** and **C0** by means of respective adders **6Y**, **6M** and **6C** and under proper selection of weight coefficients k_{ij} for primary color correction circuit **8**, any color discrepancy of the ideal color of the ink appearing on the printed picture images under the action of the sublimation transfer printer can be arbitrarily ammended. In this case, when the weight coefficients l_{ij} for the secondary correction circuit **9** are selected out properly, the color tone of the printing picture images can be modified to an arbitrary degree.

Further, as for the black color data K, correction data **K2** can be calculated by the following formula. With use of these correction data **K2**, which are added to the original black color data K, the desired correction can be executed in a similar manner.

$$K2=K+m1\cdot\Delta B+m2\cdot\Delta C+m3\cdot\Delta G+m4\cdot\Delta Y+m5\cdot\Delta R+m6\cdot\Delta M$$

wherein,

Mi represents weight coefficients:

i=**1–6**.

In this way, output data: Y, M, C and K delivered from the color correction circuit **4** are introduced into the gradation corrector **10** as inputs thereof, and each constituent of these data can be subjected to correction as desired.

FIG. **7** shows several characteristic curves illustrating corrections by means of the gradation corrector 10. More specifically, **f0** represents a standard characteristic curve; **f1** a highlight-stressing operation curve; f2 a shadow-stressing operation curve; **f3** a highlight-and-shadow stressing operation curve; and **f4** a medium tone stressing operation curve.

As indicated in FIG. **7**, by presetting, as necessary, the tone-reproducing characteristics, which determine the relationship between that concentration of color data and that of the prints printed by means of a sublimation image transferring printer, a color tone similar to that possessed by the original image can be reproduced. More specifically, when no correction is adopted, the curve **f0** is used, while in the case of correction, any selected one of these curves **f1** to **f4** may be utilized depending upon the part of gradation to be stressed. Further, it should be noted that the tone reproducing characteristic curves are not exclusively limited to those which have been specifically shown and described above. As an example, the control of gradation correction by color tone reproducing characteristic mentioned above is executed by a gradation circuit, not shown, and the setting of the color tone reproducing characteristic is brought about by manipulation of any selected one of the control knobs, not shown, which are provided separately for "highlight"; "medium tone" and "shadow".

Y.M.C.K.-data subjected to correction by the gradation corrector **10** are once stored in the memory unit 11. The thus stored data may be read out from the memory for each color by manipulation of the selection switch **12** and, after provisional storing, per one line of transfer head **16**, at the buffer **13**, introduced into the parallel/series converter **14** for conversion thereby into corresponding series data.

Another example of the data processing circuit for the sublimation transfer printer is shown only schematically in FIG. 3B. As shown, the processing circuit in **107'** comprises a level regulator **503**; a color converter **504**; an A/D converter **505** and a parallel/series converter **14**.

As the image data introduced into the processing circuit **107'** those which have been subjected to conversion into R.G.B.-signals in the color decoder **502** from composite video signals delivered from a T.V. camera, VTR or the like are used. On the other hand, R.G.B.-signals delivered from a personal computer, captain system or the like means are introduced as input into the level adjuster **503**.

As the color correction method with the use of the foregoing arrangements, it is possible, more specifically, to adjust the hue saturation and/or brightness in the color decoder **502**, or to adjust the signal level of each color light of R.G.B.-system in the level regulator **503**.

As an example, the color conversion from R.G.B.- to Y.M.C.-system can be executed in the color converter **504**. The simplest possible method in this color conversion is to procure the opposite color to each of the normal colors.

The thus produced color signals of Y.M.C.-system is subjected to A/D conversion and then fed successively through the parallel/series converter **14** and the driver **108** to the thermal head, not shown, to carry out printing in the sublimation transfer principle.

Additionally, in normal cases, with the use of the foregoing system composition, input image data must be of static mode. However, by provision of memory means in front of the color decoder or at an intermediate position between the A/D converter and parallel/series converter, animating images can be processed.

The series data converted in the foregoing manner in the data converter **107** or **107'** are fed to the shift register SR shown in FIG. **6** by n-image elements and then, upon being subjected to latching in the latch circuit LT are further delivered to NAND gate NA as its inputs. When a strobe signal ST is fed as input to the NAND gate NA, the foregoing n-image element data is fed to the thermal element HE.

FIG. **8** is a schematic diagram, showing signals for respective image elements. The gradation has been so selected that the first image element is at the highest gradation level, while the n-th image element corresponds to the lowest gradation level, and that the second to (n−1)th image elements vary linearly in gradation levels, so as to provide representatively a better understandable example of the invention.

Next, the operation of the parallel/series converter **14** will be described.

First, as shown in FIG. **5**, image elements data A, consisting of parallel data, more specifically, comprising parallel eight bit data **A0–A7**, are fed to one-side inputs of comparator **22**, while another side inputs thereof are fed with outputs B, comprising eight bit increment outputs **B0–B7**, of counter **23**. The counter **23** counts clock signals in increments, the outputs **B0–B7** being successively varied.

The comparator **22** performs comparison between the two inputs A and B, so as to deliver successively outputs of binary "1" until the increment output B is brought into coincidence with image elements data A, or more specifically, under the condition of A>B and A=B, while, thereafter, binary "0"-outputs are delivered therefrom. More specifically, comparator **22** will continue to deliver binary "1" until an increment value which corresponds to the weight of concentration of image element data A is given thereto. As an example, if the image element data A has a concentration of gradation 128 of a total 256, output "1" will be repeated to deliver 128 times first and then, output "0" will follow after again 128 times, so as to provide in total a specific series data peculiarly in this case.

These series data are taken out from the comparator **22** in the form of A>B- and A≧B-outputs and of A=B-outputs through an attributed OR-gate **24**, and in the present example, the gradation consists of **256** steps or increments. However, in practice, the gradation may represent a smaller number of steps. As an example, if the incrementing bit is **B1** instead of hitherto employed **B0**, the gradation will have **128** steps; and if **B2** is employed, it will have only **64** steps. In this way, the gradation setting may be varied in a simple manner.

When in the foregoing way, the output B from the counter **23** is stepwise incremented, such series data consisting of a first series of "1" will be delivered until the relationship between the image elements data A and the output B from counter **23** becomes A=B, and of a second series of "0" issued thereafter, as shown in FIG. **8**.

In FIG. **9**, a conversion mode at the parallel/series converter **14**, which, however, is different from that shown in FIG. **8**, as an example, is shown again in the form of a matrix. As shown, when the image data are of 8-bit parallel kind, as an example, the gradation data are ranged from 0 to 255, providing, therefore, binary series data from "00 . . . . 00" to "11 . . . . 11".

In this way, the data, per line in the transfer head **16**, kept preserved in the buffer **13** are fed to the parallel/series converter **14** for providing as outputs therefrom into corresponding series data which are then delivered through the driver **15** to the transfer head **16** and thus recorded on a print paper P supported on the transfer drum **17**.

FIG. **10** represents a flow chart illustrating the operation of the sublimate printer as employed in the present invention.

At the first step **S1**, print papers are set in position and the printing ribbon is also set in position ready for performing the required procedure.

At the second step **S2**, printing operation is initiated, and line printings are executed, line by line, accompanying necessary intermittent line shifts, with relation to any selected one of four colors: C (cyan); M (magenta); Y (yellow) and K (black) being carried out. Refer to **S3** and **S4**. When line printings with the selected-out single color have been completed (**S5**), the image transfer sheet is replaced by another color sheet (**S6**) and so on. In this way, line printings are completed in all four colors. In this case, it is naturally most preferable to use a long extended single transfer sheet on which four color ink regions are repeatedly printed in a certain predetermined pattern. The image reception paper is initiated to make print from a certain prescribed position for each of these colors (**S8**). When all of the printing steps have been completed with the four colors, the paper is discharged from position (**S9**) and the printing operation is terminated to be repeated.

In FIG. **11**, a card style sample of the final products according to this invention is shown in front view at **200**. FIG. **12** is a sectional view thereof. Numeral **201** represents the substrate material of the card; **202** a display layer; **203** a surface protecting layer; and **204** a

display image as an example. Depending upon the kind of usage and when necessary, the protecting layer **203** may be dispensed with. It should be noted that the display image **204** on the display layer **202** is represented by a sublimative dyestuff, as a characterizing feature of the present invention.

As the main and substantial material of the image transfer sheet, various plain papers, converted papers, plastic resin sheets or the like may be used per se or in combination. When a plastic resin sheet which can be colored directly with a sublimative dye or dyes is used, these image transfer substrates (articles or objects) as at **201** can be united leach with the display layer **202**. Each of these substrate materials, when it is of the card style, may have generally such dimensions: thickness of 0.68 to 0.80 mm and size: 11 to 8×8 to 5 cm.

As the material of the display layer **202**, various known materials which may be colored with sublimative dyestuffs, such as polyethylene, polypropylene, polyester, ABS, AS, polyvinylchloride, polyvinyl/vinyl acetate copolymer, polystyrene, polyacrylate, polyester, polyamide, polyurethane and the like plastic material, may be advantageously utilized. As will be more specifically described hereinafter, this material layer can be united with the substrate material layer **201**. In the case of such unified structure with substrate layer **201**, the thickness and size dimensions may be substantially as the same as before. However, when normal and/or converted papers or metals, which are practically impossible to color with sublimative dyestuffs, are used as the substrate layer **201**, various methods can be utilized for desired coloring. As an example, a solution including at least any selected one of plastic resin materials capable of coloring with sublimative dyestuffs may be coated on the substrate surface, or alternatively used in the form of a film which is laminated thereon. This kind of film preferably has a thickness of about 3 to 50 μm or so. One of main characterizing features represented in and by the final products **200** is that the appearing display image or images as at **204** is/are formed at least partially or wholly with a sublimative dyestuff or dyestuffs. Additionally, the process for formation of such images can be executed in the conventional art.

As an example, the processing method may be executed conventionally as follows.

As an example, a sublimative image transferable sheet, such as a paper sheet, plastic resin film or sheet capable of acting as the carrier is coated on its surface with any suitable binder resin carrier carrying a sublimative dyestuff or dyestuffs under heat, is overlapped on the display layer **202** and then subjected to heat from behind the heat-transferable sheet, preferably in the pattern mode, so as to transfer the dyestuff or dyestuffs into the display layer **202**. It is proper to select the molecular weight of **250** or larger of the dyestuff, for improving the fastness thereof. However, a molecular weight higher than **370** is more favorable. In the case of provision of the surface protecting layer, there is practically no limitation to the selectability of the dyestuff molecular weight.

The sublimative image transfer may be executed directly on the surface of substrate **201** provided with the display layer **202**. Or alternatively, a carrying, image transferable sheet is prepared separately and, after formation of the image **204** thereon, may be stuck onto or laminated on the substrate **201**.

Image-carrying and image-transferable sheet

In the following, structure, material, usage and application purpose of the image-transferable sheet to be employed in the present invention will be described in detail:

FIG. **13** illustrates only basically and in schematic sectional view the image-transferable sheet adopted in the present invention, while FIGS. **14** through **19** and **22** through **24** illustrate preferable embodiments thereof.

The basic structure of the image transferable sheet **310** is characterized in that, as shown in FIG. **13**, a sheet-like substrate **301** is provided at its one surface with an image-reception layer **302** capable of peel-off from the substrate. By adopting such a structural configuration of the image-transferable sheet, the image-reception layer **302** can be formed with the required image or images with the use of an image transferable sheet having thermally shiftable dyestuff, and then, the image-formed image-reception layer **302** is peeled off from substrate **301** and attached firmly, preferably as by sticking, on the surface of any selected object or article with use of any suitable means. In this way, various conventional drawbacks inherent in the comparative conventional technique can be basically overcome.

More specifically, as the material of the aforementioned image-reception layer **302**, limitation must be imposed to those which can be colored with thermally shiftable or transferable dyestuff. However, upon formation of necessary images and upon peel-off from the sheet-like substrate **301**, the image-reception layer **302** may be attached fixedly onto the surface of glass-made, metal-made or wooden-made products or plastic-resin made ones which are very difficult to color with thermally shiftable and transferable dyestuffs, indeed, by reliance on conventional sticking techniques as properly adopted in consideration of the specific nature and kind of the material of decorative products to be ornamented. Further, the image-formed and peeled-off, image-reception layer **302** from the sheet substrate **301**, is highly thin and thus sufficiently pliable so that it may be applied even onto any uneven and complicated surface of a product to be decorated or ornamented, having undulations, convexities, concavities, recesses and projections. Therefore, a maximum possible better fitness of the image-reception layer to be ornamented is attained and guaranteed by the present invention. Thus, practically no limitation in the attaching use thereof may be encountered. Further, in sharp contrast to conventional sealing seals and the like, the very thin image-reception layer bearing necessary images can be applied easily to the product per se in a very uniform manner, thus providing no raised and thickened feeling, and giving rise to no foreign feeling upon attachment.

FIG. **14** shows a further example of the image transferable sheet **310**. In this case, there is provided a parting agent layer **303** on the surface of image-reception layer **302**. Between the latter and the sheet substrate **301**, there is provided a parting agent layer **303'**. If necessary, however, any one of the two layers **303**; **303'** may be dispensed with.

The first parting agent layer **303** is provided for prevention of thermal fusion between the image-reception layer **302** and an image transferable sheet, not shown, as may occur during image transfer and formation on the first layer **302** through transfer of thermally transferable dyestuff from the said transferable sheet to the first layer. If there is no risk of such thermal fusion of the above nature, or when the image-transferable sheet has

been already provided with such a parting agent layer, the present provision thereof may be unnecessary. As for another parting agent layer **303'**, it is for the purpose of making the latter peel-off operation, to be executed after image-forming step, easier. When the sheet-like substrate **301** is made of polyester or the like material which has, as it is, sufficient separability from image-reception layer **302**, provision of parting agent layer may naturally be dispensed with.

FIG. **15** illustrates a still further example of image transferable sheet **310**. In this case, between the image-reception **302** and the sheet-like substrate **301**, an intermediate layer **304** and/or parting agent layer **303'** is/are provided. The laminating order is optional and thus not binding. The intermediate layer **304** will serve to assist the image formation to be rather firm and beautiful, the image formation being carried out by transferring the thermally shifting and transferring dyestuff from the image transferable sheet to the image-reception layer **302**. For this purpose, the intermediate layer **304** may take, for example, the form of a cushioning layer or heat insulating layer. When a cushioning layer is provided as the intermediate layer **304**, the cohesion between the image transferable sheet and the image reception layer **302** is greatly improved and the thermal shift and transfer of the dyestuff during image formation with the use of a thermal head is evenly executed, the image formation thereby being carried out amply in correspondence with the supplied image signals. Further, when a heat insulating layer consisting of a highly heat-insulative material is used as the intermediate layer **304**, ineffective release of the heat applied during shift and transfer of the dyestuff from the image transferable sheet to the image-reception layer **302** can be reduced to a minimum possible, the effective thermal efficiency thereby being correspondingly improved and ample image formation being accelerated. If necessary, however, these cushioning layer and heat-insulating layer can be prepared independently and arranged concurrently in any arranging order.

Additionally, when the intermediate layer **304** is arranged at a higher level than the parting agent layer **303'**, the intermediate layer **304** will be conjointedly peeled off in the case of peel-off of the image-reception layer **302**. On the contrary, when the intermediate layer **304** is arranged at a lower level than the parting agent layer **303'** the intermediate layer will remain on the sheet-like substrate **301** after execution of the separation of image-reception layer **302**. In this case, therefore, the intermediate layer **304** may be made preferably and at least substantially transparent, when the peeled-off image-reception layer **302** is stuck on a decorative product, while directing the surface of parting agent layer **303** towards the latter.

In the modifications shown in FIGS. **16**, **17**, and **18**, modified from the foregoing embodiment shown in FIG. **15**, a further protecting layer **305** is provided between the image-reception layer **302** and the sheet-like substrate **301**. This protecting layer **305** serves to prevent deterioration of the formed images in the image-reception layer **302** when the latter is stuck on the decorating product while directing the surface (more specifically the image-formed surface) towards the product. For example, this protecting layer **305** is prepared from a superior material which exhibits at least one of desirous properties such as antiwearing, light-fast, weather proofing and anti-chemical qualities. With the use of the protecting layer **305** having these superior qualities, the images can represent improved fastness in the above various aspects, even after execution of the foregoing sticking procedure.

In the modification shown in FIG. **16**, the protecting layer **305** is arranged between the intermediate layer **304** and the parting agent layer **303'**.

In the further modification shown in FIG. **17**, the protecting layer **305** is arranged between the image-reception layer **302** and the parting agent layer **303'**.

In still another modification shown in FIG. **18**, the intermediate layer **304** takes the role of the protecting layer **305**.

In each of these modifications, the protecting layer **305** is arranged in neighboring relationship with the partition agent layer **303'**, whereby the image-formed and remotely arranged, image-reception layer **302**, kept in its up-and-down reversed state, is capable of adhering securely to the decorative product, so as to be positioned as an uppermost layer, as may be required. In a still further modification shown in FIG. **19**, derived from that shown in FIG. **14**, a sticking layer **306** is further provided between the image-reception layer **302** and the partition agent layer **303**. It should be noted, however, that such a sticking layer as at **306** may be provided in any one of other foregoing examples and modifications, if necessary, in neighboring relationship with the parting agent layer **303'**.

The provision of such a sticking layer as at **306** is highly valuable when the image-formed and peeled-off, image-reception layer is adhering without position reversal onto the decorative product. With this arrangement mode, the protecting layer **305** shown in FIGS. **16**, **17**, and **18** may be dispensed with. If, however, the protecting layer **305** is composed of a material in the form of a sheet-like substrate, the part to be peeled off is thereby strengthed, the peel-off procedure thus being greatly facilitated.

By previous provision of the sticking layer **306**, the image-formed and peeled-off, image-reception sheet **302** can be caused to adhere as it is onto the decorative product without use of a separate sticking agent. As the sticking layer **306**, an ordinary sticking agent which is active at room temperature can be used. 0r alternatively, a heat-sensible or light-sensitive sticking agent may be used, if necessary.

In the foregoing, the main structure of the image transferable sheet employed in the present invention has been described in detail. However, other structural modes than those set forth hereinbefore which occur easily to those skilled in the art may be employable in the invention, and thus-they may be included within the scope of the invention without departing from the appended claims.

It should be further noted that, in the present invention, the sheet-like substrate may be provided on its one surface with an image-transferable layer capable of peeling off through the intermediary of only one weakly sticking layer.

FIG. **22** shows only schematically in a sectional view a preferred embodiment of such an image-transferable sheet, denoted with same reference numeral **310**.

As shown in FIG. **22**, the image-transferable sheet **310** represents a basic structural characteristic such that any suitable sheet-like substrate **301** is provided on one of the surfaces with an image-reception layer **302** through an only weakly sticking intermediate layer **402**, the layer **302** thus being easily peeled-off when desired. By providing the image-transferable sheet with such a

structural characteristic as set forth above, desired positive or negative images are formed by transferring thermally shiftable and transferable dyestuff from the image heat transferable sheet to the image-reception layer **302**, and the thus image-formed layer is peeled off from the sheet-like substrate **301** and then attached onto any suitably selected product with the use of proper means or attached per se thereon without the peeling-off operation, the substrate then being peeled off, whereby an image-formed final product can be obtained.

In the foregoing example, it should be noted that the image reception sheet **302** per se has only a thin thickness and thus represents only poor feedability during the sheet-feeding period within the printer at the time of image formation, insufficient cushioning effect and only insufficient thermal efficiency during the printing operation, and further, it is very difficult to treat in advance of as well as after execution of the image formation. Therefore, the coexistence of the image-reception layer **302** and the sheet-like substrate **301** is absolutely necessary. In addition, it is a requisite requirement that the image reception layer **302** be easily peeled off from the sheet-like substrate **301** upon execution of the image-forming operation, and thus, the layer **302** and the sheet **301** should not be stuck too strongly together. In order to satisfy this requirement, provision is made of weakly stuck layer **402** therebetween. Thus, it should be noted that the term "weakly stuck" employed in this specification and appended claims may be defined as "to be separable by finger's end and the like means from each other without entailing destruction or breakage of the parts originally stuck together". It is worthwhile to say, in considering the relative relationship between the image-reception layer **302** and the sheet-like substrate **301**, there is no necessity to provide the weakly-stuck layer **402** if the aforementioned peeling-off is very easy to bring about.

FIG. **23** illustrates still another modification of the image-transferable sheet **310** denoted by the same reference numeral **310** only for simplicity and convenience, wherein a further parting agent layer **303** is provided on the surface of image-reception layer **302**.

This layer **302** is provided for occasional thermal sticking between the thermal image transferable sheet, not shown, and the image reception layer **302** in the progress of thermal shift and transfer of the dyestuff from the sheet to the layer **302**. This provision of the parting agent layer **303** may be dispensed with if there is no risk of occurrence of such disadvantageous sticking attachment or the sheet under consideration has already been fitted with such a parting agent layer.

A modification shown in FIG. **24** from that shown in FIG. **23** has such a modified structure that a protecting layer **305** is provided between the image-reception layer **302** and the weakly stuck layer **305**. This layer **305** serves to prevent otherwise occurring deterioration of the images at the image-reception layer **302** which has been formed with preferably reversed images and subjected to peeling-off, together with protecting layer **305**, preferably a plastic sheet layer, from the sheet-like substrate **301** and finally stuck onto the decorative product, while directing the image-formed surface of the image-reception layer towards the product. The protecting layer **305** is made of a material having various excellent physical properties, such as anti-wearing-, light-fastness and antichemical characteristics. Provision of such a protecting layer improves various fastness performances of the formed images after sticking attachment of the image-reception layer **302**.

When necessary, a separate parting agent layer, not shown, may be provided between the protecting layer **305** and the weakly stuck layer **402** for providing easy peel-off capability between these two layers **305** and **402**, as being applicable to the example shown in FIG. **24**. If the surface of the protecting layer **305** should have sufficient peel-off capability, it is natural to provide such an intermediate parting agent layer as above.

Further, in the case of the image-transferable sheet **310**, it is naturally easy to separate from each other through a peel-off operation, upon the formation of necessary images thereon and before practical use thereof as the image-transfer sheet, and a cut-out slit as at **407** in the sheet-like substrate **301** may be provided for attaining such an easy separation as stated above at a portion of the sheet **310** in proximity to one end thereof. Upon the provision of such a cut-out slit as at **407**, the thus formed flap-like portion can be easily folded out by the operator's finger-tip, thereby affording convenience in a peel-off operation.

The usable materials and composing methods of the foregoing image transferable sheets will now be described.

As a material usable for the sheet-like substrate may be any one or any combination of the following categories:

(1) synthetic paper (polyolefin-series; polystyrene series and the like);

(2) fine quality paper; art paper; coated paper; cast-coated paper, wall paper; back-up paper; backing paper; resin-, emulsion- or synthetic rubber-imprignated paper; resin-admixed paper; paper board; cellulose fiber paper;

(3) polyolefin-, polyvinyl chloride-, polyethylene terephthalate; polystyrene; polymethacrylate; polycarbonate and the like plastic film or sheet.

Use of the synthetic paper belonging to the foregoing category (1) is highly-suitable for the purpose of the present invention since the surface thereof generally represents a microvoid layer which provides a low heat conductivity and thus a high heat-insulating peformance. A laminated material representing any combination of the foregoing categories (1), (2) and (3) can be used in the present invention. A representative and recommendable example of such a laminate is that of cellulose fiber paper and synthetic paper or that of cellulose fiber paper and plastic resin film or sheet. Among others, use of the first mentioned kind of laminate will provide an advantage in that the thermal instability such as thermal elongation or shrinkage possessed by the synthetic paper component is compensated for by the cellulose fiber paper, whereby a high thermal sensibility is demonstrated during the printing step due to low thermal conductivity of the synthetic paper component. Further, in the case of the present paper combination, however, a further modified combination of a three-layer laminate: synthetic paper-cellulose fiber paper-synthetic paper may be more advantageously employed for making the frequently appearing lesser by providing a well-balanced structure between both the surfaces of the final laminate.

As the synthetic paper mentioned above, any suitable one usable as a synthetic paper substrate used as a component of the image-transferable sheet layer may be used. As a recommendable example thereof, having a fine porous fine paper structure layer, the synthetic

paper called "YUPO", manufactured and sold by Oji Yuka Goseishi Kabushiki Kaisha, Tokyo, may be mentioned. This paper layer having a fine pore structure may be prepared in such a way that a suitable plastic resin material containing a filler of finely divided state is subjected to a mechanical elongation step. When the image-transferable sheet composed of the synthetic paper sheet containing finely divided air as above mentioned is formed with images through a thermal image transfer setp, the concentration of the thus formed images is surprisingly high and no fluctuation of image configuration and concentration is encountered, thanks to the heat insulation effect provided by the very existence of fine air pores, in addition to the improved thermal energy efficiency. Especially, due to the advantageous cushioning effect provided by the air-filled fine pores, the image-receiving layer is supposed to be rather advantageously affected during the image formation step. As an alternative measure, the paper-like layer containing the above-mentioned fine air pores may be, if desired, provided directly with the core material consisting of the cellulose fiber paper or the like.

It is further possible to use plastic film in addition to the cellulose fiber paper in the laminate described above. Still further, a laminate of said cellulose fiber paper and plastic film composed together can be used.

As the method for co-sticking of synthetic paper and cellulose fiber paper, use of a known adhesive agent is naturally adopted, as an example. Or alternatively, the extrusion-laminating, heat-adhesion, or the like process may be relied upon, as the case may be. On the other hand, as the sticking-process between the synthetic paper and the plastic film, the lamination process to be carried out simultaneously with the formation of the film may be adopted. Calendering or the like method may be utilized for the same purpose. Selection of any suitable one of the several foregoing sticking processes depends upon the kind of material or the like condition of the partner member to be stuck together with the synthetic paper. As for the adhesive agent mentioned above, emulsion adhesive such as ethylene-vinyl acetate copolymer, polyvinyl acetate or the like, aqueous solution type adhesive polyester containing carboxyl radicals; or the like may be mentioned. On the other hand, as the laminating use adhesive, organic solvent solution type one such as polyurethane-, acrylic- or the like, may be mentioned.

The material for the image-reception layer must be suitable for reception of heat-transfer dyestuff, such as sublimative disperse dye from the image transfer sheet and holding and maintaining the thus formed images thereon. From the view point of image-holding and blocking prevention, use of such synthetic resin as having glass transition temperature higher than 40° C. may be advantageous. For example, the synthetic resins set forth in the following items (a) through (e) may be used separately or in combination.

(a) Ester bond-bearing resins:
Polyester resin; polyacrylic ester resin; polycarbonate resin; polyvinyl acetate resin; styrene acrylate resin; vinyltoluene acrylate resin and the like.

(b) Urethane bond-bearing resins:
Polyurethane resin and the like.

(c) Amide-bond carrying resins:
Polyamide resins (nylons).

(d) Urea-bond carrying resins:
Urea resins and the like.

(e) Other high polar-bond carrying substances:
Polycaprolactone resin; polystyrene resin; polyvinylchloride resin; polyacrylonitrile resin and the like.

The image-reception layer may be prepared from a resin mixture of saturated polyester and vinyl chloride-vinyl acetate copolymer. As the saturated polyester, such commercialized products: "Vylon 200"; "Vylon 290"; "Vylon 600"; "Vylon 103" and the like, manufactured and sold by Toyoboseki K.K., Osaka, Japan; "KA-1038C" (manufactured and sold by Arakawa Kagaku K.K., Osaka, Japan; "TP 220"; "TP 235", manufactured and sold by Nippon Gosei K.K., Osaka, Japan; may be advantageously used. The vinyl chloride-vinyl acetate copolymer may have preferably 85–97 wt. % of vinyl chloride component, the polymerization degree being between about 200 and 800. The vinyl chloride-vinyl acetate copolymer may further contain a vinyl alcohol component, maleic acid component within the purpose of the invention in addition to the main components. According to our experiments, it has been found that these modified copolymers should have rather superior compatibility with polyester resin. The image-reception layer may be, if necessary, composed of polystyrene resin, for example, in this case, styrene monomer, preferably styrene, a-methyl styrene, and vinyl toluene may be used separately or in the form of copolymer or saying in general sense polystyrene resin. Further, such styrene copolymer resin may be used as specifically recommendable material in the above sense, comprising said styrene monomer(s) with other monomer, preferably for example, acrylic acid ester, methacrylic acid ester, acrylonitrile, methacrylonitrile and the acrylic or methacrylic monomer, or further styrene copolymer resin comprising maleic acid anhydride.

It should be noted, however, that among others, polyester series resin is especially superior for the purpose of the present invention.

In any of the foregoing embodiments, however, white pigment is preferably admixed with the material of the image-reception layer for improving the whiteness thereof and further accentuating the sharpness and fineness of the images when transferred thereto and to provide a manually writing-on performance. As the white pigment for this purpose, the following materials may be used separately or in any combination: titanium oxide; zinc oxide; china clay calcium carbonate; finely divided silica and the like.

For further improving the whiteness fluorescent whiteness-increasing agent or -bleaching agent may be added to. Further, for improving the light fastness of transferred images, ultraviolet absorption agent and/or photostabilizing agent may be added to, preferably in a quantity of 0.05 to 10 and 0.5 to 3 weight parts per 100 weight parts of the material resin composing the image-reception layer.

The image-transferable sheet used in the present invention is preferably constituted for improving the separability from the image-transfer sheet in such a way that the surface of the image-reception layer is formed with a partition agent layer, or instead, such agent is admixed to the image-reception layer. As for the partition agent to be used for this purpose, polyethylene wax; Amido Wax, Teflon Powder or the like solid wax; surface active agents such as fluorine-contained agent or phosphoric acid ester series surfactant; silicone oil or the like may be selectively used. Among others, silicone oil may be advantageously utilized.

The silicone oil may be used in oily state, but a hardenable type thereof may be rather advantageous. As the hardenable silicone oil, reaction-hardening one, photohardening one, catalytically hardening or the like one may be used selectively according to necessity. However, use of the reaction-hardenable one is most highly recommendable. Silicone oil of this type may be obtained, as example, by reacting amino-modified silicone oil with epoxy-modified silicone oil to obtain a reaction-hardened product. As for the amino-modified silicone oil, "KF-394", "KF-857", "KF-858"; and "X-22-3680"; "X-22-3801C" (manufactured and sold by Shinetsu Kagaku Kogyo K.K., (Tokyo, Japan)) and equivalents thereof may be used. As for the epoxy-modified silicone oil, "KF-100T"; "KF-101"; "KF-60-164"; and "KF-103" (manufactured by Shinetsu, above mentioned) and equivalents thereof may be used. Further, as the catalytically hardenable and photohardenable silicone oils in the above sense, "KS-705F"; "KS-770" of the catalytic hardenable or hardened silicone oils, manufactured by Shinetsu; and "KS-720" and "KS-774" of the photohardenable or hardened silicone oils (manufactured equally by Shinetsu) and equivalents thereof may be used. The adding quantity of each of these hardenable or hardened silicone oils may advantageously range from 0.5 to 30 wt. % depending on the material of the resin composing the image-reception layer.

At least a part of the image-reception layer is coated with a solution or dispersion of any of the foregoing partition agents in a suitable solvent and dried and further treated, a suitable parting layer being provided thereon. A particularly suitable partition agent for the formation of this kind of partition layer is the aforementioned reaction type hardenable one obtainable by reacton of an amine-modified silicone oil with an epoxy-modified one. The thickness of the partition layer is 0.01–5 μ, preferably 0.05–2 μ.

It should be noted that when silicone oil is admixed during formation of the image-reception layer, the silicone oil will bleed out after coating and the parting agent layer can be formed by the hardening even after such bleeding. In order to improve the parting ability between the image transferable layer and sheet-like substrate, it is possible to provide a parting layer consisting of a heat-hardenable resin, preferably of the melamine series, and having better affinity for the image transferable layer compositions. For the same purpose as above, however, without special provision of the parting layer, a protecting layer consisting of polymethyl methacrylate resin or cellulose acetate propionate can be provided.

For the formation of the image transferable layer, a solution or dispersion of a material composition suitable for the purpose is applied on the sheet-like substrate through conventional coating or printing. As an alternative way, a separate film or sheet for the image transferable layer **302** is formed preparatorily on a provisional carrier sheet or film and then, as a succeeding step, subjected to an image-transfer onto the substrate.

The intermediate layer is made of either a cushioning or a porous material. In some cases, the intermediate layer may additionally function as the adhesive layer.

The cushioning layer is mainly composed of such a resin which has a value of 100%-modulus as defined at JIS-K-6031 (Japanese Industrial Standard) of less than 100 kg/cm^2. If this value should exceed the above prescribed value, the rigidity will become much higher than that recommended for the intermediate layer. When the layer is formed with such disadvantageous material resin, sufficient adhesion between the heat image-transfer sheet and the image-reception layer cannot be maintained during the printing step. The lower limit of the prescribed 100%-modulus is of the order of 0.5 kg/cm^2 in actual practice.

Preferable kinds of resin to be used for the above purpose, may be enlisted as follows:

polyurethane resin; polyester resin; polybutadine resin; polyacrylic acid ester resin; epoxy resin; polyamide resin; rosin-modified phenol resin; terpene phenol resin; ethylene/vinylacetate copolymer resin; and the like.

These resins can be used independently or in combination of two or more kinds. Since these resins are rather viscous and tend to give rise to manufacturing troubles inorganic additives may be admixed, such as, for example, silica; alumina; clay; calcium carbonate; amide series substance such as amide stearate; and/or the like.

The cushioning layer is preferably formed with the use of one or more of the above specified resins, occasionally with the addition of suitable additive(s); solvent or diluent, prepared into a coating agent or printing ink which is then applied on, according to a known coating or printing process and then subjected to drying to provide a coating. The thickness of the coating should be between 0.5–50 μm, preferably 2–20 μm or so. With a thickness less than 0.5 μm, the coating will not be able to compensate for the surface irregularities on the substrate, thus being ineffective for the desired purpose. On the other hand, when the thickness exceeds the above specified maximum value or more specifically 50 μm, the overall thickness of the image-transferable layer becomes much too large, so that handling troubles may be encountered during wind-up and overlapping procedures, without attaining further effect as desired. In addition, in this case, a loss of production economy will be inevitably introduced.

The thus obtainable improvement of intimate adhesion between the heat-image transfer sheet and the thermally image-transferable sheet by the provision of the above intermediate layer may be conceivably attributed to the lower rigidity of the intermediate layer per se, whereby it is liably to be deformed under the influence of the printing pressure, and further to the generally relatively low glass transition temperature and softening temperature of the aforementioned kinds of resin resulting in further lowering of rigidity and tendency to deform than at room temperatures upon reception of heat energy during the image printing step.

The porous layer may be formed generally in the following four ways: 1) through 4).

1) Emulsion of polyurethane or the like resin, methylmethacrylate-butadiene series synthetic rubber latex is foamed by mechanical agitation, coated, and dried on the sheet substrate into a layer.
2) The synthetic resin emulsion or synthetic rubber latex is admixed with a foaming agent and the liquid mixture is coated and dried on the substrate into a layer.
3) Vinyl chloride-plastisol, polyurethane or the like synthetic resin or styrene-butadiene series or the like synthetic rubber is added with a foaming agent and the liquid mixture is coated on the substrate and subjected to heating to provide a foamed layer formed thereon.

4) A thermoplastic resin or synthetic rubber is dissolved in an organic solvent to provide a solution, and a non-solvent (including that containing aqueous main component), and the latter solution are mixed together to provide a liquid mixture, said nonsolvent being less volatile than the organic solvent and having a considerable mutual solubility with the solvent, and showing, however, non-solubility with the thermoplastic resin or synthetic rubber. The thus prepared liquid mixture is then coated on the sheet-like substrate and dried, to provide a porous membrane upon microcoagulation of the constituents. The resulting microporous layer can be utilized for the above purpose.

It should be noted that the layers produced by any of the foregoing three processes 1) to 3) have rather large foams contained therein, and thus when the foaming solution for the image-transferable layer is applied thereon and dried, the latter may exhibit excessively coarse surface conditions. Therefore, in order to obtain an optimumly image-transferable smooth surface capable of providing transferred images of high uniformity, provision of the micro-porous layer prepared by the process as set forth in the foregoing item 4) is highly recommendable.

As the thermoplastic resin suitable for the formation of the above porous layer, saturated polyester; polyurethane; vinylchloride-vinylacetate copolymer; cellulose acetopropionate and the like can be used. Further, as the synthetic rubber usable for the same purpose, those of styrene-butadiene series, isoprene series, urethane and the like series may be used. Still further, as the organic solvent and non-solvent liquid used for the formation of the microporous layer, various known substances may be used. Generally speaking, however, methyl ethyl ketone; alcohol and the like are representatively used. On the other hand, as the nonsolvent, water is mostly used.

The thickness of the porous layer usable in the present invention is preferably greater than 3 μm, especially preferably in the range of 5 to 20 μm. With the use of a porous layer having a thickness of less than 3 μm, the desired cushioning and heat-insulating effects cannot be attained.

As was referred to hereinbefore in the description stage for the formation of the image-transferable layer, the intermediate layer may act simultaneously as the sticking layer in some cases.

This kind of intermediate layer(s) may be provided on one or both of the surfaces of the thermally image-transferable sheet.

In practice, however, an electrostatic charge may accumulate in the material of the thermally image-transferable sheet during its processing step or during running through the printer. As a countermeasure, a proper antistatic agent may be applied on one surface of the image-transferable layer or on the bottom surface of the thermally image-transferable sheet or it can be included in the material of the image-transferable layer. As the antistatic agent in this sense, a surfactant such as a cation-exchange agent (for example, a quaternary ammonium salt, polyamide derivatives and the like) may be advantageously used. Further, an anion exchange type surfactant, such as alkyl sulfonate may be used. Otherwise, amphoteric ion type surfactants or even, non-ionic surfactants may be used for the same purpose.

On the other hand, the antistatic agents may be coated on the surface of image-reception layer by gravure-coating, bar-coating or the like process or alternatively, these agents may be kneaded with the material resin and then subjected to transfer towards the surface during the coating formation and drying step for preparing and providing the image-transferable layer. As the antistatic agents to be admixed with the image-transferable layer material resin, cation-type acrylic polymers may be employed.

The protecting layer is peeled off together with the image-transferred layer, from the sheet-like substrate, and then stuck, in inverted reversed state, onto any desired decorative object, the protecting layer thereby being positioned at the uppermost position, for improving the anti-wearing-light-proofing and anti-chemical performances of the image-bearing layer. As the material adapted for the formation of the protecting layer, for example, alkyd resin; phenol-modified alkyd resin; aminoalkyd resin; phenol resin; urea resin, melamine resin; silicone resin, thermosetting acryl resin, thermosetting polyurethane resin and the like thermosetting resin or normal temperature setting resin; further, ultraviolet hardenable resin; electron ray hardenable and the like activating energy flux hardenable resins or thermoplastic resins such as polyester-; polyurethane-; polyvinyl acetate resin; vinyl chloride-vinyl acetate copolymer resin; polyolefin resin, acryl resin and the like, can be used.

Preparation and use of a protecting layer comprising one or more of the above-mentioned resins are made in such a way that the material resin is dissolved in a properly selected solvent according to the necessity, so as to provide a coating liquid or ink, as the case may be, which is provided between the parting layer and the image transferable layer. The thickness thereof is generally 0.5 to 20 μm. It is also possible to form the protecting layer with the use of a resin film which consists of polyester-; acryl-; acrylpolyol-; polyvinyl chloride-; olefin resin or the like resin. It is further possible advantageously to admix an ultraviolet ray absorbing agent and/or photostabilizer to the material of the protecting layer.

The protecting layers prepared and formed in the foregoing way are thus not made integral with the sheet-like substrate or parting layer and, therefore, the peel-off operation of the sheet-like substrate upon execution of the image transfer is very simple and easy.

It is further recommendable, if necessary, to provide a slip-promoting layer on the bottom surface of the sheet-like substrate, which surface is naturally the one opposite to the image-transferable layer side, so as to properly adjust the friction between the image-transferable sheet and feed roll paper or carrier belt acting during passage through the printer and to improve the running performance of the thermally image-transferable sheet in the printer.

The slip-promoting layer can be formed by adding an organic powder such as polyethylene wax fluorine resin powder or an inorganic powder such as talc, according to necessity, to a resin such as polymethyl methacrylate resin; vinyl chloride-vinylacetate copolymer; vinyl chloride copolymer; cellulose acetate butyrate; cellulose acetate propionate; styrene-acryl series or the like resin and kneading the resulting mixture to prepare a composition, applying this composition as a coating on the sheet substrate either directly or after application of a suitable primer treatment, and drying the coating thus applied. A suitable quantity of the slip-promoting layer is 0.5 to 5 g/m^2 after drying.

In the embodiments-shown in FIGS. **22**, **23**, and **24**, as the adhesive agent to be used in the slightly weak or weak adhesive layer, it should be noted that those conventionally used adhesives for adhesive tapes and seals can all be used. Preferred examples are polyisoprene rubber; polyisobutyl rubber; styrene butadiene rubber; butadiene acrylonitrile rubber and the like rubber-series resins; (meth)acrylic acid ester-series resins; polyvinyl ether-series resins; polyvinyl acetate-series resins; vinyl-chloride-acetate copolymer series resins; polystyrene-series resins; polyester-series resins; polyamide-series resins; polychlorinated olefin-series resins; and polyvinyl butyrol-series resins. To the suitably selected adherent may be added a proper quantity of a stickness improver, such as rosin; dammar; polymerized rosin; partially hydrogenated rosin; ester rosin; polyterpene-series resins, terpene-modified substances; petroleum-originated resins; cyclopentadiene-series resins; phenol resins; styrene resins; xylene resins; and coumarone-indene resin. Further, when necessary, to the mixture may be added a softening agent, filler; antiaging substance or the like conventional agent(s). As the material for the formation of slightly or weak-adherent layer said above, emulsion type adhesive, preferably of acryl acid ester series can be used. As for the parting function after a long time of preservation, emulsion type adhesives are highly recommendable. These adhesive agents are easily procurable from market.

When necessary, these adhesives are added with proper organic solvent(s) for the adjustment of the viscosity, and then applied by roll coating, die-coating, knife coating, gravure coating or the like conventional technique on the surface of the sheet-like substrate, image-reception layer or protecting layer, so as to provide an adhesive agent layer. The thus formed adhesive layer is preferably of a thickness of 1–50 μm, although this is not limitative.

Formation of Images

In the following, the decorating process according to this invention will be set forth in detail. Utilization of the image-transferable sheet according to this invention constitutes an important main feature thereof.

In FIGS. **20** and **21**, basic practising processes will be described first.

The embodiment shown in FIG. **20** is a result of the use of the transferable sheet shown in FIG. **13**. First, a known transfer sheet **320** is applied onto the image-transferable sheet **310** in an overlapped manner such that the dye-carrying layer **321** is kept in opposition to the image-reception layer **302** of image-transfer sheet **320**, and heat energy is applied, as schematically shown by a plurality of arrows, in accordance with image signals fed at a thermal head, not shown, from the side of image-transferable sheet **310**, or preferably, from the side of the image-transfer sheet **320**, thereby forming the desired images as at **307** in the image-reception layer **302**. Next, the image-reception layer **302** formed therein with the desired images **307** is peeled off from sheet-like substrate **301** and stuck onto the decorative product **306**. Or alternatively, both the sheets **302**; **301** are stuck onto the product **306** without preparatory peeling-off. In the latter case, the peel-off step may be executed after execution of the stickingly attaching step. In the above former case, and in such a case where an adhesive agent layer **306** has preparatorily provided between image-reception layer **302** and sheet-like substrate **301** as was set forth hereinbefore, the sticking attachment is carried into effect in such a way that the adhesive layer **306** is kept in opposing contact with the product **330**, and then the sticking operation is brought about by application of heat and pressure or light and pressure, depending upon the nature and structure of the layer **306**. In this way, the decoration according to the present invention is completed as a preferred one mode thereof.

On the other hand, if there is no preparatory provision of the adhesive layer, either the surface of product **330** or of the peeled-off image reception layer **302**, may be coated with the adhesive agent, and the latter layer **302** per se or otherwise in the up-and-down reversed state may be stickingly attached onto the product **330** (refer to FIG. **21**).

Since the image-reception layer **302** is composed generally of such thermoplastic resin material as is liable to be colored with thermally transferable dyestuff, it can be thermally and fusingly attached to plastic resin-made formlings, clothes or metals even with provision of an adhesive layer, if necessary.

In this case, the image-bearing layer **302**, the image thereof having been formed in the aforementioned way, is stuck on, through the intermediary of the adhesive agent layer **306** as shown in FIG. **25**, while retaining the sheet-like substrate **301** on the surface of the image-reception layer **302**.

A modification of the last-mentioned mode is shown in FIG. **26**. In this case, sheet-like substrate **301** is formed on the surface of the product **330** and the image-reception layer **302** is formed as the outermost layer. Further, in this case, sheet-like substrate **301** and product **330** may be stuck together, and, through the intermediary of a suitable adhesive layer, sticking layer or heat-sealable sheet or the like.

As for the transparent film usable as the said sheet-like substrate, it must be transparent to such a degree as not to conceal the images formed in the image-reception layer, and, in addition, it must have superior surface properties such as, for instance, antiwearing characteristics. As an example, polyolefine; polyvinyl chloride; polyethylene terephthalate; polystyrene; polymethacrylate; polycarbonate and the like plastic resin-made films may be used upon variously surface conditioning. If these transparent films should be too thick, the images will be raised, and the unitary feelings may be lost when these are stuck on respective products to be decorated. Therefore, the film thickness is preferably of the order of 0.5 to 50 μm.

In the case of a further embodiment of the present invention, the image reception layer of image transferable sheet which has been, however, formed with necessary images is subjected to image transfer treatment onto an intermediate image transferable substrate, the latter is then subjected to an image-retransfer with the images, and the thus retransferred images are again transferred onto the surface of the product to be decorated. In the following, this image transfer mode will be set forth in detail.

Embodiments shown in FIGS. **27**, **28** and **29** represent such a process for execution of image transfer operation as by the intermediary of intermediate image transfer sheet **510**. First, as shown in FIG. **27**, a thermally image-transfer sheet **320** having a thermal transferable dyestuff layer **321** is overlapped to image-transfer sheet **510** which is, at this stage, not formed with images **307** and thus consists of a thermal image-transferable sheet, in such a way that the dyestuff layer 321 or more specifically the parting layer **322** is in opposition to the image-reception layer **302** of the foregoing

sheet **510**. In such a case, however, that heat energy is supplied in accordance with image-forming signals delivered from the thermal head, not shown, and, indeed, preferably from the side of the sheet **320** as hinted by a plurality of double-line arrows for thermal formation of desired images (positive images) as at **307** in the image-reception layer **302**, it is highly recommendable to provide an adhesive layer **402** between the layer **302** and sheet-like substrate **301**.

Then, with the use of the image transfer sheet **510** formed with positive images **307**, the images of layer **302** are transferred, as shown in FIG. **28**, to a separate intermediate substrate **501**, which is, however, fitted with a protecting film layer **305**, thus, the transfer being carried out, in fact, onto the latter, and indeed, with the correspondingly inverted images, attached with same reference numeral only for convenience, from the foregoing layer **302**. In this case, it is preferable to subject the adhesive layer **402** of the image-transfer sheet **510** to the image-transfer operation, together with the image-reception layer **302**. Further, as for the intermediate image-transfer substrate **501**, it is recommendable to provide the protecting film layer **305** through the intermediary of a weak-adhesive layer **402'** as shown. The thus provided intermediate image-transfer sheet **610** represents generally the image-transferable sheet.

FIG. **29** illustrates the step for transfer of the image-reception layer **302** now carrying positive images **307** onto the object **330** to be decorated and under utilization of the previously described intermediate image-transfer sheet **610**.

More specifically, the intermediate image-transfer sheet **610** is overlapped onto the said object **330** in such a way that the adhesive layer **402** of the former in opposition to the surface of the object **330** and pressurized together. Then, the intermediate transfer substrate **501** together with the weak-adhesive layer **402'** is peeled off from the remainder of the thus-pressurized assembly, the now image-carrying layer **302** formed with positive images **307** covered with protecting the film layer **305** thereby remaining in the transferred state on the product **330**. In the case of no provision of the protecting film layer **305** on the intermediate image-transferable sheet **610**, the layer **302** remains in an exposed state. Therefore, an overcoat layer, if necessary, can be provided on the now image-carrying layer **302**.

The previously set forth process carried out by the use of said intermediate image-transferable sheet can be executed by means of the apparatus which is shown schematically in FIG. **1E**.

In this apparatus, more specifically, there is provided a carrier system comprising a series of rolls **411, 412, 413** and **414** for conveying the intermediate transfer substrate (sheet), arranged in addition to the apparatus shown in FIG. **1B**. More specifically, the substrate is drawn out from feed roll **414**, conveyed through successive rolls **413**; **412** and retransferred onto one of the products **200**. Other operations are same as set forth hereinbefore with reference to FIG. **1B**. Further, in the case of FIG. **1E**, the final product may take the form of a roll-like substrate which is subjected to an image transfer operation through the intermediate substrate, by transferring its image-carrying, image-transferable layer, for later being punched out properly. Alternatively, under occasion, it may be subjected to half-cut operations downstream of roll **122**.

As was set forth herein above, the preferable method for the formation of desired images on the image-transferable sheet is carried out by use of a heat image-transfer sheet comprising a sheet-like substrate having a layer including a thermally transferable dye (evaporative dye). The heat image-transfer sheet which can be utilized in this method is known per se. And almost every kind of these known sheets can be useful in the practice of the present invention. It should be noted that by employing the foregoing image-transfer method, mono-color or full-color images can be easily formed as occasion may desire.

It should be further noted that details of such heat image-transferable sheet can be easily understood with reference to our U.S. patent application Ser. No. 833,039. As for the heat image-transferable sheet usable in the present invention, the coating layer of the sheet (coating film) may include a parting agent. By adopting this measure, the image-reception layer of the image-transferable sheet or the surface thereof, to be subjected to sublimative image-transfer, must not have a separate parting agent layer, the adhesive ability between the image-reception and the surface of object to be decorated can be still further improved upon execution of the sublimative image-transfer and image-formation at the image-reception layer and adherent attachment thereof to the object. As the parting agent to be included in the coating layer of the thermally image-transferable sheet (coating film), silicone oil; silicone resin; phosphoric ester or the like surfactant; and/or chelate- and the like agents, may be selectively utilized. These agents, upon mixed, will ooze out from inside to the outer surface of the coating layer, resulting in providing a better parting quality. However, it is preferable to properly select the kind and nature of the parting agent to be used for this purpose, being such that the agent cannot transfer to the image-reception layer of the image-transferable sheet during the sublimating image-transfer stage. The adding quantity of the parting agent may preferably be 3–25 wt. parts based upon the total amount of resin and coating composing the coating layer taken as 100 wt. %.

In practice, any kind of conventionally known heat transfer sheets is overlapped on the thermally image-transfer sheet employed in the present invention, and then necessary heat energy of 5–100 mJ/mm^2 is applied by use of a conventionally known heat transfer unit, for instance, "Video-printer: VY-100" manufactured and sold by Hitachi Seisakusho, Tokyo, or its equivalent machine, for the formation of necessary images on the image-reception layer of the image-transfer sheet as set forth hereinbefore.

Peel-off operation for removal of the image-reception layer formed with necessary images in the above manner may be carried into effect in a very easy manner, so as to provide it in a thin film carrying the images thereon. In case where the thus-peeled off film carrying the images is provided beforehand with an adhesive layer, composed of a suitable adhesive agent as was referred to, at the opposite surface to the image-carrying one, the peeled-off film can be, as it is, stuck on the object to be decorated. It is natural that this adhesive attachment procedure can be performed only partially and locally on selected part of the whole surface of the object, or totally thereon, as the case may be. On the contrary, if the peel-off film is provided beforehand with no adhesive layer, the film can be subjected occasionally to a heat fusion onto the surface of the object, if the physical properties or material kind thereof is suitable for such kind of thermal fusion. **0**r alternatively,

a properly selected adhesive agent can be preparatorily applied onto the surface of the film or object, and then, the stick-on job can be executed.

If the image-reception layer is provided preparatorily with a parting layer thereon, as was referred to, the latter layer can be removed off partially or wholly, by grinding or rubbing operation after execution of the sublimating image-transfer job, for avoiding otherwise occurrence of ill effect by the very presence of parting layer in the adhesive attachment of the image-carrying layer film onto the decorative object.

In case of that where the image-transferable sheet is provided with a protecting layer and the latter is composed of a plastic resin film, this film may preferably be cut into pieces or subjected to punch-cuttings.

FIG. **32** illustrates successive die-cutting steps in sectional views, serving for the above purpose. In this case, as shown in FIG. **32** at (*a*), only image-reception layer **305** of the image-transferable sheet **310**, which has been image-formed through the way of the foregoing image-transfer step, are die-cut by operation of a cutter **801**. Next, as shown in FIG. **32** at (*b*), a pair of hot stamps **132'**; **133'** are used to execute a pressurizing job under heat from opposite sides, thereby the decorative product **330** being processed into a final product provided tightly with an image-reception layer and a protecting layer, as shown in FIG. **32** at (*c*).

Further, when occasion desires, the image-carrying film is reversed up-and-down in position after execution of the peel-off job, and, the film is stuck onto the product to be decorated in such a state that the image-carrying surface of the film is kept in direct opposition to the product's decorating surface. In this case, however, it would be rather preferable that in advance of preparatory peel-off of the image-reception layer, the image-carrying transferable sheet is stuck onto the surface of the product to be decorated, and indeed, preferably with use of an adhesive agent, in such a way that the image-carrying layer is kept in direct opposition to the product surface and finally, the sheet-like substrate is peeled off, so as to leave the image-carrying surface on the product's surface.

As in the foregoing, when the images are once reversed and then stuck onto the object to be decorated, the forming images are preferable to reverse in mode (mirror-like relationship) the original to those of reversed mode.

It is further possible that the transfer or sticking-on of the image-carrying layer is carried out through the intermediary of a separate fusing sheet.

In FIG. **30**, use of such fusing sheet **701** for reimage-transfer operation of image-carrying layer **2** already formed with necessary images **307**, however, of reversed mode, and onto the surface of a product.

More specifically, the image-transferable sheet **310** is overlapped onto the product **330** to be decorated in such a way that the image-reception layer **302** carrying the necessary images **307** is kept in opposition to the surface of the product, and indeed, through the intermediary of a fusing seat **701** and then these three components are pressurized together. Further, sheet-like substrate **301**, together with parting layer **303'**, is peeled off, thereby the image-reception layer **302**, now having positive images **307** formed thereon, and protecting the latter, being transferred onto the product **330**. It will be seen in this case, that there is no need for this transfer job, to provide in advance on adhesive layer on the surface of image-reception layer **302** and/or on the surface of the product **330**, and further that a direct heat fusion onto the surface of the product **330** which may be composed of plastic resin, textile fabric, metal or the like common material, however, through the intermediary of a heat-fusible or heat-sealable sheet.

In case where the protecting layer **305** is of plastic resin, similar composing technique as mentioned above may be employed by substituting a weak-sticking layer **402'** for parting layer **303'**.

As the heat-fusible or heat-sealable sheet as at **701** employable in the present invention, it may be composed of one or other material capable of adhering under heat, pressure or both, especially suitable one of those which become soft to be adhesive upon heating. These heat adhering materials in the form of sheets will be, upon softening, charge the pores, meshes or stitches of the product material composed preferably of textiles, woven or non-woven; knits, rough-surface papers or meshed materials, thereby the surface of the product becoming highly smooth for well receiving the image-reception layer **302** for desired image-retransfer with trouble, which effect is superior in the art.

On the contrary, when such heat-fusible or heat adhesive sheet materials which may be called "heat bond sheets" as at **701** are not utilized, it is highly difficult to realize the image-retransfer operation onto certain kind of objects such as rough-surfaced or rough-meshed fabric or the like. Even if the retransfer job could be executed, the obtained images may be blurred and the adhesive may be insufficient, on account of the very thin thickness of the image-reception layer **302**, thus giving rise to technical and commercial troubles.

As for the heat fusible sheet **701** to be used in the foregoing manner, ethylene/vinyl acetate copolymer, nylon copolymer; epoxy/phenol copolymer; epoxy/vinyl copolymer; acrylic resin; polyester resin; or polyolefin resin and the like thermoplastic resins (heat sensible adhesive agents) which are formed into sheets or films may be used. These materials must be softened at 100°–250° C. or so to represent viscous adhesive characteristics. These materials are, when used, capable of being stuck to both the image-transferred product **330** and the image-carrying layer **302**.

These heat bond sheets **701** have generally thickness of 1–200 μm. When the surface of the product **330** to be decorated is relatively smooth, the sheet selected out may be of relatively thin thickness, while, on the contrary, when the surface of the decorative product **330** is relatively rough, as in the case of textile fabrics, unwoven fabrics, meshed fabrics or the like, use of thicker heat bond sheets is rather recommendable.

As set forth above, the use of heat bond sheets is highly recommendable in the decorative image-transfer onto rough surface products, such as those of rough fabrics, woven or non-woven, knitted clothes, meshed one or the like, thereby a better quality image-transfer being executed, in spite of the meshed or highly undulating surface conditions of the objects to be decorated.

Further in the present invention, during the adhering attachment of the image-reception layer already formed with necessary images onto the object or product, an additional processing step is preferably introduced for prevention of occasional interference in the foregoing adhering attachment step, by rubbing-off or grinding-off part or whole of the parting layer, provided on the surface of the now image-carrying layer, upon completion of the sublimating image-transfer step.

Still further, in such a case that the image-transferable sheet is fitted with a protecting layer which is composed of a plastic resin film, the latter must in advance be subjected to punching or the like cutting step for cutting the film into desirously sized pieces.

FIG. **32** represents such a die-cut (half-cut) process in sectional schema. In this case, at first, as shown at (*a*) of FIG. **32**, the image-reception layer **302** of an image-transferable sheet **310**, now formed with necessary images through a sublimative image-transfer step, and the protecting layer **305**, are subjected to a die-cutting process by means of a cutter **801** to shape a desired shape. And then, as shown at (*b*) in FIG. **32**, the cut-out piece is subjected to a pressurizing step under heat by means of a pair of hot stamps **132'**; **133'** to provide a final decorative object, as shown at (*c*) in FIG. **32**, which is composed of a product **330** to be decorated, however, now attached integrally and jointly with image-carrying layer **302** and protecting layer **305**. Applied Products

The products applicable with the inventive process for decorating purposes are not limited to occasionally employed kind, shape and nature of the materials. Preferred examples of the usable product may be: cartons; vessels or packages; bags; cassette cases; cassette halves; floppy cases; paper packages and envelopes; stock certificates; personal and bank cheques; bills; bonds; certificates; notifications; car tickets; travel tickets; betting tickets; tax stamps; postage stamps; entrance tickets, money-exchangeable papers and documents; cash-card, credit cards, orange cards, telephone cards; member's cards; greeting cards; postcards, name cards; driver's certificates; IC-cards; optical cards and the like various cards; accounting cards and documents-envelopes envelopes; tags; OHP-sheets; slide films; bookmark slips; calendars; posters; pamphlets; menus; passports; POP-goods and articles; coasters; displays; nameplates; keyboards; cosmetics; personal ornaments (watches; cigarette lighters); stationaries; construction materials; radio-receiving sets; T.V.-sets; speakers; table calculators; automotive gauge boards; emblems; keys; clothes; wearing commodities; footwears; appliances; CA-instruments; sample books; tickets in general; albums; computer graphic and/or medicare graphic image printouts; and the like, where the material kinds, sizes and configurations are regardless for purposes of the invention.

The aforementioned goods and instruments may have printed or the like other images in advance of execution of the process of the invention. Or conversely, the goods and instruments can be formed with necessary images in accordance with the present process, and then, additional images may be formed in conventional printing or the like process.

As an example, when the invention is applied to a card style intermediate product, it is possible to combine image-forming means of the present invention with conventional recording means. As the latter, magnetic recording by use of a magnetic material layer; optical recording by use of an optical recording layer; preferably composed of a membrane having low melting point metal; application of hologram; embossing formation of characters and numerals; application of personal face photograph; engraved formation of personal face or the like; human signatures; recorded information with use of IC-memory; mechanical printing; formation of bar codes; formation of characters and patterns by use of printer, typewriter or pen plotter may be used independently or in any combination.

In the following, the present invention will be more fully described by way of preferred embodiments. In these embodiments, parts or % will be given by weight, not otherwise specifically referred to.

As the image transfer film (dye film) used for sublimating transfer onto the image-transferable sheets, a polyester film, 6 μm thick, subjected to a heat-resisting treatment on one surface thereof only, and bearing color ink composition areas of yellow, magenta and cyan, respectively, was used. The coating rate of the color ink composition was 1.0 g/m^2 when measuring at the dry state.

These color ink compositions were as follows.

Yellow ink composition		
polyvinyl butyral resin ("Eslek-BX-1", manufactured and sold by Sekisui Kagaku K.K., Tokyo)	4.80	parts
dispersion dye ("PTY-52, Disperse Yellow-141", manufactured and sold by Mitsubishi Kasei Kogyo Co., Ltd., Tokyo)	5.50	parts;
methyl ethyl ketone	55.00	parts;
toluene	34.70	parts;
(parting agent	1.03	parts)
Magenta ink composition		
polyvinyl butyral resin (same as above in the case of yellow color ink)	3.92	parts;
dispersion dye ("MS Red G, disperse red 60", manufactured and sold by Mitsui Toatsu K.K.)	2.60	parts;
dispersion dye ("Macrolex Red Violet R, Disperse Violet 26", manufactured and sold by Beyer A.G., West Germany)	1.40	parts;
methyl ethyl ketone	43.34	parts;
toluene	43.34	parts;
(parting agent	0.40	part)
Cyan color ink composition		
polyvinyl butyral resin (same as in said yellow color ink composition)	3.92	parts;
dispersion dye ("Kayaset Blue-714, solvent blue-63", manufactured and sold by Nippon Kayaku K.K., Tokyo)	5.50	parts;
methyl ethyl ketone	68.18	parts;
(parting agent	0.94	parts)

Each of the foregoing color ink compositions was prepared with and without addition of parting agent.

As the parting agent occasionally used in each of the foregoing color ink compositions, any of the following specific agents may be employed:

(a) silicone alkyd parting agent, "KR-5206", manufactured and sold by Shinetsu Kagaku Kogyo K.K., Tokyo;

(b) graft polymer of, silicone and acryl, "GS-30", manufactured and sold by Toa Gosei Kagaku K.K.;

(c) silicone graft polymer, "US-3000", manufactured and sold by the above company;

(d) phosphoric acids ester, natrium salt, "RE-410", manufactured and sold by Toho Kagaku Kogyo K.K.;

(e) natural phosphoric acid ester, "Lecytin", manufactured and sold by Ajinomoto Co., Ltd., Tokyo;

(f) silicone oil, "KF 412", manufactured and sold by Shinetsu Kagaku Kogyo K.K., Tokyo;

(g) aluminum chelate agent, "ALM", manufactured and sold by Ajinomoto; and
(h) titanium chelate agent, "TTS", manufactured and sold by Nippon Soda K.K., Tokyo.

EXAMPLE A-1

As the substrate, a laminate of a synthetic paper, "Yupo FPG 150 μm thick" manufactured and sold by Oji Yuka Co., Ltd., Tokyo, and a polyester film, 6 μm thick, was prepared and coated on the polyester film side surface by a wire bar with a mixture of pull-separating varnish, "Hakurinisu **45**" manufactured and sold by Showa Ink Co., Ltd., Tokyo, with an ultra-violet absorbing agent, or more specifically, 2.5-bis(5'-tert-butylbenzoxazolyl (2))-thiofin, 0.5% based on the resin content of the varnish, and dried up to provide a protecting layer of 1 g/m^2, when weighed upon drying;

Then, on the surface of the foregoing protecting layer, an ink composition adapted for the formation of an image-reception layer was coatingly applied and dried up. The applied quantity amounted to 7 g/m^2 when measured upon drying.

Ink composition for the formation of image-reception layer	
polyester resin (manufactured and sold by Toyobo K.K.)	100 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu Kagaku Kogyo K.K., Tokyo)	5 parts;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu Kagaku Kogyo)	5 parts;
solvent (methyl ethyl ketone/toluene/ cyclohexanon 4/2/2)	900 parts.

The ink composition was coated, dried up and cured one day under normal temperature. Then, the layer was kept at 100° C. for 30 minutes under heat, for letting the silicone to bleed up to the surface, to provide an image-transferable layer formed on its surface with a hardened silicone layer.

On the thus-provided image-reception layer, a sublimating image-transfer film was overlapped which is composed of cyan color sublimative dye (molecular weight being higher than 250) carried by a proper binder resin and thermal energy is fed thereon from a thermal head adapted for receiving electric signals representing cyan color components obtained by a color analysis of a portrait photograph, as an example, for providing portrait images corresponding thereto. Then, two successive sublimative image-transfer jobs were executed with use of respective sublimating image-transfer films carrying sublimative magenta and yellow color dyes, each molecular weight being higher than 250, and substantially in the manner set forth above. In this way, after all, an overall combined display image composed of a full color portrait, in combination with several characters and graphics, was provided.

The image-reception layer of the sheet, now carrying these display images, was overlapped on the card substrate composed of a polyester resin sheet, 100 μm thick, which had been primed to white-opaque state, and pressurized together at 160° C. by means of heated pressure rolls. Then, the polyester film was peeled off at the interface with the protecting layer, thereby providing a final product card transferred with image-reception layer now carrying the desired-image display.

It was found that the overall surface of the product card was generally smooth and showing no raised feeling of the thus-formed and displaying images. Even upon an accelerated testing of the product card for three months held in an atmosphere of 40° C. the images showed no blurrings as well as no interlayer separation. Further, according to an accelerated light-proof test carried out as prescribed in JIS-Standard with use of a carbon arc lamp, the results showed to be classified to JIS-4 or -5 corresponding to an acceptable superior performance. Additionally, a surface scratch test and the like showed also superior durability.

EXAMPLE A-2

The foregoing image-transferable sheet, now image-carrying, as processed in Example A-1, is then subjected to a peel-off operation for separating the image-carrying layer from the sheet. Then, an adhesive agent of polyester series was coated on the exposed surface of the peeled-off film, and stuck under pressure on a curved surface part of a telephone set. The images could follow up to the stuck curvature into a unitary solid mass, and indeed, without inviting any stuck-on feeling, contrary to the case when a sticky loose-leaf stamp should have been stuck on. In this way, miracle viewing feelings as obtainable with direct-printing operation only, were created and maintained.

EXAMPLE A-3

A white polyester film, baked on one surface thereof with melamine coating, "E 20", 100 μm thick, manufactured and sold by Toray Co., Ltd. Tokyo, is formed on the opposite surface with a slipping layer, same as in the following Example C-2, through application of polyurethane primer. And an identification mark was provided thereon through the way of regular printing technique. On the melamine resin-baked surface of the white polyester resin film, a layer of peeling varnish (of polymethyl methacrylate-series), manufactured and sold by Showa Inku. Co., Ltd., Tokyo) was applied in dry quantity of 2 g/m^2 and dried up to provide a definite layer.

On the thus-formed protecting layer, the following image-reception layer-forming composition was coated and dried up, so as to form an image-heat transferable sheet. The coated composition was in quantity of 6 g/m^2 by dry weight.

Image-reception layer-forming composition	
polyester resin ("Vylon 600", Tg: 47° C., manufactured and sold by Toyobo, Osaka)	80 parts;
polyester resin ("Vylon 290", Tg: 77° C., manufactured and sold by Toyobo)	20 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu Kagaku Kogyo)	7 parts;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu Kagaku Kogyo)	7 parts;
solvent (methyl ethyl ketone/toluene = 1/1)	800 parts.

On the image-reception layer of the foregoing heat image-transferable sheet, reversed images composed of

full color portrait images together with characters and graphics by use of a thermal head, as in the same way with Example A-1, were formed.

Next, the image-reception layer, however, now carrying the reversed images formed in the foregoing manner was brought into contacting and overlapping state with the image displayable surface on a card style substrate made of white color polyester resin, 125 μm thick, preparatorily primer treated as before, and pressurized together under the action of thermal rolls, and the white polyester film, 100 μm, was peeled off between the protecting layer and the melamine-baked layer, thus providing a final card-style product transferred with the image-reception layer now carrying the necessary images.

The surface of the final card style product represented a smooth and slippery, without fear of interlayer separation and with superior light resistant power.

EXAMPLE A-4

A white foam polyester resin film, "Merinex", 125 μm , thick, manufactured and sold by ICI, was provided with an identification mark on one surface thereof, with regular printing technique.

Then, on the opposite surface of the white foam polyester resin film to the foregoing surface formed with the identification mark, a coating of a polyurethane-series primer was applied and dried up. Further, the following protecting layer-forming composition was applied in dry quantity of 3 g/m^2 and dried up to form a protecting layer.

Protecting layer-forming composition	
acrylic polyole ("Acrit 6416MA", manufactured and sold by Taisei Kako K.K.)	41 parts;
toluene	36 parts;
methyl ethyl ketone	27 parts;
diisocyanate ("Colonate", manufactured and sold by Nippon Polyurethane K.K.)	6 parts.

On the above protecting layer, the following composition was applied in dry quantity of 3 g/m^2 and dried up, to provide an intermediate layer.

Intermediate layer-forming composition	
polyester resin ("Vylon 290", manufactured and sold by Toyo Boseki (Toyobo) K.K., Osaka)	15 parts;
toluene/methyl ethyl ketone = 1/1	85 parts.

On the thus-formed intermediate layer, an image-reception layer which is substantially same with that in the foregoing Example A-3 was provided, so as to form an image-transferable sheet. Then, as same in the foregoing Example A-3, correspondingly inverted images were formed on the image-reception layer and further then, subjected to transfer onto the card substrate by use of thermal rollers. In this way, a final product card, having an image transferable, yet now image-formed layer, was provided.

This card showed favorable results of light-resisting test. Further, it showed a better scratch test result than the foregoing card obtained in Example A-3.

EXAMPLE A-5

Substrate

A white polyester film, "E-20", 100 μm thick, manufactured and sold by Toray Co., Ltd., Tokyo, was used.

Intermediate layer-forming composition	
Polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki K.K., Osaka)	15 parts;
toluene/methyl ethyl ketone = 1/1 (dry weight: 5 g/m^2)	85 parts.
Protecting layer-forming composition	
"Hakuri-Nisu" (acrylic resin varnish, manufactured and sold by Showa Ink K.K.) (dry weight)	2 g/m^2
Image-reception layer-forming composition	
polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki K.K., Osaka)	10 parts;
polyester resin ("Vylon 200", supplied by Toyo Boseki K.K.)	5 parts;
toluene/methyl ethyl ketone = 1/1	85 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu Kagaku Kogyo)	1 part;
epoxy-modified silicone ("X-22-343", supplied by Shinetsu Kagaku Kogyo)	1 part.
(coated quantity (dry)	5 g/m^2)

With use of the foregoing composition and processed in similar way as in Example A-3, to provide a final card product, having an image-reception layer transferred with necessary images.

EXAMPLE A-6

Substrate

White polyester resin film, "E-20", 100 μm thick, manufactured and sold by Toray was coated with polyurethane-series primer and dried up.

Parting layer-forming composition	
melamine resin ("Meran 45", manufactured and sold by Hitachi Kasei)	100 parts;
hardener (para-toluenesulfonic acid)	20 parts;
(coating quantity (dry), 2 g/m^2)	
Protecting layer-forming composition	
vinylchloride-vinylacetate ("Vinylite VYHH", manufactured and sold by Union Carbide Corp.)	15 parts;
methyl ethyl ketone = 2/1	85 parts;
(coating quantity (dry): 2 g/m^2)	
Intermediate layer-forming composition	
polyurethane resin ("Takelac T-3350", manufactured and sold by Takeda Pharmaceutical Company, Osaka, of 23%-concentration)	50 parts;
isopropyl alcohol	15 parts;
toluene	25 parts;
methyl ethyl ketone	10 parts.
(coating quantity (dry) 5 g/m^2)	
Image-reception layer composition	
polystyrene resin ("Picolastic D125" (Tg = 53° C.), manufactured and sold by Hercules	15 parts;
toluene/methyl ethyl ketone = 1/1	85 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu Kagaku)	1 part;

-continued

epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu Kagaku) (coating quantity (dry): 6 g/m^2)	1 part.

The foregoing composition was prepared and used as in the same manner with Example A-3, to provide a card with the image-reception layer subjected to image-transfer as desired.

EXAMPLE B-1

As the substrate, a polyester resin film, 6 μm thick, was used and a polyester resin-series primer was coated on one surface thereof and dried up. Further, the following ink composition was applied and dried up. The coating quantity of the composition was set to about 7 g/m^2.

Image-reception layer-forming composition	
polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki K.K.)	100 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu Kagaku)	5 parts;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu Kagaku)	5 parts;
solvent (methyl ethyl ketone/toluene/ cyclohexanone = 4/2/2)	900 parts.

The ink composition was coated, dried up and left standing for a full day, and then subjected to heat treatment at 100° C. for 30 minutes, so as to bleed the silicone towards the film surface for providing thereon an acceptable image-reception layer composing the active surface.

Then, a sublimative image-transferable film, composed of a resin binder evenly mixed with a proper amount of sublimative cyanic dye, the molecular weight being higher than 250, was overlapped on the above image-reception layer and applied with heat energy by means of a thermal head supplied with electric signals corresponding to cyanic color components of a portrait full color photograph as determined by regular color analysis, thus providing+cyanic color component images.

Next, as for magenta and yellow color components, similar respective processings were executed and finally, full color display portrait images could be formed.

Then, the exposed surface of image-reception layer of the thus-display image-formed film was overlapped on a card substrate composed of a white opaque, hard vinyl chloride resin sheet, 100 μm thick and pretreated with a conventional primer, and then this assembly was subjected to heat and pressure by means of a pair of heated rolls. In this way, a card product stuck with an image-transferable and now carrying layer was provided.

The surface of this card was generally smooth and slippy, the thus-formed images thereon providing no raised feelings. In an accelerated test of the se formed images in hot atmosphere of 40° C. for a continuous period of three months, the re were no appreciable image blurring and interlayer separation. Upon execution of a light exposure test in accordance with prescribed conditions in JIS with use of an arc lamp, the results were classified to JIS-4 to 5 Classes which means as acceptable and better image quality. Scratch test results were also superior.

EXAMPLE B-3

A sticking layer, 1 μm thick, was formed with a polyamide resin sticking agent on the image-carrying surface of the image-transferable sheet, image-formed in the manner as described in foregoing Example B-1, and the thus provided sheet was stuck on the curved surface of a glass tumbler. These images express practically no stuck-on feelings, rather providing such a touch and viewing feeling as if they had been formed by the regular and direct printing technique.

EXAMPLE C-1

With use of the image-transferable sheet prepared in the foregoing Example A-1, images were formed substantially in accordance with procedures mentioned therein, however, with exception of the formation of reversed images, and then, the image-carrying layer was, without execution of the foregoing peel-off operation, stuck on a portion of curved outer surface of a glass tumbler, whereupon the sheet-like substrate was peeled off, together with the weak-sticking layer. The thus-applied images represent almost no sticking-on grip and viewing feeling, as if they should have been applied through regular and direct-printing technique.

EXAMPLE C-2

On the surface of a transparent polyester film, 12 μm thick, employed as a protecting film, the following image-reception layer forming composition was applied to form a coated layer (in quantity of 6 g/m^2 when measuring upon drying), dried up and left as it was for full one day. Then, it was held at 100° C. for 30 minutes, to form an image-reception layer. On the surface thereof, a parting surface layer was found to exist, which was composed of a combined hardened product of amino-modified silicone resin and epoxy-modified silicone resin.

Image-reception layer-forming composition	
polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki)	100 parts;
amino-modified silicone resin ("KF-393", manufactured and sold by Shinetsu)	7 parts;
epoxy-modified silicone resin ("X-22-343", manufactured and sold by Shinetsu)	5 parts;
solvent (methyl ethyl ketone/toluene = 1/1)	800 parts.

As the substrate, on the other hand, white polyester resin film, "E-20", 75 μm, manufactured and sold by Toray, was used and coated on one surface thereof with a polyurethane-series primer and dried up. Then, the following composition (in the dried quantity of 1 g/m^2) and dried up, so as to provide a smooth and stick layer.

Smooth layer-forming composition	
polymethyl methacrylate resin ("Dianal BR-85", manufactured and sold by Mitsubishi Rayon Co., Ltd.,	12 parts;

-continued

Smooth layer-forming composition	
Tokyo)	
polyethylene wax ("MF8F", manufactured and sold by Dulacon Co.)	0.5 part;
toluene/methyl ethyl ketone = 1/1	85 parts.

On the opposite surface of the white-polyester resin sheet to the smoothed surface the re, a primer coating of polyurethane-series is applied and dried up, and further coated thereon with the following composition, in quantity of 3 g/m^2, so as to provide a weak-sticky layer.

Weak-sticky layer-forming composition	
weak-sticky adhering agent ("Esdyme AE-206", manufactured and sold by Sekisui Kagaku Kogyo K.K., Tokyo)	50 parts;
water	50 parts.

The weak-sticky adhering layer is brought into contact with the protecting film consisting of a polyester film, 12 μm thick, at the opposite surface to the image-reception layer, and then subjected to heat and pressure, to provide an image-transferable sheet. Upon bringing the image-reception layer of the image-transferable sheet and the dyestuff layer of the heat-image transfer sheet into contact with each other, heat energy was applied from a thermal head, as in the similar manner mentioned in the foregoing Example A-1, and thus heat image-transfer job was executed, so as to provide reversed mode images for expressing a full color portrait as well as characters and graphics.

Next, the image-reception layer formed with the reversed images thereon was overlapped onto the image-displayable surface of a card style substrate, 100 μm thick, made of a white color polyester resin material preparatorily applied with a primer layer by coating a composition, consisting of "Vylon 200", 100 μm thick, manufactured and sold by Toyo Boseki K.K., and then subjected together to heat and pressure by means of at least a heated roll at 160° C. Then, the white polyester film, 75 μm thick, and the weak-sticky adhesive layer were peeled off in unison, for providing a final decorative product card having the image-reception layer transferred with images and carrying dislay images.

This card had a highly smooth surface and was not liable to invite any interlayer separation and showed superior light fastness.

In place of white color polyester-made card substrate preparatorily formed with a primer layer, such a modification was prepared and experimented that the white polyester sheet was formed on its rear surface with a magnetic layer, while, on its front surface there is formed with a write-on layer which consists of proper filler and resin as conventionally, so as to provide a telephone card. This processed telephone card had the write-on layer provided with display images formed by image-transfer.

EXAMPLE C-3

On the surface of a transparent polyester film, 9 μm thick, used as the protecting layer, an intermediate layer was provided by coating. The coated amount was 5 g/m^2 as measured upon being dried up.

Intermediate layer-forming composition	
polyurethane resin ("Takelack T-3350", solid content 23%, manufactured and sold by Takeda Pharmaceutical Co., Ltd., Osaka)	50 parts;
isopropyl alcohol	15 parts;
toluene	25 parts;
methyl ethyl ketone	10 parts.

Onto the intermediate layer, the following composition was applied for the formation of an image-reception layer. The coated quantity was 5 g/m^2 as measured upon being dried up.

Image-reception layer-forming composition	
polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki)	10 parts;
polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki)	5 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	1 part;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	1 part;
solvent (methyl ethyl ketone/toluene = 1/1)	85 parts.

On the other hand, a white color polyester film, which was similar to that employed in the foregoing Example C-2 was formed with a slidingly smooth layer, as well as a weak-sticking adhesive layer, the latter being brought into intimate contact with a transparent polyester film, 9 μm thick, at the opposite surface to the image-reception layer and then, subjected to heat and pressure, for providing a heat image-transferable sheet. As further processed in the similar manner in the foregoing Example C-2, full-color photographic images (reversed images) were thus formed on the image-reception surface. In this way, a final product card, having its image-reception layer transferringly formed with display images.

EXAMPLE C-4

Substrate

White color polyester sheet, "E-20", 100 μm thick, manufactured and sold by Toray was formed thereon with a polyurethane-series primer coating. Then, a weak-sticking layer was applied thereon with use of the following composition.

Weak-sticking layer-forming composition	
weak-sticking agent ("Esdyne AE-206", manufactured and sold by Sekisui Kagaku Kogyo K.K., Tokyo)	50 parts;
water	50 parts.
Protecting layer-forming composition	
polyester resin ("Vylon-200", manufactured and sold by Toyo Boseki)	15 parts;
diisocyanate ("Colonate L", manufactured and sold by Nippon Polyurethane Co., Ltd.)	1 part;
toluene/methyl ethyl ketone = 1/1	84 parts.
Image-reception layer-forming composition	
polyester resin	10 parts;

-continued

("Vylon 600", manufactured and sold by Toyo Boseki K.K.)	
vinyl chloride-vinyl acetate copolymer resin ("Vinylite VAGH" (Tg = 79° C.), manufactured and sold by Union Carbide Corp)	5 parts;
toluene/methyl ethyl ketone = 1/1	85 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	1 part;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	1 part.

With use of the above composition and processed substantially same as in the foregoing Example C-2, a final card product was obtained.

EXAMPLE D-1

An image-transferable sheet was prepared as in the foregoing Example A-1 and thermally image-transferred with reversed mode images of a full color portrait photograph, to provide an intermediate image-transfer medium. The latter is overlapped by its image-reception layer onto the surface of a sheet of rough-textured cotton cloth, however, through the intermediary of an acrylic acid ester-vinyl acetate copolymer sheet, 100 μm thick. Then, the assembly was subjected to heat and pressure. Then, the substrate sheet and weak-sticky adhesive layer, together, were peeled off. The thus transfered images have sufficient surface smoothness, showing superior surface conditions.

Without use of the bond-attaching sheet in the above process and when similar image-transfer job as above was performed, the resulted images followed the surface undulations appearing disadvantageously on the material product of the rough fabrics and thus were highly uneven, and further, on account of insufficient adhering performance acting between the image-receiving layer and the woven fabrics serving as product material, easy and frequent separations took place therebetween.

EXAMPLE D-2

In the similar way as was disclosed in the foregoing Example D-1, an intermediate image-transfer medium carrying reversed images was prepared and overlapped on a polymethacrylate board preparatorily subjected to surface-toughening operation through a conventional sand-blasting step, and through the intermediary of a bond-adhering sheet pressurized together under heat, as was employed in Example D-1. Then, the sheet-like substrate was peeled off, together with the weak adhesive layer. The thus-provided images were highly smooth and even in spite of the highly rough and undulating conditions at the surface to be image-transferred. In addition, the image-carrying surface showed superior results in various resisting tests.

Without use of the foregoing bond-sticking layer, the similarly transferred images showed considerable undulations and distortions. Further, on account of insufficient adhering performance, easy and frequent peel-offs of applied images were feared.

EXAMPLE D-3

On the surface of a polyester resin film, 25 μm thick, the following composition adapted for the formation of bond-sticking layer was coated and dried up, in dried quantity of 5 g/m^2 to provide a film formed thereon a bond sticking sheet.

Bond-sticking sheet-forming composition	
polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki)	15 parts;
methyl ethyl ketone/toluene = 1/1	84 parts.

The bond-sticking sheet surface, together the polyester resin film proper, was brought into contact with the image-representing surface of a white color polyester made-card substrate, 25 μm thick, and then, subjected to heat and pressure by means of at least a heat roll kept at 200° C., arranged to supply heat energy from the side of the polyester resin surface, thereby heat bonding the bond-sticking sheet onto the card surface, whereupon the polyester resin film being forcedly peeled off.

Further then, as in the similar way as adopted in foregoing Examples C-2; A-3; A-4 and C-3, use is made of the image-reception layers representing reversed images thereon, the respective image-reception layers were whereupon brought into contact with the card's bond-sticking surface of the card and subjected to heat and pressure by use of at least a heat roll kept at 200° C. Then, the white color polyester resin substrate was peeled off, together with the weak-sticky adhering layer. In this way, a final product card displaying the portrait photograph was obtained.

EXAMPLE D-4

Substrate

A white color polyester resin sheet, "E-20", 100 μm thick, manufactured and sold by Toray Co. Ltd., was coated with a polyurethane-series primer. On the surface of the thus precoated sheet, the following composition was coated to form a weak-sticking adhesive layer.

Weak-sticking adhesive component	
weak-sticking adhesive agent, ("Esdyne AE-206", manufactured and sold by Sekisui Kagaku)	50 parts.
Image-reception layer-forming composition	
polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki)	7.5 parts;
polyester resin ("Vylon 290", manufactured and sold by Toyo Boseki)	7.5 parts;
toluene/methyl ketone = 1/1	85 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	1 part;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	1 part.

The foregoing compositions were prepared. On the other hand, a polyester resin film, 25 μm thick, was coated on one surface thereof with a 15%-solution of polyester resin, "Vylon 200", manufactured and sold by Toyo Boseki, in toluene/methyl ethyl ketone=1/1 and dried up. The coating quantity was adjusted to 5 g/m^{2}when measuring in dried state. In this way, a bond-sticking sheet was provided.

Then, the coated surface of the thus prepared bond-sticking sheet was brought into contact with the image display surface of a card style substrate of white color

hard vinyl chloride or the like resin material preparatorily subjected to a primer coating treatment in overlapping state and then, the whole assembly was subjected to heat and pressure with use of at least a heated roll to 130° C., thus the bond-sticking layer being stuck on the card surface. Under this condition, the polyester resin film, 25 μm thick, was peeled off.

Then, the image-reception layer, now carrying thereon reversed images, was brought into contact with the bond-sticking sheet and the resulted whole was subjected to heat and pressure by use of at least a heated roll and the white color polyester resin substrate, together with the weak-sticking adhesive layer, was peeled off. In this way, the card, now displaying the portrait images, was provided.

EXAMPLE D-5

Substrate

Same as in the foregoing Example D-4.

Weak-sticking adhesive layer

Same as in the foregoing Example D-4.

Protecting layer-forming composition	
polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki)	15 parts;
diisocyanate ("Colonate L", manufactured and sold by Nippon Polyurethane)	1 part;
toluene/methyl ethyl ketone = 1/1	84 parts.
Image-reception layer-forming composition	
polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki)	10 parts;
toluene/methyl ethyl ketone = 1/1	85 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	1 part;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	1 part.

With use of the foregoing materials and compositions, the processings were carried out as in the foregoing Example D-4, to provide a final product card displaying portrait images as was desired.

EXAMPLE D-6

Substrate

Same as in the foregoing Example D-4.

Weak-sticking adhesive layer

Same as in the foregoing Example D-4.

Image-reception layer-forming composition	
polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki)	10 parts;
vinyl chloride-vinyl acetate copolymer resin ("Vinylite VAGH", manufactured and sold by Union Carbide Corp.)	5 parts;
toluene/methyl ethyl ketone = 1/1	85 parts.

The foregoing materials and compositions were prepared and processed in the similar way as in the foregoing Example D-4, to provide a final product card, displaying the desired portrait images as were desired.

EXAMPLE E-1

On a polyethylene terephthalate film, 9 μm thick, a solution of saturated polyester resin, "Vylon 600", manufactured and sold by Toyo Boseki, in toluene/methyl ethyl ketone = 1/1, was coated by reliance of the known reverse roll-coating process, and dried up. The coated quantity was 7 g/m^2 when measuring in dry condition. In this way, a weak-sticking adhesive layer could be formed.

On the weak-sticking adhesive layer, the following composition, 3 g/m^2 (dry), was coated by means of an oblique-lined gravure roll for solid and full printing use and in the reverse roll-coating process, and then dried up, to provide an image-reception layer.

Image-reception layer-forming composition	
polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki)	70 parts;
polyester resin ("Vylon 290", manufactured and sold by Toyo Boseki)	30 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	5 parts;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	5 parts;
methyl ethyl ketone (wt. ratio 1/1)	700 parts.

On the opposite surface to the image-reception layer of the thus-prepared image-transferable sheet, a synthetic paper substrate, "Yupo FPG 110", 110 μm thick, manufactured and sold by Oji Yuka K.K., coated with "Vylon 600" as the adhesive agent in quantity of 10 g/m^2 (dry) was stuck intimately together.

On the other hand, a polyethylene terephthalate film substrate, 6 μm thick, preparatorily provided on one surface thereof with a heat-resisting layer was used and the following composition was applied on the opposite surface of the substrate with use of a wire bar and dried up, in the quantity of 1 g/m^2 (dry), so as to provide a dyestuff layer. In this way, a heat image-transferable sheet was prepared and provided.

Dyestuff layer-forming composition	
dispersion dye ("Kayaseo Blue-136", manufactured and sold by Nippon Kayaku K.K.)	4 parts;
ethylhydroxyethyl cellulose	6 parts;
methylethylketone/toluene (wt. ratio: 1/1)	90 parts.

The dyestuff layer of the foregoing heat image-transfer sheet was brought into contact with the image-reception layer of the image-transferable sheet in overlapping manner, then, heat energy was applied from a thermal head from the side of heat-resisting layer of the heat image-transfer sheet, thereby dyestuff being transferred to the image-reception layer of image-transferable sheet, and indeed, for the formation of positive images.

Then, the image-transferable sheet, now carrying the required positive images was stuck together under heat and pressure at 140° C. for 5 seconds on the intermediate image-transfer substrate prepared in the following manner, in mutually opposed manner. Then, the synthetic paper "Yupo" was peeled off at the intersurface between the polyester resin film and the "Vylon 600" layer. In thus way, the inventive image-transfer sheet

(intermediate image-transfer medium) carrying the corresponding reverse images was provided.

Method for the preparation of intermediate image-transfer substrate

A sheet, of fine quality or stick paper, unit weight: 82 g/m^2 was applied with a coating, about 20 μm thick, of polyethylene resin through conventional extrusion coating process. Thereon, further, a catalyst-added toluene solution of a parting agent silicone, "KS-707", manufactured and sold by Shinetsu was applied and dried up in quantity of about 2 g/m^2 (dry), for the purpose of curing. Thereon, still further, the following coating liquid composition was applied by means of a conventional coating bar and dried up, to provide an intermediate image transfer substrate. The thus coated and dried resin quantity was measured to 7 g/m^2.

Coating liquid composition	
polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki)	100 parts;
methyl ethyl ketone/toluene (mixing ratio by weight: 1/1)	700 parts.

A sheet of coated paper, pretreated for pore-filling, was coated, in the similar manner as above, with the foregoing liquid composition, to provide an image-transferable medium. On and with the presently coated surface, the image carrying surface of the foregoing intermediate image-transfer medium is brought into opposing contact and stuck together under heat and pressure at 140° C. for 7 seconds. Finally, the laminate of fine-quality paper and polyethylene was peeled off, to provide a final decorative product now displaying the positive images as required.

It will thus be seen that by adopting the above processing steps, the positive images formed under the action of the thermal head are transferred, through the intermediary of intermediate image transfer medium, onto the final object to be decorated, and indeed, in the form of positive mode. It will be further seen that, since the dyestuff is well distributed within the image-reception layer, the transferred positive images are highly sharp and fresh, in addition to much profundities.

Since a resin layer was overlappingly applied on the thus-formed images, weather fastness, frictional durability and light-fastness of the finally formed images could be highly and amazingly improved. When suitable ultraviolet absorbing agent, antioxydant, quenching agent and/or radical scavenger is added to, further improvement of the light-fastness can be attained.

EXAMPLE E-2

The substrate of image-transferable medium adopted in the foregoing Example E-1 was replaced by a hard polyvinyl chloride card, 100 μm thick, and other processing modes were same as in Example E-1. In this way, a high quality, positive-image transferred, decorative final product was successfully provided. When the image include human portrait photograph, the final product was highly useful for ID-card.

EXAMPLE E-3

The substrate of image-transferable medium adopted in the foregoing Example E-1 was replaced by a transparent polyester film, and other processing modes were same as employed the rein. In this way, a transparent film formed with the wanted positive images of better quality as before was obtained. This film was highly useful in OHP-services.

EXAMPLE E-4

A sheet of high quality paper, unit weight: 104 g/m^2, was coated with a layer of polypropylene resin, thickness: about 20 μm, through the way of conventional extrusion coating technique, then the coating was further coated with a silicone solution for use in parting service and hardenable under electron rays and dried up. The quantity of the coating silicone was about 1 g/m^{2}upon drying. In this way, an electron-hardened, provisional substrate was provided. On this substrate, the following, image-reception layer-forming composition was applied as a layer by use of a coating bar, and then dried up, for providing an image-reception layer. The coated resin quantity in the above last step amounted about 5 g/m^2.

Image-reception layer-forming composition	
polystyrene ("Picolastic D 150" (Tg = 69° C.), manufactured and sold by Rika-Hercules Co., Ltd.	100 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	7 parts;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	7 parts.

Further processing was carried out as was set forth in the foregoing Example E-2, for providing a final product card, carrying thereon the wanted positive images of same superior quality, as was in Example E-2.

EXAMPLE E-5

On the image transferable medium used in the foregoing Example E-4, however, in the present Example, a thermoplastic resin, adhesive, polyolefine-series film, "Adwin 500", manufactured and sold by Showa Denko K.K., Tokyo, was applied as a layer. Other materials were used and processed as set forth the rein. In this way, a decorative final product formed with necessary positive was obtained with superior results.

Industrial Availabilities

As will be well understood from the foregoing detailed description of the invention, it is possible according to the present inventive system, to form highly easily and evenly the desired images sharply and attractingly on any product and object to be decorated or graphically ornamented, substantially irrespective of material kind and configuration thereof, and indeed, with a surprising unitary touch and feeling with the substrate. Therefore, the invention can be utilized broadly and conveniently in such various industrial fields, where unitary formation of various images, characters, symbols, numerals and graphics, on and to the articles, objects and substrate products to a sufficiently miracle and attracting degree.

We claim:

1. A sublimatingly image-transferred product comprising:

a plastic card;

an image-reception layer provided on said plastic card, said image-reception layer having an antistatic agent applied on the surface of the image-recep-

tion layer located between said plastic card and said image-reception layer; and

a transferred image formed between said plastic card and said image-reception layer having said antistatic agent applied thereon;

said image-transferred product being formed by a two transfer step process comprising (1) sublimation transferring by thermal energy an image on an image-receiving sheet comprising a substrate and the image-reception layer having an antistatic agent applied thereon and thereafter (2) transferring said image-reception layer having the transferred image formed by the sublimation transfer step (1) from said image-receiving sheet onto said plastic card, transferring step (2) occurring by adhesion of thermal fusion between the surface of said plastic card and said image-reception layer and peeling off the substrate from the image-receiving sheet thereby to form said transferred image on the interface side between the plastic card and the image-reception layer.

2. The sublimatingly image-transferred product of claim **1**, further comprising a protecting layer on the surface of said image-reception layer.

3. The sublimatingly image-transferred product of claim **1**, further comprising a parting agent layer is provided on the surface of said image-reception layer or between the latter and the card.

4. The sublimatingly image-transferred product of claim **1**, wherein said card is a transparent card.

5. The sublimatingly image-transferred product of claim **1**, wherein a protecting layer is provided on the substrate and the image-reception layer is provided on the protecting layer, both the protecting layer and the image-reception layer being retained after transferring step (2).

[57] **ABSTRACT**

A compound objective lens is composed of a hologram lens for transmitting a part of incident light without any diffraction to form a beam of transmitted light and diffracting a remaining part of the incident light to form a beam of first-order diffracted light, and an objective lens for converging the transmitted light to form a first converging spot on a front surface of a thin type of first information medium and converging the diffracted light to form a second converging spot on a front surface of a thick type of second information medium. Because the hologram lens selectively functions as a concave lens for the diffracted light, a curvature of the transmitted light differs from that of the diffracted light. Therefore, even though the first and second information mediums have different thicknesses, the transmitted light incident on a rear surface of the first information medium is converged on the its front surface, and the diffracted light incident on a rear surface of the second information medium is converged on the its front surface. That is, the compound objective lens has two focal points.

COMPOUND OBJECTIVE LENS HAVING TWO FOCAL POINTS

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to a compound objective lens composed of an objective lens and a hologram lens which has two focal points, an imaging optical system for converging light on two converging spots placed at different depths of an information medium with the compound objective lens, an optical head apparatus for recording, reproducing or erasing information on or from an information medium such as an optical medium or a magneto-optical medium like an optical disk or an optical card with the imaging optical system, an optical disk in which a series of high density recording pits and a series of comparatively low density recording pits are provided, an optical disk apparatus for recording or reproducing information on or from the optical disk with the compound objective lens, a binary focus microscope having two focal points in which two types of images drawn at different depths are simultaneously observed, and an alignment apparatus for aligning two types of images drawn at different depths with the binary focus microscope.

2. Description of the Related Art

An optical memory technique has been put to practical use to manufacture an optical disk in which a pit pattern formed of a series of pits is drawn to record information. The optical disk is utilized as a high density and large capacity of information medium. For example, the optical disk is utilized for a digital audio disk, a video disk, a document file disk, and a data file disk. To record information on the optical disk and to reproduce the information from the optical disk, a light beam radiated from a light source is minutely converged in an imaging optical system, and the light beam minutely converged is radiated to the optical disk through the imaging optical system. Therefore, the light beam is required to be reliably controlled in the imaging optical system with high accuracy.

The imaging optical system is utilized for an optical head apparatus in which a detecting system is additionally provided to detect the intensity of the light beam reflected from the optical disk. Fundamental functions of the optical head apparatus are classified into a converging performance for minutely converging a light beam to form a diffraction-limited micro-spot of the light beam radiated on the optical disk, a focus control in a focus servo system, a tracking control in a tracking serve system, and the detection of pit signals (or information signals) obtained by radiating the light beam on a pit pattern of the optical disk. The fundamental function of the optical head apparatus is determined by the combination of optical sub-systems and a photoelectric transfer detecting process according to a purpose and a use. Specifically, an optical head apparatus in which a holographic optical element (or hologram) is utilized to minimize and thin the optical head apparatus has been recently proposed.

PREVIOUSLY PROPOSED ART

FIG. 1 is a constitutional view of a conventional optical head apparatus proposed in Japanese Patent Application No. 46630 of 1991 which is applied by inventors of the present invention.

As shown in FIG. 1, a conventional optical head apparatus **11** for recording or reproducing information on or from an information medium **12** such as an optical disk is provided with a light beam source **13** such as a semiconductor laser, a transmission type of blazed hologram **14** for transmitting a light beam L1 radiated from the light beam source **12** without any diffraction in an outgoing optical path and diffracting a light beam L2 reflected on the information medium **12** in a returning optical path, an objective lens **15** for converging the light beam L1 transmitting through the hologram **13** on the information medium **14** to read the information, an actuator **16** for integrally moving the objective lens **15** with the blazed hologram **13** to focus the light beam L1 on the information medium **12** with the objective lens **15**, and a photo detector **17** for detecting the intensity of the light beam L2 reflected on the information medium **12** to reproduce the information.

As shown in FIG. 2A, a relative position between the blazed hologram **14** and the objective lens **15** is fixed by a fixing means **18**. Or, as shown in FIG. 2B, a blazed pattern is formed on a side of the objective lens **15** to integrally form the blazed hologram **14** with the objective lens **15**.

In the above configuration, a light beam L1 (or a laser beam) radiated from the light beam source **13** is radiated to the blazed hologram **14**, and the light beam L1 mainly transmits through the blazed hologram **14** without any diffraction in an outgoing optical path. The light beam L1 transmitting through the blazed hologram **14** is called zero-order diffracted light. Thereafter, the zero-order diffracted light L1 is converged on the information medium **12** by the objective lens **15**. In the information medium **12**, information indicated by a series of patterned pits is recorded and read by the zero-order diffracted light L1. Thereafter, a beam light L2 having the information is reflected toward the objective lens **15** in a returning optical path and is incident to the blazed hologram **14**. In the blazed hologram **14**, the light L2 is mainly diffracted. The light L2 diffracted is called first-order diffracted light. Thereafter, the first-order diffracted light L2 is received in the photo detector **17**.

In the photo detector **17**, the intensity distribution of the first-order diffracted light L2 is detected. Therefore, a servo signal for adjusting the position of the objective lens **15** by the action of the actuator **16** is obtained. Also, the intensity of the first-order diffracted light L2 is detected in the photo detector **17**. Because the information medium **12** is rotated at high speed, the patterned pits radiated by the light **17** are changed so that the intensity of the first-order diffracted light L2 detected is changed. Therefore, an information signal indicating the information recorded in the information medium **12** is obtained by detecting the change in intensity of the first-order diffracted light L2.

In the above operation, a part of the light beam L1 is necessarily diffracted in the blazed hologram **14** when the light beam L1 is radiated to the blazed hologram **14** in the outgoing optical path. Therefore, unnecessary diffracted light such as first-order diffracted light and minus first-order diffracted light necessarily occurs. In

cases where the hologram **14** is not blazed, the unnecessary diffracted light in the outgoing optical path also reads the information recorded in the information medium **12**, and the unnecessary light is undesirably received in the photo detector **17**. To prevent the unnecessary light from transmitting to the information medium **12**, the blazed hologram **14** is manufactured to form a blazed hologram pattern on the surface thereof, so that the intensity of the unnecessary light received in the photo detector **17** is decreased.

Also, because an objective lens of a conventional microscope has only a focal point, images placed within a focal depth of the objective lens can be only observed with the conventional microscope.

Also, a minute circuit is formed on a semiconductor such as a group III–V compound semiconductor to form a microwave circuit, an opto-electronic detector or a solid state laser. In this case, a photo-sensitive material is coated on a sample made of the semiconductor. Thereafter, a relative position between the sample and a photo mask covering the sample is adjusted by utilizing an alignment apparatus, and the photo-sensitive sensitive material is exposed by a beam of exposure light through the photo mask to transfer a circuit pattern drawn on the photo mask to the photo-sensitive material in an exposure process by utilizing an exposure apparatus. For example, an alignment pattern is drawn on a reverse side of the sample, and a relative position between the sample and the photo mask is adjusted with high accuracy while simultaneously observing the alignment pattern of the sample and the circuit pattern of the photo mask with the conventional microscope. Thereafter, the circuit pattern of the photo mask is transferred to a front side of the sample.

In this case, because images placed within a focal depth of an objective lens utilized in the conventional microscope can be only observed with the conventional microscope, it is required to utilize the conventional microscope having a deep focal depth in the alignment apparatus in cases where the alignment pattern and the circuit pattern are simultaneously observed with the conventional microscope. Therefore, the magnification of the conventional microscope having a deep focal depth is lowered.

PROBLEMS TO BE SOLVED BY THE INVENTION

An optical disk having a high density memory capacity has been recently developed because of the improvement in a design technique of an optical system and the shortening of the wavelength of light radiated from a semiconductor laser. For example, a numerical aperture at an optical disk side of an imaging optical system in which a light beam converged on an optical disk is minutely narrowed in diameter is enlarged to obtain the optical disk having a high density memory capacity. In this case, the degree of aberration occurring in the imaging optical system is increased because an optical axis of the system tilts from a normal line of the optical disk. As the numerical aperture is increased, the degree of the aberration is enlarged. To prevent the increase of the numerical aperture, it is effective to thin the thickness of the optical disk. The thickness of the optical disk denotes a distance from a surface of the optical disk (or an information medium) radiated by a light beam to an information recording plane on which a series of patterned pits are formed.

FIG. **3** shows a relationship between the thickness of the optical disk and the numerical aperture on condition that the tilt of the optical axis is constant.

As shown in FIG. **3**, because the numerical aperture is 0.5 when the thickness of the optical disk is 1.2 mm, it is effective to thin the optical disk to 0.6 mm in thickness when the numerical aperture is increased to 0.6. In this case, even though the numerical aperture is increased on condition that the tilt of the optical axis is not changed, the degree of the aberration is not increased. Therefore, it is preferred that the thickness of the optical disk be thinned to obtain the optical disk having a high density memory capacity.

Accordingly, it is expected that the thickness of a prospective optical disk having a high density memory capacity becomes thinner than that of a present optical disk such as a compact disk appearing on the market now. For example, the thickness of the compact disk is about 1.2 mm, and the thickness of the prospective optical disk is expected to range from 0.4 mm to 0.8 mm. In this case, it is required to record or reproduce information on or from an optical disk with an optical head system regardless of whether the optical disk is the present optical disk or the prospective optical disk having a high density memory capacity. That is, an optical head apparatus having an imaging optical system in which a light beam is converged on an optical disk within the diffraction limit regardless of whether the optical disk is thick or thin is required.

However, in a conventional optical head apparatus, a piece of information is only recorded or reproduced on or from an optical disk having a fixed thickness. For example, in cases where the thickness of the information medium **12** is off a regular range by about ± 0.1 mm or more, an aberration such as a spherical aberration occurs when the optical head apparatus **11** is operated. Therefore, the recording or the reproduction of the information is impossible. Accordingly, there is a drawback that an optical head apparatus in which a piece of information is recorded or reproduced on or from an optical disk regardless of whether the optical disk is the present optical disk or the prospective optical disk having a high density memory capacity cannot be manufactured in a conventional technique.

Also, there is a problem in the conventional microscope. That is, because an objective lens of the conventional microscope has only a focal point and images placed within a focal depth of the objective lens can be only observed with the conventional microscope, the magnification of the conventional microscope and an observed range in an optical axis direction are in a trade-off relationship. Therefore, there is a drawback that it is impossible to observe the images over a wide observed range in the optical axis direction at high magnification

Also, there is a problem in the alignment apparatus. That is, when a circuit pattern drawn on the photo mask is transferred to the front side of the sample after an alignment pattern is drawn on the reverse side of the sample, the alignment of the photomask and the sample is performed by simultaneously observing the circuit pattern of the photo mask and the alignment pattern of the sample with the conventional microscope having a deep focal depth and a low magnification. Therefore, because the conventional microscope has a low magnification, there is a drawback that it is impossible to align the photo mask with the sample at a high accuracy ranging within 5 μm.

SUMMARY OF THE INVENTION

A first object of the present invention is to provide, with due consideration to the drawbacks of such a conventional objective lens having a focal point, a compound objective lens having two focal points.

A second object of the present invention is to provide an imaging optical system having the compound objective lens in which light transmitting through the compound objective lens is converged at a diffraction limit on two converging spots placed at different depths of an information medium.

A third object of the present invention is to provide an optical head apparatus having the imaging optical system in which information is recorded, reproduced or erased on or from one of the converging spots of the information medium at which light is converged by the action of the imaging optical system.

A fourth object of the present invention is to provide a high density optical disk in which a series of first recording pits is formed to record pieces of information at high density on a thin substrate.

A fifth object of the present invention is to provide an optical disk apparatus in which information is recorded or reproduced on or from the optical disk with the compound objective lens regardless of whether a series of recording pits expressing pieces of information is recorded or reproduced on or from the high density optical disk having a thin thickness or a conventional compact disk having an ordinary thickness.

A sixth object of the present invention is to provide a binary focus microscope having two focal points in which two types of images drawn at different depths are simultaneously observed.

A seventh object of the present invention is to provide an alignment apparatus in which two types of images drawn at different depths are aligned with the binary focus microscope.

An eighth object of the present invention is to provide a focusing method for focusing light on an information medium with the optical head apparatus.

A ninth embodiment of the present invention is to provide an information reproducing method for reproducing a piece of recording information recorded on a high density optical disk having a thin thickness.

The first object is achieved by the provision of a compound objective lens having two focal points, comprising:

hologram means for transmitting a part of incident light without any diffraction to form a beam of transmitted light and diffracting a remaining part of the incident light to form a beam of diffracted light, the hologram means functioning as a lens for the diffracted light to diverge the diffracted light from the hologram means or converge the diffracted light; and

lens means for converging the transmitted light formed in the hologram means to form a first converging spot at a first focal point and converging the diffracted light formed in the hologram means to form a second converging spot at a second focal point, the second focal point differing from the first focal point.

In the above configuration, a part of incident light transmits through the hologram means without any diffraction. Therefore, a beam of transmitted light not diverged from the hologram means or not converging is formed. Thereafter, the transmitted light is refracted and converged by the lens means, so that the transmitted light is focused on a first converging spot positioned at a first focal point.

In contrast, a remaining part of incident light is diffracted by the hologram means. Therefore, a beam of diffracted light such as a beam of first-order diffracted light which is diverged from the hologram lens or converges is formed. Thereafter, the diffracted light is refracted and converged by the lens means, so that the diffracted light is focused on a second converging spot positioned at a second focal point.

In this case, because a propagation direction of the transmitted light differs from that of the diffracted light, the first focal point of the compound objective lens for the transmitted light differs from the second focal point of the compound objective lens for the diffracted light. Therefore, the compound objective lens has two focal points, and the incident light transmitting through the compound objective lens are converged on two converging points.

Accordingly, the incident light transmitting through the compound objective lens can be reliably converged on an information medium regardless whether the information medium has a first thickness or a second thickness.

It is preferred that a grating pattern be drawn in the hologram means in a concentric circle shape, the grating pattern of the hologram means be formed in relief to concentrically form alternating rows of bottom portions and top portions, a height H of relief in the grating pattern be set to $H<\lambda/(n(\lambda)-1)$ where a symbol λ denotes a wavelength of the incident light and a symbol $n(\lambda)$ denotes a refractive index of the hologram means made of a glass material for the incident light having the wavelength λ, and a difference in phase modulation degree between the incident light transmitting through a bottom portion of the grating pattern and the incident light transmitting through a top portion of the grating pattern be lower than 2π radians to set a diffraction efficiency of the hologram means to a value lower than 100%.

In the above configuration, because the height of the relief in the grating pattern is lower than a value $\lambda/(n(\lambda)1)$, the difference in phase modulation degree is induced to be lower than 2π radians. Therefore, the diffraction efficiency of the hologram means is set to a value lower than 100% over the entire grating pattern, so that the transmitted light and the diffracted light are simultaneously formed in the hologram lens.

The first object is also achieved by the provision of a compound objective lens, comprising:

lens means for converging a beam of first incident light on a front surface of a first information medium having a first thickness T1 and converging a beam of second incident light on a front surface of a second information medium having a second thickness T2 (T2<T1), the first incident light passing through the first information medium from its rear surface, and the second incident light passing through the second information medium from its rear surface; and

aperture limiting means for selectively limiting an aperture of the lens means for the second incident light which is incident on the lens means, a second numerical aperture of the lens means for the second incident light which is incident on the lens means being lower than a first numerical aperture of the

lens means for the first incident light which is incident on the lens means.

In the above configuration, an aperture of the lens means for the second incident light is limited by the aperture limiting means, and another aperture of the lens means for the first incident light is limited. Thereafter, the first incident light is converged by the lens means on the first information medium at a high numerical aperture, and the second incident light is converged by the lens means on the second information medium at a low numerical aperture. Accordingly, the compound objective lens has two focal points. Also, the intensity of the first incident light can be larger than that of the second incident light.

The first object is also achieved by the provision of a compound objective lens, comprising:

lens means for converging a beam of first incident light on a front surface of a first information medium having a first thickness and converging a beam of second incident light on a front surface of a second information medium having a second thickness, the first incident light passing through the first information medium from its rear surface, and the second incident light passing through the second information medium from its rear surface; and

curvature changing means for changing a curvature of spherical waves of a part of incident light to form the first incident light which is incident on the lens means and not changing a curvature of spherical waves of a remaining part of incident light to form the second incident light which is incident on the lens means.

In the above configuration, a curvature of spherical waves of a part of incident light is changed by the curvature changing means to form a beam of first incident light, and a curvature of spherical waves of a remaining part of incident light is not changed to form a beam of second incident light. Thereafter, the first incident light is converged on the first information medium, and the second incident light is converged on the second information medium.

Accordingly, the compound objective lens has two focal points.

The second object is achieved by the provision of an imaging optical system, comprising:

a light source for radiating a beam of incident light of which a far field pattern is distributed to decrease intensity of the incident light toward a peripheral portion of the beam;

hologram means for transmitting a part of the incident light radiated from the light source without any diffraction to form a beam of transmitted light and diffracting a remaining part of the incident light to form a beam of diffracted light, a grating pattern being formed in relief in the hologram means to concentrically form alternating rows of bottom portions and top portions on condition that a height H of relief in the grating pattern is set to $H<\lambda/(n(\lambda)-1)$ where a symbol λ denotes a wavelength of the incident light and a symbol $n(\lambda)$ denotes a refractive index of the hologram means made of a glass material for the incident light having the wavelength λ, a difference in phase modulation degree between the incident light transmitting through the bottom portions of the grating pattern and the incident light transmitting through the top portions of the grating pattern being lower than 2π radians to set a diffraction efficiency of the hologram means to a value lower than 100%, the height H of the relief in the grating pattern being gradually lowered toward an outer direction of a pattern region in which the grating pattern is drawn, and the diffraction efficiency of the hologram means for the incident light being gradually lowered toward the outer direction of the pattern region to distribute intensity of the transmitted light in a gently-sloping shape; and

lens means for converging the transmitted light formed in the hologram means to form a first converging spot at a first focal point and converging the diffracted light formed in the hologram means to form a second converging spot at a second focal point.

In the above configuration, a beam of incident light is radiated from a light source. A far field pattern of the incident light is distributed to decrease intensity of the incident light toward a peripheral portion of the beam. For example, the light source is a semiconductor laser, the far field pattern of the incident light is distributed in the Gaussian distribution. Thereafter, the incident light transmits through the hologram means. In this case, because a grating pattern is drawn in relief in the hologram means and because the height of the relief is lower than a value $\lambda/(n(\lambda)-1)$, the difference in phase modulation degree between the incident light transmitting through a bottom portion of the grating pattern and the incident light transmitting through a top portion of the grating pattern is induced to be lower than 2π radians. Therefore, the diffraction efficiency of the hologram means for the incident light is set to a value lower than 100% over the entire grating pattern, so that the transmitted light and the diffracted light are simultaneously formed in the hologram lens. In addition, because the height H of the relief in the grating pattern is gradually lowered toward the outer direction of the pattern region, the diffraction efficiency of the hologram means for the incident light is gradually lowered toward the outer direction of the pattern region. Therefore, the incident light positioned at a center portion of its beam are mainly changed to the diffracted light, and the incident light positioned at a peripheral portion of its beam are mainly changed to the transmitted light.

Thereafter, the transmitted light is refracted and converged by the lens means, so that the transmitted light is focused on a first converging spot positioned at a first focal point. Also, the diffracted light is refracted and converged by the lens means, so that the diffracted light is focused on a second converging spot positioned at a second focal point. In this case, because a propagation direction of the transmitted light differs from that of the diffracted light, the first focal point for the transmitted light differs from the second focal point for the diffracted light.

Accordingly, even though the far field pattern of the incident light is distributed in the Gaussian distribution, the far field pattern of the transmitted light is distributed in a gently-sloping shape. Therefore, secondary maxima (or side lobes) of the transmitted light can be prevented from occurring at the first converging spot.

Also, because the height H of the relief in the grating pattern is gradually lowered over the entire pattern region, a numerical aperture of the lens means for the diffracted light can be sufficiently heightened.

The second object is also achieved by the provision of an imaging optical system, comprising:

a light source for radiating a beam of incident light of which a far field pattern is distributed to decrease intensity of the incident light toward a peripheral portion of the beam;

hologram means for transmitting a part of the incident light radiated from the light source without any diffraction to form a beam of transmitted light and diffracting a remaining part of the incident light to form a beam of diffracted light, a grating pattern being formed in relief in the hologram means to concentrically form alternating rows of bottom portions and top portions on condition that a height H of relief in the grating pattern is set to $H<\lambda/(n(\lambda)-1)$ where a symbol λ denotes a wavelength of the incident light and a symbol $n(\lambda)$ denotes a refractive index of the hologram means made of a glass material for the incident light having the wavelength λ, a difference in phase modulation degree between the incident light passing through the bottom portions of the grating pattern and the incident light passing through the top portions of the grating pattern being lower than 2π radians to set a diffraction efficiency of the hologram means to a value lower than 100%, the height H of the relief in the grating pattern being gradually lowered toward an inner direction of a pattern region in which the grating pattern is drawn, and the diffraction efficiency of the hologram means for the incident light being gradually lowered toward the inner direction of the pattern region to distribute intensity of the diffracted light in a gently-sloping shape; and

lens means for converging the transmitted light formed in the hologram means to form a first converging spot at a first focal point and converging the diffracted light formed in the hologram means to form a second converging spot at a second focal point.

In the above configuration, the transmitted light and the diffracted light are simultaneously formed in the hologram lens in the same manner. Also, because the height H of the relief in the grating pattern is gradually lowered toward the inner direction of the pattern region, the diffraction efficiency of the hologram means for the incident light is gradually lowered toward the inner direction of the pattern region. Therefore, the incident light positioned at a center portion of its beam are mainly changed to the transmitted light, and the incident light positioned at a peripheral portion of its beam are mainly changed to the diffracted light.

Accordingly, even though the far field pattern of the incident light is distributed in the Gaussian distribution, the far field pattern of the diffracted light is distributed in a gently-sloping shape. Therefore, secondary maxima (or side lobes) of the diffracted light can be prevented from occurring at the second converging spot.

Also, because the height H of the relief in the grating pattern is gradually lowered over the entire pattern region, a numerical aperture of the lens means for the transmitted light can be sufficiently heightened.

The third object is achieved by the provision of an optical head apparatus for recording or reproducing a piece of information on or from a thin type of first information medium having a first thickness or a thick type of second information medium having a second thickness larger than the first thickness, comprising:

a light source for radiating a beam of incident light;

hologram means for transmitting a part of the incident light radiated from the light source without any diffraction on an outgoing path to form a beam of transmitted light and diffracting a remaining part of the incident light radiated from the light source on the outgoing path to form a beam of diffracted light, the hologram means functioning as a lens for the diffracted light to diverge the diffracted light from the hologram means or converge the diffracted light;

lens means for converging the transmitted light formed in the hologram means at a first focal length on the outgoing path to form a first converging spot at a front surface of the first information medium or converging the diffracted light formed in the hologram means at a second focal length on the outgoing path to form a second converging spot at a front surface of the second information medium, the transmitted light being incident on a rear surface of the first information medium and being converged at the front surface of the first information medium, the transmitted light being reflected at the rear surface of the first information medium and again passing through the lens means and the hologram means on an incoming path, the diffracted light being incident on a rear surface of the second information medium and being converged at the front surface of the second information medium, and the diffracted light being reflected at the rear surface of the first information medium and again passing through the lens means and the hologram means on the incoming path;

wavefront changing means for changing a wavefront of the transmitted light or the diffracted light passing through the lens means and the hologram means on the incoming path to form one or more beams of information light; and

detecting means for detecting intensities of the information light formed by the wavefront changing means and generating an information signal according to the intensities of the information light, the information signal expressing a piece of information recorded on the first information medium or the second information medium.

In the above configuration, a beam of incident light is radiated from the light source, and a part of the incident light transmits through the hologram lens to form a beam of transmitted light. Also, a remaining part of the incident light is diffracted by the hologram lens to form a beam of diffracted light. Thereafter, the transmitted light and the diffracted light are converged by the converging means. In cases where a piece of information is recorded or reproduced on or from the first information medium, the transmitted light is incident on the rear surface of the first information medium and is converged at the front surface of the first information medium to form the first converging spot. Thereafter, the transmitted light is reflected at the rear surface of the first information medium and again passes through the lens means and the hologram means without any diffraction. In contrast, in cases where a piece of information is recorded or reproduced on or from the second information medium, the diffracted light is incident on the rear surface of the second information medium and is converged at the front surface of the second information medium to form the second converging spot. Thereafter, the diffracted light is reflected at the rear surface of the second information medium and again

passes through the lens means. Thereafter, the diffracted light is again diffracted by the hologram means.

Thereafter, a wavefront of the transmitted light or the diffracted light is changed by the wavefront changing means to form a plurality of beams of reflected light, and the intensities of the reflected light is detected by the detecting means. Therefore, an information signal expressing the information recorded on the first or second information medium is generated according to the intensities of the reflected light.

Accordingly, because the first converging spot of the transmitted light differs from the second converging spot of the diffracted light, a compound objective lens composed of the hologram lens and the lens means has two focal points. Therefore, a piece of information can be recorded or reproduced on or from an information medium regardless of whether the information medium has the first thickness or the second thickness.

The third object is also achieved by the provision of an optical head apparatus for recording or reproducing a piece of information on or from a first information medium having a first thickness T1 or a second information medium having a second thickness T2 (T1<T2), comprising:

lens means for converging a beam of first incident light on a front surface of a first information medium having a first thickness T1 or converging a beam of second incident light on a front surface of a second information medium having a second thickness T2 (T2<T1), the first incident light passing through the first information medium from its rear surface, and the second incident light passing through the second information medium from its rear surface;

aperture limiting means for selectively limiting an aperture of the lens means for the second incident light which is incident on the lens means, a second numerical aperture of the lens means for the second incident light which is incident on the lens means being lower than a first numerical aperture of the lens means for the first incident light which is incident on the lens means, the first incident light being reflected at the front surface of the first information medium and again passing through the lens means and the aperture limiting means on an incoming path, and the second incident light being reflected at the front surface of the second information medium and again passing through the lens means and the aperture limiting means on the incoming path;

a light source for radiating the first incident light and the second incident light to the aperture limiting means;

wavefront changing means for changing a wavefront of the first or second incident light passing through the lens means and the aperture limiting means on the incoming path to form one or more beams of information light; and

detecting means for detecting intensities of the information light formed by the wavefront changing means and generating an information signal according to the intensities of the information light, the information signal expressing a piece of information recorded on the first information medium or the second information medium.

In the above configuration, a compound objective lens composed of the lens means and the aperture limiting means has two focal points, and the intensity of the first incident light is larger than that of the second incident light.

Accordingly, a piece of information can be recorded or reproduced on or from an information medium regardless of whether the information medium has the first thickness or the second thickness. Also, a piece of information can be efficiently recorded on the first information medium with the first incident light having a high intensity, and a piece of information can be efficiently reproduced from the second information medium with the second incident light having a comparatively low intensity.

The third object is also achieved by the provision of an optical head apparatus for recording or reproducing a piece of information on or from a first information medium having a first thickness or a second information medium having a second thickness, comprising:

lens means for converging a beam of first incident light on a front surface of the first information medium and converging a beam of second incident light on a front surface of the second information medium, the first incident light passing through the first information medium from its rear surface, and the second incident light passing through the second information medium from its rear surface; and

curvature changing means for changing a curvature of spherical waves of a part of incident light to form the first incident light which is incident on the lens means and not changing a curvature of spherical waves of a remaining part of incident light to form the second incident light which is incident on the lens means, the first incident light being reflected at the front surface of the first information medium and again passing through the lens means and the curvature changing means on an incoming path, and the second incident light being reflected at the front surface of the second information medium and again passing through the lens means and the curvature changing means on the incoming path;

a light source for radiating the incident light to the curvature changing means;

wavefront changing means for changing a wavefront of the first or second incident light passing through the lens means and the curvature changing means on the incoming path to form one or more beams of information light; and

detecting means for detecting intensities of the information light formed by the wavefront changing means and generating an information signal according to the intensities of the information light, the information signal expressing a piece of information recorded on the first information medium or the second information medium.

In the above configuration, because a compound objective lens is composed of the lens means and the curvature changing means, the compound objective lens has two focal points. Accordingly, a piece of information can be recorded or reproduced on or from an information medium regardless of whether the information medium has the first thickness or the second thickness.

The fourth object is achieved by the provision of an optical disk, comprising:

an information recording substrate partitioned into a first region and a second region, the first region having a first thickness, and the second region

having a second thickness smaller than the first thickness;

a plurality of first recording pits placed at the first region of the information recording substrate for recording pieces of recording information at a high recording density, the first recording pits being formed at narrow intervals; and

a plurality of second recording pits placed at the second region of the information recording substrate for recording pieces of distinguishing information at an ordinary recording density of a compact disk, the distinguishing information informing that the recording information are recorded on the information recording substrate having the first thickness, and the recording density of the recording information being higher than that of the distinguishing information.

In the above configuration, a substrate of a conventional compact disk has the same second thickness as that of the second region of the information recording substrate in the optical disk according to the present invention. Therefore, in cases where a beam of reproducing light is incident on a prescribed region of an unknown disk selected from a group of the conventional compact disk and the optical disk, the reproducing light is focused on a recording pit of the conventional compact disk or one of the second recording pits of the optical disk regardless of whether the unknown disk is the conventional compact disk or the optical disk.

In cases where the unknown disk is the optical disk, a piece of distinguishing information is read by the reproducing light. Because the distinguishing information informs that pieces of recording information are recorded on the information recording substrate having the first thickness, a curvature of the reproducing light is automatically changed to focus the reproducing light on the information recording substrate having the first thickness, and the reproducing light is automatically focused on one of the first recording pits. Therefore, a piece of recording information is reproduced.

In contrast, in cases where the unknown disk is the conventional compact disk, a piece of recording information is read by the reproducing light in the same manner as in a prior art.

Accordingly, a piece of recording information formed on an information recording substrate can be reliably reproduced even though the thickness of the information recording substrate is unknown.

The fourth object is also achieved by the provision of an optical disk, comprising:

an information recording substrate having a thin thickness, the thin thickness of the information recording substrate being thinner than that of a compact disk;

a plurality of first recording pits placed at a first region of the information recording substrate for recording pieces of recording information at a high recording density, the first recording pits being formed at narrow intervals; and

a plurality of second recording pits placed at a second region of the information recording substrate for recording pieces of distinguishing information at a low recording density, the distinguishing information informing that the recording information are recorded on the information recording substrate having the thin thickness, the recording density of the recording information being higher than that of the distinguishing information, each of the second recording pits being larger than that of a recording pit in the compact disk, and a converging spot of a beam of reproducing light, which is converged to focus on an ordinary recording pit formed on a substrate having an ordinary thickness of the compact disk, being formed in one of the second recording pits to read the distinguishing information.

In the above configuration, a beam of reproducing light, of which a curvature is adjusted to focus the reproducing light on a recording pit formed on an information recording substrate of the compact disk, is incident on a prescribed region of an unknown disk selected from a group of the compact disk having an ordinary thickness and the optical disk according to the present invention, In cases where the unknown disk is the optical disk, the reproducing light is converged on one of the second recording pits in defocus because the information recording substrate of the optical disk has the thin thickness. However, because each of the second recording pits is large in size, a converging spot of the reproducing light is formed in the second recording pit. Therefore, a piece of distinguishing information is read by the reproducing light. Because the distinguishing information informs that pieces of recording information are recorded on the information recording substrate having the thin thickness, a curvature of the reproducing light is automatically changed to focus the reproducing light on the information recording substrate having the thin thickness, and the reproducing light is automatically focused on one of the first recording pits. Therefore, a piece of recording information is reproduced.

In contrast, in cases where the unknown disk is the compact disk, a piece of recording information is read by the reproducing light in the same manner as in a prior art.

Accordingly, a piece of recording information formed on an information recording substrate can be reliably reproduced even though the thickness of the information recording substrate is unknown.

The fifth object is achieved by the provision of an optical disk apparatus for recording or reproducing pieces of recording information on or from an optical disk in which the recording information are recorded or reproduced at a high density on or from a first substrate having a first thickness and a piece of distinguishing information informing that the recording information are recorded or reproduced on or from the first substrate having the first thickness is recorded at an ordinary density on a second substrate having a second thickness larger than the first thickness, comprising:

rotating means for rotating the optical disk at a regular speed;

a light source for radiating a beam of incident light;

hologram means for transmitting a part of the incident light radiated from the light source without any diffraction on an outgoing path to form a beam of transmitted light and diffracting a remaining part of the incident light radiated from the light source on the outgoing path to form a beam of diffracted light, the hologram means functioning as a lens for the diffracted light to diverge the diffracted light from the hologram means;

lens means for converging the transmitted light formed in the hologram means on the first substrate of the optical disk rotated by the rotating means to record or reproduce a piece of recording informa-

tion on or from the optical disk and converging the diffracted light formed in the hologram means on the second substrate of the optical disk rotated by the rotating means to reproduce the distinguishing information from the optical disk, the transmitted light being reflected by the first substrate of the optical disk and again passing through the lens means and the hologram means on an incoming path, and the diffracted light being reflected by the second substrate of the optical disk and again passing through the lens means and the hologram means on the incoming path;

wavefront changing means for changing a wavefront of the transmitted light passing through the lens means and the hologram means on the incoming path to form one or more beams of recording information light and changing a wavefront of the diffracted light passing through the lens means and the hologram means on the incoming path to form one or more beams of distinguishing information light;

detecting means for detecting intensities of the recording information light formed by the wavefront changing means to generate a recording information signal according to the intensities of the recording information light and detecting intensities of the distinguishing information light formed by the wavefront changing means to generate a distinguishing information signal according to the intensities of the distinguishing information light, the distinguishing information signal expressing the distinguishing information recorded on the second substrate of the optical disk, and the recording information signal expressing the recording information recorded on the first substrate of the optical disk; and

moving means for moving an optical head apparatus comprising the light source, the hologram means, the lens means and the detecting means to converge the diffracted light formed in the hologram means on the second substrate of the optical disk and moving the optical disk, in which the diffracted light formed in the hologram means is converged on the second substrate of the optical disk, to converge the transmitted light formed in the hologram means on the first substrate of the optical disk in cases where the distinguishing information is detected in the detecting means.

In the above configuration, an optical head apparatus comprising the light source, the hologram means, the lens means and the detecting means has the same configuration as that described before. Initially, the optical head apparatus is moved by the moving means to converge in focus the diffracted light formed in the hologram means on the second substrate of the optical disk rotated by the rotating means. Therefore, the distinguishing information recorded on the second substrate is reproduced in the detecting means, and it is informed that pieces of recording information are recorded or reproduced on or from the first substrate having the first thickness. Thereafter, the optical head apparatus is moved by the moving means to converge in focus the transmitted light formed in the hologram means on the first substrate of the optical disk rotated by the rotating means. Therefore, a piece of recording information is recorded or reproduced on or from the first substrate of the optical disk.

Accordingly, even though a high density type of optical disk, in which pieces of recording information is recorded or reproduced on or from the substrate having the first thickness smaller than the second thickness of a conventional optical disk, is utilized, the recording information can be reliably recorded or reproduced.

The fifth object is also achieved by the provision of an optical disk apparatus for recording or reproducing pieces of recording information on or from an optical disk in which the recording information are recorded or reproduced at a high density on or from a first substrate having a thin thickness thinner than that of a compact disk and a piece of distinguishing information informing that the recording information are recorded or reproduced on or from the first substrate having the thin thickness is recorded at a low density on a second substrate having the thin thickness, comprising:

rotating means for rotating the optical disk at a regular speed;

a light source for radiating a beam of incident light;

hologram means for transmitting a part of the incident light radiated from the light source without any diffraction on an outgoing path to form a beam of transmitted light and diffracting a remaining part of the incident light radiated from the light source on the outgoing path to form a beam of diffracted light, the hologram means functioning as a lens for the diffracted light to diverge the diffracted light from the hologram means;

lens means for converging in focus the transmitted light formed in the hologram means on the first substrate of the optical disk rotated by the rotating means to record or reproduce a piece of recording information on or from the optical disk and converging in defocus the diffracted light formed in the hologram means on the second substrate of the optical disk rotated by the rotating means to reproduce the distinguishing information from the optical disk, the transmitted light being reflected by the first substrate of the optical disk and again passing through the lens means and the hologram means on an incoming path, and the diffracted light being reflected by the second substrate of the optical disk and again passing through the lens means and the hologram means on the incoming path;

wavefront changing means for changing a wavefront of the transmitted light passing through the lens means and the hologram means on the incoming path to form one or more beams of recording information light and changing a wavefront of the diffracted light passing through the lens means and the hologram means on the incoming path to form one or more beams of distinguishing information light;

detecting means for detecting intensities of the recording information light formed by the wavefront changing means to generate a recording information signal according to the intensities of the recording information light and detecting intensities of the distinguishing information light formed by the wavefront changing means to generate a distinguishing information signal according to the intensities of the distinguishing information light, the distinguishing information signal expressing the distinguishing information recorded on the second substrate of the optical disk, and the recording information signal expressing the recording infor-

mation recorded on the first substrate of the optical disk; and

moving means for moving an optical head apparatus comprising the light source, the hologram means, the lens means and the detecting means, to converge the diffracted light formed in the hologram means in defocus on the second substrate of the optical disk and moving the optical disk, in which the diffracted light formed in the hologram means is converged on the second substrate of the optical disk in defocus, to converge the transmitted light formed in the hologram means on the first substrate of the optical disk in focus in cases where an intensity of the distinguishing information signal generated in the detecting means is larger than a threshold value.

In the above configuration, an optical head apparatus comprising the light source, the hologram means, the lens means and the detecting means has the same configuration as that described before. Initially, the optical head apparatus is moved by the moving means to converge in defocus the diffracted light formed in the hologram means on the second substrate of the optical disk rotated by the rotating means. In this case, because the distinguishing information is recorded at a low density, a plurality of recording pits expressing the distinguishing information are respectively large in size. Therefore, even though the diffracted light is converged on each of the recording pits in defocus, a converging spot of the diffracted light is formed in each of the recording pits. Therefore, the distinguishing information recorded on the second substrate is reproduced in the detecting means, and it is informed that pieces of recording information are recorded or reproduced on or from the first substrate having the thin thickness. Thereafter, the optical head apparatus is moved by the moving means to converge in focus the transmitted light formed in the hologram means on the first substrate of the optical disk rotated by the rotating means. Therefore, a piece of recording information is recorded or reproduced on or from the first substrate of the optical disk.

Accordingly, even though a high density type of optical disk, in which pieces of recording information are recorded or reproduced on or from the substrate having the thin thickness smaller than an ordinary thickness of a conventional optical disk, is utilized, the recording information can be reliably recorded or reproduced.

The sixth object is achieved by the provision of a binary focus microscope for simultaneously observing a first image put on a first image plane and a second image put on a second image plane, comprising:

an objective lens for refracting a beam of first light diverging from the first image and a beam of second light diverging from the second image, a first distance between the objective lens and the first image of the first image plane differing from a second distance between the objective lens and the second image of the second image plane;

a hologram lens for transmitting the first light refracted by the objective lens without any diffraction to form a beam of transmitted light and diffracting the second light refracted by the objective lens to form a beam of diffracted light, the hologram lens functioning as a lens for the second light to pass the diffracted light through the same optical path as the transmitted light passes through, and a beam of superposed light being formed of the transmitted light and the diffracted light;

an inner lens for converging the superposed light formed by the hologram lens at an image point of a third image plane to simultaneously form the first image and the second image enlarged on the third image plane; and

an ocular lens for converging the superposed light which is converged by the inner lens and diverges from the image point to simultaneously form the first image and the second image moreover enlarged.

In the above configuration, a beam of first light diverging from the first image and a beam of second light diverging from the second image are refracted together by the objective lens. In this case, because a first distance between the objective lens and the first image of the first image plane differs from a second distance between the objective lens and the second image of the second image plane, a curvature of the first light refracted differs from another curvature of the second light refracted. Thereafter, the first light refracted transmits through the hologram lens without any diffraction to form a beam of transmitted light, and the second light refracted is diffracted by the hologram lens to form a beam of diffracted light. In this case, because the hologram lens functions as a lens for the diffracted light, a curvature of the diffracted light agrees with that of the transmitted light. In other words, the diffracted light passes through the same optical path as the transmitted light passes through. Therefore, a beam of superposed light is formed of the transmitted light and the diffracted light. Thereafter, the superposed light is converged by the inner lens at an image point of a third image plane, so that the first image and the second image enlarged are simultaneously formed on the third image plane. Thereafter, the superposed light diverging from the image point is converged by the ocular lens, so that the first image and the second image moreover enlarged are simultaneously formed.

Accordingly, an operator can observe the first image and the second image sufficiently enlarged.

The sixth object is also achieved by the provision of a binary focus microscope for simultaneously observing a first image put on a first image plane and a second image put on a second image plane, comprising:

an objective lens for refracting a beam of first light diverging from the first image and a beam of second light diverging from the second image, a first distance between the objective lens and the first image of the first image plane differing from a second distance between the objective lens and the second image of the second image plane;

a hologram lens for transmitting the first light refracted by the objective lens without any diffraction to form a beam of transmitted light and diffracting the second light refracted by the objective lens to form a beam of diffracted light, the hologram lens functioning as a lens for the second light to pass the diffracted light through the same optical path as the transmitted light passes through, and a beam of superposed light being formed of the transmitted light and the diffracted light;

an inner lens for converging the superposed light formed by the hologram lens at an image point of a third image plane to simultaneously form the first image and the second image enlarged on the third image plane; and

photographing means for photographing a superposed image formed of the first and second images enlarged on the third image plane by converging the superposed light in the inner lens.

In the above configuration, the first image and the second image enlarged are simultaneously formed on the third image plane in the same manner. Thereafter, the first image and the second image enlarged are photographed by the photographing means as a superposed image.

Accordingly, the first image and the second image enlarged can be observed.

The seventh embodiment is achieved by the provision of an alignment apparatus for aligning a first reference image drawn on a photomask with a second reference image drawn on a sample, comprising:

a light source for radiating beams of alignment light to illuminate the first and second reference images;

an objective lens for refracting both a beam of first alignment light diverging from the first reference image and a beam of second alignment light diverging from the second reference image which are illuminated with the alignment light radiated from the light source, a first distance between the objective lens and the first reference image of the photomask differing from a second distance between the objective lens and the second reference image of the sample;

a hologram lens for transmitting the first alignment light refracted by the objective lens without any diffraction to form a beam of transmitted light and diffracting the second alignment light refracted by the objective lens to form a beam of diffracted light, the hologram lens functioning as a lens for the second alignment light to pass the diffracted light through the same optical path as the transmitted light passes through, and a beam of superposed light being formed of the transmitted light and the diffracted light;

an inner lens for converging the superposed light formed by the hologram lens at an image point of an image plane to simultaneously form the first and second reference images enlarged on the image plane, an optical axis passing through centers of the objective lens, the hologram lens and the inner lens;

photographing means for photographing a superposed image formed of the first and second images enlarged on the image plane by converging the superposed light in the inner lens; and

moving means for moving the photomask or the sample according to the superposed image photographed by the photographing means to align the first reference image with the second reference image along the optical axis.

In the above configuration, the objective lens, the hologram lens and the inner lens are the same as those in the binary focus microscope. Therefore, the first and second images enlarged on the image plane is photographed by the photographing means as a superposed image. Thereafter, the photomask or the sample is moved in a direction perpendicular to the optical axis by the moving means to align the first reference image with the second reference image along the optical axis.

Accordingly, because the superposed image formed of the first and second reference images enlarged is photographed by the photographing means, a relative position between the first and second reference images can be accurately observed. Therefore, the first reference image can be accurately aligned with the second reference image.

The eighth embodiment is achieved by the provision of a focusing method for focusing light on a first information medium having a first thickness or a second information medium having a second thickness to record or reproduce a piece of information on or from the first information medium or the second information medium, comprising the steps of:

moving an optical head apparatus in a direction to decrease or increase the distance between the optical head apparatus and the first or second information medium, the optical head apparatus comprising

a light source for radiating a beam of incident light,

hologram means for transmitting a part of the incident light radiated from the light source without any diffraction on an outgoing path to form a beam of transmitted light and diffracting a remaining part of the incident light radiated from the light source on the outgoing path to form a beam of diffracted light, the hologram means functioning as a lens for the diffracted light to diverge the diffracted light from the hologram means or converge the diffracted light,

lens means for converging the transmitted light formed in the hologram means at a first focal length on the outgoing path to form a first converging spot at a front surface of the first information medium or converging the diffracted light formed in the hologram means at a second focal length on the outgoing path to form a second converging spot at a front surface of the second information medium, the transmitted light being incident on a rear surface of the first information medium and being converged at the front surface of the first information medium, the transmitted light being reflected at the rear surface of the first information medium and again passing through the lens means and the hologram means on an incoming path, the diffracted light being incident on a rear surface of the second information medium and being converged at the front surface of the second information medium, and the diffracted light being reflected at the rear surface of the first information medium and again passing through the lens means and the hologram means on the incoming path,

wavefront changing means for changing a wavefront of the transmitted light or the diffracted light passing through the lens means and the hologram means on the incoming path to form one or more beams of information light, and

detecting means for detecting intensities of the information light formed by the wavefront changing means and generating an information signal and a focus error signal according to the intensities of the information light, the information signal expressing a piece of information recorded on the first information medium or the second information medium;

judging whether or not an intensity of the focus error signal generated in the detecting means is larger than a threshold value; and

adjusting the position of the optical head apparatus to decrease the intensity of the focus error signal to zero when the intensity of the focus error signal becomes larger than the threshold value.

In the above steps, the focusing method is performed by utilizing the optical head apparatus described above. The intensity of the focus error signal is largely increased when the distance between the lens means and the first or second information medium is near to a focal length of the lens means. Therefore, when the intensity of the focus error signal becomes larger than a threshold value, the lens means is placed near to a just-focus point in which the transmitted light or the diffracted light is converged on the first or second information medium in focus.

Accordingly, in cases where the position of the optical head apparatus is adjusted to decrease the intensity of the focus error signal to zero when the intensity of the focus error signal becomes larger than the threshold value, the transmitted light or the diffracted light can be focused on the first or second information medium.

The ninth embodiment is achieved by the provision of an information reproducing method for reproducing a piece of recording information from an optical disk in which the recording information are recorded at a high density on a first substrate having a first thickness and a piece of distinguishing information informing that the recording information are recorded on the first substrate is recorded at an ordinary density on a second substrate having a second thickness larger than the first thickness, comprising the step of:

moving an optical disk apparatus under the second substrate of the optical disk, the optical disk comprising

rotating means for rotating the optical disk at a regular speed,

a light source for radiating a beam of incident light;

hologram means for transmitting a part of the incident light radiated from the light source without any diffraction on an outgoing path to form a beam of transmitted light and diffracting a remaining part of the incident light radiated from the light source on the outgoing path to form a beam of diffracted light, the hologram means functioning as a lens for the diffracted light to diverge the diffracted light from the hologram means,

lens means for converging the transmitted light formed in the hologram means on the first substrate of the optical disk rotated by the rotating means to record or reproduce a piece of recording information on or from the optical disk and converging the diffracted light formed in the hologram means on the second substrate of the optical disk rotated by the rotating means to reproduce the distinguishing information from the optical disk, the transmitted light being reflected by the first substrate of the optical disk and again passing through the lens means and the hologram means on an incoming path, and the diffracted light being reflected by the second substrate of the optical disk and again passing through the lens means and the hologram means on the incoming path,

wavefront changing means for changing a wavefront of the transmitted light passing through the lens means and the hologram means on the incoming path to form one or more beams of recording information light and changing a wavefront of the diffracted light passing through the lens means and the hologram means on the incoming path to form one or more beams of distinguishing information light, and

detecting means for detecting intensities of the recording information light formed by the wavefront changing means to generate a recording information signal according to the intensities of the recording information light and detecting intensities of the distinguishing information light formed by the wavefront changing means to generate a distinguishing information signal according to the intensities of the distinguishing information light, the distinguishing information signal expressing the distinguishing information recorded on the second substrate of the optical disk, and the recording information signal expressing the recording information recorded on the first substrate of the optical disk; and

converging the diffracted light on the second substrate of the optical disk to reproduce the distinguishing information;

moving the optical disk apparatus to a position under the first substrate of the optical disk to converge the transmitted light on the first substrate of the optical disk when the distinguishing information is detected in the detecting means; and

reproducing the recording information by generating the recording information signal in the detecting means.

In the above steps, the information reproducing method is performed by utilizing the optical disk apparatus described above. The distinguishing information placed on the second substrate of the optical disk is reproduce with the diffracted light. In this case, because the second substrate has the second thickness, the diffracted light is just focused on the second substrate. Thereafter, when the distinguishing information is detected, the optical disk apparatus is moved to a position under the first substrate of the optical disk, and the transmitted light is converged on the first substrate of the optical disk. In this case, because the first substrate has the first thickness, the diffracted light is just focused on the first substrate.

Accordingly, the recording information can be reliably reproduced.

BRIEF DESCRIPTION OF THE DRAWINGS

The objects, features and advantages of the present invention will be apparent from the following description taken in conjunction with the accompanying drawings, in which:

FIG. **1** is a constitutional view of a conventional optical head apparatus proposed in Japanese Patent Application No. 46630 of 1991;

FIGS. **2A**, **2B** are respectively a cross sectional view of a set of an objective lens and a blazed hologram shown in FIG. **1**;

FIG. **3** shows a relationship between the thickness of an optical disk and a numerical aperture of an objective lens on condition that the tilt of the optical axis is constant;

FIG. **4A** is a constitutional view of an imaging optical system having a compound objective Lens according to a first embodiment of the present invention, a beam of transmitted light not diffracted being converged on a thin type of information medium;

FIG. **4B** is a constitutional view of the imaging optical system shown in FIG. **4A**, a beam of first-order diffracted light being converged on a thick type of information medium;

FIG. 5 is a plan view of a hologram lens shown in FIGS. 4A, 4B, a grating pattern of the hologram lens being depicted;

FIG. 6 is a cross sectional view of the hologram lens shown in FIG. 5, the grating pattern formed in relief on the hologram lens being shown;

FIG. 7 is an explanatory diagram showing an intensity distribution of transmitted light L4 converged on a converging spot S1 of a first information medium, a primary maximum and secondary maxima suppressed occurring in the converging spot S1;

FIG. 8A is a cross sectional view of the hologram lens shown in FIG. 5, the grating pattern approximating to a step-wise shape composed of four stairs being shown;

FIG. 8B is a cross sectional view of the hologram lens shown in FIG. 5, the grating pattern approximating to a step-wise shape composed of a plurality of stairs being shown;

FIG. 9A is a constitutional view of an imaging optical system having a compound objective lens according to a modification of the first embodiment, a beam of first-order diffracted light being converged on a thin type of information medium;

FIG. 9B is a constitutional view of the imaging optical system shown in FIG. 9A, a beam of transmitted light not diffracted being converged on a thick type of information medium;

FIG. 10A is a constitutional view of an imaging optical system having a compound objective lens according to a second embodiment of the present invention, a beam of transmitted light not diffracted being converged on a thin type of information medium;

FIG. 10B is a constitutional view of the imaging optical system shown in FIG. 10A, a beam of first-order diffracted light being converged on a thick type of information medium;

FIG. 11 shows a change of a diffraction efficiency of a hologram lens shown in FIGS. 10A, 10B;

FIGS. 12A to 12E are respectively a cross sectional view of the hologram lens shown in FIGS. 10A, 10B, the grating pattern of the hologram lens approximating to a step-wise shape;

FIG. 13A shows an intensity distribution of incident light utilized in the second embodiment, a far field pattern of the incident light being distributed in a Gaussian distribution;

FIG. 13B shows an intensity distribution of transmitted light transmitting through a hologram lens shown in FIGS. 10A, 10B, a far field pattern of the incident light being distributed in a gently-sloping shape;

FIGS. 14A to 14C show intensity distributions of transmitted light and diffracted light transmitting through a hologram lens shown in FIGS. 10A, 10B;

FIG. 15A is a plan view of a hologram lens according to a modification of the second embodiment, a grating pattern of the hologram lens being depicted;

FIGS. 15B, 15C are respectively a constitutional view of an imaging optical system having a compound objective lens according to another modification of the second embodiment;

FIG. 16A is a constitutional view of an imaging optical system having a compound objective lens according to a third embodiment of the present invention, a beam of first-order diffracted light being converged on a thin type of information medium;

FIG. 16B is a constitutional view of the imaging optical system shown in FIG. 16A, a beam of transmitted light not diffracted being converged on a thick type of information medium;

FIG. 17 shows a change of a diffraction efficiency of a hologram lens shown in FIGS. 16A, 16B;

FIGS. 18A to 18C show intensity distributions of transmitted light and diffracted light transmitting through a hologram lens shown in FIGS. 16A, 16B;

FIG. 19A is a cross sectional view of a compound objective lens according to a fourth embodiment of the present invention;

FIG. 19B is a cross sectional view of a compound objective lens according to a modification of the fourth embodiment of the present invention;

FIG. 20 is a cross sectional view of a compound objective lens according to a fifth embodiment of the present invention;

FIG. 21 is a constitutional view of an optical head apparatus according to a sixth embodiment of the present invention;

FIG. 22 is a plan view of a wavefront changing device utilized in the six, ninth and twelfth embodiments, a grating pattern of a hologram lens utilized as the wavefront changing device being depicted;

FIG. 23 shows a positional relation between focal points of diffracted light occurring in the wavefront changing device shown in FIG. 22 and a photo detector;

FIG. 24 is a plan view of a photo detector utilized in the six, ninth, tenth, twelfth, thirteenth and seventeenth embodiments;

FIG. 25A and 25C respectively show a converging spot of first-order diffracted light radiated to detecting sections SE1, SE2 and SE3 of a sextant photo-detector shown in FIG. 24 and another converging spot of minus first-order diffracted light radiated to detecting sections SE4, SE5 and SE6 of the sextant photo-detector on condition that an objective lens shown in FIG. 21 is defocused on an information medium;

FIG. 25B shows a converging spot of first-order diffracted light radiated to the detecting sections SE1, SE2 and SE3 of the sextant photo-detector and another converging spot of minus first-order diffracted light radiated to the detecting sections SE4, SE5 and SE6 of the sextant photo-detector on condition that the objective lens is just focused on the information medium;

FIG. 26 shows a relationship between beams of diffracted light occurring in the wavefront changing device shown in FIG. 22 and the photo detector shown in FIG. 24;

FIG. 27 is a constitutional view of an optical head apparatus according to a seventh embodiment;

FIG. 28 is a plan view of a photo detector utilized in the seven, ninth, tenth, twelfth and thirteenth embodiments;

FIGS. 29A, 29B, 29C show various shapes of converging spots converged on the photo detector shown in FIG. 28;

FIG. 29D shows a radial direction Dr and a tangential direction Dt;

FIG. 30 is a constitutional view of an optical head apparatus according to a first modification of the seventh embodiment;

FIG. 31 is a constitutional view of an optical head apparatus according to a second modification of the seventh embodiment;

FIG. 32 is a constitutional view of an optical head apparatus according to a third modification of the seventh embodiment;

FIG. 33 is a constitutional view of an optical head apparatus according to a forth modification of the seventh embodiment;

FIG. 34 shows a beam of transmitted light not diffracted on an incoming optical path and a beam of transmitted light diffracted on the incoming optical path, the beams being utilized to detect an information signal;

FIG. 35A graphically shows a change of a focus error signal obtained by detecting the intensity of transmitted light, the strength of the focus error signal depending on a distance between an objective lens and a first information medium;

FIG. 35B graphically shows a change of a focus error signal obtained by detecting the intensity of diffracted light, the strength of the focus error signal depending on a distance between an objective lens and a second information medium.

FIG. 62 is a constitutional view of an alignment apparatus according to a twenty-third embodiment.

DETAIL DESCRIPTION OF THE PREFERRED EMBODIMENTS

Preferred embodiments of a compound objective lens, an imaging optical system, an optical head apparatus, an optical disk, an optical disk apparatus, a binary focus microscope and an alignment apparatus according to the present invention are described with reference to drawings.

(First Embodiment)

FIG. 4A is a constitutional view of an imaging optical system having a compound objective lens according to a first embodiment of the present invention, a beam of transmitted light not diffracted being converged on a thin type of information medium. FIG. 4B is a constitutional view of the imaging optical system shown in FIG. 4A, a beam of first-order diffracted light being converged on a thick type of information medium. FIG. 5 is a plan view of a hologram lens shown in FIGS. 4A, 4B, a grating pattern of the hologram lens being depicted.

As shown in FIGS. 4A, 4B, an imaging optical system 21 for converging light on a first substrate 22 of a thin type of first information medium 23 (a thickness T1) or a second substrate 24 of a thick type of second information medium 25 (a thickness T2) to form a diffraction-limited converging spot comprises a blazed hologram lens 26 for transmitting a part of incident light

L3 radiated from a light source without any diffraction to form a beam of transmitted light L4 and diffracting a remaining part of the incident light L3 to form a beam of first-order diffracted light L5, and an objective lens 27 for converging the transmitted light L4 on the first information medium 23 or converging the first-order diffracted light L5 on the second information medium 25.

The first information medium 23 represents a prospective optical disk having a high density memory capacity, and the thickness T1 of the first information medium 23 ranges from 0.4 mm to 0.8 mm. The second information medium 25 represents a compact disk or a laser disk appearing on the market now, and the thickness T2 of the second information medium 25 is about 1.2 mm.

The term "convergence" denotes in this specification that divergent light or collimated light is focused to form a diffraction-limited micro spot.

In the above configuration, a part of incident light L3 collimated transmits through the hologram lens 26 without any diffraction, and a beam of transmitted light L4 (that is, a beam of zero-order diffracted light L4) is formed. Thereafter, the transmitted light L4 is converged by the objective lens 27. Also, a remaining part of the incident light L3 is diffracted and refracted by the hologram lens 26, and a beam of first-order diffracted light L5 is formed. In this case, the hologram lens 26 selectively functions as a concave lens for the first-order diffracted light L5, so that the first-order diffracted light L5 diverges from the hologram lens 26. Thereafter, the first-order diffracted light L5 is converged by the objective lens 27.

In cases where the thin type of first information medium 23 is utilized to record or reproduce pieces of information on or from a front surface of the medium 23, as shown in FIG. 4A, the transmitted light L4 is incident on a rear surface of the first information medium 23 and is focused on its front surface by the objective lens 27 to form a diffraction-limited converging spot S1 on the first information medium 23. In contrast, in cases where the thick type of second information medium 25 is utilized to record or reproduce pieces of information on or from a front surface of the medium 25, the diffracted light L5 is incident on a rear surface of the second information medium 25 and is focused on its front surface to form a diffraction-limited converging spot S2 on the second information medium 25. Because the hologram lens 26 functions as a concave lens to diverge the first-order diffracted light L5, the diffraction-limited converging spots S1, S2 are formed even though the thickness T1 of the first information medium 23 differs from the thickness T2 of the second information medium 25. Therefore, a compound objective lens 29 composed of the hologram lens 26 and the objective lens 27 has substantially two focal points.

As shown in FIG. 5, the hologram lens 26 is formed by drawing a grating pattern P1 in a pattern region 26A of a transparent substrate 28 in a concentric circle shape. The pattern region 26A is positioned in a center portion of the transparent substrate 28, and a no-pattern region 26B is positioned in a peripheral portion of the transparent substrate 28 to surround the pattern region 26A. An optical axis of the imaging optical system 21 passes through a central point of the grating pattern P1 and a central axis of the objective lens 27.

In addition, as shown in FIG. 6, the grating pattern P1 of the hologram lens 26 is formed in relief to produce a phase modulation type of hologram lens. That is, blocks which each are composed of a bottom portion and a top portion are concentrically formed in the grating pattern P1. The height H of the relief in the grating pattern P1 is set to:

$$H<\lambda/(n(\lambda)-1), \quad (1)$$

where the symbol λ denotes a wavelength of the incident light L3 and the symbol $n(\lambda)$ denotes a refractive index of the transparent substrate 28 for the incident light L3. In this case, a difference in phase modulation degree between the incident light L3 transmitting through a bottom portion of the grating pattern P1 and the incident light L3 transmitting through a top portion of the grating pattern P1 is lower than 2π radians. Therefore, a diffraction efficiency of the hologram lens 26 for the incident light L3 transmitting through the grating pattern P1 is less than 100% to generate the light L4 transmitting through the grating pattern P1. Also, the incident light L3 transmitting through the no-pattern region 26B is not diffracted. As a result, the intensity of the transmitted light L4 can be sufficient to record or reproduce pieces of information on or from the first information medium 23.

Also, because the intensity of the transmitted light L4 is sufficient over the entire surface of the hologram lens 26, secondary maxima (side lobes) of the transmitted light L4 undesirably occurring in the converging spot S1 can be suppressed. In detail, as an intensity distribution of the transmitted light L4 converged on the converging spot S1 is shown in FIG. 7, a primary maximum (a main lobe) of the transmitted light L4 positioned in a center of the converging spot S1 is utilized to record or reproduce a piece of information on or from the first information medium 23, and secondary maxima positioned around the primary maximum are unnecessary because the secondary maxima deteriorate a recording pit or a reproducing signal formed by the primary maximum.

The grating pattern P1 of hologram lens 26 formed in relief is blazed as shown in FIG. 6, so that the occurrence of minus first-order diffracted light is considerably suppressed. Therefore, the intensity sum of the transmitted light L4 and the first-order diffracted light L5 is maximized. In other words, a utilization efficiency of the incident light L3 is enhanced.

The numerical aperture NA of the objective lens 27 is equal to or more than 0.6. Also, when the transmitted light L4 is converged by the objective lens 27, the diffraction-limited converging spot S1 is formed on the first information medium 23 having a thickness T1.

A diameter of the hologram lens 26 is almost the same as an aperture of the objective lens 27, so that a diameter of the pattern region 26A is smaller than the aperture of the objective lens 27. Because the incident light L3 transmitting through the no-pattern region 26B is not diffracted, not only the light L4 transmitting through the pattern region 26A but also the light L4 transmitting through the no-pattern region 26B are converged on the first information medium 23 by the objective lens 27 having a high numerical aperture. Therefore, the intensity of the transmitted light L4 converged at the converging point S1 can be increased. In contrast to the transmitted light L4, only the incident light L3 transmitting through the pattern region 26A of the hologram lens 26 is changed to the first-order diffracted light L5, and the first-order diffracted light L5 is converged on

the second information medium **25** by the objective lens **27** having substantially a low numerical aperture.

The phase of the light **L4** transmitting through the grating pattern **P1** of the pattern region **26A** is determined by an average value of the phase modulation degrees in the light **L4** transmitting through the bottom and top portions of the grating pattern **P1**. In contrast, because the height of the no-pattern region **26B** is constant, the phase of the light **L4** transmitting through the no-pattern region **26B** is modulated at a phase modulation degree. Therefore, as shown in FIG. **6**, the height of the no-pattern region **26B** is set even with an average height of the grating pattern **P1** to enhance the convergence function of the objective lens **27**.

For example, as shown in FIG. **8A**, in cases where each block of the grating pattern **P1** in the hologram lens **26** shown in FIG. **6** approximates to a step-wise shape composed of four stairs, a first step is etched at a depth $h1+h2$ and a width **W1**, a second step is etched at a depth **h1** and a width **W2**, a third step is etched at a depth **h2** and a width **W2**, and a fourth step is etched at a width **W1**. Therefore, the grating pattern **P1** approximating to the step-wise shape is formed in the pattern region **26A**. Thereafter, a peripheral portion of the transparent substrate **28** is etched by a depth **h1** or **h2** to form the no-pattern region **26B**. Therefore, the height of the no-pattern region **26B** is almost the same as an average height of the pattern region **26A**, so that the phase of the light **L4** transmitting through the pattern region **26A** is almost the same as that of the light **L4** transmitting through the no-pattern region **26B**.

In addition, as shown in FIG. **8B**, an ideal blazed shape of the hologram lens **26** shown in FIG. **6** can approximate to a step-wise shape which is obtained by etching a center portion of the transparent substrate **28** many times. In this case, the height **H0** of the step-wise shape is set to satisfy an equation $H0<\lambda/(n(\lambda)-1)$ so that the difference in phase modulation degree is set to a value lower than 2π radians. Specifically, in cases where the step-wise shape of the hologram lens **26** is composed of a flight of N stairs having the same difference n_0 in level, the difference n_0 in level is set to satisfy an equation $n_0<\lambda/\{(n(\lambda)-1)*N\}$ to set the difference in phase modulation degree of each stairs to a value lower than $2\pi/N$ radians. A peripheral portion of the transparent substrate **28** is etched to set the thickness of the no-pattern region **26B** to a thickness of the pattern region **26A** at one of the N stairs which is not the top stair or the bottom stair. Therefore, the height of the no-pattern region **26B** is almost the same as an average height of the pattern region **26A**, so that the phase of the light **L4** transmitting through the pattern region **26A** is almost the same as that of the light **L4** transmitting through the no-pattern region **26B**.

The grating pattern **P1** of the hologram lens **26** is designed to correct any aberration occurring in the objective lens **27** and the second information medium **25**, so that the first-order diffracted light **L5** transmits through the second information medium **25** having a thickness **T2** and is converged on the medium **25** to form the diffraction-limited converging spot **S2** without any aberration. A method for designing the hologram lens **26** having an aberration correcting function is described.

After the first-order diffracted light **L5** is converged on the second information medium **25**, spherical waves diverge from the converging spot **S2** and transmit through the second substrate **24** and the objective lens **27**. Thereafter, the spherical waves transmit through the transparent substrate **28** and optically interfere with the incident light **L3**. Therefore, an interference pattern is formed by the interference between the spherical waves and the incident light **L3**. The interference pattern can be calculated by subtracting the phase of the spherical waves from an inverted phase obtained by inverting the phase of the incident light **L3**. Accordingly, the grating pattern **P1** of the hologram lens **26** which agrees with the interference pattern calculated can be easily formed according to a computer generated hologram technique.

Accordingly, because the compound objective lens **29** is composed of the objective lens **27** and the hologram lens **26** in which a part of the incident light **L3** is diffracted and refracted, a diffraction-limited converging spot can be reliably formed on an information medium regardless of whether the information medium has a thickness **T1** or a thickness **T2**. Also, two diffraction-limited converging spots can be simultaneously formed on an information medium at difference depths. In other words, the compound objective lens has substantially two focal points.

Also, because the diffraction efficiency of the hologram lens **26** is less than 100% and the intensity of the light **L4** transmitting through the hologram lens **26** is sufficient to record or reproduce information on or from the first information medium **23**, the secondary maxima of the transmitted light **L4** converged on the converging spot **S1** can be suppressed.

Also, because the hologram lens **26** is blazed, the occurrence of minus first-order diffracted light can be considerably suppressed. Therefore, the intensity sum of the transmitted light **L4** and the first-order diffracted light **L5** can be maximized, and a utilization efficiency of the incident light **L3** can be enhanced.

Also, because the hologram lens **26** functions as a lens only for the first-order diffracted light, the position of the converging point **S1** formed by the transmitted light **L4** differs from that of the converging point **S2** formed by the first-order diffracted light **L5** in an optical axis direction. Therefore, when the transmitted light **L4** is converged in focus on an information recording plane of the information medium **23** to record or read a piece of information, the first-order diffracted light **L5** converged on the information medium **23** is out of focus at the information recording plane. In the same manner, when the first-order diffracted light **L5** is converged in focus on an information recording plane of the information medium **25**, the transmitted light **L4** converged on the information medium **25** is out of focus at the information recording plane. Accordingly, when the light **L4** (or **L5**) is converged on the converging spot **S1** (or **S2**) in focus to record or read the information, the light **L5** (or **L4**) not converged on the converging spot **S1** (or **S2**) in focus does not adversely influence on the recording or reading of the information. To reliably prevent the adverse influence on the recording or reading of the information, a difference in the optical axis direction between the converging spots **S1**, **S2** is required to be equal to or more than 50 μm. That is, when the difference is equal to or more than 50 μm, the light **L5** (or **L4**) largely diverges to reduce the intensity of the light **L5** (or **L4**) at an information recording plane when the light **L4** (or **L5**) is converged on the converging spot **S1** (or **S2**) of the information recording plane at a high intensity.

Also, because the thickness T2 of the second information medium **25** representing the compact disk or the laser disk is about 1.2 mm and because the thickness T1 of the first information medium **23** representing a prospective optical disk ranges from 0.4 mm to 0.8 mm, the difference in the optical axis direction between the converging points **S1**, **S2** is required to be equal to or less than 1.0 mm by considering a moving range of an actuator with which the position of the compound objective lens **29** composed of the objective lens **27** and the hologram lens **26** is adjusted according to a focus servo signal. Because the hologram lens **26** functions as a concave lens for the first-order diffracted light, the difference between the converging points **S1**, **S2** can be increased to about 1 mm.

Accordingly, even though the transmitted light **L4** and the first-order diffracted light **L5** are simultaneously converged by the objective lens **27**, no adverse influence is exerted on the recording or reproduction of the information on condition that the difference between the converging points **S1**, **S2** ranges from 50 μm to 1 mm.

Examples of the utilization of the imaging optical system **21** for various types of optical disks are described.

In cases where the image optical system **21** is utilized for an optical disk device in which pieces of information recorded in a thin type of high density optical disk and a thick type of compact disk are exclusively reproduced, the diffraction efficiency of the hologram lens **26** for changing the incident light **L3** to the diffracted light **L5** is set in a range from about 20% to 70%. In this case, the intensity of the transmitted light **L4** converged on the high density optical disk is almost the same as that of the first-order diffracted light **L5** converged on the compact disk. Therefore, the output power of the incident light **L3** can be minimized.

Also, in cases where the image optical system **21** is utilized for an optical disk device in which pieces of information recorded in a thin type of high density optical disk are recorded or reproduced and pieces of information recorded in a thick type of optical disk are exclusively reproduced, the diffraction efficiency of the hologram lens **26** for changing the incident light **L3** to the first-order diffracted light **L5** is set to a value equal to or lower than 30%. In this case, even though a high intensity of transmitted light **L4** is required to record a piece of information on the high density optical disk, the recording of the information can be reliably performed without increasing the intensity of the incident light **L3** because a transmission efficiency of the hologram lens **26** for the incident light **L3** is high. In other words, a utilization efficiency of the incident light **L3** can be enhanced when a piece of information is recorded on the high density optical disk, so that the output power of the incident light **L3** can be minimized.

In the first embodiment, the hologram lens **26** functions as a concave lens for the first-order diffracted light LS. However, it is applicable that a hologram lens **26M** functioning as a convex lens for the first-order diffracted light **L5** be utilized in place of the hologram lens **26**. That is, as shown in FIGS. **9A**, **9B**, the diffracted light **L5** is converged on the first information medium **23** by the objective lens **27** to form the diffraction limited converging spot **S1**, and the transmitted light **L4** is converged on the second information medium **25** by the objective lens **27** to form the diffraction limited converging spot **S2**. In this case, the difference between the converging points **S1**, **S2** is required to be equal to or less than 0.5 mm by considering the moving range of the actuator. However, the occurrence of a chromatic aberration can be prevented in an imaging optical system **21M** in which the hologram lens **26M** functioning as a concave lens for the diffracted light **L5** is utilized. The achromatization function in the imaging optical system is described in detail.

When a focal length of the hologram lens **26M** for the incident light **L3** having a wavelength λ is represented by f_{H0} and another focal length of the hologram lens **26M** for the incident light **L3** having a wavelength λ_1 is represented by f_{H1}, an equation (2) is satisfied.

$$f_{H1}=f_{H0}\times\lambda_0/\lambda_1 \tag{2}$$

The focal length f_h of the hologram lens **22** is shortened as the wavelength λ of the incident light **L3** becomes longer. Also, when a refractive index of the objective lens **27** for the incident light **L3** having a wavelength λ_0 is represented by $n(\lambda_0)$ and another refractive index of the objective lens **27** for the incident light **L3** having a wavelength λ_1 is represented by $n(\lambda_1)$, a focal length $f_D(\lambda)$ of the objective lens **27** for the incident light **L3** having a wavelength λ is formulated by an equation (3).

$$f_D(\lambda_1)=f_D(\lambda_0)\times(n(\lambda_0)-1)/(n(\lambda_1)-1) \tag{3}$$

The focal length $f_D(\lambda)$ of the objective lens **27** is lengthened as the wavelength λ of the incident light **L3** becomes longer. That is, the dependence of the focal length $f_D(\lambda)$ on the wavelength λ in the objective lens **27** is opposite to that of the focal length f_H on the wavelength λ in the hologram lens **26M**. Therefore, a condition that the compound objective lens **29M** composed of the objective lens **27** and the hologram lens **26M** functions as an achromatic lens is formulated by an equation (4).

$$1/f_{HO}+1/f_D(\lambda_o)=1/f_{H1}+1/f_D(\lambda_1)= \tag{4}$$
$$1/(f_{HO}\times\lambda_o/\lambda_1)+(n(\lambda_1)-1)/\{f_D(\lambda_o)\times(n(\lambda_o)-1)\}$$

Accordingly, because the dependence of the focal length $f_D(\lambda)$ on the wavelength λ in the objective lens **27** is opposite to that in the hologram lens **22**, the compound objective lens **29M** having an achromatic function can be formed by the combination of the lenses **26M**, **27**, and the occurrence of the chromatic aberration can be prevented. Also, even though the equation (4) is not strictly satisfied, the occurrence of the chromatic aberration can be largely suppressed.

Also, a curvature of the objective lens **27** can be small because the hologram lens **26M** functions as a convex lens for the first-order diffracted light **L5**. Also, because the hologram lens **26M** is a plane type of element, a lightweight type of compound objective lens having an achromatic function can be made in large scale manufacture. A principal of the achromatization has been proposed in a first literature (D. Faklis and H. Morris, Photonics Spectra(1991), November p.205 & December p.131), a second literature (M. A. Gan et al., S.P.I.E. (1991), Vol. 1507, p.116), and a third literature (P. Twardowski and P. Meirueis, S.P.I.E. (1991), Vol. 1507, p.55).

(Second Embodiment)

FIG. **10**A is a constitutional view of an imaging optical system having a compound objective lens according to a second embodiment of the present invention, a beam of transmitted light not diffracted being converged on a thin type of information medium. FIG. **10**B is a constitutional view of the imaging optical system shown in FIG. **10**A, a beam of first-order diffracted light being converged on a thick type of information medium.

As shown in FIGS. **10**A, **10**B, an imaging optical system **31** for converging light on the first substrate **22** of the first information medium **23** (the thickness T1) or the second substrate **24** of the second information medium **25** (the thickness T2) to form a diffraction-limited converging spot, comprises a blazed hologram lens **32** for transmitting a part of incident light L3 without any diffraction to form a beam of transmitted light L4 and diffracting a remaining part of incident light L3 to form a beam of first-order diffracted light LS, and the objective lens **27** for converging the transmitted light L4 on the first information medium **23** or converging the first-order diffracted light L5 on the second information medium **25**.

The hologram lens **32** is formed by drawing a grating pattern P2 in a pattern region **32**A of the transparent substrate **28** in a concentric circle shape. The pattern region **32**A is positioned in a center portion of the transparent substrate **28**. An diameter of the grating pattern P2 is equal to or larger than an aperture of the objective lens **27**. Also, a diffraction efficiency of the hologram lens **32** for the incident light L3 transmitting through the grating pattern P2 is less than 100% in the same manner as in the first embodiment, so that the intensity of the transmitted light L4 is sufficient to record or reproduce a piece of information on or from the first information medium **23**.

In addition, as shown in FIG. **11**, the diffraction efficiency in a central portion of the pattern region **32**A is high, and the diffraction efficiency is gradually decreased toward an outer direction of the pattern region **32**A. In other words, in cases where the grating pattern P2 of the hologram lens **32** is formed in relief, the height H of the relief in the grating pattern P2 is gradually lowered toward the outer direction of the pattern region **32**A. Or, in cases where an ideal blazed shape of the hologram lens **26** approximates to a step-wise shape, each block of the grating pattern P2 positioned in the central portion of the transparent substrate **28** is formed in a step-wise shape shown in FIG. **12**A in which an inclined angle θ_1 of stairs is large and a relationship W1>W2 between a first etching width W1 and a second etching width W2 is satisfied, and the grating pattern P2 formed in the step-wise shape shown in FIG. **12**A is gradually changed by decreasing the first etching width W1 and increasing the second etching width W2 toward the outer direction of the pattern region **32**A while the height H of the grating pattern P2 is gradually decreased. Therefore, each block of the grating pattern P2 positioned in a peripheral portion of the transparent substrate **28** is formed in a step-wise shape shown in FIG. **12**B in which an inclined angle θ_2 of stairs is small and a relationship W1<W2 between the etching widths is satisfied. Also, each block of the grating pattern P2 positioned in a middle portion between the central and peripheral portions is formed in a step-wise shape shown in FIG. **12**C in which the etching widths W1, W2 is the same.

In the above configuration of the imaging optical system **31**, a part of the incident light L3 transmits through the hologram lens **32** without any diffraction to form a beam of transmitted light L4, and the transmitted light L4 is converged by the objective lens **27**. Also, a remaining part of the incident light L3 is diffracted and refracted by the hologram lens **32**. In this case, the hologram lens **32** functions as a concave lens for the incident light L3, so that a first-order diffracted light L5 diverges from the hologram lens **32**. Thereafter, the first-order diffracted light L5 is converged by the objective lens **27**.

In cases where the thin type of first information medium **23** is utilized to record or reproduce pieces of information on or from a front surface of the medium **23**, as shown in FIG. **10**A, the transmitted light L4 is incident on a rear surface of the first information medium **23** and is focused on its front surface by the objective lens **27** to form a diffraction-limited converging spot S3 on the first information medium **23**. In this case, because the diffraction efficiency in the central portion of the grating pattern P2 is high and because the diffraction efficiency is gradually decreased toward the outer direction of the grating pattern P2, a diffraction probability of the incident light L3 is lowered in the peripheral portion of the grating pattern P2. Therefore, the light L4 transmits through the objective lens **27** on condition that the numerical aperture NA of the objective lens **27** is high.

In contrast, in cases where the thick type of second information medium **25** is utilized to record or reproduce pieces of information on or from a front surface of the medium **25**, the diffracted light L5 is incident on a rear surface of the second information medium **25** and is focused on its front surface to form a diffraction-limited converging spot S5 on the second information medium **25**. In this case, because the hologram lens **32** functions as a concave lens to diverge the first-order diffracted light LS, the diffraction-limited converging spots S3, S4 are formed even though the thickness T1 of the first information medium **23** differs from the thickness T2 of the second information medium **25**. Therefore, a compound objective lens **34** composed of the hologram lens **32** and the objective lens **27** has substantially two focal points.

Accordingly, because the light L4 transmits through the objective lens **27** on condition that the numerical aperture NA of the objective lens **27** is high, the intensity of the transmitted light L4 converged on the first information medium **23** can be high.

Also, in cases where the incident light L3 is radiated from a semiconductor laser, a far field pattern of the incident light L3 is distributed in a Gaussian distribution as shown in FIG. **13**A. Therefore, because the diffraction efficiency is gradually decreased toward the outer direction of the grating pattern P2, a far field pattern of the transmitted light L4 is distributed in a gently-sloping shape as shown in FIG. **13**B. In contrast to the second embodiment, because the incident light L3 is not diffracted in the no-pattern region **26***b* of the hologram lens **26** in the first embodiment, the intensity of the transmitted light L4 is suddenly increased at the peripheral portion of the hologram lens **26**.

Accordingly, secondary maxima of the transmitted light L4 converged on the converging spot S3 can be moreover suppressed in the second embodiment as

compared with in the first embodiment. That is, the recording and reproducing of the information can be performed without any deterioration of the information by utilizing the imaging optical system **31**.

In addition, in cases where the first-order diffracted light **L5** is converged on the second information medium **25** to form the diffraction-limited converging spot **S4**, a numerical aperture of the objective lens **27** for the first-order diffracted light **L5** is low because the diffraction efficiency of the hologram lens **32** is decreased toward an outer direction of the pattern region **32A**. As a result, the intensity of the first-order diffracted light **L5** becomes lowered. In cases where the diffraction efficiency of the hologram lens **32** is heightened to increase the intensity of the first-order diffracted light LS, the intensity of the transmitted light **L4** at its inner beam portion is largely decreased, and secondary maxima (or side lobes) of the transmitted light **L4** at the converging spot **S3** is undesirably increased. Therefore, the incident light **L3** of which the far field pattern is distributed in the Gaussian distribution is radiated to the hologram lens **32** to increase the intensity of the first-order diffracted light **L5** without any increase of the second maxima. In detail, as shown in FIG. **14A**, the incident light **L3** distributed not only in a central portion of the Gaussian distribution but also in a peripheral portion of the Gaussian distribution transmits through the hologram lens **32** and is refracted by the objective lens **27** because the diameter of the grating pattern **P2** is equal to or larger than the aperture of the objective lens **27**. Therefore, a numerical aperture NA of the objective lens **27** at a light source side for the incident light **L3** becomes higher than that in the first embodiment, and the diffraction efficiency of the hologram lens **32** is heightened. As a result, the intensity of the first-order diffracted light **L5** converged on the second information medium **25** can be increased, as shown in FIG. **14B**. Also, because the intensity of the incident light **L3** at the peripheral portion of the Gaussian distribution is low and because the diffraction efficiency of the hologram lens **32** is increased toward the inner direction of the grating pattern region **32A**, intensity of the transmitted light **L4** is distributed in a gently-sloping shape as shown in FIG. **14C**. Accordingly, secondary maxima of the transmitted light **L4** at the converging spot **S3** can be suppressed.

Examples of the utilization of the imaging optical system **31** for various types of optical disks are described.

In cases where the image optical system **31** is utilized for an optical disk device in which pieces of information recorded in a thin type of high density optical disk and a thick type of compact disk are exclusively reproduced, the diffraction efficiency of the hologram lens **32** for the incident light **L3** is set in a range from about 20% to 70%. In this case, the intensity of the transmitted light **L4** converged on the high density optical disk is almost the same as that of the first-order diffracted light **L5** converged on the compact disk. Therefore, the output power of the incident light **L3** can be minimized.

Also, in cases where the image optical system **31** is utilized for an optical disk device in which pieces of information recorded in a thin type of high density optical disk are recorded or reproduced and pieces of information recorded in a thick type of optical disk are exclusively reproduced, the diffraction efficiency of the hologram lens **32** for the incident light **L3** is set to a value equal to or lower than 30%. In this case, even though a high intensity of transmitted light **L4** is required to record a piece of information on the high density optical disk, the recording of the information can be reliably performed without increasing the intensity of the incident light **L3** because a transmission efficiency of the hologram lens **32** for the incident light **L3** is high. In other words, a utilization efficiency of the incident light **L3** can be enhanced when a piece of information is recorded on the high density optical disk, so that the output power of the incident light **L3** can be minimized.

In the second embodiment, the grating pattern **P2** positioned in the central portion of the transparent substrate **28** is gradually changed toward the outer direction of the pattern region **32A** from the step-wise shape shown in FIG. **12A** to the step-wise shape shown in FIG. **12B** through the step-wise shape shown in FIG. **12C**. However, because the occurrence of unnecessary diffracted light such as minus first-order diffracted light can be effectively prevented in the middle portion of the transparent substrate **28** in which the grating pattern **P2** is formed in the step-wise shape shown in FIG. **12C**, it is preferred that the middle portion occupy a large part of the pattern region **32A** of the hologram lens **32**. In this case, the intensity sum of the transmitted light **L4** and the first-order diffracted light **L5** can be maximized, so that a utilization efficiency of the incident light **L3** can be enhanced.

Also, because the first etching width **W1** of the grating pattern **P2** is gradually decreased toward the outer direction of the pattern region **32A**, it is applicable that the grating pattern **P2** formed in the step-wise shape shown in FIG. **12B** be changed to a step-wise shape shown in FIG. **12D** when the first width **W1** is decreased to a value lower than about 1 μm. That is, a flight of four stairs shown in FIG. **12B** is changed to a flight of two stairs. In this case, the grating pattern **P2** formed in the step-wise shape shown in FIG. **12D** can be easily made. In addition, in cases where a height **H4** of the grating pattern **P2** formed in the step-wise shape shown in FIG. **12D** is moreover decreased toward the outer direction of the pattern region **32A**, it is preferred that the grating pattern **P2** be formed in a step-wise shape shown in FIG. **12E**. That is, a third etching width **W3** is gradually decreased toward the outer direction of the pattern region **32A** while decreasing a height **H5** of the grating pattern **P2**. Therefore, the diffraction efficiency of the hologram lens **32** can be gradually decreased toward the outer direction of the pattern region **32A** without any manufacturing difficulty of the grating pattern **P2**.

In addition, as shown in FIG. **15A**, it is applicable that a hologram lens **33** be formed, in place of the hologram lens **32**, by placing the grating pattern **P1** of the pattern region **32A** in a central portion of the transparent substrate **28** and placing four types of diffraction regions **33A**, **33B**, **33C** and **33D** which surround the grating pattern **P1**. A part of the incident light **L3** transmitting through each of the diffraction regions **33A** to **33D** is diffracted to control a transmission efficiency of the hologram lens **33**. In this case, the intensity of the transmitted light **L4** at its peripheral portion is decreased, so that secondary maxima occurring in the converging spot **S3** can be suppressed. Also, it is applicable that the grating pattern **P1** of the hologram be replaced with the grating pattern **P2**. Also, it is applicable that grating directions of the diffraction regions **33A** to **33D** differ from each other. In this case, even though

the first-order diffracted light L5 diffracted in the diffraction region 33A is, for example, incident on the diffraction region 33c after the diffracted light L5 is reflected by the second information medium 25, the diffracted light L5 again diffracted in the diffraction region 33c does not pass in parallel to the optical axis. Therefore, in cases where a piece of information read from the second information medium 25 is detected in a detector to reproduce the information, the first-order diffracted light L5 diffracted in the diffraction regions 33A to 33D is not detected by the detector as stray light. Accordingly, the reproduction of the information does not deteriorate.

Also, as shown in FIG. 15B, it is applicable that the hologram lens 32 function as a convex lens. In this case, the diffracted light L5 is converged on the first information medium 23, and the transmitted light L4 is converged on the second information medium 25, as shown in FIG. 15C.

(Third Embodiment)

FIG. 16A is a constitutional view of an imaging optical system having a compound objective lens according to a third embodiment of the present invention, a beam of first-order diffracted light being converged on a thin type of information medium. FIG. 16B is a constitutional view of the imaging optical system shown in FIG. 16A, a beam of transmitted light not diffracted being converged on a thick type of information medium.

As shown in FIGS. 16A, 16B, an imaging optical system 41 for converging light on the first substrate 22 of the first information medium 23 (the thickness T1) or the second substrate 24 of the second information medium 25 (the thickness T2) to form a diffraction-limited converging spot comprises a blazed hologram lens 42 for transmitting a part of incident light L3 without any diffraction to form a beam of transmitted light L4 and diffracting a remaining part of incident light L3 to form a beam of first-order diffracted light L6, and the objective lens 27 for converging the first-order diffracted light L6 on the first information medium 23 or converging the transmitted light L4 on the second information medium 25.

The hologram lens 42 is formed by drawing a grating pattern P3 in a pattern region 42A of the transparent substrate 28 in a concentric circle shape. The pattern region 42A is positioned in a center portion of the transparent substrate 28. An diameter of the grating pattern P3 is equal to or larger than an aperture of the objective lens 27. Also, a diffraction efficiency of the hologram lens 42 for the incident light L3 transmitting through the grating pattern P3 is less than 100% in the same manner as in the first embodiment, so that the intensity of the transmitted light L4 is sufficient to record or reproduce a piece of information on or from the second information medium 25.

In addition, as shown in FIG. 17, the diffraction efficiency of the hologram lens 42 is high in a peripheral portion of the pattern region 42A, and the diffraction efficiency is gradually decreased toward an inner direction of the pattern region 42A. In other words, in cases where the grating pattern P3 of the hologram lens 42 is formed in relief, the height H of the relief in the grating pattern P3 is gradually lowered toward the inner direction of the pattern region 42A. Or, in cases where an ideal blazed shape of the hologram lens 26 approximates to a step-wise shape, each pitch of the grating pattern P3 positioned in the peripheral portion of the transparent substrate 28 is formed in a step-wise shape shown in FIG. 12A in which the inclined angle θ_1 of stairs is large and the relationship W1>W2 between the first and second etching widths W1, W2 is satisfied, and the grating pattern P3 formed in the step-wise shape shown in FIG. 12A is gradually changed by decreasing the first etching width W1 and increasing the second etching width W2 toward the inner direction of the pattern region 42A while the height H of the grating pattern P3 is gradually decreased. Therefore, each pitch of the grating pattern P3 positioned in a central portion of the transparent substrate 28 is formed in a step-wise shape shown in FIG. 12B in which the inclined angle θ_2 of stairs is small and the relationship W1<W2 is satisfied. Also, each pitch of the grating pattern P3 positioned in a middle portion between the central and peripheral portions is formed in a step-wise shape shown in FIG. 12C in which the etching widths W1, W2 is the same.

In the above configuration of the imaging optical system 41, as shown in FIG. 16B, a part of the incident light L3 transmits through the hologram lens 42 without any diffraction to form a beam of transmitted light L4, and the transmitted light L4 is converged by the objective lens 27. Also, a remaining part of the incident light L3 is diffracted by the hologram lens 42 to form a beam of first-order diffracted light L6. In this case, the hologram lens 42 functions as a convex lens for the incident light L3, so that a first-order diffracted light L6 formed in the hologram lens 42 converges. Thereafter, the diffracted light L6 is converged by the objective lens 27.

In cases where the thin type of first information medium 23 is utilized to record or reproduce pieces of information on or from a front surface of the medium 23, as shown in FIG. 16A, the diffracted light L6 is incident on a rear surface of the first information medium 23 and is focused on its front surface to form a diffraction-limited converging spot S5 on the first information medium 23. In contrast, in cases where the thick type of second information medium 25 is utilized to record or reproduce pieces of information on or from a front surface of the medium 25, the transmitted light L4 is incident on a rear surface of the second information medium 25 and is focused on its front surface to form a diffraction-limited converging spot S6 on the second information medium 25.

In this case, because the hologram lens 42 functions as a convex lens to converge the diffracted light L6, the diffraction-limited converging spots S5, S6 are formed even though the thickness T1 of the first information medium 23 differs from the thickness T2 of the second information medium 25. Therefore, a compound objective lens 43 composed of the hologram lens 42 and the objective lens 27 has substantially two focal points.

Also, because the hologram lens 42 functions as a convex lens for the diffracted light L6, the diffracted light L6 transmits through the objective lens 27 on condition that the numerical aperture NA of the objective lens 27 is substantially high.

In addition, because the diffraction efficiency in the peripheral portion of the grating pattern P3 is high and because the diffraction efficiency is gradually decreased toward the inner direction of the grating pattern P3, a diffraction probability of the incident light L3 is higher in the peripheral portion of the grating pattern P3.

The grating pattern P3 of the hologram lens 42 is designed to correct any aberration occurring in the
