Es gibt für viele geniale Einfälle schon zahlreiche Patente. Was viele nicht wissen ist, dass man durch Verbesserungen bestehender Patente recht leicht an ein eigenes Patent gelangen kann. Es lohnt sich ebenfalls etwas Neues zu entwickeln (so bekommt man statt ein paar Krümeln vielleicht sogar eine ganze Torte). Falls ein genialer Einfall nach erster Abschätzung und Prüfung nicht umsetzbar sein, so muss man ihn nicht zwangsläufig verwerfen. Mit geeigneten Problemlösungsstrategien und Kreativtechniken ist manchmal trotzdem eine Umsetzung möglich, wenngleich diese Techniken oft zu völlig anderen Ansätzen führen.

Welche Kreativtechniken können hier Anwendung finden?

Das Brainstorming ist eine der beliebtesten Kreativitätstechniken. Es ist geeignet für Gruppen zwischen vier und acht Teilnehmern. Obwohl mehrere Studien die Effektivität dieser Methode kritisieren, wird dieser Klassiker dennoch in zahlreichen Unternehmen eingesetzt.

Was kann Brainstorming?

Durch die Technik des Brainstormings wird innerhalb kurzer Zeit eine Vielzahl von Ideen produziert. Sie führt sowohl zu zahlreichen Denkanstößen als auch zu sehr originellen Lösungen, die sich effektiv weiterverarbeiten lassen. Dies trifft insbesondere dann zu, wenn sie noch am Anfang stehen und noch sehr viele Ideen benötigen, um eine konkrete Fragestellung zu beantworten. Das Brainstorming ist insbesondere für jene Bereiche geeignet, in denen die Art der Lösungsvorschläge eine breite Streuung zeigen soll. Beispiele hierfür sind Bereiche, die die Gruppe selbst betreffen, wie bei der Frage: „Wie kann ich effektiver arbeiten? Auch wenn Experten aus unterschiedlichen Bereichen zusammenarbeiten müssen, ist das Brainstorming die Methode der Wahl.

Weniger geeignet ist das Brainstorming, um komplexe Probleme zu lösen oder wenn ein bestimmtes Spezialwissen erforderlich ist, welches die Gruppe nicht besitzt. Diese Technik funktioniert nur dann effektiv, wenn alle Teilnehmer in der Gruppe gleichrangig sind.

Um eine Brainstorming Sitzung durchzuführen benötigen sie eine Gruppe mit 4 bis 8, maximal 15 Teilnehmern. Weiterhin bedarf es eines Moderators, der die Vorschläge auf einem Flipchart, einer Tafel oder Moderationswand aufzeichnet bzw. protokolliert. Eine solche Sitzung dauert ca. 15 bis 20 Minuten in der Ideenfindungsphase und 30 bis 40 Minuten in der Bewertungsphase.

Brainstorming zeichnet sich durch seine ungemein hohe Flexibilität aus, welche in fast allen Bereichen Anwendung findet, in denen kreativ gedacht werden soll.

Ein Moderator präsentiert das Thema und erläutert die Regeln, sofern sie den Teilnehmern noch nicht bekannt sind. Die Einhaltung der Regeln wird vom Moderator überwacht. Die Teilnehmer sollen spontan Vorschläge äußern, welche vom Moderator dokumentiert werden.

Die vier Grundregeln

- Solange nicht alle Vorschläge geäußert wurden, darf nicht beurteilt werden. Jede Kritik ist untersagt.
- Jeder Vorschlag ist willkommen, und sei er auch noch so ungewöhnlich. Der Grund ist: es ist leichter, ungewöhnliche Ideen durch die anschließende Bewertungsphase abzuschwächen, als sie zu entwickeln.
- Die Quantität geht vor Qualität, das heißt es sollen so viele Vorschläge wie möglich entwickelt werden.
- Es ist gestattet die Ideen anderer aufzugreifen, sie weiterzuentwickeln oder neu zu kombinieren.

Ideen Sturm mit zwei Wellen

Es ist ein interessantes Phänomens das nach fünf bis zehn Minuten den Teilnehmern die Ideen ausgehen. Sie sollten jedoch die Sitzung auf keinen Fall abbrechen, auch wenn es so aussieht, als wenn keinem mehr etwas einfiele. Wenn sie weitermachen, werden sie feststellen, dass den meisten Teilnehmern nach kurzer Zeit weitere Vorschläge einfallen; zwar nicht mehr so viele, aber häufig wesentlich originellere. Es lohnt sich in jedem Fall die zweite Welle der Ideen abzuwarten. Es kommt bei manchen Gruppen vor, dass sie auch noch eine dritte Welle der Ideenproduktion erfolgreich abschließen.

Bewertung

Nach der Ideenproduktion folgt die Bewertungsphase. Nach der Phase der Ideenproduktion haben sich alle Teilnehmer der Gruppe eine Pause verdient. Oftmals ist es sinnvoll mit der Bewertungsphase erst am darauf folgenden Tag zu beginnen. Die Teilnehmer müssen für die Bewertung von der flexiblen Kreativität zur Objektivität wechseln. an dieser Stelle ist die zuvor verbotene sachliche Kritik durchaus erwünscht, und so manche ungewöhnliche Idee muss eine Prüfung auf Brauchbarkeit über sich ergehen lassen.

Von den Teilnehmern werden alle Vorschläge bewertet. Die Kriterien sind Praktikabilität und Gefühlsmäßiger Anspruch. Es sollte eine Rangfolge der Ideen festgelegt werden, in der sie bearbeitet werden. Oder sie wählen nur einzelne Ideen aus, die weiter ausgearbeitet werden. Die restlichen Ideen können anhand der Osborn-Checkliste (kommt später) weiterbearbeitet werden.

Welche Rolle hat der Moderator?

Das Gelingen des Brainstormings hängt entscheidend von der guten Moderation ab. Es ist dem Moderator nicht erlaubt sich einzumischen oder gar in den Vordergrund zu spielen und auf keinen Fall dürfen Vorschläge von ihm gemacht werden. Seine Aufgaben sind die folgenden: Er soll

- für eine vertrauensvolle Atmosphäre sorgen
- alle Teilnehmer ermutigen, mitzumachen.
- auf die Einhaltung der Regeln achten und verhindern, dass in der Phase der Ideenfindung schon Bewertungen vorgenommen werden
- alle Vorschläge dokumentieren, ohne selbst zu kommentieren oder sie abzuändern.
- die Bewertung leiten, ohne selbst Stellung zu nehmen.
- die Sachlichkeit der Bewertung gewährleisten.

Wie sollte die Gruppe zusammengesetzt sein?

Am günstigsten sind die Voraussetzungen, wenn es sich um ein eingespieltes Team in der Gruppe handelt. Sehr hinderlich ist, wenn es innerhalb der Gruppe zu einem ausgeprägten Konkurrenzneid oder zu Statuskämpfen kommt. Es ist weiterhin umstritten, ob es sinnvoll ist ein Brainstorming mit zufällig zusammengestellten Teilnehmern durchzuführen. Manche halten die doch genau dies für die besten Voraussetzungen dafür viele Anregungen aus unterschiedlichen Blickwinkeln zu bekommen.

Ist Brainstorming ein kreatives Allheilmittel?

Die Hochzeit des Brainstormings waren die sechziger und siebziger Jahre. In der Zwischenzeit jedoch, haben mehrere Studien Zweifel an der Wirksamkeit dieser Methode aufgebracht. In diesen Studien wird in Frage gestellt, ob Brainstorming zwangsläufig zu mehr und besseren Ergebnissen führt, als wenn jeder Teilnehmer separat nach einer Lösung sucht. Man ist sich heute einig, dass Brainstorming eine der wichtigsten Kreativitätstechniken ist, die auch von ihren Kritikern als eine höchst effiziente Technik zur Stimulierung des kreativen Denkens dargestellt wird. Es lässt sich anhand vieler Beispiele belegen, dass sie zu brauchbaren Ergebnissen führt.

Es gibt einige Varianten des Brainstormings. Ein populäres Beispiel ist das Destruktiv-Konstruktiv-Brainstorming. Hierbei ist die Phase der Ideenfindung zweigeteilt: negative Ideen, die eine Lösung verhindern können, sollen zunächst gesammelt werden. In der anschließenden Phase dürfen die Teilnehmer konstruktive Vorschläge äußern. Auf diese Weise sind reichere und originellere Ideen zu erwarten.

Im Kontrast zum Gruppen Brainstorming gibt es noch das Einzel Brainstorming. In diesem Fall sind Ihr eigener Moderator, durchlaufen wie bereits beschrieben ein Ideenfindungsphase, in der sie in jedem Fall noch keine Bewertung vornehmen sollten, und werden diese Ideen hinterher kritisch bewerten. Bei diesem Verfahren müssen sie sehr diszipliniert sein, was sich jedoch mit ein wenig Übung bewerkstelligen lässt. Auch hier ist es anzuraten, nicht gleich nach der Ideenfindungsphase mit der Bewertungsphase fortzusetzen, sondern vielleicht ein oder zwei Tage verstreichen zu lassen.

Brainwriting

Das Brainwriting funktioniert ganz ähnlich wie das Brainstorming, der Hauptunterschied ist der, dass alle Einfälle schriftlich festgehalten werden. Man unterscheidet zwischen zwei sehr unterschiedlichen Varianten:

- Die bekanntere, die Methode 635, welche auf die Kreativität fördernde Wirkung von akutem Stress setzt. Diese Methode produziert wesentlich mehr Ideen als beim Brainstorming, die zudem noch durch die Originalität spontaner Antworten geprägt sind.
- Die Collective-Notebook-Methode, welche langwieriger aber auch wesentlich gründlicher, sowie zeitlich und räumlich flexibler ist.

- **Was kann Brainwriting leisten?**

Neben den Vorteil, dass beim Brainwriting wesentlich mehr Ideen produziert werden als beim Brainstorming, gesellen sich noch weitere, wie die Tatsachen:

- dass gruppendynamische Prozesse kaum eine Rolle spielen
- die Zahl der Teilnehmer theoretisch unbegrenzt ist
- kein Moderator benötigt wird, der manchmal Kreativität eher verhindert, als sie zu fördern.

Brainwriting ist besonders geeignet, wenn:

- einfache und klar strukturierten Frage vorliegen (Methode 635), aber auch komplexere Probleme (collective Notebook)
- Teilnehmer schwer verfügbar sind (collektive Notebook)
- es in der Gruppe Kommunikation Probleme gibt oder aber keinen Moderator zur Verfügung steht

-

Brainwriting ist dagegen weniger geeignet:

- Zur Lösung komplexer Fragen (Methode 635)
- Wenn starke Unterschiede im Erfahrungs- und Wissenshorizont der einzelnen Teilnehmer bestehen
- Wenn die Zahl Lösungen *a priori* stark eingeschränkt ist.

-

Konzeptfächer und

Was wird für ein Brainwriting benötigt?

- Eine Gruppe, die im Idealfall aus sechs Teilnehmern besteht (Methode 635), die Teilnehmeranzahl kann jedoch auch variabel sein.
- Schreibwerkzeug und Papier (im Idealfall dafür vorbereitete Vordrucke) oder ein vernetztes Computersystem.

-

Wie ist Ablauf beim Brainwriting?

Methode 635

Ein Blatt auf dem die Fragestellung vorformuliert ist, wird jedem Teilnehmer ausgehändigt. In den nächsten fünf Minuten sollen drei Lösungsvorschläge auf dem Blatt notiert werden. Danach reicht der Teilnehmer das Blatt an seinen Nachbarn weiter. Im Gegenzug bekommt er dessen Blatt. Auf dieses Blatt soll er in den folgenden fünf Minuten drei neue Ideen hinzufügen, wobei er sich idealerweise von den bereits bestehenden Vorschlägen inspirieren lässt. Danach wird auch dieses Blatt wieder weitergegeben.

Wenn jeder Teilnehmer jedes Blatt gehabt hat ist die Sitzung beendet. Bei sechs Teilnehmern sollte also nach einer guten halben Stunde ein Pool von 108 Lösungsvorschlägen bereitliegen. Die Auswertung verläuft wie beim Brainstorming.

Auch diese Methode lässt sich nach der bereits beschrieben Collective-Notebook-Methode durchführen. Hierbei erhält jeder Teilnehmer ein Notizbuch mit der Problemstellung. Innerhalb einer bestimmten Frist soll er das Problem analysieren und die Vorschläge darin notieren. Der Austausch dieser Notizbücher geschieht analog nach der Methode 635.

Wenn man sich zwischen den zwei oberen vorgestellten Methoden entscheiden muss, sollte man sich vor Augen halten, dass die erste Methode die Teilnehmer sehr unter Druck setzt. Sie müssen innerhalb kürzester Zeit eine Vielzahl von Ideen produzieren, was nicht selten ein Grund für eine Denkblockade ist. Der Vorteil dieses Stresses ist allerdings auch, dass die Teilnehmer gezwungen sind, sich zu konzentrieren und sich nicht in der Gruppe verstecken können. Im Vergleich zum Brainstorming kommen auf diese Weise nicht nur wesentlich mehr Ideen zustande, sondern der gesamte Ablauf führt dazu, dass die Teilnehmer gedanklich neue Wege einschlagen müssen.

Der Effekt ist, dass erstaunlich viele Entdeckungen zu machen sind. Es wird von vielen als angenehmer Nebeneffekt empfunden, wie kreativ und produktiv sie eigentlich sein können.

Die Collective-Notebook-Methode dagegen erfordert ein hohes Maß an Selbstdisziplin. Der Vorteil ist sicher, dass die Teilnehmer sich ihre Zeit frei einteilen können. Dadurch fällt allerdings auch der vorgenannte Stress mit seinen positiven Effekten weg. Außerdem dauert das Verfahren natürlich wesentlich länger.

Mind Mapping

Diese Technik ist sehr schnell zu lernen, universell und fast überall einsetzbar, und es ist sehr wahrscheinlich, dass immer etwas dabei herauskommt. Diese Technik wurde von Tony Buzan entwickelt und erfreut sich außerordentlicher Beliebtheit.

Um ein Mind Mapping durchzuführen bedarf es nicht viele Werkzeuge, es schafft Übersicht und bringt sie mit einfachen Mitteln auf neue Ideen.

Was leistet Mind Mapping?

Mit den Mind Mapping wird unser bildlich-räumliches Denken stimuliert und eine neue Sichtweise wird ermöglicht. Da durch, dass wir unser Thema oder unser Problem im wörtlichen Sinne verbildlichen, können wir es neu strukturieren. Wesentliche Punkte können herausgearbeitet werden, es können leicht neue Verbindungen hergestellt werden und Nebenaspekte miteinbezogen werden. Die offene Struktur der Mind Maps hat den Vorteil, dass sie später ergänzt werden können.

Für folgende Bereiche ist das Mind Mapping besonders geeignet:

- Problemanalyse
- Überblick über komplexe Themen
- Vorbereitung von Vorträgen und Aufsätzen
- Planung und Strategie

Dass Mind Mapping hat allerdings auch seine Schwächen:

- Durch einen Mind Map entsteht leicht der Eindruck, ein Problem zu überblicken, selbst wenn dies nicht der Fall ist.
- Die entstandenen Bilder können suggestiv wirken und Ihr Denken in die falsche Richtung lenken
- Komplexe Sachverhalte werden stark verkürzt dargestellt

Konzeptfächer und

Dies benötigt man für einen Mind Map

- Ein mindestens DIN-A4 großes Blatt Papier
- Schreibwerkzeug, möglichst in verschiedenen Farben

-

Zeitbedarf: 20 bis 30 Minuten

Neben dem strategischen Vorteil die das Erstellen eines Mind Maps hat, funktioniert es auch sehr gut als Erinnerungstütze und versetzt Sie in der Lage auch später noch ein Thema wieder aufzugreifen und schnell die Orientierung zu finden.

Wie er stellt man einen Mind Map?

Man beginnt in der Mitte des Blattes. Dort sollte der zentrale Begriff, um den es geht, stehen. Es steht ihnen frei diesen zentralen Begriff auch bildlich darzustellen. Von diesem zentralen Bild oder Begriff beginnt man nun mehrere Linien abzweigen zu lassen. Auf jede diese Linien wird ein Begriff geschrieben, den man aus dem vorgegebenen Thema ableiten kann. Dabei sollte man nicht zu lang überlegen, sondern einfach, was einem in den Sinn kommt, niederschreiben.

Nehmen wir als Beispiel das Thema Effektivität. Hier lassen sich Begriffe ableiten wie etwa:

- Zeit sparen
- Schnelligkeit
- Ökonomie
- Gewinnbringend
- Hilfsmittel.

- Von diesen Begriffen ausgehend fallen einem wieder Andere ein, die auf neue Linien beschrieben werden. Nach und nach werden Zusammenhänge erkennbar, die es ermöglichen, auch abseitige Aspekte zu betrachten. Zunehmend füllt sich ihr Blatt. Sobald man das Gefühl hat, man hat das Wichtigste notiert, ist das Mind Map vorläufig fertig. Ein Beispiel für ein Mind Map ist auf der nebenstehenden Abbildung dargestellt.

Die Osborn- Checkl
Konzeptfächer und

Tony Buzan, der Erfinder des Mind Maps hat sieben Grundregeln formuliert, nach denen ein Mind Map zu gestalten ist:

- Beginnen sie mit einem farbigen Bild in der Mitte
- Schreiben Sie alle Wörter in Großbuchstaben, das fördert die Übersichtlichkeit.
- Die Wörter sollen auf Linien stehen, wobei jede Linie mit anderen Linien verbunden ist
- Verwenden Sie nach Möglichkeit nur ein Stichwort pro Linie
- Benutzen sie möglichst viele Farben
- Ignorieren sie kontrolliertes denken und halten Sie möglichst alles fest, was ihnen im Zusammenhang mit der Zentralidee in den Sinn kommt.

- Beispiel

Um Mind Maps noch übersichtlicher zu gestalten, steht es Ihnen frei individuelle Symbole zu verwenden. Sie verwenden diese Symbole einheitlich, um beispielsweise Fragen, Ziele oder Wünsche gegeneinander abzugrenzen.

Wie kann man Mind Maps effektiv nutzen?

Wenn sie gerade damit anfangen sich mit einem Thema zu beschäftigen, ist es sehr sinnvoll ein Mind Map zu erstellen.

Schreiben Sie alles auf, was ihnen einfällt, und sie werden sich wundern, wie viel sie bereits über dieses Thema wissen, selbst wenn sie geglaubt haben noch gar nichts zu wissen.

Wenn sie beginnen ein Mind Maps in die Praxis umzusetzen, so sollten sie das Mind Map kontinuierlich ergänzen, um es den gegenwärtigen Umständen anzupassen. Irgendwann kann es natürlich passieren, dass ein Mind Map unübersichtlich wird. Dies ist der beste Zeitpunkt ein neues anzufangen. Denn ein aktuelles Mind Map lässt sich auch am besten nutzen.

Sobald dann meint man fertig ist, sollten sie es sich sehr genau anschauen und vielleicht mit jemand anderem darüber reden. Möglicherweise ergeben sich neue Zusammenhänge die sie dazu verleiten neue Prioritäten zu setzen.

Seien Sie jedoch vorsichtig, obwohl ein Mind Map fast immer sehr strukturiert aussieht, muss das nicht bedeuten, dass damit das Problem auch strukturiert gelöst ist. Machen Sie sich die Grenzen dieser Technik genau bewusst. Nur dann können sie Mind Mapping wirklich effektiv und zielführend einsetzen.

Die Individualität der Mind Maps macht es schwierig die, von fremden Personen Erstellten zu verstehen. Sie sollten sich diese, so Sie daran interessiert sind, genau erklären lassen. Nur so lassen sich Missverständnisse der individuellen Schreibweise verhindern.

Es gibt eine Variante des Mind Mapping die bei komplexen Problemen zielführend ist.

Sie notieren die einzelnen Schlüsselbegriffe und Ideen nicht direkt in das Mind Map, sondern zunächst auf Kartei Karten oder Haft Notizen. Diese können dann leicht auf dem zu erstellenden Mind Map verschoben, weggenommen oder neu kombiniert werden. Obwohl mit dieser Technik die Gestaltungsmöglichkeiten nicht so groß sind, sind sie doch wesentlich flexibler. Sind sie mit ihrem Ergebnis zufrieden, sollten Sie daraus möglichst bald ein „echtes Mind Map herstellen, ansonsten ist das Ergebnis äußerst flüchtig.

Bisoziation oder Benchmarking

Bei der Frage „Woher kreative Leistungen kommen stößt man relativ schnell auf das Prinzip der Bisoziation. Bei dieser Technik wird in zwei, vorher unverbundenen Denkdimensionen gedacht. Ein sehr schönes Beispiel ist Johannes Gutenberg. Als er die Merkmale der Weinpresse mit denen des Münzprägestempels verband, erfand er die Druckpresse mit beweglichen Lettern.

Was leistet die Bisoziation?

Hier handelt sich um eine sehr vielseitige Technik. Ihre Effektivität hängt sehr stark von der Wahl der beiden Denkdimensionen ab. Das Prinzip der Bisoziation liegt auch anderen Kreativitätstechniken zugrunde, die später noch beschrieben werden. Bei diesen wird Ihnen die Wahl der zweiten Denkdimension jedoch abgenommen.

Für die folgenden Bereiche ist die Technik der Bisoziation besonders geeignet:

- Technische Probleme und Erfindungen
- Im künstlerischen Bereich
- Gut strukturiertes Fragen und Probleme

Die Technik hat aber auch ihre Schwächen:

- Es ist besser vorher zu wissen, wo sie suchen müssen
- Sie kann sehr langwierig sein
- Brauchbarer Analogien sind relativ selten, prüfen Sie daher jeder Einzelne sorgfältig.

Die folgenden Dinge benötigen Sie für die Technik der Bisoziation:

- Beobachtungsgabe
- Fantasie
- Zeit
- Neugier
- Glück
- fachliche Kompetenz
- strukturelle Intelligenz

Je nach Fragestellung, benötigen sie von diesen Dingen mehr oder weniger.

Dauer: diese Technik kann sehr zeitaufwendig sein, daher empfiehlt sich eine zeitliche Begrenzung für diese Gruppen Sitzung anzusetzen (zwei bis vier Stunden). Die Technik der Bisoziation ist eine äußerst flexible Denktechnik, die sich auf viele Fragestellungen anwenden lässt.

Auf welche Weise lassen sich nun geeignete Bisoziation und finden?

(c) 2004 Verlag Dr. Thorsten Schwerte

Mindmapping
Bisoziation
Auf welche W
Synektik
Denkhüte und Denk
Die Osborn- Checkl
Konzeptfächer und

Bei der Lösungssuche werden vier Phasen durchlaufen:

- Problemdefinition
- Auffinden der zweiten den Denkimension
- Erkennen von Analogien
- Transfer der Lösung

Das Problem definieren

Das Problem sollte zu Beginn klipp und klar definiert werden. Beispiel: Sie möchten ein Werkzeug konstruieren, dass sehr vielseitig ist und trotzdem in jede Hosentasche passt.

Sie sollten sich fragen: „worum geht es hier eigentlich? Die beste Taktik ist, das Problem von möglichst vielen Seiten einzukreisen. Erstellen Sie eine Liste, welche die Anforderungen ihre Lösung erfüllen muss.

Finden sie den Einstieg in die zweite Denk Dimension.

An dieser Stelle fängt die Sache an, kreative Leistung zu fordern: es ist nicht leicht die zweite Denkdimension aufzuspüren, die geeignet ist, Ihr Problem zu lösen.

Der beste Einstieg ist die Überlegung, was ist so ähnlich, was sie erreichen möchten. Warum funktioniert etwas in einem Bereich, welches bei ihnen nicht funktioniert. Dabei ist es unerheblich, wie weit sie sich von ihrem Ausgangspunkt entfernen. Ob sie sich bei der Entwicklung ihres Werkzeugs, welches in jede Hosentasche passen soll, von Insekten, Regenschirmen oder anderen Dingen, die es vielleicht schon gibt anregen lassen, ist völlig unerheblich solange die Sache funktioniert.

Analogien erkennen

Dies ist eine der wichtigsten Teile dieser Technik: sie sollten sehr aufmerksam sein, nach Analogien und gemeinsame Prinzipien suchen. Am besten ist es wenn sie die Gesetzmäßigkeiten erkennen und prüfen ob sich diese in ihrem Bereich übertragen lassen.

Das heißt nicht, dass sie in diesem fremden Bereich zum Experten werden müssen. Dies wäre unter Umständen sogar nachteilig. Das heißt, dass ein Flugzeugkonstrukteur, der die Flügel eines Vogels untersucht, nicht zum Vogelkundler werden muss. Aber oftmals ist es hilfreich einen solchen Experten zu befragen.

Bei der Suche nach Analogien sollten sie auch nahe liegende Bereiche berücksichtigen. Denn nicht immer ist die Entfernteste auch die beste Lösung: wenn Sie ein Werkzeug entwerfen wollen müssen Sie also nicht unbedingt ein Vorbild in der Natur suchen, manchmal reicht es auch aus ein wenig bei anderen Herstellern zu spionieren. Dies klingt natürlich sehr naheliegend und wenig kreativ, doch in vielen Fällen kommen so nicht nur gute sondern auch äußerst kreative Ideen zustande. Damit sind wir noch nicht am Ende angekommen, denn der entscheidende Schritt steht ihnen noch bevor: sie müssen die Lösung auf ihren Bereich übertragen.

Der Transfer

Eine gute Idee aus anderen Bereichen einfach zu übernehmen klingt vielleicht einfach, ist jedoch nicht ausreichend. Sie muss in dem neuen Bereich, den sie anstreben, auch funktionieren. Das heißt, es müssen in der Regel noch einige Dinge verändert werden. Wie Sie sich sicher vorstellen können, fliegt ein Flugzeug eben nicht genauso wie ein Vogel, weshalb zwei Elemente des Flügels übernommen werden können, andere jedoch möglicherweise abgeändert werden müssen. Dann heißt es, dass sie die Idee ihrer Routine anpassen müssen. Denn erst dann zeigt sich, ob sie wirklich brauchbar, und damit kreativ ist.

Die oben vorgestellte Strategie erinnert uns berechtigterweise an den Forschungsbereich der **Bionik**. In einem Bereich werden viele Erfinder und Konstruktor fündig: der Natur. Sie kennen sicher die geniale Erfindung des Klettverschluss, welche sich von ihrem Vorbild den eher lästigen Kletten ableitet. Die Hautoberfläche von Delphinen und Haien inspirierte Konstrukteure, die Fortbewegung von U-Boten zu optimieren. Die Übertragung von Vorbildern aus der Natur in den Bereich der Technik heißt Bionik und gilt als außerordentlich leistungsfähige Methode.

Hierbei handelt sich um einen Klassiker der Kreativitätstechniken, der Anfang der sechziger Jahre von dem Amerikaner William Gordon entwickelt wurde. Es handelt sich hier um eine recht anspruchsvolle Verfremdungsmethode die auch von zahlreichen namhaften Unternehmen eingesetzt wird. In abgewandelter Form lässt sie sich auch von Einzelpersonen nutzen. Im Prinzip arbeitet die Synektik ähnlich wie die Bisoziation. Jedoch weicht sie in einem entscheidenden Punkt wesentlich ab: Sie suchen sich nicht irgendeinen selbst gewählten fremden Bereich, in dem sie nach Anregungen für ihre Lösung forschen, sondern sie entfernen sich über drei bis vier Verfremdungsschritte immer weiter von ihrem Problem.

Was leistet Synektik?

Dadurch, dass sie ihren Problemkreis gedanklichen weit verlassen, ermöglicht diese Technik, dass Sie unvoreingenommen und ohne Scheu oder Betriebsblindheit an ihr Problem heran gehen und es lösen.

Die Synektik ist für folgende Bereiche besonders geeignet:

- Ausgesprochen schwierige Probleme
- Neue Entwicklungen oder Produkte
- Versierte Problemlöser als Teilnehmer

Auch die Synektik hat ihre Schwächen, denn sie ist **für Anfänger grundsätzlich ungeeignet.**

Die folgenden Dinge benötigen Sie für eine Synektik Sitzung:

- Vier bis acht Teilnehmer
- Einem Moderator
- Einen Protokollanten (das kann auch vom Moderator übernommen werden)
- Eine Tafel, Flipchart- oder Moderationswand zum Aufzeichnen der Vorschläge

Dauer: 4 bis 8 Stunden

Diese Technik ist nicht nur außerordentlich aufwändig, sie ist auch sehr anspruchsvoll und fordert viel von Teilnehmern und Moderator.

Ablauf einer Synektik Sitzung

Ablauf einer S
Denkhüte und Denk
Die Osborn- Check
Konzeptfächer und

1. Das Problem wird formuliert

Diese Phase dauert ungefähr 15 bis 30 Minuten. Zu Beginn informiert der Moderator die Teilnehmer über den zeitlichen Ablauf der Sitzung und erklärt das Problem. Zu diesem Zeitpunkt können auch noch Verständnisfragen geklärt werden. Alle notwendigen Informationen müssen zu diesem Zeitpunkt verstanden sein. Sollte einer der Teilnehmer ergänzende Information und bereit haben, so sollte er sie der Gruppe nicht vorenthalten.

2. Brainstorming

Dauer dieser Phase ist 10 Minuten. In einem kurzen Brainstorming werden spontane Lösungsvorschläge gesammelt. Dies hat den Vorteil, dass die Teilnehmer unbelastet in den eigentlichen Synektik Prozess eintreten können. Die Ideen werden formuliert und z.B. auf den Flipchart notiert, zu diesem Zeitpunkt jedoch noch nicht ausgewertet.

3. Formulieren sie das Problem neu

Dauer: 5 bis 10 Minuten. Meistens ergeben sich durch das Brainstorming neue Aspekte. Dann kann es sinnvoll sein das Problem um zu formulieren mit dem Hintergrund, dass alle Teilnehmer von der gleichen Fragestellung ausgehen. Ob das nötig ist wird vom Moderator entschieden.

4. Bilden sie eine so genannte direkte Analogie

Dauer dieser Phase:20 Minuten.

Nach den Regeln der Bisoziation wird versucht eine Entsprechung des Problems aus einem anderen Bereich zu finden. Dieser Bereich wird in der Regel vom Moderator vorgegeben und ist in den meisten Fällen aus dem Bereich der Natur. Auch hier ist die Natur wieder so beliebt, weil fast jedes Problem auf dieses Gebiet projiziert werden kann. Nun werden die Antworten gesammelt und am Ende wählt die Gruppe eine Antwort aus.

5. Bilden sie eine persönliche Analogie

Dauer:20 Minuten.

Die Antwort aus der letzten Phase bildet den Ausgangspunkt für ihre persönliche Analogie. Jeder Teilnehmer versucht sich in den Gegenstand hinein zu versetzen und stellt sich die Frage " Wie fühle ich mich/verhalte ich mich als...?" Auch hier wird von der Gruppe ein Vorschlag ausgewählt.

6. Finden Sie eine symbolische Analogie

Dauer:10 Minuten.

Wieder wird ausgehend vom Vorschlag aus dem Vorhergehenden Schritt von den Teilnehmern nach ungewöhnlichen Vergleichen gesucht. Hier jedoch kommen die Vergleiche aus dem Bereich der Formen, Bilder oder Klänge. Es geht hierbei um die Verdichtung des Gefühls. Dabei können auch recht widersprüchliche Vergleiche und Paradoxa wie "Strahlende Dunkelheit" gebildet werden. Am Ende entscheidet wieder die Gruppe mit welcher Lösung weiter gearbeitet wird

7. Bilden sie eine zweite direkte Analogie

Dauer:20 Minuten.

Hier sollte die Lösung denkbar weit von der Ursprungsfrage entfernt sein. Es soll noch einmal auf einen bestimmten Bereich projiziert werden. Wurde im Schritt vier der Bereich Natur ausgewählt, so ist es nun häufig der Bereich Technik, der zum Einsatz kommt. Alle stellen sich auch hier wieder die Teilnehmer eine Frage: " auf welche technischen Geräte oder Verfahren könnte die Antwort des vorhergehenden Schrittees zutreffen?" Hier können ebenfalls eine bis drei Lösungen ausgewählt werden

8. Analysieren Sie die Analogien

Dauer dieser Phase:20 Minuten.

Ziel ist es eine Liste der Merkmale und Funktionsprinzipien der ausgewählten Analogien aufzuzeichnen. Was zeichnet die gefundenen Geräte oder Verfahren aus?

9. Force fit

Dauer:30 Minuten.

Dies ist die entscheidende Phase: die zuvor aufgestellte Merkmalsliste wird nun auf die Ausgangsfrage zurückbezogen. Welche Bedeutung haben die Merkmale dieser Liste in Hinsicht auf unser Problem?

Wurde zuvor in vier Schritten ein großer Abstand zur Ausgangsfrage erzielt, so müssen nun die Teilnehmer nun mit einem Riesensatz zurückspringen und brauchbare Ideen finden. Wichtig ist jedoch, dass sie sich auf eine Lösung einigen müssen, wie auch immer diese aussieht, denn dieser Schritt heißt nicht ohne Grund „force fit oder übersetzt: "erzwungene Einigung".

Die Methode der Synektik ist nicht ganz unproblematisch, denn der Zwang zu kreativen Ideen kann eine sog. kreative Denkfalle öffnen, mit dem Ergebnis, dass die Teilnehmer die abwegigsten Ideen produzieren, die sich nie in die Praxis umsetzen lassen. Aus diesem Grund ist das „Force Fit ein unbedingter Bestandteil dieser Methode, die er sowohl von den Teilnehmern als auch vom Moderator ein Höchstmaß an Fantasie und Konzentration abverlangt. Es empfiehlt sich daher vor diesem Schritt eine Pause einzulegen.

10. Formulieren sie Lösungsansätze

Dauer:20 Minuten.

Ausgehend von den Ideen aus der letzten Phase, formuliert die Gruppe ihre Lösungsansätze. Dabei ist weniger die Anzahl der Lösungsansätze wichtig, als dass diese auch weiter ausgearbeitet werden können. Damit ist das Ziel der synektischen Sitzung erreicht.

So setzen Sie
Die Osborn- Checkl
Konzeptfächer und

Es gibt Kreativitätstechniken die darauf beruhen, dass sich der Anwender in eine Situation oder gar in einer Person oder Rolle hinein versetzt. Stellen Sie sich die Frage: " was würde ein zehnjähriges Kind dazu sagen?" Obwohl diese Techniken vielfach als unseriös angesehen werden, sind sie oft erstaunlich effektiv; flexibel und auch sehr erfolgreich. Obwohl Sie sich prinzipiell in jede Rolle hinein versetzen könnten, gibt es Technikern die es nicht bei unverbindlichen Vorgaben belassen. Auf diese Art und Weise sind die "6 Denkhüte" von De Bono oder die " drei Denkstühle " von Walt Disney entstanden.

Was leisten solche Techniken?

Diese Techniken versetzen Sie in der Lage, ihr Problem aus unterschiedlichen Perspektiven zu durchdenken. Dabei werden alle Aspekte erfasst, und zwar wesentlich effizienter, als wenn sie " direkt " darüber nachdenken. Sie können wesentlich spielerischer und „rücksichtsloser vorgehen, wenn sie sich in bestimmte Rollen oder Standpunkte projizieren. Dies erweitert ihren Ideenradius erheblich.

Die Stärken dieser Techniken:

- Ermöglicht eine Distanz zu ihrem Problem
- Betrachtet das Problem aus mehreren Perspektiven
- Kann bei Gruppensitzungen Spannungen lösten

Aber auch hier gibt es Schwächen:

Die Technik bleibt verhältnismäßig nah an ihrem gewohnten Denken; wenn sie kreativer sein möchten, sollten Sie auf andere Techniken zurückgreifen.

Die Technik wirkt zunächst etwas unnatürlich; ihre Wirksamkeit entfaltet sich erst nach einiger Übung

Im Folgenden werden diese Techniken am Beispiel von Disney´s Denkstühlen erklärt.

Von Walt Disney wird berichtet, dass es sich bei seiner kreativen Arbeit nacheinander in verschiedenen Rollen versetzt hat:

- Die des Träumers
- Des Realisten
- Des Kritikers

Disney habe diese Rollen zuvor ist so gut wie möglich getrennt. Dies tat er daher durch, dass er beim Wechsel der Rolle auch seinen Platz in seiner Firma wechselte. So soll er zunächst drei unterschiedliche Denkstühle gehabt haben, später sogar drei unterschiedliche Räume für seine unterschiedlichen Denkhaltungen.

So setzen Sie diese Strategie für sich ein

Die Osborn- Checkl
Konzeptfächer und

So setzen Sie diese Strategie für sich ein:

- Sie nehmen nacheinander verschiedene Denkhaltungen ein
- Diese Denkhaltungen verknüpfen sie mit bestimmten Ort zum „Verankern
-

Es ist ganz normal, dass sie zu Beginn etwas Mühe haben werden, sich in die entsprechende Denkhaltung hinein zu finden. Dies wird durch die Verbindung mit einem festen Platz erleichtert.

Der Stuhl des Träumers

Auf diesem Stuhl produzieren sie die fantastischsten Einfälle und spielen mit verschiedenen Möglichkeiten und auch Unmöglichkeiten. Sie dürfen fast alles, nur eines sollten sie tunlichst unterlassen: ernsthaft über das Problem nachzudenken. Spinnen sie ihre Ideen und Vorstellungen und bringen sie sie zu Papier.

Der Stuhl des Kritikers

Unterziehen sie ihre Ideen einer schonungslosen Kritik. Sie sollten prüfen, was sich umsetzen lässt und was nicht. Sie sollten sich die Frage stellen, ob sich die Sache lohnt und ob sie sie überhaupt wollen. Was überflüssig ist, sollte jetzt gestrichen werden.

Der Stuhl des Realisten

An diesem Platz kommen sie wieder zur " Normalität " zurück. Sie versuchen die verrückten Ideen des Träumers weiterzuentwickeln, greifen Anregungen auf und suchen schon jetzt nach neuen Lösungen. Weiterhin wählen Sie den kürzesten und zweckmäßigsten Weg aus. Dabei sollten sie sehr pragmatisch vorgehen.

Der Wechsel der Stühle

Sie sollten nicht zu lange auf einer bestimmten Stufe verweilen. Auch während der Fragestellung können sie mehrmals die Stühle wechseln. Wenn sie das Projekt abschließen wollen, sollten sie im Idealfall auf dem Stuhl des Realisten sitzen.

Die Osborn- Check
Wie wird mit
Konzeptfächer und

Alex Osborn, der Erfinder des Brainstorming, hat noch weitere Kreativtechniken entwickelt. Die Bekannteste ist die nach ihm benannte Checkliste, mit der Sie aus bereits existierenden Ideen neue Lösungen kreieren können.

Was leistet die Osborn- Checkliste?

Sollte die Lösung für ein vorhandenes Problem nur konventioneller oder unbefriedigender Natur sein, so können Sie anhand der Checkliste überprüfen, wo etwas verändert werden kann, um eine kreativere Lösungen zu finden.

Die Osborn- Checkliste ist besonders geeignet:

- Bei bereits vorliegenden Ideen oder Produkten
- Die Nachbearbeitung einer Brainstorming Sitzung
- Zum Auffinden origineller Produktideen

Diese Technik ist weniger geeignet:

- Wenn man erst am Anfang ganz Projektes steht
- Texte und Verfahren
- Wenn Originalität nicht gefragt ist

Es was benötigen sie um diese Technik durchzuführen?

- Eine existierende Idee oder ein Produkt, welches sie verbessern möchten
- Die hier vorliegende Checkliste

Dauer: etwa eine Stunde; Unterbrechungen sind möglich.

Mit der Osborn Checkliste lassen sich schwache Ideen oder Produkte mit Kreativität "aufpeppen".

Wie wird mit der Osborn Checkliste gearbeitet?

Die Osborn- Check
Wie wird mit
Konzeptfächer und

Für jede Idee oder jedes Produkt welches Sie bearbeiten möchten, sollten Sie die Checkliste komplett durchgehen. Sie sollten sich genügend Zeit für jeden einzelnen Punkt einräumen und zu jedem Punkt mindestens eine Ideen notieren.

- **Anderes verwenden!** - Gibt es eine andere Möglichkeit das Produkt zu gebrauchen? Können Sie die Idee woanders einsetzen?
- **Anpassen!** - Gibt es etwas, was dieser Idee ähnelt? Existieren Parallelen? Was könnten Sie nachahmen?
- **Ändern!** - Können sie die Größe, Form, Farbe, Bewegung etc. verändern?
- **Vergrößern!** - Können sie ist größer machen? Etwas hinzufügen? Die Stärke, die Höhe, den Wert, die Länge, oder den Abstand ferneren? Können Sie es duplizieren? Oder gar übertreiben, vielleicht vergröbern?
- **Verkleinern!** - Kann man es kleiner machen? Etwas wegnehmen oder tiefer machen? Geht es kürzer, dünner oder leichter? Was ist wenn sie es heller, von einer oder gar aufspalten? Kann man es als Miniatur verwenden?
- **Ersetzen!** - Was kann an dieser Idee ausgetauscht werden? Kann der Prozess anderes gestaltet werden? Lassen sich die Positionen, Tonlagen, oder Elemente durch andere ersetzen?
- **Umstellen!** - Können Teile oder Abschnitte ausgetauscht werden? Was ist mit der Reihenfolge, kann man Ursache und Wirkung umdrehen?
- **Umkehren!** - Kann man aus der Idee das Gegenteil machen? Wie sieht Idee spiegelverkehrt aus? Oder lässt sich die Idee gar um 180 Grad drehen?
- **Kombinieren!** - Lassen sich andere Ideen mit der bestehenden Idee verbinden oder kombinieren? Oder lässt sich die Idee in ein bestehendes größeres Ganzes einfügen, in Module oder Bausteine zerlegen?
- **Transformieren!** - Kann man die Eigenschaften der Idee verändern? Kann man die Idee ausdehnen, transparent machen, verhärten oder verflüssigen?

Wie geht man

Manchmal hat man sich bei einem Problem festgefahren und kommt nicht mehr weiter. Dann es ist oft sehr hilfreich, wenn sie die Betrachtungsebene ändern. Das heißt in den meisten Fällen: die Frage muss grundsätzlicher formuliert werden. Mit diesen Techniken lässt sich das Problem oft überraschend einfach lösen.

Die folgenden zwei Techniken greifen auf genau dieses Prinzip zurück. Diese Methoden wurden von Edward de Bono (Konzeptfächer) und von H. Geschka (progressive Abstraktion) entworfen.

Beide Techniken helfen systematisch eine Vielzahl von Lösungsmethoden zu entwickeln und dabei die beste Alternative zu finden.

Für folgende Fälle sind die Techniken besonders geeignet:

- Wenn man sich an einer Frage festgefahren hat
- Bei strategischen Fragen
- Wenn eine bestehende Lösung verbessert werden soll
-

Weniger geeignet sind diese Technik und für:

- Den Fall, dass sie keine Lösung oder Belegung haben, von der sie ausgehen können
- Wilde Ideen und kreative Sprünge
-

Was benötigen Sie für diese Techniken?

Wenn sie diese Techniken in Einzelarbeit durchführen benötigen sie Schreibzeug und Papier. Bei Gruppenarbeit (vier bis sechs Teilnehmer) benötigen sie einen Moderator, der auch Protokollieren kann, sowie eine Tafel oder Flipchart.

Dauer: sehr unterschiedlich und abhängig von der Aufgabenstellung; oft kommt man ganz schnell zu einer Lösung.

Die progressive Abstraktion bzw. die Konzeptfächer ermöglichen es ihnen systematisch dem Grundsätzlichen ihrer Idee auf die Spur zu kommen. Sie können, ohne die bereits geleistete Arbeit zu verwerfen, den Denkprozess noch einmal von vorne beginnen.

Wie geht man bei der Arbeit mit dem Konzeptfächern und der progressiven Abstraktion vor?

[Konzeptfächer und progressive Abstraktion]
[Wie geht man bei der Arbeit mit dem Konzeptfächern und der prog ressiven Abstraktion vor?]

Wie geht man bei der Arbeit mit der

Das Prinzip ist simpel, einfach und einleuchtend: als Ausgangspunkt nehmen Sie die unzulängliche Lösung des Problems und versuchen es auf eine allgemeine Ebene zurückzuführen (= Abstraktion). Sie können sich auch fragen, welches Konzept hinter dieser Lösung steht. Im Folgenden werden die drei Schritte beschrieben, mit denen sie zu einer besseren Lösung kommen. Diese Abfolge ist beliebig wiederholbar.

- Worum geht es eigentlich? Legen Sie dies bitte fest.
- Sie erschließen sich Handlungsalternativen
- Sie entscheiden sich für eine Lösung

-

Worum geht es?

Durch Abstraktion verlagern Sie das Problem auf die nächst höhere Ebene. Hierbei sollten Sie nicht zu übertrieben vorgehen.

- Welche Alternativen gibt es?
- Mit welchen Möglichkeiten kann man dieses Konzept realisieren?
- Für welche Lösung entscheiden Sie sich?

-

Sie prüfen die Alternativen auf ihre Brauchbarkeit und entscheiden sich für eine von ihnen. Haben sie eine passende Lösung gefunden, ist Ihr Problem gelöst. In dem Fall, dass sie nicht zufrieden sind sollten Sie auf keinen Fall aufhören. Abstrahieren sie einfach weiter! Der nächste Schritt entspricht dann wieder dem Ersten, nur arbeiten sie jetzt auf einer noch allgemeineren Ebene und können noch mehr Alternativen in Betracht ziehen. Das wiederholte abstrahieren führt zu einer fächerförmigen Struktur. Je weiter sie sich von ihrem Ausgangspunkt wegbewegen, also stärker abstrahieren, umso mehr Optionen ergeben sich auf der unteren Ebene. Allerdings müssen diese Optionen zunächst aus den übergeordneten Konzepten abgeleitet werden. Im folgenden Schaubild ist dargestellt wie solche Konzeptfächer aussehen können. Das Beispiel ist natürlich banal, aber die Methode lässt sich auch auf komplexere Fragestellungen anwenden.

(57) **ABSTRACT**

The present invention relates to a method and system for evaluating the quality of encoded video data without gaining access to the source data or the compressed video bitstream. The system is configured to decode compressed video data using an MPEG decoder to produce decompressed video data. The decoded data is analyzed to determine whether the decompressed video data is intra-coded. If so, a discrete cosine transform (DCT) is performed to produce a set of DCT coefficients for at least one AC frequency band in the decompressed video data. At the same time, quantization matrix data of a frame of the decompressed video data as well as a quantizer scale for each block of the decompressed video data are extracted. Thereafter, the variance of the converted DCT coefficients is obtained, and then an average quantization error for each set of said DCT coefficients is determined based on the variance, the quantization matrix, and the quantizer scale. Lastly, a peak signal to noise ratio (PSNR) is calculated based on the resultant average quantization error.

FIG. 7

METHOD AND SYSTEM FOR ESTIMATING OBJECTIVE QUALITY OF COMPRESSED VIDEO DATA

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to a method and system for measuring the quality of compressed video data and, in particular, to a method and system for assessing the objective quality of compressed pictures, namely Peak-Signal to Noise-Ratio (PSNR), without referring to the source video data.

2. Description of the Related Art

It is the ultimate goal of the video experts to provide most perceptually appealing video images to viewers. One way to determine whether the resulting image quality is good or poor is to ask a panel of viewers to watch certain video sequences to provide their opinions. Another way to analyze video sequences is to provide an automated mechanism to evaluate the excellence or the degradation of the video quality. This type of procedure is known as "objective video quality assessment."

A common approach for measuring the picture quality of a compression process is to make a comparison between the processed image and the unprocessed source images (hereinafter referred to as "double-ended measurement"). Various metrics are used, i.e., Block Artifact Metric (BAM), PSNR, Perceptually Weighted PSNR, etc., to evaluate an objective picture quality measure. In particular, the PSNR is most commonly used parameter for measuring any picture quality, especially in evaluating MPEG-2 video bitstream. However, the double-ended measurement has some drawbacks in that access to both the processed picture and the source picture is not feasible if the source data or the alignment between the source and processed pictures are unavailable. In order to overcome this problem, a "single-ended measurement" has been proposed to monitor the video quality when the source is neither available nor controllable. Unlike the double-ended measurement, the single-ended measurement technique operates on the compressed picture without access to the source picture when evaluating video quality. Although there are various single-ended methods that have been proposed, no single-ended measurement uses the PSNR metric in evaluating the compressed pictures alone without access to the source picture or the compressed video bitstream. Accordingly, the present invention proposes an objective quality assessment using the PSNR metric to evaluate the objective quality of compressed pictures without utilizing the source data or the compressed video bitstream.

SUMMARY OF THE INVENTION

The present invention is directed to an apparatus and method for evaluating the quality of encoded video data without access to the source data or the compressed video bitstream, by utilizing quantization parameters estimated directly from the decompressed picture.

According to an aspect of the invention, the method of evaluating the picture quality includes the steps of: performing a discrete cosine transform (DCT) on at least a substantial portion of the decompressed video data to produce a set of DCT coefficients for at least one AC frequency band; simultaneously, extracting quantization matrix data for at least one AC frequency band and extracting a quantizer scale for each block of the decompressed video data; estimating a variance of the DCT coefficients; determining an average quantization error for each set of the DCT coefficients based on the resultant variance, quantization matrix, and quantizer scale; and, calculating a peak signal to noise ratio (PSNR) based on the average quantization error.

According to another aspect of the invention, the method includes the steps of: performing a DC computation operation to recover an intra-dc-precision level from the decompressed video data; and, if the intra-dc-precision level is less than a predefined threshold, classifying the decoded video data as an intra-coded; performing a discrete cosine transform (DCT) on the decompressed video data to produce a set of DCT coefficients for at least one AC frequency band; extracting quantization matrix data for the at least one AC frequency band; extracting a quantizer scale for each block of the decompressed video data; estimating a variance of the DCT coefficients; determining an average quantization error for each set of the DCT coefficients; and, calculating a peak signal to noise ratio (PSNR) based on the average quantization error.

According to anther aspect of the invention, the apparatus capable of evaluating the quality of encoded video data includes: a decoder for decoding at least a substantial portion of the encoded video data to produce decoded video data including a plurality of blocks; a discrete cosine transform (DCT) configured to transform the decompressed video data into a set of DCT coefficients for at least one AC frequency band; an extractor for extracting quantization matrix data for at least one AC frequency band and for extracting a quantizer scale for each block of the decompressed video data; a collector for estimating a variance of the DCT coefficients; a first calculator for determining an average quantization error for each set of the DCT coefficients based on the variance, the quantization matrix, and the quantizer scale; a second calculator for determining a peak signal to noise ratio (PSNR) based on the resultant average quantization error; and, a picture detector for detecting an intra-coded picture in each block of the decompressed video data. The picture detector further includes a means for performing a DC computation operation to recover intra-dc-precision level from the decompressed video data; and, a means for classifying the decoded video data as an intra-coded picture when the intra-dc-precision level is less than a predefined threshold.

According to another aspect of the invention, the apparatus includes: a decoder configured to decode compressed variable-length Huffman codes and for producing therefrom decoded data, and for extracting quantization matrix data and a quantizer scale for each block of the decoded video data; an inverse quantizer configured to perform inverse-quantizing of the decoded data output from the decoder to produce a set of DCT coefficients; an inverse DCT configured to transform values of pixels in blocks of signals output from the inverse quantizer to dequantize decoded data including the difference data; a motion compensation and adder for receiving reference data within the encoded video data and the difference data from said inverse DCT to form motion compensated pictures therefrom; a collector coupled to the output of the inverse quantizer for estimating a variance of the DCT coefficients; a first calculator for determining an average quantization error for each set of the DCT coefficients based on the variance, quantization matrix, and quantizer scale; and, a second calculator for determining a peak signal to noise ratio (PSNR) based on the resultant average quantization error. The apparatus further includes a video memory configured to store reproduced video data.

The foregoing and other features and advantages of the invention will be apparent from the following, more detailed description of preferred embodiments as illustrated in the accompanying drawings in which reference characters refer to the same parts throughout the various views. The drawings are not necessarily to scale; the emphasis instead is placed upon illustrating the principles of the invention.

BRIEF DESCRIPTION OF THE DRAWINGS

DETAILED DESCRIPTION OF THE EMBODIMENTS

In the following description, for purposes of explanation rather than limitation, specific details are set forth such as the particular architecture, interfaces, techniques, etc., in order to provide a thorough understanding of the present invention. For purposes of simplicity and clarity, detailed descriptions of well-known devices, circuits, and methods are omitted so as not to obscure the description of the present invention with unnecessary detail.

In order to facilitate an understanding of this invention, background information relating to MPEG2 coding is explained. In general, the MPEG2 coding is performed on an image by dividing the image into macro-blocks of 16×16 pixels, each with a separate quantizer scale value associated therewith. The macro-blocks are further divided into individual blocks of 8×8 pixels. Each 8×8 pixel block is subjected to a discrete cosine transform (DCT) to generate DCT coefficients for each of the 64 frequency bands therein. The DCT coefficients in an 8×8 pixel block are then divided by a corresponding coding parameter, i.e., a quantization weight. The quantization weights for a given 8×8 pixel block are expressed in terms of an 8×8 quantization matrix. Thereafter, additional calculations are affected on the DCT coefficients to take into account, namely the quantizer scale value, among other things, and thereby complete MPEG2 coding. It should be noted that other coding techniques, such as JPEG or the like, may be used in the present invention.

FIG. **1** is a simplified circuit diagram whereto the embodiment of the present invention is applied. The inventive system **10** includes a video source **12**, an encoder **14**, a decoder **16**, and an estimator **18**. The source **12** may be any type of video generating device, such as a television camera or other video equipment that is capable of generating video data based on a particular image. The encoder **14** and decoder **16** may be any conventional encoder and decoder known in this art for encoding/decoding MPEG2 video data, respectively. The estimator **18** processes the decoded video data to evaluate the objective quality of compressed pictures without utilizing the source video data or the compressed video bitstream. To achieve this, the present invention relies on a statistical analysis to determine the quality of the picture that has been compressed in a previous coding operation. The statistics of pictures are gathered from the DCT coefficients either after the decompression stage or during the decompression stage, thereby eliminating the need for gaining access to the source picture in accordance with the present invention.

Now, a description will be made in detail regarding this invention with reference to FIGS. **2–7**.

FIG. **2** depicts a representative hardware of the decoder **16** and the estimator **18** illustrated in FIG. **1** according to a first embodiment of the present invention. In particular, the first embodiment provides a mechanism for estimating video quality after the coded video data has been decompressed via the decoder **16**. The estimator **18** includes a picture determinator **20**, a 8×8 DCT **22**, a statistics collector **24**, a quantization parameter extractor **26**, a distortion calculator **28**, and a PSNR calculator **30**. A key principle of the present invention relies on the fact that the quality of P and B pictures and hence the overall video is in general consistent with that of the intra pictures for the MPEG-2 coded video. Therefore, if the PSNR can be estimated only for intra-coded pictures, it serves as a quality metric for the overall video as a good video encoder strives to maintain a consistent quality from picture to picture.

In operation, the decoded video data, after being decoded by the decoder **16**, is forwarded to the picture determinator **20** of the estimator **18**. The picture determinator **20** then determines whether the decoded video data is intra-coded. In MPEG-2 video, intra_dc_precision controls the quantization coarseness of DC DCT coefficients in intra-coded macroblocks or intra-coded pictures and ranges from 8 to 11 bits, with 11 bits as the highest which results when no quantization error occurs in the intra DC coefficients. In most broadcast quality digital video, the lowest intra_DC_precision is typically set to 8. Accordingly, if the estimated intra_DC_precision less than 11, the current picture is determined to be intra-coded in the present invention. If intra-coded, the DCT block **22** subjects the decoded video data to DCT processing in order to generate DCT coefficients for AC frequency bands. Thereafter, the statistics collector **24** estimates the variance of the DCT coefficients, whereafter the estimated DCT variance is transmitted to the distortion calculator **28**. At the same time, the quantization extractor **26** extracts quantization matrices that correspond to those used in a previous coding operation. U.S. Pat. No. 6,101,278 entitled, "System for Extracting Coding Parameters from Video Data," assigned to the same assignee, explains how to extract the quantization matrices (W_{ij}), thereby incorporated herein as a reference. The distortion calculator **28** then uses the extracted quantization matrices, quantizer step size and the estimated DCT variance to determine the average quantization error. Thereafter, the PSNR calculator **26** determines the PSNR, using the average quantization error obtained by the distortion calculator block **28**. The value of PSNR is used to evaluate any degradation in the video quality.

FIG. **3** is a flow diagram depicting the operation steps of evaluating video quality in accordance with the first embodiment of the present invention. It should be noted that the processing and decision blocks may represent steps performed by functionally equivalent circuits, such as a digital signal processor circuit or an application-specific integrated circuit (ASIC). The flow diagrams do not depict the syntax of any particular programming language. Rather, the flow diagrams illustrate the functional information that a person of ordinary skill in the art requires to fabricate circuits or to generate computer software to perform the processing required of the particular apparatus.

Upon receiving the decoded video output from the decoder **14**, an 8×8 block DC precision computation is performed by the picture type determinator **20** to determine whether the decoded video is intra-coded for each macroblock in step **100**. It is noted that the intra-coded pictures

possess unique statistical properties from non-compressed pictures, or P and B coded pictures, and the number of bits used to represent intra DC coefficients is 11 bits before compression. Hence, if the intra DC precision is less than 11, the current picture being analyzed is classified as an intra-coded picture

In step **120**, the detected intra code picture is then subjected to a DCT transform by the DCT block **22** to generate DCT coefficients for AC frequency bands in the video data. In step **140**, quantization matrices (W_{ij}) and a quantizer step size for each macroblock (Q_m) for the whole picture are obtained. That is, after determining that the current picture being analyzed is an intra-coded picture, the quantization parameter extractor **26** operates to extract a quantization matrix for each frame that correspond to those used in a previous coding operation. A quantization matrix consists of sixty-four entries, each entry being designated with a weight. The sixty-four entries, each being an 8-bit integer ranging from 1 to 255, correspond to 8×8 DCT coefficients in a block. The weight and the quantizer scale-value determine the quantization step-sizes for a block of DCT coefficients. The process of extracting quantization matrices (W_{ij}) is explained in U.S. Pat. No. 6,101,278, entitled, "System for Extracting Coding Parameters from Video Data," assigned to the same assignee, thereby incorporated herein as a reference. The quantization parameter extractor **26** further operates to extract a quantizer step size/scale for each macroblock. In order to extract a quantizer step size/scale for each macroblock, the AC coefficients in the macroblock is averaged. In the case of MPEG-2, a quantization matrix is first extracted as discussed in U.S. Pat. No. 6,101,278 to obtain the weights W_{ij}, for i, j=0, 1 . . . 7 and i, j (0, 0). Each AC coefficient is then weighed according to the equation below:

$$\overline{C}_{i,j} = \frac{C_{i,j} \times 16}{W_{i,j}},$$

wherein $C_{i,j}$ represents the (i, j)th AC coefficient in the current macroblock, and $\overline{C}_{i,j}$ represents the weighted or normalized AC coefficient. In other DCT-based compression schemes where quantization matrix is not utilized, i.e., where all AC coefficients in the same macroblock are quantized with the same step size, this step may be skipped. After averaging the AC coefficients in the macroblock, the operation of finding a quantization scale and a DCT type is executed by finding the largest common divider for all normalized AC coefficients in the macroblock, or just for a selected set of coefficients, such as the first 4 AC coefficients in a zig-zag scanning order. For MPEG-2 video, this is performed on both the frame DCT data and field DCT data. Finding the largest common divider for all normalized AC coefficients in the macroblock can be processed as follows:

```
First for frame DCT block:
q=max_Q
d_max=large number
while (q>lowest_q_allowed)
{
    d=0
    for i,j = 0,. . .7 and i,j    (0,0)
    {
        quantize C̄i,j with q:    i,j = quantize(C̄i,j, q)
        d = d + abs(C̄i,j− i,j)
        if (abs(d_prev / d) > threshold) return current_DCT_Type
        and q
        q=next_lower_q
        d_prev=d
    }
}
```

In the above pseudo-code, abs( ) stands for "absolute value" operation. quantize( ) is the quantization procedure which is specified by the video coding scheme. A nominal value for threshold is 1.5.next_lower_q and determined according to different coding schemes. The above code essentially performs a search operation through possible quantization scale values and DCT types. When the search starts, the DCT type is initiated to frame DCT as the frame-based DCT is more likely used in MPEG-2 coded video. For other video coding standards, such as MPEG-1, MPEG-4 and H.263, or MPEG-2 field pictures, the DCT type will remain as frame based. The quantization scale is initiated to the highest value allowed by the standard. For example, in MPEG-2, this number is 62 or 112 depending on the coding scheme used for quantization scale. For each quantization scale value, the quantization distortion is computed for the current macroblock. The computed distortion is then compared with the previous computed and stored distortion. If the reduction in distortion in terms of ratio between the two exceeds a certain threshold (set to 1.5 above), then the current quantization scale is extracted and returned. If not, the current distortion is stored, and the search resumes with the next higher quantization scale as dictated by the standard or coding scheme. If a quantization scale is not extracted from frame DCT data, then the same search options are performed on the field DCT data. Alternatively, the search can start with the lowest possible quantization scale and proceeds up, or start with more likely quantization scales. For example, 10 for DVD video or DVB video, and higher than 10 for lower bit rate video. Accordingly, the largest common divider for all normalized AC coefficients calculated, as described in the preceding paragraphs, to determine the DCT type and the quantization scale per macroblock.

Meanwhile, in step **160**, estimating statistics of DCT coefficients is performed. For each AC location (i, j), the variance of the coefficients $\lambda^2_{i,j}$ is estimated according to the formula below:

$$\lambda^2_{i,j} = \frac{\sum_{b=1}^{N} (C^b_{i,j})^2}{2N}$$

wherein C^b_{ij} represents the (i, j)th AC coefficient in block b, and N represents the total number of blocks in the picture. It should be noted that step **140** and step **160** can be performed simultaneously in accordance with the present invention.

After determining the DCT statistics $\lambda^2_{i,j}$, in step **160**, the average quantization error is estimated in step **180**. This is performed for each set of DCT coefficients corresponding to the same DCT location. Calculating the quantization error is explained in the U.S. Pat. No. 6,067,118 entitled, "Method of Frame-By-Frame Calculation of Quantization Matrices," assigned to the same assignee, and herein incorporated by simple reference. For DC, the quantization error $D_{0,0}$ is estimated to be half that of the intra-DC quantization step size according to the table below.

Intra_DC_Precision	Average DC quantization error
8	4
9	2
10	1
11	0

Hence, the (i, j)th AC location, the quantization error $D_{i,j}$ is estimated as follows:

$$D_{i,j} = 2\lambda_{i,j}^2\left(1 - \frac{\beta_{i,j}}{e^{\beta_{i,j}/2} - e^{-\beta_{i,j}/2}}\right)$$

$$\text{where } \beta_{i,j} = \Delta_{i,j}/\lambda_{i,j} = \frac{W_{i,j}Q}{16\lambda_{i,j}}.$$

In the event that all coefficients corresponding to an AC location are zero, either because of coarse quantization during encoding or small magnitude of the coefficients, $\lambda_{i,j}$ may be estimated according to the following equation:

$$\frac{1}{\lambda_{i,j}} e^{-\frac{W_{i,j}Q/16}{2\lambda_{i,j}}} = \frac{1}{N},$$

wherein N represents the number of blocks in the picture. Alternatively, a look-up-table may be utilized to solve the equation quickly. The average quantization error or distortion for this AC location is then estimated as follows:

$$D_{i,j}=2\lambda^2_{i,j},$$

Here, it is assumed that the true distribution of the (i, j)th coefficients range from all 0 (with no quantization error) to the Laplacian distribution with parameter $\lambda_{i,j}$ (with quantization error $2\lambda^2_{i,j}$). Finally, the overall average distortion in the DCT domain is computed as follows:

$$D = \frac{\sum_{i=0,j=0}^{i=7,j=7} D_{i,j}}{64}.$$

Finally, in step **200**, the PSNR is calculated as follows:

$$PSNR = 10\log_{10}\frac{255\times 255}{D}$$

The peak signal-to-noise ratio (PSNR) obtained, as described in the preceding paragraph, can be used to evaluate the picture quality in accordance with the present invention.

FIG. **4** depicts a representative hardware of the decoder **16** and the estimator **18** illustrated in FIG. **1** according to a second embodiment of the present invention. The decoder **16** includes a parser **40**, DCT block **42**, a statistics collector **44**, a distortion calculator **46**, and a PSNR calculator **48**. In operation, an incoming bitstream is decoded by the decoder **16**, and the decoded video data is subjected to DCT processing by the DCT block **42** in order to generate DCT coefficients for AC frequency bands in the video data. The statistics collector **44** estimates variance of the DCT coefficients, whereafter the estimated DCT variance is transmitted to the distortion calculator **46**. Meanwhile, the parser **40** extracts quantization matrices from the incoming bitstream that correspond to those used in a previous coding operation. The distortion calculator block **46** uses the quantization matrices and the DCT variance to determine the average quantization error. Finally, the PSNR calculator block **48** determines the PSNR using the average quantization error obtained by the distortion calculator block **24**.

FIG. **5** depicts a representative hardware of the decoder **16** and estimator **18** illustrated in FIG. **1** according to a third embodiment of the present invention. The construction and operation of the second embodiment are essentially the same as that described above with respect to FIG. **2**(*a*). The only notable difference is that the function of the parser **40** is incorporated in the estimator **18** in the second embodiment. Hence, the discussion of similar components described in the preceding paragraphs is omitted to avoid redundancy, as they are described with respect to FIG. **4**.

FIG. **6** is a flow diagram depicting the operation steps of evaluating video quality in accordance with the second and third embodiments of the present invention. It should be noted that the processing and decision blocks may represent steps performed by functionally equivalent circuits such as a digital signal processor circuit or an application specific integrated circuit (ASIC). In addition, the flow diagrams illustrate the functional information that a person of ordinary skill in the art requires to fabricate circuits or to generate computer software to perform the processing required of the particular apparatus. Specifically, with reference to FIGS. **4** and **5**, the incoming video data is decoded in step **100**. From the decoded video data, the intra_DC_precision, quantization matrices (W_{ij}), and quantization step size for each macroblock Q_m for the whole picture are extracted in step **320**. A quantization matrix consists of sixty-four entries, each entry being designated with a weight. The sixty-four entries, each being an 8-bit integer ranging from 1 to 255, correspond to 8×8 DCT coefficients in a block. The weight and the quantizer scale-value determine quantization step-sizes for a block of DCT coefficients. Thereafter, in step **340**, the decoded video data is subjected to a DCT transform to generate DCT coefficients for AC frequency bands in the video data.

In step **360**, estimating statistics of DCT Coefficients is performed. For each AC location (i, j), the variance of the coefficients $\lambda^2_{i,j}$ is estimated according to the formula below:

$$\lambda^2_{i,j} = \frac{\sum_{b=1}^{N}(C^b_{i,j})^2}{2N}$$

wherein C^b_{ij} represents the (i, j)th AC coefficient in block b, and N represents the total number of blocks in the picture.

After determining the DCT statistics $\lambda^2_{i,j}$, in step **380**, the average quantization error is estimated. This is performed for each set of DCT coefficients corresponding to the same DCT location. Calculating the quantization error is explained in the U.S. Pat. No. 6,067,118 entitled, "Method of Frame-By-Frame Calculation of Quantization Matrices," assigned to the same assignee, and herein incorporated by simple reference. For DC, the quantization error $D_{0,0}$ is estimated to be half that of the intra-DC quantization step size according to the table below:

Intra_DC_Precision	Average DC quantization error
8	4
9	2

-continued

Intra_DC_Precision	Average DC quantization error
10	1
11	0

For the (i, j)th AC location, the quantization error $D_{i,j}$ is estimated as follows:

$$D_{i,j} = 2\lambda_{i,j}^2\left(1 - \frac{\beta_{i,j}}{e^{\beta_{i,j}/2} - e^{-\beta_{i,j}/2}}\right)$$

where $\beta_{i,j} = \Delta_{i,j}/\lambda_{i,j} = \frac{W_{i,j}Q}{16\lambda_{i,j}}$.

In the event that all coefficients corresponding to an AC location are zero either because of coarse quantization during encoding or a small magnitude of the coefficients, $\lambda_{i,j}$ may be estimated according to the following equation:

$$\frac{1}{\lambda_{i,j}} e^{\frac{W_{i,j}Q/16}{2\lambda_{i,j}}} = \frac{1}{N},$$

wherein N represents the number of blocks in the picture. Alternatively, a look-up-table may be utilized to solve the equation quickly. The average quantization error or distortion for this AC location is then estimated as follows:

$$D_{i,j} = 2\lambda^2_{i,j}.$$

Here, it is assumed that the true distribution of the (i, j)th coefficients range from all 0 (with no quantization error) to the Laplacian distribution with the parameter $\lambda_{i,j}$ (with quantization error $2\lambda^2_{i,j}$). The overall average distortion in DCT domain is computed as follows:

$$D = \frac{\sum_{i=0,j=0}^{i=7,j=7} D_{i,j}}{64}.$$

Finally, in step **400**, the PSNR is calculated as follows:

$$PSNR = 10\log_{10}\frac{255\times 255}{D}.$$

Accordingly, the peak signal-to-noise ratio (PSNR) necessary to evaluate the picture quality is obtained.

FIG. **7** illustrates a fourth embodiment of the present invention in which the hardware of the estimator is integrated into a conventional decoder. The decoder according to the present invention is a programmable video decoding system, which includes: a variable length decoder (VLD) **60** configured to receive and decode a stream of block-based data packets; an inverse quantizer **62** coupled to receive the output of the VLD **60** to operatively inverse quantize the quantized data received from the VLD **60**; an inverse discrete cosine transformer (IDCT) **61** coupled to the output of the inverse quantizer for transforming the dequantized data from a frequency domain to a spatial domain; a motion compensator (MC) **68** configured to receive motion vector data from the quantized data and to generate a reference signal based on motion-compensated block of a preceding frame stored in a preceding frame stage and a motion-compensated block of a succeeding frame stored from a frame storage **70**; an adder for receiving the reference signal and the spatial domain data from the IDCT **64** to form motion-compensated pictures; a statistics collector **72** for estimating the variance of the DCT coefficients; a distortion calculator block **74** for determining the average quantization error **74** based on the quantization matrices; and, a PSNR calculator **76** for determining the PSNR using the average quantization error obtained by the distortion calculator block **74**.

While the preferred embodiments of the present invention have been illustrated and described, it will be understood by those skilled in the art that various changes and modifications may be made, and equivalents may be substituted for elements thereof without departing from the true scope of the present invention. In addition, many modifications may be made to adapt to a particular situation and the teaching of the present invention without departing from the central scope. Therefore, it is intended that the present invention not be limited to the particular embodiment disclosed as the best mode contemplated for carrying out the present invention, but that the present invention include all embodiments falling within the scope of the appended claims.

What is claimed is:

1. A method for evaluating the quality of encoded video data, the method comprising the steps of:

decoding at least a substantial portion of said encoded video data to produce decompressed video data including a plurality of blocks;

performing a discrete cosine transform (DCT) on said decompressed video data to produce a set of DCT coefficients for at least one AC frequency band;

simultaneously, extracting quantization matrix data for the at least one AC frequency band and extracting a quantizer scale for each block of said decompressed video data;

estimating a variance of said DCT coefficients;

determining an average quantization error for each set of said DCT coefficients based on said variance, said quantization matrix, and said quantizer scale; and,

calculating a peak signal to noise ratio (PSNR) based on said average quantization error.

2. The method of claim **1**, wherein said quantizer step size is calculated by averaging the AC coefficients in each of said decompressed video data as follows:

$$\overline{C}_{i,j} = \frac{C_{i,j}\times 16}{W_{i,j}},$$

where $C_{i,j}$ represents the (i, j)th AC coefficient in the current block, $\overline{C}_{i,j}$ represents the normalized AC coefficient, and $W_{i,j}$ represents the (i, j)th quantization matrix.

3. The method of claim **2**, wherein the variance of the coefficients (λ^2_{ij}) is determined by the following equation:

$$\lambda^2_{i,j} = \frac{\sum_{b=1}^{N}(C^b_{i,j})^2}{2N},$$

where C^b_{ij} represents the (i, j)th AC coefficient in each block (b), and N represents the total number of blocks.

4. The method of claim **3**, wherein the average quantization error (D) is computed as follows:

$$D = \frac{\sum_{i=0,j=0}^{I=7,j=7} D_{i,j}}{64},$$

and $D_{i,j}=2\lambda^2_{i,j}$,

where λ^2_{ij} represents the variance of the coefficients (λ^2_{ij}), and $D_{i,j}$ represents the quantization error for the (i, j)th AC coefficient in each block.

5. The method of claim **4**, wherein said PSNR is calculated as follows:

$$PSNR = 10 \log_{10} \frac{255 \times 255}{D},$$

where D represents an average quantization error.

6. The method of claim **1**, wherein said quantization matrix and said quantizer scale correspond substantially to coding parameters used in a coding operation that was previously performed on said encoded video data.

7. The method of claim **1**, wherein said quantization matrix and said quantizer scale correspond substantially to coding parameters used in a coding operation that was previously performed on said encoded video data.

8. A method for evaluating the quality of encoded video data, the method comprising the steps of:

at least partially decompressing said encoded video data in an MPEG decoder and outputting a decompressed video data including a plurality of blocks;

detecting an intra-coded picture in each block of said decompressed video data;

if detected, performing a discrete cosine transform (DCT) on said decompressed video data to produce a set of DCT coefficients for at least one AC frequency band;

extracting quantization matrix data for the at least one AC frequency band;

extracting a quantizer scale for each block of said decompressed video data;

estimating a variance of said DCT coefficients;

determining an average quantization error for each set of said DCT coefficients; and,

calculating a peak signal to noise ratio (PSNR) based on said average quantization error.

9. The method of claim **8**, wherein said detecting step comprises the steps of:

performing a DC computation operation to recover the intra-dc-precision level from said decompressed video data; and,

if said intra-dc-precision level is less than a predefined threshold, classifying said decoded video data as an intra-coded picture.

10. The method of claim **8**, wherein said quantizer step size is calculated by averaging the AC coefficients in each of said decompressed video data as follows:

$$\overline{C}_{i,j} = \frac{C_{i,j} \times 16}{W_{i,j}},$$

where $C_{i,j}$ represents the (i, j)th AC coefficient in the current block, $\overline{C}_{i,j}$ represents the normalized AC coefficient, and $W_{i,j}$ represents the (i, j)th quantization matrix.

11. The method of claim **10**, wherein the variance of the coefficients (λ^2_{ij}) is determined by the following equation:

$$\lambda^2_{i,j} = \frac{\sum_{b=1}^{N} (C^b_{i,j})^2}{2N}$$

where C^b_{ij} represents the (i, j)th AC coefficient in each block (b), and N represents the total number of blocks.

12. The method of claim **11**, wherein the average quantization error (D) is computed as follows:

$$D = \frac{\sum_{i=0,j=0}^{I=7,j=7} D_{i,j}}{64},$$

and $D_{i,j}=2\lambda^2_{i,j}$,

where λ^2_{ij} represents the variance of the coefficients (λ^2_{ij}), and $D_{i,j}$ represents the quantization error for the (i, j)th AC coefficient in each block.

13. The method of claim **12**, wherein said PSNR is calculated as follows:

$$PSNR = 10 \log_{10} \frac{255 \times 255}{D}$$

where D represents an average quantization error.

14. An apparatus for evaluating the quality of encoded video data comprising:

a decoder for decoding at least a substantial portion of said encoded video data to produce decoded video data including a plurality of blocks;

a discrete cosine transform (DCT) configured to transform said decompressed video data into a set of DCT coefficients for at least one AC frequency band;

an extractor for extracting quantization matrix data for the at least one AC frequency band and for extracting a quantizer scale for each block of said decompressed video data;

a collector for estimating a variance of said DCT coefficients;

a first calculator for determining an average quantization error for each set of said DCT coefficients based on said variance, said quantization matrix, and said quantizer scale; and,

a second calculator for determining a peak signal to noise ratio (PSNR) based on said average quantization error.

15. The apparatus of claim **14**, further comprising a picture detector for detecting for an intra-coded picture in each block of said decompressed video data.

16. The apparatus of claim **15**, wherein said picture detector comprises:

means for performing a DC computation operation to recover an intra-dc-precision level from said decompressed video data; and,

means for classifying said decoded video data as an intra-coded picture when said intra-dc-precision level is less than a predefined threshold.

17. The apparatus of claim **14**, wherein said quantization matrix and said quantizer scale correspond substantially to coding parameters used in a coding operation that was previously performed on said encoded video data.

18. The apparatus of claim **14**, wherein said quantizer step size is calculated by averaging the AC coefficients in each of said decompressed video data as follows:

$$\overline{C}_{i,j} = \frac{C_{i,j} \times 16}{W_{i,j}},$$

where $C_{i,j}$ represents the (i, j)th AC coefficient in current block, $\overline{C}_{i,j}$ represents the normalized AC coefficient, and $W_{i,j}$ represents the (i, j)th quantization matrix.

19. The apparatus of claim **18**, wherein the variance of the coefficients (λ^2_{ij}) is determined by the following equation:

$$\lambda^2_{i,j} = \frac{\sum_{b=1}^{N} (C^b_{i,j})^2}{2N},$$

where C^b_{ij} represents the (i, j)th AC coefficient in each block (b), and N represents the total number of blocks.

20. The apparatus of claim **19**, wherein the average quantization error (D) is computed as follows:

$$D = \frac{\sum_{i=0,j=0}^{I=7,j=7} D_{i,j}}{64},$$

and $D_{i,j}=2\lambda^2_{i,j}$,

where λ^2_{ij} represents the variance of the coefficients (λ^2_{ij}), and $D_{i,j}$ represents the quantization error for the (i, j)th AC coefficient in each block.

21. The apparatus of claim **20**, wherein said PSNR is calculated as follows:

$$PSNR = 10 \log_{10} \frac{255 \times 255}{D},$$

where D represents an average quantization error.

22. An apparatus for evaluating the quality of encoded video data comprising:

a decoder configured to decode compressed variable-length Huffman codes and for producing therefrom decoded data, and for extracting quantization matrix data and a quantizer scale for each block of said decoded video data;

an inverse quantizer configured to perform inverse-quantizing of the decoded data output from said decoder to produce a set of DCT coefficients;

an inverse DCT configured to transform values of pixels in blocks of signals output from said inverse quantizer to dequantize decoded data including difference data;

a motion compensation and adder for receiving reference data within the encoded video data and said difference data from said inverse DCT to form motion-compensated pictures therefrom;

a collector coupled to the output of said inverse quantizer for estimating a variance of said DCT coefficients;

a first calculator for determining an average quantization error for each set of said DCT coefficients based on said variance, said quantization matrix, and said quantizer scale; and,

a second calculator for determining a peak signal to noise ratio (PSNR) based on said average quantization error.

23. The apparatus of claim **22**, further comprising a video memory configured to store reproduced video data.

24. The apparatus of claim **22**, wherein said quantization matrix and said quantizer scale correspond substantially to coding parameters used in a coding operation that was previously performed on said encoded video data.

25. A system for evaluating the quality of encoded video data comprising:

a memory for storing a computer-readable code; and,

a processor operatively coupled to said memory, said processor configured to:

decompress said encoded video data to produce a decompressed video data including a plurality of blocks;

detect an intra-coded picture in each block of said decompressed video data;

if detected, perform a discrete cosine transform (DCT) on said decompressed video data to produce a set of DCT coefficients for at least one AC frequency band;

extract quantization matrix data for the at least one AC frequency band;

extract a quantizer scale for each block of said decompressed video data;

estimate a variance of said DCT coefficients;

determine an average quantization error for each set of said DCT coefficients; and,

calculate a peak signal to noise ratio (PSNR) based on said average quantization error.

26. The system of claim **25**, wherein the detection of said intra-coded picture includes the steps of:

performing a DC computation operation to recover an intra-dc-precision level from said decompressed video data; and,

classifying said decoded video data as an intra-coded picture when said intra-dc-precision level is less than a predefined threshold.

27. The apparatus of claim **25**, wherein said quantization matrix and said quantizer scale correspond substantially to coding parameters used in a coding operation that was previously performed on said encoded video data.

(57) **ABSTRACT**

A solid immersion mirror (SIM) type objective lens and an optical pickup employing the same. The objective lens has a first curved surface which condenses incident light and a second curved surface surrounding the first curved surface which diverges incident light. A second transmission surface disposed to face the first transmission surface has an area which transmits incident light and a first reflection surface surrounding the second transmission surface which reflects incident light. A second reflection surface which surrounds the second curved reflects incident light. The objective lens realizes an NA of 0.7 or more with a single lens; has a working distance enabling far field recording/reproducing; has a smaller blocking area than that of the conventional SIM; and generates a smaller amount of side lobe. Where the objective lens is adopted in an optical pickup device, generation of jitter during reproduction or cross erasure during recording is minimized.

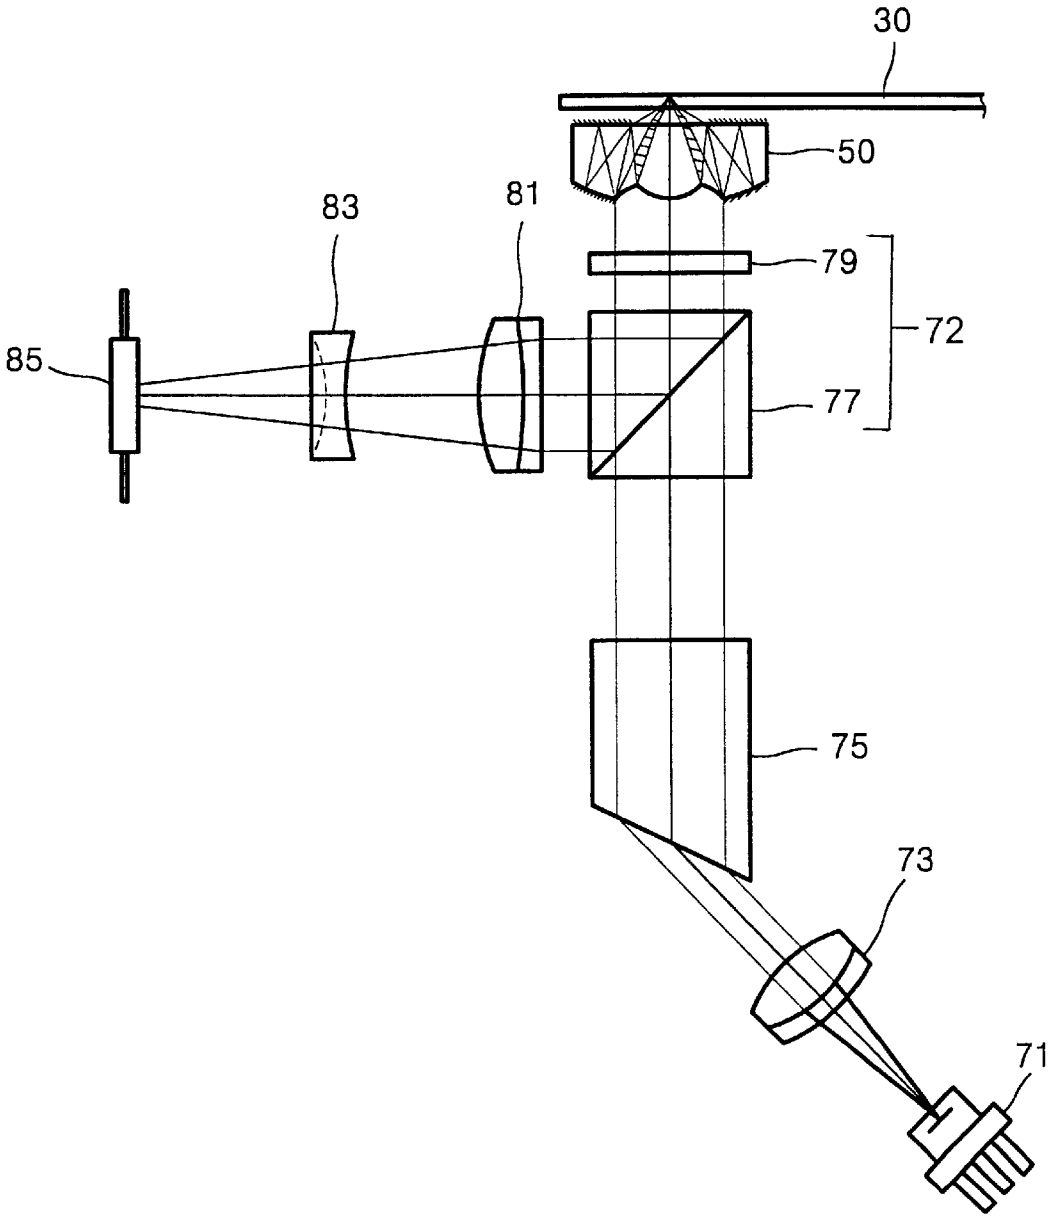
FIG. 7



SOLID IMMERSION MIRROR TYPE OBJECTIVE LENS AND OPTICAL PICKUP DEVICE ADOPTING THE SAME

CROSS REFERENCE TO RELATED APPLICATIONS

This application claims the benefit of Korean Application No. 2000-76492 filed Dec. 14, 2000, in the Korean Patent Office, the disclosure of which is incorporated herein by reference.

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to a solid immersion mirror (SIM) type objective lens and an optical pickup device adopting the same, and particularly, to a modified SIM type objective lens for far field recording/reproducing, and an optical pickup device adopting the same.

2. Description of the Related Art

In general, information recording/reproducing density increases as a size of a light spot formed on an optical disc by an optical pickup device is decreased. The size of a light spot decreases as a wavelength of a light beam in use becomes shorter and an NA of an objective lens which focuses the light spot becomes greater. A relationship of the size of a light spot to wavelength and NA is shown in equation (1).

$$\text{Size of light spot} \propto \lambda/\text{NA} \quad (1)$$

Thus, an optical pickup device for high density should adopt a light source emitting a light beam having a shorter wavelength and an objective lens having a high NA. To realize a stable system, the objective lens should have a working distance (a distance from a light exit surface of an objective lens to a light input surface of an optical disc) which is large. An optical pickup device for recoding/reproducing information on/from an optical disc of a next generation DVD family, or a so-called HD-DVD (high definition digital versatile disk) family, may adopt, for example, a light source for emitting a light beam having a wavelength of 405 nm and an objective lens having an NA of 0.85 and a large working distance.

However, due to a limit in manufacture, it is difficult to manufacture an objective lens formed of a single lens having an NA of 0.7 or more and satisfying an allowance condition of optical aberration. Thus, to realize an NA of 0.7 or more and satisfy an allowance condition of optical aberration, an objective lens **10** formed of two lenses as shown in FIG. **1** has been suggested.

Referring to FIG. **1**, a conventional objective lens **10** includes a first condensing lens **11** for condensing incident light and a second condensing lens **13** arranged between the first condensing lens **11** and an optical disc **1** for increasing an NA of the objective lens **10**. In the objective lens **10**, for example, where a 0.6 NA is secured by the first condensing lens **11**, the NA may be increased by the second condensing lens **13**. For the objective lens **10** to have a 0.85 NA, a light input surface of each of the first and/or second condensing lenses **11** and **13**, facing a light source (not shown), is formed to have a large curvature, or at least one of the first and second condensing lenses **11** and **13** is formed of a material exhibiting a high refractive index, to produce a sharp refraction of light.

Thus, the objective lens **10** as shown in FIG. **1** is sensitive to decenter, being off an optical axis, and coma is greatly

generated according to an amount of the decenter. Also, the objective lens **10** is difficult to manufacture because processing a lens surface having a large curvature is difficult.

Also, the working distance WD1 of the objective lens **10** is short, for example, about 0.15 mm due to a sharp refraction of light. It is difficult to design the objective lens **10** to have a working distance of 0.15 mm or more. For reference, the working distance of an objective lens in an optical pickup device for DVD is about 1.8 mm.

Since the objective lens **10** realizes a high NA by the structure of two lenses, where the first and second condensing lenses **11** and **13** are inclined to each other, it is impossible to maintain a small optical aberration. Thus, allowance of distance and inclination between the first and second condensing lenses **11** and **13** is very strictly obeyed.

Referring to FIG. **2**, a conventional solid immersion mirror **20** includes a first transmission surface **21** for diverging and transmitting incident light, a second transmission surface **23** disposed to face the first transmission surface **21**, a first reflection surface **25** formed around the second transmission surface **23**, for reflecting incident light passing through the first transmission surface **21** and a second reflection surface **27**, formed around the first transmission surface **21**, for reflecting incident light reflected by the first reflection surface **25** to proceed toward the second transmission surface **23**.

The solid immersion mirror **20** as described above may realize an NA of 0.7 or more with a single lens structure. In the solid immersion mirror **20**, since a blocking area, indicated by a hatched area **29** in FIG. **2**, exists where the light input to the first transmission surface **21** is relatively near the optical axis, some of the input light is not focused on a recording surface of the optical disc **1** and is lost. Here, the light lost by not being focused on the recording surface of the optical disc **1** is light directly input to the second transmission surface **23** from the first transmission surface **21**, and light which is lost at a boundary between the first transmission surface **21** and the second reflection surface **27** among the light from the fist transmission surface **21**, reflected by the first reflection surface **25**, and proceeding toward the second reflection surface **27**. In FIG. **2**, to show the blocking area, only a proceeding path of the light input to the first transmission surface **21** is shown. Light reflected by the recording surface of the optical disc **1** and input to the second transmission surface **23** proceeds in the reverse order along the light proceeding path shown in FIG. **2**.

The solid immersion mirror **20** can realize a high NA of 0.7 or more with a single lens. Since the solid immersion mirror **20** has a structure in which light is condensed after reflected from the two reflection surfaces **25** and **27**, curvature may be small so that the solid immersion mirror **20** may be insensitive to the decenter, exhibit relatively superior chromatism quality, and be manufactured easily.

However, since the blocking area exists due to the structure of the solid immersion mirror **20**, as shown in FIG. **2**, all of the incident light is not used, and the efficiency of light is reduced. About ⅓ of the incident light is blocked in the conventional solid immersion mirror **20**.

Also, since the quantity of the blocked light depends on the size of the first transmission surface **21**, the diameter of the first transmission surface **21** is made less than ¼ of an overall effective diameter of the solid immersion mirror **20** to minimize reducing the light efficiency. To maximize efficiency in an optical pickup device employing the solid immersion mirror **20** as an objective lens, an incident light beam having a diameter slightly greater than that of the first transmission surface **21** is input to the first transmission

surface **21**. Accordingly, the quantity of light input to the first transmission surface **21** is greatly affected by movement of the solid immersion mirror **20** for tracking in a radial direction perpendicular to the optical axis.

FIG. **3** shows a light beam intensity profile of light focused by the solid immersion mirror **20**. As can be seen from FIG. **3**, since a side lobe S1 which amounts to 5–6% of a peak value of the light intensity is relatively great, where the solid immersion mirror **20** is adopted as an objective lens of an optical pickup device, a great amount of jitter is generated during reproduction of information recorded on the optical disc **1** and a cross erasure problem of removing signals recorded on adjacent tracks may occur during recording. The conventional solid immersion mirror **20** used to generate the light intensity profile shown in FIG. **3** has an NA of 0.85, an overall effective diameter of 4.5 mm, and the first transmission surface **21** has a diameter of 1.0 mm. Thus, where about 33% of the quantity of light input to the first transmission surface **21** is blocked. FIG. **3** shows a light intensity profile of a beam having a 400 mm wavelength and focused by the conventional solid immersion mirror **20**. A side lobe is also produced in light focused by the objective lens **10** as shown in FIG. **1**. However, the side lobe produced in light focused by the objective lens **10** is about 2–3% or less of a peak value of the light intensity so that it does not cause a serious increase of jitter in a reproduction signal and cross erasure.

Further, since the conventional solid immersion mirror **20** having the structure shown in FIG. **2** has a short working distance WD2, the SIM **20** is usable as an objective lens for high density light condensation in a near field recording/reproducing needing a working distance of several tens to hundreds nano meters, but is not useable as an objective lens for far field recording/reproducing.

SUMMARY OF THE INVENTION

To solve the above-described and other problems, it is a first object of the present invention to provide a solid immersion mirror type objective lens formed of a single lens and having a high NA of 0.7 or more.

It is a second object of the invention to provide an optical pickup device which adopts the solid immersion mirror type lens formed of a single lens and having a high NA of 0.7 or more. The solid immersion mirror type objective lens of the present invention has a superior efficiency of light and a drastically reduced side lobe component compared with a conventional solid immersion mirror. Thus, where the solid immersion mirror type objective lens of the present invention is adopted in an optical pickup device, excess jitter is not generated during reproducing and cross erasure does not occur during recording. Also, since a relatively great working distance (compared with a conventional solid immersion mirror) is realizable, the solid immersion mirror type objective lens of the present invention is applicable to far field recording/reproducing.

Additional objects and advantages of the invention will be set forth in part in the description which follows, and, in part, will be obvious from the description, or may be learned by practice of the invention.

To achieve the first and other objects of the invention, there is provided an objective lens comprising a first transmission surface formed of a first curved surface which condenses incident light and a second curved surface formed around the first curved surface which diverges incident light, a second transmission surface disposed to face the first transmission surface and which transmits incident light, a first reflection surface formed around the second transmission surface which reflects incident light, and a second reflection surface formed around the first transmission surface which reflects incident light.

To achieve the second and other objects of the invention, there is provided an optical pickup device comprising a light source which generates and emits a laser beam, an optical path changer which changes a proceeding path of incident light, an objective lens arranged on an optical path between the optical path changer and a recording medium which condenses incident light emitted from the light source to form a light spot on the recording medium, and a photodetector which detects incident light reflected by the recording medium and passing through the objective lens and the optical path changer, wherein the objective lens comprises a first transmission surface comprising a first curved surface and which condenses incident light and a second curved surface formed around the first curved surface which diverges incident light, a second transmission surface disposed to face the first transmission surface which transmits incident light, a first reflection surface formed around the second transmission surface which reflects incident light, and a second reflection surface formed around the first transmission surface which reflects incident light.

BRIEF DESCRIPTION OF THE DRAWINGS

The above object and advantages of the present invention will become more apparent by describing in detail preferred embodiments thereof with reference to the attached drawings in which:

FIG. **1** is a view showing an example of a conventional objective lens formed of two lenses;

FIG. **2** is a view showing an example of a conventional solid immersion mirror;

FIG. **3** is a graph showing a beam profile of light condensed by the solid immersion mirror of FIG. **2**;

FIG. **4** is a perspective view of a solid immersion mirror type objective lens according to an embodiment of the present invention;

FIG. **5** is a side view of the solid immersion mirror type objective lens according to an embodiment of the present invention;

FIG. **6** is a graph showing a beam profile of light condensed by an objective lens according to the present invention; and

FIG. **7** is a view showing the optical arrangement of an optical pickup device adopting the objective lens according to the present invention.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

Reference will now be made in detail to the present embodiments of the present invention, examples of which are illustrated in the accompanying drawings, wherein like reference numerals refer to like elements throughout.

Referring to FIGS. **4** and **5**, an objective lens **50** according to the present invention is a modified solid immersion mirror (SIM). The objective lens **50** comprises a first transmission surface **51** formed of a first curved surface, preferably, a convex surface **51***a*, disposed on an optical axis, and a second curved surface, preferably, a concave surface **51***b*, formed around the first curved surface, a second transmission surface **53** disposed to face the first transmission surface **51**, a first reflection surface **55** formed around the second transmission surface **53**, and a second reflection surface **57** formed around the first transmission surface **51**.

The convex curved surface **51***a* of the first transmission surface **51** condenses light from a light source which is input relatively near the optical axis. The concave surface **51***b* is formed around the convex curved surface **51***a* and diverges light input radially outward from the convex curved surface **51***a*.

Preferably, the first transmission surface **51** has a diameter within a range including ⅔ and ⅘ of an overall effective diameter of the objective lens **50**. Considering conditions such as minimization of a blocking area, realization of high NA and a great working distance, minimizing generation of coma due to decenter, and ease in manufacture, the convex surface **51***a* of the first transmission surface **51** preferably has a diameter within a range including ⅕ and ⅔ of the overall effective diameter of the objective lens **50**. The diameter is maximum on a plane perpendicular to the optical axis of the first transmission surface **51** or the convex surface **51***a*.

Where light is input to the first transmission surface **51** of the objective lens **50** according to the present invention, the light incident upon the convex surface **51***a* of the first transmission surface **51** is condensed by the convex surface **51***a*, directly proceeds toward the second transmission surface **53** and passes the second transmission surface **53**, and is focused on a recording surface of the recording medium **30**, for example, a disc of a next generation DVD family. The light incident upon the concave surface **51***b* of the first transmission surface **51** is diverged and most light proceeds toward the first reflection surface **55**. Then, the light which is incident on the first transmission surface **55** is sequentially reflected by the first and second reflection surfaces **55** and **57** and passes through the second transmission surface **53**. Like the light passing through the convex surface **51***a*, the light passing through the concave surface **51***b* is focused on the recording surface of the recording medium **30**.

Part of the light passing a boundary of the convex surface **51***a* and the concave surface **51***b* of the first transmission surface **51**, reflected by the first reflection surface **55**, and proceeding toward the second reflection surface **57**, for example, light incident upon a boundary between the first transmission surface **51** and the second reflection surface **57**, is lost and is not focused on the recording surface of the recording medium **30**. The area of light which is not focused on the recording surface of the recording medium **30** is a blocking area which is indicated by hatching **59** in FIG. **5**.

The modified SIM type objective lens **50** according to the present invention has all merits of the conventional SIM **20** and simultaneously exhibits superior decenter and chromatism features and a higher efficiency of light, compared with the conventional SIM **20**. As shown in FIG. **5**, the SIM type objective lens **50** according to the present invention has a great working distance (WD) and as shown in FIG. **6**, the SIM type objective lens **50** generates a smaller quantity of side lobe S which does not cause serious jitter of a reproduction signal or cause cross erasure of the recording medium.

Since the modified SIM type objective lens **50** having the structure according to the present invention focuses the light incident on the convex surface **51***a* of the first transmission surface **51**, the blocking area is drastically reduced, compared with the conventional SIM **20**. Thus, an efficiency of light is high and the side lobe S is reduced, compared with the conventional SIM **20** described with reference to FIG. **2**.

FIG. **6** shows a beam profile of light condensed by the objective lens **50** according to the present invention. Performance of the objective lens of the present invention and performance of the conventional SIM are compared by comparing the light intensity profile of FIG. **6** with the light intensity profile of FIG. **3**. Here, the light intensity profile of the objective lens **50** as shown in FIG. **6** is formed under the same conditions as the light intensity profile of the conventional SIM **20** as shown in FIG. **3**. The data shown in FIG. **6** corresponds to an objective lens **50** having a convex surface **51***a* of which a radius of curvature and a diameter are 1.67 mm and 0.34 mm, respectively. Comparing FIG. **3** with FIG. **6**, shows that the side lobe S of the SIM **50** of the present invention is reduced to 2% or less of a peak value of light intensity, compared with a peak of 5% to 6% in a case of the conventional SIM **20**.

Experiments with the SIM type objective lens **50** of the present invention have confirmed that a 0.6 mm working distance (WD) is obtainable where the modified SIM type objective lens **50** is made such that an overall effective diameter of the objective lens **50** is about 5.0 mm, a diameter of the first transmission surface **51** is about 3.0 mm, a diameter of the convex surface **51***a* of the first transmission surface **51** is about 1.5 mm, and a maximum thickness of the objective lens **50** is about 1.7 mm. According to the experiments, the modified SIM type objective lens **50** as shown in FIGS. **4** and **5** obtains a working distance within a range including 0.1 mm and 0.6 mm, and indicates that a longer working distance is obtainable by a more strict design.

Here, the working distance is not necessarily limited to the values obtained experimentally and the working distance is changeable depending on design conditions such as size and curvature of the first and second transmission surfaces **51** and **53**, and the first and second reflection surfaces **55** and **57**. Nevertheless, by forming the center portion of the first transmission surface **51** to be the convex surface **51***a*, a design having an NA of 0.7 or more, preferably, 0.85, and simultaneously having a working distance greater than that of the conventional objective lenses **10** and **20** described with reference to FIGS. **1** through **3** is obtainable.

Thus, since the objective lens **50** according to the present invention realizes a great working distance, the objective lens **50** is easily adopted as an objective lens of an optical pickup device for recording/reproducing a recording medium of a next generation DVD family for far field recording/reproducing.

Also, since a ratio of the diameter of the first transmission surface **51** and the overall effective diameter of the objective lens **50** is greater than a ratio of the diameter of the first transmission surface **21** and the overall effective diameter of the conventional SIM **20**, an input light beam having a greater diameter than the conventional technology may be used. Thus, the quantity of light input to the first transmission surface **51** is relatively less affected by movement for tracking in a radial direction perpendicular to the optical axis than a similar movement in the technology incorporating the conventional SIM **20**.

FIG. **7** shows the optical arrangement of an optical pickup device for recording/reproducing a recording medium of a next generation DVD family adopting the modified SIM type objective lens **50** according to the present invention.

Referring to FIG. **7**, an optical pickup device according to the present invention comprises a light source **71**, a optical path changer **72** which changes a proceeding path of incident light, an objective lens **50** according to the present invention which condenses light emitted from the light source **71** to form a light spot on a recording medium **30**, and a photodetector **85** which receives light reflected by the recording medium **30** and passing through the optical path changer **72**.

The light source **71** comprises blue semiconductor laser which emits light having a wavelength of about 400–420 nm, preferably, about 405 nm. The semiconductor laser may be, for example, an edge emitting laser or a vertical cavity surface emitting laser.

The optical path changer **72** is arranged on the optical path between the light source **71** and the objective lens **50** to change a proceeding path of incident light. Preferably, the optical path changer **72**, as shown in FIG. **7**, comprises a polarized beam splitter **77** which selectively transmits or reflects incident light according to a polarization thereof, and a quarter wave plate **79** which changes a phase of the incident light. Alternatively, a beam splitter (not shown) which transmits and reflects incident light at a predetermined ratio may be provided as the optical path changer.

The objective lens **50** has an NA of 0.7 or more, preferably, 0.85, so that a light spot which enables recording/reproducing of a high density recording medium **30** such as a next generation DVD, or a so-called an HD-DVD, is formed. The photodetector **85** receives the light reflected by the recording medium **30** and detects an information signal and an error signal.

Preferably, a collimating lens **73** is provided on the optical path between the light source **71** and the optical path changer **72**. The collimating lens **73** condenses the divergent light emitted from the light source **71** into a parallel light beam. As shown in FIG. **7**, where the collimating lens **73** is arranged on the optical path between the light source **71** and the optical path changer, a condensing lens **81** is provided between the optical path changer **72** and the photodetector **85**.

Where the edge emitting laser is adopted as the light source **71**, a beam shaping prism **75** is preferably provided on the optical path between the collimating lens **73** and the optical path changer **72**, so that information is recorded with a relatively low light power. The beam shaping prism **75** shapes an oval beam emitted from the edge emitting laser into a circular beam. Alternatively, the beam shaping prism **75** may be arranged between the light source **71** and the collimating lens **73**. Where a vertical cavity surface emitting laser which emits an approximately circular beam is adopted as the light source **71**, the beam shaping prism **75** is omitted from the optical arrangement shown in FIG. **7**.

A sensing lens **83** is interposed between the condensing lens **81** and the photodetector **85**. For example, where a focus error signal is detected by an astigmatism method, an astigmatism lens which causes astigmatism to the incident light may be provided as the sensing lens **83**.

Since the optical pickup device according to the present invention adopts the modified SIM type objective lens **50** formed of a single lens, the optical pickup device is adapted to record or reproduce information on or from the recording medium **30** of a next generation DVD family. Also, an increase of jitter during reproduction of a signal and cross erasure do not occur. Cross erasure refers to erasing a signal recorded in an adjacent track.

Also, since the objective lens **50** having two reflection surfaces **55** and **57** is insensitive to chromatism, chromatism produced with respect to a change in wavelength according to a change in the amount of light output during a switch between reproduction and recording modes and/or an increase in width of a line width of a wavelength because the light source **71** is driven by HF (high frequency), is within a scope of allowance. Thus, by using the optical pickup device according to the present invention, quality recording and/or reproduction signals are obtained. Light having a wavelength of 405 nm is emitted from the light source **71** during output of reproduction power and light having a longer wavelength, for example, a wavelength of 406 nm, is emitted from the light source **71** during output of recording power.

FIG. **7** shows an embodiment of the optical pickup device adopting the objective lens **50** of the present invention. However, the optical pickup device according to the present invention is not limited to the optical arrangement of FIG. **7**. Since the objective lens **50** according to the present invention secures an NA of 0.7 or more and a relatively great working distance by a structure using a single lens, the objective lens **50** may be adopted in various optical systems, in addition to the optical pickup device for recording/reproducing information on/from a recording medium of a next generation DVD family. For example, the objective lens **50** according to the present invention may be adopted to various optical systems needing a high NA and a relatively great working distance such as a microscopic apparatus, a microscopic apparatus with a CCD camera connected thereto, a semiconductor exposure apparatus having an objective lens, a light source, and a collimating lens to focus light on a semiconductor material. The objective lens **50** is also usable in an apparatus for exposing an optical mask pattern on a photosensitive medium and a mastering apparatus for manufacturing an optical disc by using an objective lens.

In FIGS. **4**, **5**, and **7**, only a proceeding path of the light input to the first transmission surface **51** of the objective lens **50** is shown. The light reflected by the recording medium **30** and input to the second transmission surface **53** proceeds in the reverse order along the path shown in the drawings.

As described above, according to the present invention, by forming a surface on the optical axis on the first transmission surface and a concave surface around the convex surface in the SIM structure, an objective lens which has superior performance and which realizes a high NA of 0.7 or more with a single lens is obtainable.

That is, in the objective lens according to the present invention, since the blocking area is smaller than that of the conventional SIM, an efficiency of light is high. Also, in the objective lens according to the present invention, since a very small amount of side lobe is generated compared to the conventional SIM, where the objective lens of the present invention is adopted in an optical pickup device, excess generation of jitter during reproduction or cross erasure during recording does not occur. Further, the objective lens according to the present invention has a working distance which enables far field recording/reproducing. Therefore, the objective lens according to the present invention is especially suitable for use in an optical pickup device for recording/reproducing information on/from a recording medium of a next generation DVD family.

Although a few embodiments of the present invention have been shown and described, it would be appreciated by those skilled in the art that changes may be made in these embodiments without departing from the principles and spirit of the invention, the scope of which is defined in the claims and their equivalents.

What is claimed is:

1. An objective lens comprising:

a first transmission surface which transmits incident light, the first transmission surface comrprising:

a first curved surface disposed on an optical axis which condenses a first portion of the incident light, and

a second curved surface formed around the first curved surface which diverges a second portion of the incident light;

a second transmission surface disposed to face the first transmission surface and which transmits the incident light;

a first reflection surface formed around the second transmission surface which reflects the second portion of the incident light; and

a second reflection surface formed around the first transmission surface which condenses the reflected second portion of the incident light.

2. The objective lens as claimed in claim **1**, wherein the first curved surface of the first transmission surface is convex and the second curved surface is concave.

3. The objective lens as claimed in claim **2**, wherein a ratio of a diameter of the first curved surface and an overall effective diameter of the objective lens is in a range including ⅕ and ⅖.

4. The objective lens as claimed in claim **1**, wherein a ratio of a diameter of the first transmission surface and an overall effective diameter of the objective lens is in a range including ⅖ and ⅘.

5. The objective lens as claimed in claim **4**, wherein a ratio of a diameter of the first curved surface and an overall effective diameter of the objective lens is in a range including ⅕ and ⅖.

6. The objective lens as claimed in claim **1**, wherein a ratio of a diameter of the first curved surface and an overall effective diameter of the objective lens is in a range including ⅕ and ⅖.

7. An optical pickup device comprising:

a light source which emits light;

an optical path changer which changes a proceeding path of incident light;

an objective lens arranged on an optical path between the optical path changer and a recording medium which condenses the emitted light to form a light spot on the recording medium; and

a photodetector which detects light reflected by the recording medium and passing through the objective lens and the optical path changer,

wherein the objective lens comprises:

a first transmission surface which transmits incident light, the first transmission surface comprising:

a first curved surface disposed on an optical axis which condenses a first portion of the incident light, and

a second curved surface formed around the first curved surface which diverges a second portion of the incident light;

a second transmission surface disposed to face the first transmission surface which transmits the incident light;

a first reflection surface formed around the second transmission surface which reflects the second portion of the incident light; and

a second reflection surface formed around the first transmission surface which condenses the reflected second portion of the incident light.

8. The optical pickup device as claimed in claim **7**, wherein the first curved surface of the first transmission surface is convex and the second curved surface is concave.

9. The optical pickup device as claimed in claim **8**, wherein a ratio of a diameter of the first curved surface and an overall effective diameter of the objective lens is in a range including ⅕ and ⅖.

10. The optical pickup device as claimed in claim **8**, wherein the objective lens has an NA of 0.7 or more.

11. The optical pickup device as claimed in claim **8**, wherein a working distance between the second transmission surface and the recording medium is in a range including 0.1 mm and 0.6 mm.

12. The optical pickup device as claimed in claim **7**, wherein a ratio of a diameter of the first transmission surface and an overall effective diameter of the objective lens is in a range including ⅖ and ⅘.

13. The optical pickup device as claimed in claim **12**, wherein a ratio of a diameter of the first curved surface and an overall effective diameter of the objective lens is in a range including ⅕ and ⅖.

14. The optical pickup device as claimed in claim **12**, wherein the objective lens has an NA of 0.7 or more.

15. The optical pickup device as claimed in claim **7**, wherein a ratio of a diameter of the first curved surface and an overall effective diameter of the objective lens is in a range including ⅕ and ⅖.

16. The optical pickup device as claimed in claim **7**, wherein the light source emits light having a wavelength in a range including 400 nm and 420 nm.

17. The optical pickup device as claimed in claim **16**, wherein the objective lens has an NA of 0.7 or more.

18. The optical pickup device as claimed in claim **7**, wherein the objective lens has an NA of 0.7 or more.

19. An apparatus comprising:

an objective lens which focuses light onto an object;

a light source which emits the light; and

an optical system which transmits the light to the objective lens;

wherein the objective lens comprises:

a first curved surface which condenses a first portion of the emitted light to form a light spot on the object,

a second curved surface formed around the first curved surface and which diverges a second portion of the emitted light;

a transmission area disposed adjacent the recording medium;

a first reflection surface disposed radially outward from the transmission area which reflects the diverged light; and

a second reflection surface formed around the second curved surface which condenses the reflected light toward the light spot.

20. The apparatus of claim **19**, wherein the object is an optical recording medium.

21. The apparatus of claim **19**, wherein the aparatus is an optical disc mastering apparatus.

22. The apparatus of claim **19**, wherein the apparatus exposes an optical mask pattern on a photosensitive medium.

23. The apparatus of claim **19**, wherein the apparatus is a semiconductor exposure apparatus and the object is a semiconductor material.

24. The optical head of claim **19**, wherein:

the objective lens has an NA of 0.7 or more, and

a working distance between the transmission area and the object is in a range including 0.1 mm and 0.6 mm.

25. An optical head comprising:

an objective lens which gathers light from an object;

a photodetector which converts the gathered light into an electrical signal;

an optical system which transmits the gathered light to the photodetector;

wherein the objective lens comprises:

a transmission area disposed adjacent the object which transmits the gathered light;

a first curved surface which converges a first portion of the gathered light;

a first reflection surface formed around the transmission area;

a second curved surface formed around the first curved surface; and

a second reflection surface formed around the second curved surface;

wherein a second portion of the gathered light is sequentially reflected by the second and first reflection surfaces and diverged by the second curved surface.

26. The optical head of claim **25**, wherein the photodetector is a CCD camera.

27. The optical head of claim **25**, wherein:

the photodetector is a CCD camera, and

the optical system is a microscope apparatus.

28. The optical head of claim **25**, wherein:

the objective lens has an NA of 0.7 or more, and

a working distance between the transmission area and the object is in a range including 0.1 mm and 0.6 mm.

29. The optical head of claim **25**, wherein the object is an optical recording medium.

(57) **ABSTRACT**

An apparatus for determining the objective refraction of a patient's eye includes a transparent window and a wavefront measurement device that determines aberrations in a return beam from the patient's eye after the beam passes through a corrective test lens in the apparatus. The wavefront measurement device outputs an instant display representative of the quality of vision afforded the patient through the test lens. The display can be a representation of a Snellen chart, convoluted with the optical characteristics of the patient's vision, an overall quality of vision scale or the optical contrast function, all based on the wavefront measurements of the patient's eye. The examiner may use the display information to conduct a refraction examination and other vision tests without the subjective response from the patient.

APPARATUS AND METHOD FOR DETERMINING OBJECTIVE REFRACTION USING WAVEFRONT SENSING

FIELD OF THE INVENTION

The present invention relates generally to methods and apparatus for determining a person's visual characteristics, and more particularly to apparatus for determining the refraction of the eye.

BACKGROUND

Phoropters are apparatus used by optometrists to determine a patient's visual characteristics, so that proper eye diagnoses can be made and eyewear can be prescribed. In conventional phoropters, a patient looks through the phoropter, in which various test lenses are disposed, at a target eye chart, referred to as a "Snellen chart", while an optometrist moves the test corrective lenses into the patient's field of view. In some applications, the target may be positioned at a predetermined distance from the patient. The patient is then asked to verbally compare the quality of the perceived image as afforded by one lens versus the prior lens presented. The optometrist takes note of either an improvement or a deterioration in the patient's vision through such lenses. Systematically, the test progresses towards the "best" test lens entirely based on the patient's responses. The lens parameters are then used as the basis for a prescription for eyewear.

Unfortunately, as recognized herein the patient can become fatigued during the process and/or misjudge the vision afforded by the various lenses. This can lead to the selection of a less than optimum prescription. Moreover, some patients, such as a very ill or a very young patient, might not be capable of articulating the quality of vision the various lenses afford the patient.

Objective methods of determining the patient's refraction errors have been proposed, but these other methods introduce further complications that are not present when using phoropters. In a retinoscopy method, for example, a streak of light is projected to a patient's retina, and the characteristics of the reflected light at the patient's corneal plane is analyzed to determine whether the patient is myopic, or hyperopic, and with or without astigmatism. However, the method does not provide sufficient accuracy for prescribing spectacle lenses. Consequently, its measurement results are typically used only as a starting point of a standard phoropter measurement.

Another objective measurement instrument for determining refractive errors is an autorefractor, which, owing to its speed of use, is more popular than retinoscopy. To use the autorefractor, a patient is asked to look inside an enclosed box that is part of the autorefractor. A target image is optically projected into patient's eye, and a series of lenses is automatically moved into position of the patient's line of sight to the target, to neutralize the patient's refractive errors (autorefraction). Unfortunately, the measurement outcome often differs from the patient's ideal prescription. Accordingly, like retinoscopy, autorefractor outcomes typically are used only as starting points for standard phoropter measurements.

Moreover, both retinoscopy and autorefraction fail to account for the accommodation effect of the patient, that is, for the propensity of a patient to alter his or her focus or sight to make the best of the vision test. An autorefractor measurement essentially is a snapshot of the patient's vision at a particular instant at which the autorefractor has identified a so-called neutralization point, and at this point if it happens that the patient focuses his vision for seeing an image at a distance other than what is intended, or if the patient is momentarily looking elsewhere other than the target, the output of the autorefractor is erroneous. Such deceptive focussing on the part of the patient can arise because the patient is conscious of the working distance inside the box, and when an image of an object presented to the patient which is modelled to be located at, e.g., twenty feet, the patient automatically focusses for an image at a much closer distance, knowing the actual size of the box. Examination results that include patient accommodation effects are inaccurate for prescribing spectacle lenses.

Another limitation of the autorefractor is that the examiner has no control over which lens is to be used in test. The result is that repeated measurements are likely to provide different results for the same eye from the same patient, which results in laborious and time consuming tests and retests when using the device to finalize a prescription. The present invention, having made the above-noted critical observations, provides the solutions disclosed herein.

SUMMARY OF THE INVENTION

A phoropter includes plural test lenses that can be disposed into a line of sight defined between a patient and a target, such that a patient looking at the target perceives light from the lens. A wavefront measurement apparatus is positioned to detect aberrations in light returning from the patient. The aberrations are caused by the eye of the patient.

In a preferred embodiment, the wavefront measurement apparatus includes a light source, such as a laser, for generating the light and a light detector that outputs a signal representative of the aberrations. Also, the apparatus includes a processor that receives the signal from the light detector and outputs a diagnostic signal representative thereof. The diagnostic signal is useful for generating an image representative of the test object, and/or for generating at least one visual display representative of an effectiveness of the lens in correcting a patient's vision. The visual display can include a bar chart, a pie chart, and/or a line chart, and it can be color coded.

In another aspect, a method for indicating the quality of a patient's vision includes providing a device through which a patient can look at a target. The method also includes directing a laser beam into the eye of a patient when the patient looks at the target, and then detecting aberrations in a wavefront of the light beam as the light beam returns from the patient's eye. Based on the wavefront, the method indicates a quality of a patient's vision.

In still another aspect, a method for indicating the quality of a patient's vision includes providing a device into which a patient can look, and that generates an instantaneous visual indication of a quality of a patient's vision.

In yet another aspect, a device for aiding a practitioner in knowing the integrated effect of a patient's eye and a test lens placed in front of the eye includes means for sensing a wavefront of light returning from the eye through the lens. Means are coupled to the wavefront sensing means for generating an indication of the integrated effect of the eye and the test lens.

In another aspect, a device for generating an indication of the quality of vision of a patient viewing a target includes a light beam generator directing light into the eye of the patient, and a wavefront sensing device detecting the wavefront in light returned from the eye of the patient while the

patient is looking at the target. A computing device receives input from the wavefront sensing device that is representative of the wavefront. The computing device outputs a continuous update of at least one of: a point spread function, and a modular transfer function, while the patient is looking at the target. A display device displays at least one of: a simulated image of the target at the patient's retina, a quality of vision indicator indicating the quality of vision, and a graph indicating a contrast function of the patient, based at least in part on at least one of the point spread function and the modular transfer function.

In yet another aspect, a vision quantifying device includes a beamsplitter through which a patient can look at a target. A source of light emits light into an eye of the patient, which reflects from the eye as a return beam. A processor receives a signal representative of a wavefront of the return beam and generates at least one signal in response thereto, and a display receives the signal and presents a visual indication of the patient's sight.

Another aspect of the device is to provide automatic refraction process. The patient looks at a target, a test lens is positioned between the target and the patient's eye, and in the line of sight of the patient. A light beam is directed through the test lens and into the patient's eye. Using a portion of that light reflected from the surfaces within the eye a wavefront profile is reconstructed. From the reconstructed wavefront profile, A quality vision factor ("QVF") may be calculated. In order to improve the accuracy of the measurements of the patient's eye, a number of measurements of the returning wavefront profile are taken, and the corresponding QVF values for each of the measurements for that particular test lens, is analyzed. The analysis of this data provides for a determination that the correction with that particular lens is optimal. If the correction is not optimal, a next test lens is selected, and the process is then repeated the next test lens after it is positioned by mechanical means in the patient's line of sight. On the other hand, if the correction with that particular lens is optimal, than the process ends and resulting in the proper refractive correction having been identified.

The details of the present invention, both as to its structure and operation, can best be understood in reference to the accompanying drawings, in which like reference numerals refer to like parts, and in which:

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a perspective view of the present apparatus, in one intended environment;

FIG. **2** is a perspective view of the apparatus, showing a patient in phantom;

FIG. **3** is a block diagram of the components of one preferred apparatus;

FIG. **4** is a flow chart of the presently preferred logic;

FIGS. **5–9** are exemplary non-limiting diagrams of quality of vision displays; and

FIG. **10** is a flow chart showing the automatic refraction method of the present invention.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENT

Referring initially to FIGS. **1** and **2**, an apparatus of the present invention is shown, generally designated **10**, and includes a housing **12** that can be mounted on a movable stand **14** for positioning the housing **12** in front of a patient **15** who might sit in an examination chair **16**. As can be appreciated in cross-reference to FIGS. **1** and **2**, the patient **15** can position his or her head against the housing **12**. Alternatively, the housing **12** can be supported on the head of the patient **15** and/or be suspended from a flexible overhanging arm which may be attached to a stand, to provide weight balance and to facilitate mounting and dismounting of the head mounted-apparatus. Or, the apparatus of the present invention can be co-mounted with a conventional phoropter (not shown), in which case the test lenses of the present invention can be established by the lenses of the conventional phoropter.

Now referring to FIG. **3**, the patient **15** can look through the housing **12** to a target **18**, such as but not limited to a Snellen chart. The target **18** can be positioned at any appropriate distance from the patient **15**, e.g., twenty feet or closer. Since the target **18** can be positioned at a distance that actually is the distance intended, the above-noted patient accommodation effects related to autorefractors, are reduced or eliminated.

FIG. **3** shows one exemplary implementation of the housing **12**. While FIG. **3** shows that various components are located inside the housing **12** and various other components such as the output display is located outside the housing **12**, it is to be understood that the principles advanced herein apply to phoropter systems having multiple housings, or a single housing.

In the embodiment shown, the patient looks at the target **18** through a transparent window within the housing **12**, such as can be established by a primary beamsplitter **20**. Interposed in the line of sight of the patient **15** are one or more movable test, or test lenses **22**. By "movable" is meant physically movable by hand or computer-controlled mechanism "M" as indicated as M in FIG. **3**, and more fully disclosed below to be selectively interposed within or without the line of sight of the patient **15**, or movable in the sense that a variable focal length lens can be used, with its optical characteristics being variable in accordance with principles known in the art, for example those utilized in various designs of autorefractors. That is, the test lens **22** can be, but not limited to, a single concave convex lens, or a combination of optical components, including a cylindrical lens and a prism.

As also shown, a light source such as but not limited to a laser **24** generates a light beam **26** that can be directed, in one preferred embodiment, toward a laser beamsplitter **28**. The laser beamsplitter **28** reflects the light beam **26** toward the primary beamsplitter **20**, which in turn reflects the beam through the test lens **22** and onto the eye of the patient.

The beam **26** is then reflected by the eye of the patient **15**, back through the lens **22**, and is reflected off the primary beamsplitter **20**. The beam passes through the laser beamsplitter **28**, and a portion of the beam is reflected off a pupil detection beamsplitter **30** toward a pupil light detector **32** through one or more focussing lenses **33**, for purposes to be shortly disclosed. A portion of the return beam passes through the pupil detection beamsplitter **30** and propagates through an optical relay unit **34**, which focusses the beam onto a wavefront analyzer optics **36**. The wavefront analyzer optics **36** generates a signal representative of the wavefront of the return beam, and a wavefront detector **38** transforms the signal into an electrical signal for analysis by a processor **40**. In one preferred embodiment, the processor **40** can be associated with control electronics known in the art for undertaking control of one or more components (e.g., the light source **24**) of the system **10** as more fully set forth below. Also, the processor **40** can generate the below-

described visual indications of the patient's vision as corrected by the test lens **22** and can cause the indications to be displayed on a display **42**, such as a video monitor, that can be mounted on the housing **12** or apart therefrom. Or, the display **42** can be a liquid crystal display that can be mounted on the housing **12** of the system **10**, or a standalone display unit conveniently located for the examiner's viewing. Suitable displays may include, but not be limited to, numerical and/or graphical representations indicative of the patient's quality of vision, more details are provided in the following.

If desired, an illumination light **44**, e.g., a ring-shaped fiber optic, can be mounted on the housing **12** and can be connected to the processor **40** to control the pupil size of the patient **15**. The illumination light **44** can be a source of diffused light. The light intensity of the illumination light **44** is controlled by the processor **40** in response to feedback from the pupil light detector **32**, which can comprise a CCD camera, or reticon detector arrays to monitor the size of the pupil, so that a predetermined pupil size can be maintained for the patient during the measurement. The locations of the pupil detection unit, including the components, beamsplitter **30**, lens **33**, and pupil light detector **32** can be in other appropriate locations along the optical path of the return light from the eye, including locations inside the optical relay unit **34**.

As a further improvement to the accuracy of the refraction measurement, the system also monitors the first Purkinge image, an image formed by reflection at the anterior surface of the cornea of the light beam **26**. The position of this image relative to the pupil boundary is an indication of gazing direction of the patient under examination. Unless the patient has strabismus in that eye, the relative position of the First Perkinge image is a well defined bright spot, and it is typically inside the pupil boundary. Therefore, in a preferred but non-limiting embodiment, the pupil detector **32** can also function as a patient gazing monitor. In this case, the relative position of the First Perkinge image to the pupil is determine by processing of the image data from the CCD camera, for example, using data filtering, contrast enhancement, and pupil boundary determination methods known in the art.

All software processing can be done in real time in a matter of a fraction of a second. The objective of this analysis is to determine whether the patient is looking at the target, or momentarily drifting off. The information is electromagnetically transmitted to the central control unit **40**. If the patient is not looking at the target, the data set from the wavefront detector unit **38** is rejected, and shall not be displayed or accumulated for data analysis.

The following comments are germane to implementation details of preferred, non-limiting embodiments. The light source **24** can be a diode laser that emits light at near infrared wavelengths. Moreover, the light detectors **32**, **38** can be implemented by CCD arrays or linear reticon arrays. Further, the primary beamsplitter **20** can be coated to transmit visible light and to reflect infrared light. On the other hand, the laser beamsplitter **28** can be a polarization dependent reflector, in which case the laser light is polarized, and a quarter wave plate (not shown) is disposed in the beam path to the patient **15** such that the return beam is rotated ninety degrees (90°) upon double passing the quarter wave plate for facilitating passage thereof through the laser beamsplitter **28** toward the wavefront analyzer optics **36**. Alternatively, the laser beamsplitter **28** can be plate coated for high transmission and low reflectivity at forty five degrees (45°) incident angle, such that only a small portion of the laser light is reflected into the eye, but a high percentage of the return light propagates through the laser beamsplitter **28**.

Continuing with the implementation details of a preferred, non-limiting embodiment, the optical relay unit **34** can include two convex lenses F1 and F2 that together establish a telescope. The lenses F1, F2 are separated from each other by a distance equal to the sum of their focal lengths, with the focal plane of the first lens F1 being located at the front surface of the test lens **22**, i.e., the surface facing the primary beamsplitter **20**. The focal plane of the second lens F2 is located at the image plane of the wavefront analyzer optics **36**. The purpose of the telescope structure of the relay unit **34** is to relay the wavefront at the exit surface of the test lens **22** to the image plane of the wavefront analyzer optics **36**. Alternative relay optics can be used to achieve the same purpose.

With respect to the non-limiting details of the wavefront analyzer optics **36**, the optics **36** can include an array of lenslets arranged as in a Shack-Hartmann wavefront sensor, an example of which can be found in page 37, "Customized Corneal Ablation The Quest for Super Vision" edited by MacRae, et. al. published by Slack Incorporated, 2001, incorporated herein by reference. Various Shack-Hartmann wavefront sensors and processors are available, for example, from commercial vendors such as Wavefront Sciences, in Albuquerque, N. Mex., Zeiss/Humphrey Instruments, in Dublin, Calif., or Bausch and Lomb, in Irvine, Calif. More preferably, the optics **36** can include ruled reticles such as those disclosed in co-pending application U.S. patent application Ser. No. 10/014,037, entitled "SYSTEM AND METHOD FOR WAVEFRONT MEASUREMENT", filed Dec. 10, 2001, incorporated herein by reference, which uses a self-imaging diffraction principle to detect the wavefront in the return beam.

Regardless of the type of wavefront analyzer optics **36** used, the processor **40** analyzes the profile of the wavefront of the light returned from the patient's eye, and quantifies the wavefront aberrations in two regimes: low order aberrations, including spherical refractive error, cylinder, and axis, and higher order aberrations, including coma, spherical aberrations and other higher order terms that can be described by Zernike polynomials. Quantitative data representing the patient's quality of vision are then graphically presented on the display **42**.

Now referring to FIG. **4**, an exemplary mode of operation of the present invention can be seen. The patient **15** views the target **18** through the phoropter system **10**, and in particular through the transparent window that is established by the primary beamsplitter **20**. At block **44** the examiner initiates the vision test by inserting a selected test lens **22** in the line of sight of the patient, or by configuring a variable focal length lens **22** to have a predetermined focal length. Inserting means either a manual positioning or positioning using a motorized means. Or, the processor **40** can select a particular lens **22** and cause it to be automatically moved in the line of sight, in accordance with disclosure below.

Proceeding to block **46**, the processor **40** determines the point spread function (PSF) that is derived from using, for instance, the terms of Zernicke polynomials, which is in turn derived from the wavefront passing through the wavefront analyzer optics **36** and transformed into an electrical signal by the wavefront detector **38** at the instant when the wavefront data is acquired. The processor **40** Fourier transforms the signal from the wavefront detector **38** using the following equation:

$$PSF(x, y)=FT(P(x, y))|^2$$

wherein FT designates a Fourier Transform calculation and P(x, y) is the spatial distribution of the wavefront profile of light with the same phase (phase front) returned at the corneal plane.

Proceeding to block **48**, if desired an Optical Transfer Function (OTF) can be calculated from an inverse operation of Fourier Transform as follows:

$$OTF(f_x, f_y)=FT^{-1}(PSF(x, y)),$$

wherein f_x, f_y are spatial frequencies in x and y directions, respectively, that are orthogonal to each other.

Moreover, a Modular Transfer Function (MTF) can be determined as the amplitude of the OTF:

$$MTF(f_x, f_y)=|OTF(f_x, f_y)|.$$

The above functions are used to generate visual indications of the quality of vision that is afforded by the test lens **22** currently being viewed by the patient **15**. For instance, once the PSF is determined at block **46**, the logic can flow to block **50** to determine a convolutional function G as follows:

$$G(x_{img}, y_{img})=\int\int PSF(x-x_{img}, y-y_{img})f(x_{img}, y_{img})dx\ dy,$$

wherein $f(x_{img}, y_{img})$ is the test target **18** (FIG. **3**), i.e., an ideal image function, $x-x_{img}$ is the difference in the x-dimension between each point in the PSF and the corresponding ideal point in the ideal image, and $y-y_{img}$ is the difference in the y-dimension between each point in the PSF and the corresponding ideal point in the ideal image.

The convolutional function G can be used at output state **52** to generate an appropriately blurred image, point by point, of an ideal image as affected by the imperfection of the patient's eye in combination with the lens **22**. For example, when the target **18** is a Snellen chart, the ideal image function can be the letter "E" or a series of other letters, e.g., of various physical sizes as conventionally used in the various lines in the Snellen chart. FIG. **5** shows one such blurred image at **54**, which can be presented on the display **42**. Alternatively, the target can be a picture, and the convoluted image $G(x_{img}, y_{img})$ of the picture is blurred point by point, according to the PSF, which represents an image of the target formed at the patient's retina.

Accordingly, the letters in the simulated blurred image have the same blurring as perceived by the patient **15**. In this way, the examiner can visualize the clarity and sharpness of the image as a result of the lens **22** as it is perceived by the patient **15**.

Alternatively or in addition to the image shown in FIG. **5**, the processor **40** can generate the displays shown in FIGS. **6–8** as follows. At block **56** the wavefront profile, as indicated by the above-mentioned linear combination of Zernike polynomials, is filtered to eliminate terms with coefficient below a threshold amplitude. Moving to block **58**, a psychometric weighting factor "P" is inserted for each of the remaining Zernike terms as shown in the following. This weighting factor "P" represents the effect of the brain to discriminate objects despite certain types of ocular aberrations. For example, most people can discern a letter in a Snellen chart with a certain amount of defocus while the same amplitude of aberration in coma would not allow the same patient to discern that letter. To compensate for this, a Quality of Vision Factor (QVF) is determined as follows:

$$QVF=exp(-(\Sigma_n P_n Z_n^2))$$

wherein P_n is the psychometric weight factors for the corresponding n^{th} term of the Zernike polynomials, and Z_n is the coefficient of the n^{th} term of the Zernike polynomials in the PSF.

The psychometric weighting factors "P" can be determined by presenting a particular aberration to a normative group of people, for example, between one hundred to four hundred people, depending on the accuracy level desired and the range of the scatter value of each type of aberration measurement. The patients are presented one at a time with particular types of aberrations selected from the Zernike polynomials, and then the patients are scored for the extent of success in discerning the target, for example, by the number of letters correctly read on the Snellen chart, or other standardized vision test chart. Other scoring methods base on contrast level, standardized letter size, sine or square wave patterns can also be used as targets.

The presenting means can be an aberration plate on which a selected type of aberration has been imprinted. For example, the aberration type can be a coma, or a trefoil, having the refractive index profile as specified by the corresponding Zernike polynomial.

The relative effect of each type of aberration is tabulated for the group and averaged to obtain statistically meaningful weight factors. For most practical purposes, Zernike coefficients for terms higher then the sixth order (term number twenty nine or higher) minimally contribute to the overall aberration profile of normal eyes. The method of producing various types of aberrations with desired amplitudes according to each of the Zernike terms is set forth in co-pending U.S. patent application Ser. No. 09/875,447 filed Jun. 4, 2001, incorporated herein by reference. In the event that no data for the psychometric weight factors are available, all weighting factors P_n can be set to unity.

Once the QVF has been determined, one or more of the displays shown in FIGS. **6–8** can be generated and displayed as indicated in block **60**. For example, as shown in FIG. **6**, a bar chart display can be generated to present an overall indication of the patient's quality of vision as afforded by the lens **22** under test. As shown, the indicator can be in the form of a graduated bar **62**, the height of which is proportional to the QVF determined at block **60**, with zero indicating poor vision and perfect vision being indicated by a bar extending from the bottom to the top **64** of the scale. If desired, the display scale can be a log scale, in which case the "best" is indicated by the bar **62** being at zero, and rising logarithmetrically with worse vision using a root-mean-square function of the QVF. Enhancements to the bar **62** such as color-coding can be used. For instance, the bar **62** can be colored red for poor vision and green for good vision, with other colors being used to indicate intermediate qualities of vision. In lieu of the bar chart of FIG. **6**, the QVF can be used to generate a pie chart as shown in FIG. **7**, with the size of a pie slice **66** relative to the entire circle being linearly or logarithmetrically proportional to the QVF.

The system **10** can continuously measure the wavefront profile of the light beam returned from the patient's eye. Accordingly, in one preferred, non-limiting embodiment, a sequence of QVF measurements (e.g., twenty) for a single test lens **22** can be made in a second or two and grouped together.

As described earlier, the measurement accuracy can be improved by monitoring the gazing direction of the patient, and the computing device in block **40** can reject the data points acquired when the patient was not looking at the designated target. Furthermore, the computing device can also accumulate data and perform calculations for average values and standard deviation for selected subsets of measurement.

FIG. **8** shows a resulting display. As can be appreciated from the exemplary embodiment shown, five lenses **22** have been tested and several QVF values obtained over a short period for each. Each group of QVF values is plotted as a respective vertical line **68** on a plot of QVF versus lens, with the length of each error bar line **68** representing the standard deviation of the measurements for that particular lens and the center of each line representing the mean QVF value. The prescription can be based not only on a high mean QVF value, as indicated at points **70** and **72**, but also on a small standard deviation, as indicated by bar **74**. That is, the lens corresponding to the bar **74** might be selected because its QVF values had a small standard deviation from each other and it had a high mean QVF value, even if not as high as the point **70**. This recognizes that some patients prefer a lens power which may not necessarily provide the sharpest image but which does result in more comfort, since a patient does relatively little searching for the "better focus" using lenses that exhibit smaller standard deviations in the QVF. For example, a patient did not have a vision check for an extended period of time, and the required correction is more than 1.5 diopters in cylinder, for example. The patient may feel uncomfortable with the full correction as afforded by the sharpest image, rather the patient prefers a smaller amount of correction which represents improvement in his vision, yet not causing dizziness or head strains. Therefore, the present invention provides objective data based on the subjective response of the patient to a test lens set **22** presented to the patient.

As recognized by the present invention, to diagnose a patient's contrast, the patient can be presented with a series of standardized patterns of sine wave gratings of increasing spatial frequency frequencies, with the patient offering subjective responses. The resulting examination report can be a curve that depicts a cutoff contrast intensity at various spatial frequencies. The present invention can provide a quantitative evaluation of a patient's contrast, which can be generated in addition to or in lieu of those displays disclosed above. Such a display can be generated at output state **76** in FIG. **4** and is shown in FIG. **9**, showing a curve **78** depicting actual patient optical contrast function (OCF) and a reference curve **80** depicting a diffraction-limited reference. To determine OCF, the following relation is used:

$$OCF=MTF\times M_{lat.}$$

wherein MTF is the modulation transfer function determined at block **48** and M_{lat} is a mathematical function accounting for the low frequency filtering of the neural system, the value of which linearly increases with spatial frequencies with a slope of unity in a log—log scale plot and reaching the maximum value of one at and above the spatial frequency of seven cycles per degree.

Accordingly, the OCF does not include the effect of the brain processing at frequencies higher than seven cycles per degree, but it does provide valuable information about the patient's ability to discern sine gratings of various spatial low frequencies based on a patient's optics.

The above process of measuring and displaying indications of the improvement in vision afforded by a particular test lens **22** to the patient **15** can be continued at block **82** until the "best" test lens is found. This can be done by the examiner manually swapping lenses **22** as in a conventional phoropter, or, as mentioned above, the positioning of test lenses **22** can be done automatically by the processor **40** controlling the moving mechanism "M", which can include a motor and coupling structure connecting the motor to one or more lenses **22**, such that the mechanism follows an instruction from the processor **40** to insert the particular lens in the line of sight of the patient, as requested by the processor.

When done by the processor **40**, the sequence of test lenses **22** to be used in an examination may be programmed into the processor **40** in accordance with examination strategy and routines known in the art. The starting lens can be selected based on the patient's current spectacle prescription or based on the wavefront measurement without any test lens **22** in the patient's line of sight. Consequently, in reconstructing the return beam wavefront without a test lens **22** being in the beam path, the processor **40** essentially models the uncorrected aberrations of the patient's eye in Zernike terms. Recall that the second order Zernike terms represent defocus, astigmatism and axis information. Based on the patient's pupil size and the uncorrected wavefront error amplitudes, the processor **40** can determine the equivalent diopter power in sphere and cylinder and its axis, and select the appropriate lens **22** being used to start the examination. In selecting test lenses **22**, the processor **40** can use the above-disclosed QVF values in lieu of subjective responses from the patient, and can then execute the examination strategy as if it is performed with the subjective response from the patient.

The automatic refraction process is depicted in FIG. **10**, and generally designated **100**. Process **100** begins with a first step **102** wherein the patient looks at a target. In step **104** a test lens is positioned between the target and the patient's eye, and in the line of sight of the patient. A light beam is directed through the test lens and into the patient's eye in step **106**. A portion of that light is reflected from the surfaces within the eye and returns along the line of sight of the patient.

In step **108**, the light returning from the patient's eye is detected. From this detected light, the wavefront profile may be reconstructed, as shown in step **110**. From the reconstructed wavefront profile, the quality vision factor ("QVF") may be calculated in step **112**. In order to improve the accuracy of the measurements of the patient's eye, "N" number of measurements are performed using the returning light. Thereby, "N" wavefront measurements are taken, thereby yielding N wavefront profiles and corresponding QVF values. These successive measurements are taken by returning from step **112** to step **108**, in which the returning light is again detected "N" times.

Once "N" measurements have been taken and the QVF for each measurement has been calculated, the QVF for that particular test lens, is analyzed in step **114**. The analysis of this data provides for a determination that the correction with that particular lens is optimal. This decision is made in step **116**, and if the correction is not optimal, a next test lens is selected in step **120**, and the process returns to step **104** where the next test lens is positioned in the patient's line of sight. On the other hand, if the correction with that particular lens is optimal, than the process ends in step **122** resulting in the proper refractive correction having been identified.

In a typical automatic refraction process, a series of lenses in ¼ diopters increments are used to determine the patient's optical correction. However, the present invention contemplates using more or less than the typical number of lenses, and the diopter increments can be in ⅛ instead of ¼, depending upon the magnitude of correction necessary. Also, as shown in FIG. **10**, a number ("N") of measurements of the returning light are taken in steps **108** through **112** to calculate the VQF for the particular test lens. Typically, "N" will equal for example, 10–20 separate measurements being taken to provide an accurate measurement of the VQF.

However, the present invention contemplates taking more or less than the typical number of measurements depending upon the particular wavefront sensor device used, and the magnitude of correction necessary.

The prescription can be determined by a person viewing the display of FIG. **8**, or automatically by the processor **40** based on a high QVF value and low standard deviation, as follows: The examiner, or the processor will examinate the curve shown in FIG. **9**, which connects the average values of the QVF's for various lens sets presented to the patient. An improvement may include the step of performing a best fit to the average values, suing a polynomial of up to 4 order, for example. The processor searches for the maximum value, of the "peak" of the curve. This can be accomplished by monitoring the peak value of the curve, or slope of the curve from decreasing lens power, from right to left, in FIG. **8**. When the curve reaches its maximum value, the slope changes sign, and the maximum is at the zero slope value. Now, the processor send the peak value of the QVF and the corresponding lens power to the display or a printer.

Additionally, the processor also searches for the minimum value among the standard deviation in the data set as shown in FIG. **8**. A figure similar to FIG. **8** showing standard deviations versus lens power can be useful (not shown) in determining the minimum value, suing the steps of a best fit curve, and search for the sign change of the slope as described above for determining the maximum QVF value. Again, this minimum standard deviation value and the corresponding lens power are sent to the display or a printer for record. For example, on the display or the printout the processor may indicate that lens power with the maximum QVF value provides for the sharpest image, while the lens power with the minimum standard deviation provides for the most comfortable prescription to the patient.

While FIG. **3** illustrates a system **10** wherein the return beam from the lens **22** is detected and analyzed and, hence, the integrated effect on the wavefront introduced by the eye and lens **22** is measured, it is to be understood that as mentioned above the return beam from the eye can also be analyzed without passing through the lens **22**. In such an embodiment, the effect of the lens **22**, which has a known deviation from spherical, can be accounted for by adding or subtracting the lens **22** effect as appropriate from the eye-only wavefront. To facilitate this, a sensor (not shown) can be provided that senses which lens **22** is moved into the patient's line of sight. The sensor sends a signal representative of the lens (and, hence, of the optical contribution of the lens) to the processor **40**.

In any case, it may now be appreciated that if desired, the examiner can use conventional tactics in the steps of selecting test lenses **22** as if the whole process were done using a conventional phoropter that requires subjective responses from the patient. For example, the examiner can use "fogging" in accordance with principles known in the art to form an artificial image before the retina of the patient to cause the patient to relax the above-mentioned accommodative power. However, owing the present display capability of the system **10**, the examiner can identify the test lens **22** with which the patient achieves good vision without accommodation, regardless of patient verbal cooperation or ability to judge and articulate which lens **22** is best. That is, by observing the present displays and continuing to decrease the focusing power of the test lenses being used and moving the image behind the patient's retina, the examiner can determine the range of accommodation of the patient.

Once the best lens **22** has been identified, the examiner may indicate this decision by pressing a "finish" button (not shown), and a printout of the examination result can be output using a printer or similar device (not shown) that is connected to the processor **40**. The processor **40** may also automatically transmit via modem, internet or other appropriate means, the prescription to a remote location for lens manufacturing. A prescription to correct low order aberrations including sphere, cylinder and axis, can be used for prescribing conventional ophthalmic lenses, or a "supervision" prescription to correct all orders of aberrations can be used to prescribe improved vision lenses, such as are described in co-pending U.S. patent application Ser. No. 10/044,304, filed Oct. 25, 2001 and incorporated herein by reference.

While the particular APPARATUS AND METHOD FOR DETERMINING OBJECTIVE REFRACTION USING WAVEFRONT SENSING as herein shown and described in detail is fully capable of attaining the above-described objects of the invention, it is to be understood that it is the presently preferred embodiment of the present invention and is thus representative of the subject matter which is broadly contemplated by the present invention, that the scope of the present invention fully encompasses other embodiments which may become obvious to those skilled in the art, and that the scope of the present invention is accordingly to be limited by nothing other than the appended claims, in which reference to an element in the singular is not intended to mean "one and only one" unless explicitly so stated, but rather "one or more". All structural and functional equivalents to the elements of the above-described preferred embodiment that are known or later come to be known to those of ordinary skill in the art are expressly incorporated herein by reference and are intended to be encompassed by the present claims. Moreover, it is not necessary for a device or method to address each and every problem sought to be solved by the present invention, for it to be encompassed by the present claims. Furthermore, no element, component, or method step in the present disclosure is intended to be dedicated to the public regardless of whether the element, component, or method step is explicitly recited in the claims. No claim element herein is to be construed under the provisions of 35 U.S.C. §112, sixth paragraph, unless the element is expressly recited using the phrase "means for" or, in the case of a method claim, the element is recited as a "step" instead of an "act".

What is claimed is:

1. An apparatus for determining the refraction and aberrations of a patient's eye focused on an external physical target, comprising:

a light source;

optics directing light from said light source to the patient's eye;

a test lens having an optical power, said test lens disposable in an optical path between the patient's eye and said external physical target, such that the patient'eye looking at said external physical target receives light from said light source through the lens;

at least one wavefront measurement device positioned to detect aberrations in light returning from the patient's eye;

a housing containing said optics and said test lens, said housing having an input port and an output port, said optical path between the patient's eye and said physical target passing through said input port into said housing and through said output port thereby exiting said housing, said target being external to said housing; and

processing electronics configured to compute variation in multiple wavefront measurements performed by said

wavefront measurement device using said test lens having said optical power to measure a patient's subjective response to said optical power.

2. The apparatus of claim **1**, wherein said housing further comprises a substantially transparent window in said optical path between the patient's eye and said external physical target through which the patient's eye views said external physical target, said window separating said optical path into a portion inside said housing and a portion of said optical path external to said housing.

3. The apparatus of claim **1**, wherein the light source includes a laser for generating the light and said laser is within said housing.

4. The apparatus of claim **1**, wherein the wavefront measurement device includes at least one light detector receiving a wavefront from the light returning from the patient's eye, and outputting a signal representative of the aberrations.

5. The apparatus of claim **4**, further comprising at least one visual display configured to receive input from said processing electronics generated substantially instantaneously by said processing electronics using the diagnostic signal from the light detector, said processing electronics and said display configured to generate at least one data representation selected from the group consisting of (1) an image generated by a convolution of the image of the target based on the wavefront returning from the patient's eye and through the test lens; (2) a numerical and/or graphic display representative of the effectiveness of the test lens; (3) a numerical and/or graphic display of the contrast function of the patient's vision.

6. The apparatus of claim **5**, wherein said processing electronics is configured to provide the visual display with representations selected from the group consisting of a bar chart, a pie chart, and a line chart.

7. The apparatus of claim **5**, wherein the visual display comprises a color display and said data representation is color coded, said processing electronics being configured to provide input to said color display to create said color coded data representation.

8. The apparatus of claim **4**, wherein the wavefront measurement device includes electronics that outputs a diagnostic signal substantially instantly, and wherein said diagnostic signal corresponds to the objective assessment of quality of vision.

9. The apparatus of claim **8**, wherein said processing electronics is configured to generate an image representative of the target as seen by the patient's eye.

10. The apparatus of claims **9**, wherein said processing electronics is configured to use said objective assessment of quality of vision to select a next lens to determine a successive objective measurement of quality of vision corresponding to said next lens.

11. The apparatus of claim **8**, wherein said processing electronics is configured to use the diagnostic of signal for generating at least one visual display representative of an effectiveness of the lens in correcting a patient's vision.

12. The apparatus of claim **8**, wherein said processing electronics is configured to compute the standard deviation of said objective measurement of quality of vision and one or more successive objective measurements of quality of vision and identifies an optimal vision correction lens for the patient.

13. The apparatus of claim **1**, wherein said processing electronics are configured to compute the standard deviation of multiple wavefront measurements performed using said test lens having said optical power to assess a patient's subjective refraction.

14. An apparatus for determining the refraction of a patient's eye focused on a physical target, said apparatus comprising:

a light source;

optics directing light from said light source to the patient's eye, said light reflecting from a surface of said eye, said reflected light comprising a plurality of wavefronts;

a wavefront measurement device positioned along a first optical path to said eye to measure the shape of said wavefronts reflected from the patient's eye;

at least one test lens disposable along a second optical path between the patient's eye and the physical target; and

processing electronics configured to determine the variation in multiple wavefront measurements that are performed by said wavefront measurement device for a fixed amount of refractive correction using said at least one test lens having said fixed refractive correction to quantify accommodation of the patient's eye,

wherein said optics and said at least one test lens are arranged such that when said patient looks at said physical target through said test lens, said light from said light source is directed through said eye so as to determine said refraction from said wavefronts returning from said eye.

15. The apparatus of claim **14**, further comprising a beamsplitter for merging said first optical path from said wavefront sensor to said eye and said second optical path from said eye to said physical target such that they overlap in a region between said beam splitter and said eye.

16. The apparatus of claim **15**, wherein said test lens is disposed in said region between said patient's eye and said beamsplitter where said first and second optical paths overlap.

17. The apparatus of claim **14**, wherein said test lens is positioned an optical path length of L from said physical target, said eye being adjusted to view said physical target said distance, L, away from said eye.

18. The apparatus of claim **17**, wherein said distance between said eye and said physical target is about 20 feet.

19. The apparatus of claim **14**, further comprising a housing containing said optics, said wavefront measurement device, and said at least one test lens, said housing having an input port and an output port, said second optical path between said patient's eye and said physical target passing through said input port into said housing and through said output port thereby exiting said housing, said physical target being external to said housing, wherein said housing includes a substantially transparent window disposed in said second optical path between said patient's eye and said physical target such said patient's eye can focus on said physical target, said window separating said second output path into a portion inside said housing and a portion of said second optical path external to said housing.

20. The apparatus of claim **19**, wherein said light source comprises a laser and said laser is within said housing.

21. The apparatus of claim **14**, wherein said wavefront measurement device includes at least one light detector receiving the light returning from the patient's eye and sending a signal to at least one processor, said at least one processor generating at least one diagnostic output based on said wavefront measurements.

22. The apparatus of claim **14**, wherein said processing electronics is configured to determine the standard deviation of said multiple wavefront measurements performed by said

wavefront measurement device for said fixed refractive correction to quantify accommodation of said patient's eye.

23. The apparatus of claim **14**, wherein said at least one lens comprises a plurality of test lens having different amounts of refractive correction, wherein said processing electronics are configured to determine variation in multiple wavefront measurements for each of said plurality of test lens so as to quantify accommodation of the patient's eye for each of said plurality of test lens.

24. The apparatus of claim **14**, wherein said at least one lens comprises an adjustable lens system having a plurality of settings that provide different amounts of refractive correction, wherein said processing electronics are configured to determine variation in multiple wavefront measurements for said different amounts of refractive correction provided by said adjustable lens system so as to quantify accommodation of the patient's eye for each of said different amounts of refractive correction.

25. The apparatus of claim **1**, further comprising a housing containing said optics and said test lens, said housing having an input port and an output port, said second optical path between said patient's eye and said physical target passing through said input port into said housing and through said output port thereby exiting said housing, said physical target being external to said housing.

26. An apparatus for determining the refraction and aberrations of a patient's eye focused on a target, comprising:

a light source;

optics directing light from said light source to the patient's eye;

a test lens having an optical power, said test lens disposed in an optical path between the patient's eye and said target, such that the patient's eye looking at said target receives light from said light source through the lens;

at least one wavefront measurement device positioned to detect aberrations in light returning from the patient's eye; and

processing electronics configured to determine variation in multiple wavefront measurements performed by said wavefront measurement device using said test lens having said optical power to measure a patient's subjective response to said optical power.

27. The apparatus of claim **26**, wherein said processing electronics are configured to determine the standard deviation of multiple wavefront measurements performed using the test lens having said optical power to assess a patient's subjective refraction.

(57) **ABSTRACT**

An objective for a movie camera for digital cinematography comprises a cylindrical main barrel with a bayonet or K mount, an inner tube, fixed optical elements, adjustable optical sliding elements and drive rings with scales for adjusting the optical sliding elements that are mounted rotatably in the axial direction on the main barrel. The objective also comprises an iris diaphragm with a diaphragm ring rotating on the main barrel, an internal focusing system and a back focus correction device. The inner tube is mounted on the main barrel in a fashion displaceable along the optical axis for the purpose of back focus correction by means of the back focus correction device. The fixed optical elements, the iris diaphragm and sliding holders for holding the adjustable optical sliding elements are inserted into the inner tube.

OBJECTIVE FOR A MOVIE CAMERA

BACKGROUND OF THE INVENTION

CROSS REFERENCE TO RELATED APPLICATION

This application relates to and claims priority to corresponding German Patent Application No. 102 15 140.7, which was filed on Apr. 5, 2002.

1. Field of the Invention

The invention relates to an objective for a movie camera for digital cinematography in accordance with the preamble of claim **1**, and to a set of objectives in accordance with the preamble of claim **15**.

2. Description of the Related Art

Apart from a rotating mirror that splits up the light in the viewfinder direction and the film direction, in conventional movie cameras only air is located between the bearing surface of the objective and the image plane, that is to say the film. The mirror is, as it were, the only mechanism that is always located between objective and film. This distance can therefore be kept very accurately and can likewise be produced exactly. Moreover, this distance is largely constant even at different temperatures, and so additional adjustment is not required here. The objective is therefore responsible only for the usual tasks, specifically the imaging optical system, the regulation of the diaphragm, the focusing and, if appropriate, a zoom mechanism. An additional mechanism is not required to compensate possible camera tolerances.

The situation is different from this in the case of digital movie cameras. Here, a plurality of optical elements affected by tolerance are located between the bearing surface of the objective and the image plane, which is represented by three CCDs. For example, complicated prismatic devices split up the images into the RGB color channels. Again, additional specific properties are further achieved with the aid of a complicated upstream filter system. A suitable compensation is required owing to this additional quantity of tolerance-affected optical elements, this also being due to the summation of the respective individual tolerances. It should therefore be possible to correct the mount-to-film distance. Movie cameras do not offer this possibility of correction, and this must therefore be integrated into the objectives. Moreover, it is further to be remarked that this correction must also be possible during normal operation, since, firstly, the tolerances can change permanently owing to the development of heat or similar and, secondly, for example, there is generally no use of zoom objectives in digital cinematography, that is to say depending on setting on a camera use is made of a plurality of objectives with different focal lengths in each case.

The necessity of correcting the mount-to-film distance, the so-called back focus correction, is sufficiently known. In the video field (for example newscasts or similar), it is customary to use zoom objectives and in this case the rear element thereof can be displaced for the purpose of back focus correction. It is very disadvantageous that in this operation there is a substantial change in the distance setting. The indication (normally the rings for distance setting/focusing of the objective) no longer corresponds exactly to the distance set, and this entails unsharpness of the image. However, viewfinders are used in the video field, and so the camera operators see when the image becomes unsharp and then immediately correct the distance setting. Here, the camera operators work less with the distance scale of the objective. It is disadvantageous, in addition, that each objective requires a different back focus traveling stroke, although the error in the mount-to-film distance is always the same.

Whereas in the case of the video technology described above, for example in order to record news or television reports, the setting and/or the accuracy of the distance scale plays a rather subordinate role, because any instances of unsharpness that occur can be detected by the camera operator in the viewfinder and corrected, this state of affairs is entirely different in cinematography, the production of movies or advertising films. Here, it is already fixed before shooting at which time actors or props are situated at which location. It is normal in cinematography for movie cameras to be operated by two camera operators, of whom one is responsible for viewing and the other, the so-called camera assistant, is responsible for image sharpness. The latter observes the scenes to be filmed and readjusts the distance without a camera viewfinder merely with the aid of the distance scale on the basis of his own estimate. This is necessary chiefly when actors may move faster or differently than was previously laid down. Since the camera assistant works only with the aid of the distance scale, the latter must be exactly correct because, by contrast with normal TV technology, in cinematography instances of unsharpness have substantial effects (size of the cinema screen, etc.).

Since the camera assistant regulates the sharpness only with the aid of the rotary distance ring with reference to the scale engraved on the objective, the latter must be very accurate. This was not much of a problem with conventional movie cameras (non-digital) since, as already mentioned above, there was no need for back focus correction. However, with digital cinematography there is a need to correct the back focus because of the tolerances of the digital movie camera. This correction of the back focus entails altering the distance scale to the effect that so-called scale spreading occurs. In the case of scale spreading, the distances of the scale marks on the rotary distance ring would actually have to change relative to one another, but said ring is a solid element that is unalterably engraved. Consequently, when correcting the back focus it is no longer possible to read off the scale accurately, as is required in cinematography.

In conjunction with fixed focal lengths, for the purpose of adjusting the back focus previous objectives for digital cinematography have an adjustable index mark for the distance scale of the rotary distance ring. By subsequently rotating this so-called index ring, the indicated value of the distance scale can be corrected for exactly one distance. Otherwise than in the case of conventional objectives, in which a rotatable scale and a fixed part with the index mark are always rotated. The sequence when shooting a movie then shapes up approximately as follows: for cameras and objectives there are so-called rental stocks that have a large number of different cameras and associated objectives. The movie people assemble their equipment for the respective set. This also includes, for example, lighting, stands, etc. Before filming is started, the optical system, that is to say camera and objective, is firstly checked and, if appropriate, corrected. This task is usually carried out by the camera assistant. The latter mounts the camera on a stand and sets up a so-called test image, with structures that can be focused with appropriate sharpness, at a specific prescribed distance (for example 3 meters). The prescribed distance is then set with the aid of the distance setting at the objective. This is followed by using the back focus correction for focusing with reference to the test image, something which can be accomplished with the aid of an HD monitor, for example.

Filming is started thereafter. This process naturally has to be repeated if appropriate when changing the camera or the objective (for example for other instances of viewing).

It is very disadvantageous in this case that when a different distance is being set the indicated scale value of the objective is no longer exactly correct, since the objectives have a so-called internal focusing in which only a portion of the optics in the system is moved and this is not in a linear relationship with the adjustment of the overall objective or with the correction to the back focus.

SUMMARY OF THE INVENTION

It is therefore the object of the present invention to provide an objective for a movie camera for digital cinematography of the type mentioned at the beginning, and a set of objectives by means of which the disadvantages of the prior art are eliminated, the aim being, in particular, for the scale values to be correct in every situation, a correction of the back focus having no influence on the calibration of the distance scale, and it is also intended that the external controls of the objective do not take part in any axial movement during back focus correction, and that all objectives are based on the same mechanism in the sense of a modular system.

This object is achieved according to the invention by virtue of the fact that the inner tube is mounted on the main barrel in a fashion displaceable along the optical axis for the purpose of back focus correction by means of the back focus correction device, the fixed optical elements, the iris diaphragm and sliding holders for holding the adjustable optical sliding elements being inserted into the inner tube.

The object is achieved with reference to the set of objectives wherein the arrangement of said optical elements in the sequence of fixed front element, sliding holders with associated adjustable optical sliding elements, fixed intermediate element, iris diaphragm and fixed rear element is constant, the focusing mounts of the respective objectives differing from one another only in the external lettering or engraving and in the pitches of the respective motion-transmitting threads of the internal focusing devices, and/or in the focal lengths of the objectives.

The measures named above result in a nested arrangement of functional elements which permits the movements required for back focus correction to be done in the objective without the need for the drive rings also to move axially on the outside, in particular electric drives, suppressors, compendiums etc., and without changing the accuracy with which the scales, in particular the distance scale, are read off. Since the back focus drive is always the same in a simple and advantageous way and the arrangement of the optical elements (fixed front element, moveable sliding elements, fixed intermediate element, iris diaphragm, fixed rear element) has also been kept constant for all objectives in the set, the focusing mounts differ only in the external lettering (engraving) and in the pitch of the motion-transmitting thread of the internal focusing system (different traveling strokes have to be produced here in conjunction with the same angle of rotation). As a result, there is, firstly, a reduction in the number of different parts of the objective, and secondly an increase in the number of items of same parts, and so the production of the focusing mount exhibits large economic advantages.

It is also advantageous when the back focus ring can be locked by the clamping element after the back focus correction, and the clamping element is designed as a clamping screw.

It can be ensured through these measures that the back focus correction mechanism is secured against accidental or undesired adjustment.

In an advantageous development of the invention, it can also be provided that the objective has a zoom setting system, at least one of the adjustable optical sliding elements being designed as a lens group for zoom setting, and at least one of the drive rings being designed as a zoom ring.

Zoom objectives can also be produced in a simple way by means of these measures. Provided to that end is a further sliding holder for holding a lens group for the zoom setting system. The optical sliding element for the zoom setting system is adjusted by an associated drive ring designed as a zoom ring.

Advantageous refinements and developments of the invention emerge from the further subclaims and from the exemplary embodiment described below in principle with the aid of the drawing, in which:

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** shows a schematic of the principle of the design of an objective according to the invention; and

FIG. **2** shows a longitudinal section through an objective according to the invention.

DETAILED DESCRIPTION

As may be seen from FIG. **1**, an objective **1** for a movie camera that is suitable for digital cinematography has a cylindrical main barrel **2** with a bayonet or K mount **3** for mounting the objective **1** onto a movie camera (not illustrated), and a compendium ring **4** for connecting a compendium objective (not illustrated). Rotating outside on the main barrel **2** are drive rings **5**, specifically a rotary distance ring **5***a*, a diaphragm ring **5***b* and a back focus ring **5***c*. These drive rings **5** partly have scales (not illustrated) for accurate setting by the user. The core of the objective **1** is the main barrel **2**, in which an inner tube **6** is mounted such that it can be displaced in the direction of an optical axis **21** indicated by dashes in FIGS. **1** and **2**. Fixed optical elements **7**, specifically a front element **7***a*, an intermediate element **7***b* and a rear element **7***c*, as well as an iris diaphragm **8** are fastened on the inner tube **6**. Moreover, a sliding holder **9** that for its part supports the adjustable optical sliding element **10** for internal focusing is displaceably mounted in the inner tube **6**. The adjustable optical sliding element is designed as a lens group **10**.

If the rotary distance ring **5***a* is now turned, a traveling stroke displaces only the sliding holder **9** with the adjustable optical sliding element **10**, all other elements remaining stationary. If the diaphragm ring **5***b* is rotated, the iris diaphragm **8** opens or closes. If the back focus ring **5***c* is rotated, the complete inner tube **6** with all elements contained is displaced for the purpose of back focus correction. The accuracy of the distance setting is retained by the overall displacement of the optical system when the back focus ring **5***c* is actuated.

In another exemplary embodiment, the objective **1** could additionally include a zoom setting system. It would be possible for this purpose to mount on the main barrel a zoom ring that resembles the rotary distance ring **5***a* and uses a further adjustable optical zoom element to adjust a further sliding holder arranged between the adjustable optical sliding element **10** and the front element **7***a*.

As may further be seen from FIG. **1**, the back focus ring can be locked by a clamping element that is designed as a

clamping screw **11**, in order to avoid undesired rotation after the setting of the back focus.

As may be seen from FIG. **2**, the back focus ring **5***c* is mounted on a back focus input drive part **12** that rotates on the main barrel **2** and produces a traveling stroke in the back focus output drive part **13** by means of a motion-transmitting thread (not illustrated in more detail). This traveling stroke is transmitted onto the inner tube **6** through the main barrel **2** via a through-passage (not illustrated). Consequently, when the back focus ring **5***c* is rotated a movement of the inner tube **6** relative to the fixed main barrel **2** is produced. In other words, the main barrel **2** with the drive rings **5** mounted thereupon remains in its position during the back focus correction.

The diaphragm ring **5***b* rotates on the main barrel **2**. The rotary movement of the diaphragm ring **5***b* is transmitted onto the iris diaphragm **8** via a driver **14** comprising groove and pin. Nothing changes at the iris diaphragm **8** during a movement for back focus correction. The rotary distance ring **5***a* is mounted on a bearing ring **15** that rotates on the main barrel **2** and transmits the rotary movement onto a distance input drive **17** via an Oldham coupling **16**. The Oldham coupling **16** in this case permits the back focus traveling stroke and transverse offsets between the bearing ring **15** and the distance input drive **17**. The distance input drive **17** rotates on a bearing ring **18** that is connected to the inner tube **6**, and produces a traveling stroke of the distance output drive **19** by means of a motion-transmitting thread (not illustrated in more detail). This traveling stroke is transmitted onto the sliding holder **9** by means of a web **20** via a through-passage through the main barrel **2** and the inner tube **3**. Thus, when the rotary distance ring **5***a* rotates a movement of the sliding holder **9** relative to the inner tube **6** is produced that is independent of the back focus.

There is in each case between the sliding holder **9** and the inner tube **6** and between the inner tube **6** and the main barrel **2** a rotation-prevention means (not illustrated) that permits traveling strokes of the elements relative to one another, but no rotary movements.

Owing to the nested arrangement of functional elements in the present exemplary embodiment, it becomes possible to produce the required movements in the objective **1** without the need for the drive rings **5** also to move axially on the outside, and without changing the accuracy with which the scales are read off. Since the back focus drive is always the same, and the arrangement of the optical elements (fixed front element **7***a*, moveable sliding element **10**, intermediate element **7***b*, iris diaphragm **8** and fixed rear element **7***c*) is also kept constant for all objectives **1** in a set, the focusing mounts differ from one another only in the external lettering (engraving) and the pitch of the motion-transmitting thread of the internal focusing system (different traveling strokes must be produced here for the same angle of rotation). Owing to these measures, on the one hand there is advantageously a reduction in the number of different parts, and on the other hand an increase in the number of items of the same parts, as a result of which the focusing mount has great economical advantages.

Objectives **1** in the set have between 14 and 19 lenses.

What is claimed is:

1. An objective for a movie camera for digital cinematography, comprising:

a cylindrical main barrel with a bayonet or K mount,

an inner tube,

fixed optical elements,

adjustable optical sliding elements,

drive rings with scales for adjusting the optical sliding elements, which are mounted rotatably in the axial direction on the main barrel,

an iris diaphragm with a diaphragm ring rotating on the main barrel,

an internal focusing system, and

a back focus correction device,

wherein said inner tube is mounted on said main barrel in a fashion displaceable along the optical axis for the purpose of back focus correction by means of said back focus correction device, said fixed optical elements, said iris diaphragm and sliding holders for holding said adjustable optical sliding elements being inserted into said inner tube.

2. The objective as claimed in claim **1**, wherein said back focus correction device has a back focus ring mounted on said main barrel, a back focus input drive part, a back focus output drive part, and a clamping element.

3. The objective as claimed in claim **2**, wherein said displacement of said inner tube is performed by axial rotation of said back focus ring rotatably mounted on said main barrel, without varying the setting or the calibration or the accuracy of said adjustable optical sliding elements or of their drive rings, in particular of said internal focusing system, without varying the diaphragm setting and without changing the position of said main barrel with said drive rings mounted thereupon.

4. The objective as claimed in claim **2**, wherein said back focus ring is mounted on said back focus input drive part.

5. The objective as claimed in claim **2**, wherein said back focus input drive part is mounted rotatably on said main barrel, and a motion-transmitting thread is provided for producing traveling stroke in the back focus output drive part, a through-passage being provided for transmitting the traveling stroke through said main barrel onto said inner tube.

6. The objective as claimed in claim **2**, wherein after back focus correction said back focus ring can be locked by said clamping element.

7. The objective as claimed in claim **2**, wherein said clamping element is designed as a clamping screw.

8. The objective as claimed in claim **1**, wherein a driver is provided for transmitting onto said iris diaphragm the rotary movement of said diaphragm ring mounted rotatably on said main barrel.

9. The objective as claimed in claim **1**, wherein at least one of said adjustable optical sliding elements is designed as a lens group for internal focusing, at least one of said drive rings being designed as rotary distance ring in order to set said focusing.

10. The objective as claimed in claim **9**, wherein said rotary distance ring is mounted on a bearing ring that rotates on said main barrel and an Oldham coupling is provided for transmitting this rotary movement onto a distance input drive, said Oldham coupling permitting the back focus traveling stroke and transverse offsets between said bearing ring and said distance input drive, said distance input drive likewise being mounted on a bearing ring, the latter being connected to said inner tube and a motion-transmitting thread being provided for producing a traveling stroke onto a distance output drive, a web being provided for transmitting the traveling stroke onto the sliding holder, in which the lens group for internal focusing is mounted, via a through-passage through said main barrel and said inner tube, and a movement of said sliding holder relative to said inner tube being performed, independently of the back focus setting.

11. The objective as claimed in claim 1, wherein a rotation-prevention means that permits traveling strokes of the elements relative to one another without rotary movements is arranged in each case between said sliding holders and said inner tube and between said inner tube and said main barrel.

12. The objective as claimed in claim 1, defined by a zoom setting system, at least one of said adjustable optical sliding elements being designed as a lens group for zoom setting, and at least one of said drive rings being designed as a zoom ring.

13. The objective as claimed in claim 1, wherein said fixed optical elements are designed as a front element, an intermediate element and a rear element.

14. The objective as claimed in claim 1, wherein said fixed optical elements are designed as lens groups.

15. A set of objectives as claimed in one of claims 1 to 15, wherein the arrangement of said optical elements in the sequence of fixed front element, sliding holders with associated adjustable optical sliding elements, fixed intermediate element, iris diaphragm and fixed rear element is constant, the focusing mounts of the respective objectives differing from one another only in the external lettering or engraving and in the pitches of the respective motion-transmitting threads of the internal focusing devices, and/or in the focal lengths of the objectives.

(57) **ABSTRACT**

A method for computing the visual performance of a human or animal subject based on objective measurements of visual refraction, including higher order aberrations, includes measuring wavefront aberrations of a subject ocular pupil, computing a point-spread-function from the measured pupil aberration, providing a test image, and convolving the test image with the point-spread-function. A simulated image may be produced from the convolution result of the test image with the point-spread-function. One or more specific terms of the point-spread-function may be subtracted therefrom prior to the convolving step to simulate an effect of a correcting means, such as spectacles lenses, contact lenses, or laser surgery. A best correction for a given subject may be determined by adjusting the terms that are subtracted to optimize the resultant image.

METHOD FOR COMPUTING VISUAL PERFORMANCE FROM OBJECTIVE OCULAR ABERRATION MEASUREMENTS

CROSS REFERENCE TO RELATED APPLICATIONS

This is a continuation application claiming the priority benefit under 35 U.S.C. §119 of International Application Serial No. PCT/US01/32505 filed on Oct. 19, 2001, under 35 U.S.C. §119, and U.S. Provisional Patent Application No. 60/241,789 filed on Oct. 20, 2000, the entirety of each of which is hereby incorporated by reference for all purposes as if fully set forth herein.

BACKGROUND OF THE INVENTION

1) Field of the Invention

This invention pertains to the field of characterization and measurement of human and animal visual performance, and more particularly, to a method of performing objective measurement of human and animal visual performance.

2) Description of the Related Art

Traditional measures of human and animal visual performance have been limited by the need for subjective feedback from patients, or to examination of a limited number of parameters. The Snellen chart is often used to measure the visual acuity of the subject. The visual acuity is defined in terms of the ability to distinguish letters or shapes in a standard chart, the size of the letters that can be recognized being a measure of the optical system performance of the eye.

Unfortunately, the most common method for measuring visual performance, subjective refraction, cannot be applied to animal subjects used for research, for very young children, or those with learning or communication difficulties. New instruments have been developed in recent years to make objective measurements of the eye. These instruments include: autorefractors for measuring the basic refractive error; corneal topography instruments that can measure the corneal surface; and a variety of aberrometers that have recently been shown to be able to measure higher order aberrations. With each new advance, more information can be measured about the eye.

Auto-Refractor.

The auto-refractor is an instrument that uses one of a variety of methods to analyze the cornea and lens of an eye to determine the basic refractive error. This error is presented in terms of the spherical and cylindrical power of a lens that is needed for its correction. In the event that higher order irregularities are present, these are included only in the effect that they have on the overall visual performance.

Corneal Topography.

A corneal topography instrument uses one of a number of techniques to measure the shape of the cornea. Since this shape is, in many cases, the source of the aberrations, it provides a useful and more complete measure of the optical performance of the eye. The information can be used to predict the visual acuity and optical performance with greater accuracy than using the sphero-cylinder terms alone. However, assumptions about the interior structure of the eye must be made in inferring the visual performance from corneal topography measurements alone.

Aberrometer (Also Known as Wavefront Analyzer).

The aberrometer is a system for measuring the aberrations of the eye by projecting light onto the retina and thus

observing the effect of the entire ocular optical system. Using these methods both the basic refractive error (sphero-cylinder) and higher order aberrations may be determined. However, since this represents a measurement of the full optical path through the eye, a complete estimate of all the important optical effects can be obtained. It is not necessary to make assumptions about the internal or external structure of the eye since the aberrations can be measured directly. An objective aberrometer does not rely on subjective feedback, but measures the aberrations by projecting light into the eye and measuring it using objective means.

Given this new level of accurate information that can be determined about the eye, it remains an important task for the clinician to interpret the data in light of both the historical measures, and in terms that can be readily understood by patients. For example, Mrochen, Kaemmerer, Mierdel and Seiler used an objective aberrometer to measure the effect of laser refractive surgery on ocular aberrations. Mrochen, Kaemmerer, Mierdel and Seiler, 27 J. CATARACT REFRACT SURG. (March 2001). But while they were able to relate their results in terms of the optical aberrations of the eye, they were not able to make the connection to patient satisfaction or degradation in visual acuity in scotopic conditions. While the aberrometer is capable of providing a precise wavefront map of the aberrations of the optical system, unless the information can be interpreted by the clinician or researcher, it may have little value for diagnosis and treatment.

There are a number of methods currently used to measure performance of the ocular system. The most widely used and well established are psycho-physical methods, i.e., methods relying on subjective patient feedback. The oldest of the psycho-physical methods is the phoropter or trial lens method, which relies on trial and error to determine the required correction. There are psycho-physical methods for measuring visual acuity, ocular modulation transfer function, contrast sensitivity and other parameters of interest. While new advances in this field continue (see, e.g., PCT Publication No. WO 93/002614, European Patent Number 00600963/EP B1), they rely on subjective feedback and hence suffer from the limitations cited above.

In addition to these subjective methods, there are also objective methods for assessing the performance of the ocular system. Such objective methods include corneal topography, wavefront aberrometry, corneal interferometry, and auto-refraction. Many of these methods only measure the contribution of specific elements to the total refractive error. For example, much work has been directed to measuring the topography of the cornea and characterizing the corneal layer. However, the corneal shape only contributes about 30–40% of the total refractive error in most cases. In order to measure the bulk of the refractive error and to provide a complete mapping for diagnosis and correction, additional information and measurements are needed.

Another method for determining the refraction of the eye is auto-refraction, which uses a variety of techniques to automatically determine the required corrective prescription. These automated techniques include projecting one or more spots or patterns onto the retina, automatically adjusting optical elements in the auto-refractor until the desired response is achieved, and determining the required correction from this adjustment. However, auto-refractors are not considered especially reliable. Further, auto-refractors measure only lower order components of the aberrations, e.g., focus and astigmatic errors.

Recently, the eye has been considered an optical system, leading to the application of methods previously used for

other optical systems to the measurement of the eye. These methods include interferometry and Shack-Hartmann wavefront sensing. These techniques are of particular interest because they measure the complete aberrations of the eye. These include the low order aberrations such as defocus and astigmatism, as well as higher order aberrations such as coma, spherical aberration or other more rapidly varying components. This additional information allows measurement of non-uniform, asymmetric errors that may be affecting vision. Further, this information may be linked with any of the various corrective techniques to provide improved vision. For example, U.S. Pat. No. 5,777,719 to Williams describes the application of Shack-Hartmann wavefront sensing and adaptive optics for correcting ocular aberrations to make a super-resolution retina-scope. U.S. Pat. No. 5,949,521 to Williams et al. describes using this information to make better contacts, intra-ocular lenses and other optical elements. Several types of objective aberrometers have been developed which can provide the wavefront information. These include the Shack-Hartmann (or Hartmann-Shack), Moiré deflectometry, Tscheming aberrometer, scanning resolved refractometer (ray-tracing), and a variety of other wavefront aberrometer technologies.

Wavefront aberrometry measures the full, end-to-end aberrations through the entire optics of the eye. In these measurements, a spot is projected onto the retina, and the resulting returned light is measured with an optical system, thus obtaining a full, integrated, line-of-sight measurement of the eye's aberrations. U.S. patent application Ser. No. 09/692,483 describes a method for designing practical clinical instruments for measuring full, end-to-end aberrations through the entire optics of the eye.

Williams, and others, have been able to use a full adaptive optics system to present a corrected eye chart to a subject. However, this is still not useful for determining the objective visual acuity. While such a system can produce images with arbitrary effects included (up to the mechanical ability of the deformable mirror components), it introduces a significant additional cost and complexity.

Camp, McGuire, Cameron and Robb attempted to simulate the image quality and visual performance based on a model of the internal structure and measurements of the corneal surface. 109 AM. J. OPHTHALMOLOGY 4 (Apr. 15, 1990). Klonos, Pallikaris and Fitzke extended this work using an improved model of the internal structure. 12 J. REFRACT. SURG. 2 (February 1996). Barsky, Garcia, Klein, and Van De Pol reported a method for computing the visual acuity from the wavefront inferred from corneal topography measurements and a model of the interior structure of the eye in SPIE 3591, pp. 303–310 (1999). In these cases the internal structure of the eye was simulated based on a priori assumptions.

While ray-tracing and other techniques have attempted to predict visual acuity based on the refraction or corneal topography data, in all cases these relied on assumptions, rather than measurements, of the ocular optical system.

Accordingly, it would be advantageous to provide a method is needed to predict visual acuity and other ocular performance metrics from the aberrometry data. In particular, it would be advantageous to provide a method of evaluating of visual performance that relies on only measured values for the ocular aberrations. It would also be advantageous to provide a method for computing the ocular performance, predicting the appearance of images viewed by a subject, and determining the visual acuity in an objective fashion. Other and further objects and advantages will appear hereinafter.

SUMMARY OF THE INVENTION

The present invention comprises a method for computing the visual performance of a human or animal subject by using measurements of the subject's aberrations obtained from an aberrometer that measures the full aberrations through the ocular optical system.

In one aspect of the invention, a method for computing the visual performance of a human or animal subject based on objective measurements of visual refraction including higher order aberrations, includes measuring wavefront aberrations of a subject ocular pupil, computing a point-spread-function from the measured pupil aberration, providing a test image, and convolving the test image with the point-spread-function. Beneficially, a simulated image, that is similar to a subject's view, is produced from the convolution result of the test image with the point-spread-function. Also beneficially, the convolution of the test image with the point-spread-function includes performing an inverse Fourier transform of a modulus squared of the point-spread-function to compute an optical transfer function, computing a Fourier transform of the test image, and computing an inverse Fourier transform of a product of the optical transfer function and the test image Fourier transform.

Moreover, in another aspect of the invention, the subject's visual acuity and visual acuity number can be determined objectively from these computations. In that case, the test image may be a Snellen acuity chart.

In another aspect of the invention, a method for computing an image, includes measuring wavefront aberrations of a subject ocular pupil, computing a point-spread-function from the measured pupil aberration, providing a test image, convolving the test image with the point-spread-function, and producing a simulated image from a convolution result of convolving the test image with the point-spread-function, wherein at least one specific term of the point-spread-function is adjusted prior to the convolving step to simulate an effect of a correcting means. Beneficially, adjusting the specific term comprises subtracting or eliminating the specific term, e.g., by setting a high order Zernike coefficient in the pupil aberration function to zero.

In yet another aspect of the invention, a method for computing an effect of corrective means on a subject's visual acuity, includes measuring a subject pupil aberration function with an objective aberrometer, adjusting (e.g., adding or subtracting) terms to the measured subject pupil aberration function that correspond to specific corrective means, producing a modified pupil aberration function, computing a point-spread-function from the modified pupil aberration function, computing an optical transfer function (OTF) of the computed point-spread-function, multiplying a Fourier transform of a test image by the OTF to produce a Fourier result, and performing an inverse Fourier transform on the Fourier result. The corrective means may be spectacle lenses, contact lenses, laser refractive surgery, or Laser Thermal Keratotomy.

In still another aspect of the invention, a method of determining a best correction for a given subject, includes measuring a subject pupil aberration function with an objective aberrometer, subtracting terms from the pupil aberration function that correspond to specific corrective means, producing a modified pupil aberration function, computing a point-spread-function from the modified pupil aberration function, computing an optical transfer function (OTF) of the computed point-spread-function, multiplying a Fourier transform of a test image by the OTF to produce a Fourier result, performing an inverse Fourier transform on the

Fourier result, and adjusting the terms that are subtracted to optimize a resultant image.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1**A shows the Modulation Transfer Function (MTF) for an eye with perfect vision, and FIG. **1**B shows a corresponding visual acuity chart computed according to a preferred embodiment of the invention.

FIG. **2**A shows the MTF of an eye having a weak aberration, V_4 wave of defocus, and FIG. **2**B shows a corresponding visual acuity chart computed according to a preferred embodiment of the invention.

FIG. **3**A shows the MTF of an eye having a significant aberration, 2 waves of defocus, and FIG. **3**B shows a corresponding visual acuity chart computed according to a preferred embodiment of the invention.

FIG. **4**A shows the result of measuring the MTF of a human eye with an objective aberrometer, and FIG. **4**B shows a corresponding visual acuity chart computed according to a preferred embodiment of the invention.

FIG. **5** illustrates the effect of subtracting the lower order Zernike terms (focus and astigmatism) from a wavefront before computation of a simulated image.

FIG. **6** presents a cross section through a target. FIG. **6**A shows a cross section through the original target, FIG. **6**B shows a resolved image of the target, FIG. **6**C shows the target image that just meets the Rayleigh criterion, and FIG. **6**D shows an unresolved image.

FIG. **7** shows a simulated target that is used to determine a visual acuity number.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

Embodiments and other aspects of the invention described herein, including the system embodiments described below, may be made or used in conjunction with inventions described, in whole or in part, in co-pending U.S. patent application Ser. No. 09/692,483, filed on Oct. 20, 2000, filed in the name of inventors Daniel R. Neal, Darrel Armstrong, James Gruetzner, and James Copland, entitled "Dynamic Range Extension Techniques for a Wavefront Sensor Including Use in Ophthalmic Measurement," the entirety of which is hereby incorporated herein by reference for all purposes as if fully set forth herein.

This invention relies on a measurement of the aberrations, including both the low and high orders to calculate the effect of these aberrations on an image. The aberrometer generates a measured map of the appropriate aberrations, which may be expressed either in terms of a wavefront error distribution, or in terms of a set of representative polynomials. This map, which may be called the pupil aberration function, can be analyzed to predict the effect of these aberrations on the image.

The method described herein consists of two basis steps:

1. Computation of the point-spread-function. That is, the response of the measured optical system to a single point source; and
2. Convolution of the point-spread-function with an appropriate image.

These steps are the minimum necessary to evaluate the effect of the aberrations on visual acuity. The point-spread-function may be computed from the aberration map alone, with no a priori assumptions about the internal structure of the eye. Any image can be used for the second, convolution, step. This can be a scene, a color or black and white image, a letter or series of letters, a Snellen acuity chart, or a pattern of geometric shapes that may be useful for determining other properties of vision.

It may be possible to perform both operations at once by taking advantage of certain properties of the Fourier transform. Both the point-spread-function and convolution operations may be performed using Fourier-transform techniques.

Some specific shapes can be used to determine the Snellen Acuity number, or objective visual acuity. The simplest such shape is a pair of points. When convolved with the point-spread-function, the visual acuity number may be related to the resolvable separation of the points. An absolute criterion, such as the Rayleigh criterion, may be used to determine this number from the data. Better targets, such as a series of bars at different separations may be more readily interpreted automatically.

It is also possible to compute the visual acuity directly from the point-spread-function by analyzing its spatial extent. Since the point-spread-function (by definition) is the response of the optical system to a point input, the spatial extent of this function contains all the information needed to compute the visual acuity number. An appropriate algorithm can be used to objectively determine the spatial extent, such as 2^{nd} moment, or fitting to a Gaussian profile or other a priori shapes.

Algorithm.

A wavefront aberrometer measures the full aberrations of the eye (e.g., cornea and lens) to provide the pupil aberration function $\phi(x,y)$. Beneficially, the wavefront aberrometer is an objective aberrometer that measures the low order aberrations such as defocus and astigmatism, as well as higher order aberrations such as coma, spherical aberration or other more rapidly varying components. With this information, it is possible to simulate how these aberrations reduce the fidelity of a subject's eyesight, i.e., to visualize a patient's lack of acuity. The procedure follows these steps:

(1) construct the impulse response function, or point-spread-function (PSF), of the cornea and lens using either the fitted Zernike coefficients from measured data or a measured wavefront map;

(2) perform the inverse Fourier transform of the intensity-PSF (modulus squared of the PSF) to produce the measured optical transfer function (OTF);

(3) multiply the OTF with the spectral distribution of an image (e.g., eye chart); and

(4) calculate the inverse Fourier transform to simulate how a patient's visual acuity affects his or her eyesight.

The first step is to form the generalized pupil aberration function, P, utilizing measured sensor data.

$$P(x,y)=P(x,y)\cdot e^{i\phi(x,y)}, \tag{1}$$

where P(x,y) is the pupil aberration function,

$$P(x,y)\equiv P(\rho,\theta)=circ(\rho), \tag{2}$$

and the wavefront may be represented by the phase function:.

$$\phi(\rho,\theta)=k\cdot\sum_{n=1}^{15} z_n\cdot P_n(\rho,\theta), \tag{3}$$

where z_n represents the coefficients for the Zernike polynomials P_n (see, e.g., MALACARA, OPTICAL SHOP TESTING, p. 455–499, John Wiley & Sons 1992) and k is

the wave-number of the laser source, $2\pi/k$. The pupil aberration function may be expressed as an expansion in terms of known polynomials, e.g. Zernike polynomials, or as a distribution map of wavefront values, determined numerically or analytically. From P the PSF is calculated by taking the Fourier transform F{ }:

$$PSF=F\{P(x,y)\}. \quad (4)$$

The next step solves for the OTF to be used for incoherent illumination. It is the normalized autocorrelation function of the intensity impulse response function, the magnitude squared of the PSF.

$$OTF = \frac{F^{-1}\{PSF^* \cdot PSF\}}{\pi \cdot r^2}, \quad (5)$$

where r is the pupil radius.

Convolution takes place in the frequency domain. The OTF is multiplied by the spectral content of an image, e.g., the Fourier transform of the eye chart input image. The final step performs the inverse Fourier transform on the above product to determine the form of the image on the retina (see FIGS. **1**B, **2**B, **3**B and **4**B).

$$\text{Retinal image}=|F^{-1}\{OTF \cdot F\{\text{image}\}\}| \quad (6)$$

Computational Considerations.

Two inter-related issues include how to sample the image and the sampling resolution of the above calculation. The resolution of an image on the retina (i.e., sampling rate) is defined by the minimal distance between rods or cones, which is 1.5–2.0 μm. Therefore, an image placed one focal length in front of the eye has a magnification of 1 and the same spatial resolution. Therefore, all eye charts represent letter sizes and line-widths with a specific number of pixels. This has been measured and tabulated in Table 1 below.

TABLE 1

Resolution requirements for simulating letters in an Eye Chart

Visual Acuity	Eye Chart	samples
20/200	E	185.2
20/100	F P	92.6
20/70	T O Z	64.8
20/50	L P E D	46.3
20/40	P E C F D	37.0
20/30	E D F C Z P	27.8
20/25	F E L O P Z D	23.2
20/20	D E F P O T E C	18.5

The Fourier transforms may advantageously be computed using Fast Fourier Transform (FFT) techniques.

The eye chart displays the letter E for the following levels of visual acuity: 20/200, 20/100, 20/50, 20/40, 20/30, and 20/20 (FIGS. **1**B, **2**B, **3**B and **4**B). Defining the retinal sample size to 2 μm, the number of samples is 512. This sample size ignores the diffractive effects of the pupil, only the effects of the aberrations on the object are simulated.

FIGS. **1**–**4** display the Modulation Transfer Function and visual acuity charts. (eye chart simulations) for the following cases: perfect visual acuity ($z_n 0$) (FIGS. **1**A–B); vision with slight defocus ($z_5 \sim \lambda/4$) (FIGS. **2**A–B); vision with a lot of defocus ($z_5 \sim 2\%$) (FIGS. **3**A–B); and the vision of a human subject (FIGS. **4**A–B). The Modulation Transfer Function (MTF) is the modulus of the Optical Transfer Function (OTF), which is a complex function.

FIG. **1**A shows the MTF for an eye with perfect vision, i.e., excellent visual acuity, no aberrations measured (i.e., Zernike coefficients approach zero). This produces an MTF having nearly a perfect cone shape. The degradation in acuity is only a result of the fact that the image was transmitted through a finite pupil. FIG. **1**B shows an eye chart simulation produced by the convolution of the OTF whose MTF is shown in FIG. **1**A, with an exemplary eye chart.

Aberrations distort the OTF and thus an image. Slowly increasing the defocus term (Zernike coefficient five) attenuates higher frequency acuity causing edges to appear "fuzzy."As an example, FIG. **2**A shows the MTF of an eye having a weak defocus term, ¼ wave of defocus, and FIG. **2**B shows the an eye chart simulation produced by convolution of the OTF whose MTF is shown in FIG. **2**A, with the exemplary eye chart of FIG. **1**B. A slice of the MTF cone through the origin appears "L-shaped." As this aberration becomes worse ($>\lambda/2$), the OTF can change sign, an indication of contrast reversal. FIG. **3**A shows the effect of a significant aberration, 2 waves of defocus, on the MTF, and FIG. **3**B shows the corresponding acuity chart (eye chart simulation) obtained by convolution of the OTF whose MTF is shown in FIG. **3**A, with the exemplary eye chart of FIG. **1**B. While the aberrations are still symmetric, a significant effect is evident. Oscillations in the MTF, reversals in contrast, and the loss of visual acuity (20/100) are noted.

FIGS. **4**A–B show the results of measuring a human eye with an objective aberrometer, and applying the method described above to the computation of the visual acuity of a human subject. It is noted that the aberrations produce an MTF and visual acuity chart which are no longer symmetric, but which represent the effects of focus, astigmatism, and other higher order aberrations. The strong difference between horizontal and vertical visual acuity is seen in the MTF of FIG. **4**A. The eye chart simulation of FIG. **4**B, produced by convolution of the OTF whose MTF is shown in FIG. **4**A, with the exemplary eye chart of FIG. **1**B, indicates weak visual acuity in the horizontal direction, and reasonable acuity in the vertical. This agrees well with testimonial description from the subject regarding the subject's vision without the use of corrective lenses.

Subtraction of Specific Terms.

One key advantage to the numerical technique of computing the visual acuity image is that the effect of specific types of aberration may be considered. For example, it is quite common for a post-Lasik patient to complain of poor night vision, especially while driving. The patient may describe star shapes or double images surrounding headlights. In this case it may be desirable to isolate the effects of the various aberration terms in order to identify which is the most significant. This can be done by adjusting (e.g., adding to, subtracting from, eliminating, etc.) the appropriate terms in the aberration distribution that is used as the input to the algorithm.

This technique is particularly powerful when used with correction means that may introduce higher order aberrations in the process of correcting low order effects. As an example, it is common for the Lasik procedure to introduce significant spherical aberration in the process of correcting low order terms. Using the invention described herein, these effects could be correctly simulated to determine the effect on the subject's vision, before performing the procedure.

As an example of this, consider FIG. **5**, which illustrates the effect of subtracting the lower order Zernike terms (focus and astigmatism) from the wavefront before computation of a simulated image. The left hand side of FIG. **5** shows the effect of all measured aberrations on a projected image, and right hand side of FIG. **5** shows the effect of only the higher

order aberrations. This case is particularly useful since it represents correction of the ocular system with the best-fit conventional glasses. The residual aberrations can be evaluated for the effectiveness of other corrective means, or for screening and diagnosis.

Computation of the Visual Acuity Number.

One of the key parameters used to describe visual performance is the visual acuity number. This describes the comparative visual performance relative to a standard. Thus a subject is described as having 20/20, or 20/40 visual acuity. An objective means for determining this numerical representation is needed to allow interpretation of the measured aberration information. To determine the visual acuity number from the computed image, a special set of images may be used. The visual acuity is related to the ability to resolve a pair of points or targets. To this end a special set of images that may be test targets may be used to advantage. These may be sets of bars similar to an Air Force test target, or may be as simple as a pair of points with known separation. If the target image is configured with a number of different spatial frequencies, the resulting image (after convolution) may be used to automatically determine the visual acuity number.

FIG. **7** shows a typical target that may be used to determine the visual acuity number. In this case a series of targets, each in different rows corresponding to a different visual acuity number (20/200, 20/50, 20/40, 20/20, etc.), is used as the input image to the convolution algorithm described herein. Each row contains targets with different spatial frequency information. By presenting several different targets for each line of a visual acuity number, the effect of non-symmetric aberrations may be included in the analysis. By determining the last line that may be distinguished, the visual acuity number may be measured. Each of these targets is analyzed using the Rayleigh or other criteria to determine if it meets the resolution requirements. The Rayleigh criteria states that two point or line sources may be considered distinguishable if the intensity distribution between the sources falls to ½ of the peak intensity, as shown in FIG. **6**. FIG. **6** shows a cross section through a target. Proceeding from left to right, the first graph on the left shows a cross section through the original target, the second graph shows a resolved image of the target, the third graph shows the target image that just meets the Rayleigh criterion, and the last graph shows an unresolved image.

To determine the visual acuity number an image with a number of targets arranged in rows, each row consisting of the same size target corresponding to a given visual acuity. The targets may have both horizontal and vertical features, as appropriate. A section through each of the targets, in either the horizontal or vertical direction, as appropriate, is analyzed to determine if the Rayleigh criterion has been met for that target. If all targets on one row meet this criterion, but none on the next successive rows meet this criteria, then the visual acuity is the number associated with the last successful row.

Partial or fractional visual acuity may be obtained by counting the number of targets that pass the criteria on a given row. Other means for determining the visual acuity number from this arrangement of targets will be apparent to those skilled in the art.

A method for using measured wavefront information from an objective aberrometer to compute a simulated image has been presented. This method allows wavefront information to be interpreted in terms of a subject's visual performance, and allows a clinician to ascertain the effect of various aberrations. The visual acuity of the subject can be computed, either by a view of the computed eye chart, or through objective calculation of standardized targets. The effect on the subject visual performance of corrective means, including the effect of increased aberrations, can be computed, allowing evaluation of candidate treatments.

Several potential benefits may be obtained.

For example, conventional objective methods for measuring optical quality of the eye require a subjective evaluation by the interpreter. Accordingly, these conventional methods are not useful for measuring optical qualities for non-communicative subjects (e.g., deceased subjects, animals, infants, etc.). However, the methods described herein maybe used to predict the acuity of animal eyes both in vivo and ex vivo. Consequently, the usefulness of animal and cadaver studies of corrective measures can be increased.

Also, the methods described herein open the possibility of studying the relative importance of certain aberrations (such as spherical aberrations) for visual perception. Such a study may involve the combination of the objective measurements provided by the disclosed methods, in combination with subjective measurements (e.g., having a patient evaluate simulated acuity against what they perceive from an actual eye chart). This knowledge can lead to improvements in the manufacture of spectacles and contact lenses and improvement in surgical prescription techniques.

Moreover, according to the disclosed methods, it is possible for doctors to provide correction techniques by allowing them to show a prospective patient the potential improvement in their sight.

While preferred embodiments are disclosed herein, many variations are possible which remain within the concept and scope of the invention. Such variations would become clear to one of ordinary skill in the art after inspection of the specification, drawings and claims herein. The invention therefore is not to be restricted except within the spirit and scope of the appended claims.

What is claimed is:

1. A method for computing the visual performance of a human or animal subject based on objective measurements of visual refraction including higher order aberrations, comprising the steps of:

measuring wavefront aberrations of a subject ocular pupil;

computing a point-spread-function from the measured pupil aberration;

providing a test image; and

convolving the test image with the point-spread-function.

2. The method of claim **1** wherein the wavefront aberrations are measured with an objective aberrometer.

3. The method of claim **1** wherein the wavefront aberrations are measured with one selected from a group consisting of a Shack-Hartmann wavefront sensor system, a Tscherning aberrometer, a scanning resolved refractometer, and a Moire deflectometer.

4. The method of claim **1** where the wavefront aberrations are measured objectively by projecting a beam of light onto a retina and analyzing resulting return images.

5. The method of claim **1**, further comprising producing a simulated image from a convolution result of convolving the test image with the point-spread-function.

6. The method of claim **1** wherein the test image is a Snellen acuity chart, and further comprising producing a simulated subject view of the Snellen acuity chart from a convolution result of convolving the Snellen acuity chart with the point-spread-function.

7. The method of claim **1** wherein convolving the test image with the point-spread-function comprises the steps of:

performing an inverse Fourier transform of a modulus squared of the point-spread-function to compute an optical transfer function;

computing a Fourier transform of the test image; and

computing an inverse Fourier transform of a product of the optical transfer function and the test image Fourier transform.

8. The method of claim **7**, wherein the Fourier transform and inverse Fourier transforms are computed with Fast Fourier Transforms.

9. A method for computing a point-spread-function of a human or animal ocular system from objective aberrometry measurements, comprising the steps of:

measuring a pupil aberration function with an objective aberrometer; arid

computing the point-spread-function as a modulus squared of a Fourier transform of the measured pupil aberration function.

10. A method for determining a visual acuity of an ocular optical system, comprising:

measuring a pupil aberration function with an objective aberrometer;

computing a point-spread-function as a modulus squared of a Fourier transform of the measured pupil aberration function; and

analyzing a spatial extent of the point-spread-function.

11. A method for determining Snellen acuity from evaluation of a double object when convolved with a point-spread-function, comprising the steps of:

measuring a subject pupil aberration function with an objective aberrometer;

computing a point-spread-function from the modified pupil aberration function;

computing an Optical Transfer Function (OTF) from the computed point-spread-function;

providing an input image which consists of appropriate targets coded so that known image features can be correlated to a visual acuity number; and

convolving the input image with the point-spread-function by multiplying a Fourier transform of the input image by the OTF and then performing an inverse Fourier transform.

12. The method of claim **11** where the double object is a series of bars with different orientations.

13. A method for computing an image, comprising the steps of:

measuring wavefront aberrations of a subject ocular pupil;

computing a point-spread-function from the measured pupil aberration;

providing a test image;

convolving the test image with the point-spread-function; and

producing a simulated image from a convolution result of convolving the test image with the point-spread-function,

wherein at least one specific term of the point-spread-function is adjusted prior to the convolving step to simulate an effect of a correcting means.

14. The method of claim **13**, wherein adjusting the specific term comprises subtracting the specific term from the point-spread-function.

15. A method for computing an effect of corrective means on a subject's visual acuity, comprising the steps of:

measuring a subject pupil aberration function with an objective aberrometer;

adjusting terms in the measured subject pupil aberration function that correspond to specific corrective means, producing a modified pupil aberration function;

computing a point-spread-function from the modified pupil aberration function;

computing an optical transfer function (OTF) of the computed point-spread-function;

multiplying a Fourier transform of a test image by the OTF to produce a Fourier result; and

performing an inverse Fourier transform on the Fourier result.

16. The method of claim **15** wherein the corrective means is spectacle lenses.

17. The method of claim **15** wherein the corrective means is contact lenses.

18. The method of claim **15** wherein the corrective means is laser refractive surgery.

19. The method of claim **15** wherein the corrective means is Laser Thermal Keratotomy.

20. The method of claim **15**, wherein the corrective means includes one selected from a group consisting of Interocular lenses, femto-second laser correction, and corneal implants.

21. A method of determining a best correction for a given subject, comprising the steps of:

measuring a subject pupil aberration function with an objective aberrometer;

subtracting terms from the pupil aberration function that correspond to specific corrective means, producing a modified pupil aberration function;

computing a point-spread-function from the modified pupil aberration function;

computing an optical transfer function (OTF) of the computed point-spread-function;

multiplying a Fourier transform of a test image by the OTF to produce a Fourier result;

performing an inverse Fourier transform on the Fourier result; and

adjusting the terms that are subtracted to optimize a resultant image.

(57) **ABSTRACT**

A shutter for use as an objective for improving the depth of focus in a camera is disclosed. The shutter has, in a central area, a radially uniform transmission function averaged over the circumferential angle. The radial transmission function first drops off toward zero in a radial transition area which is a continuation of the central area and which has a quantity n of cutouts which extend toward the radial outside and are spaced apart from one another at equal angles 360°/n in the circumferential direction. The quantity n of cutouts has the value 5, 6 or 7.

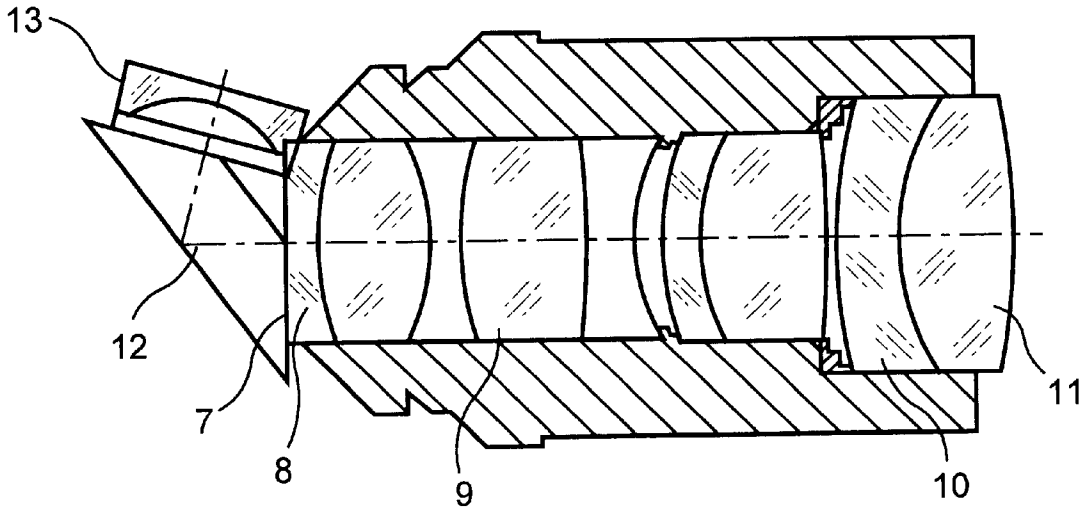

FIG. 4

SHUTTER, IN PARTICULAR FOR AN OBJECTIVE, AND A CCD-CAMERA

BACKGROUND OF THE INVENTION

a) Field of the Invention

The invention is directed to a shutter, in particular for an objective, for improving the depth of focus in a camera, wherein the shutter has, in a central area, a radially uniform transmission function averaged over the circumferential angle. The invention is further directed to a CCD-camera, especially for endoscopes, in which the shutter can advantageously be used together with the objective.

b) Description of the Related Art

Objectives are known from photographic cameras, for example. In order to limit the light intensity in the exposure of a photographic film, a shutter is normally provided in objectives of this type. While the shutter is usually adjustable in this application and, for that reason, does not appear completely round, this shutter still essentially constitutes a round hole optically, that is, it has a radially independent transmission function in the area of a hole.

However, this shutter has additional functions. First, by limiting the light to rays in the vicinity of the optical axis, the imaging characteristics of the objective are improved by stopping out the outer lens areas. On the other hand, an increased depth of focus is achieved as the shutter decreases in size.

However, the design of this shutter can be problematic particularly in small cameras, for example, CCD-cameras in endoscopes which often require small shutters because of miniaturized construction. A shutter which is too small also has worsened resolving capability for image presentation because, in view of the wavy nature of the light at the edge of the shutter, there is always a noticeable diffraction which limits the possible image resolution and predominates when the shutter is reduced in size below a certain lower limit.

Particularly in the case of CCD-cameras in which the individual elements for image presentation are usually in the order of magnitude of micrometers and with which diffraction effects can also be detected in the micrometer range, a clearly visible diffraction limitation occurs already in shutters in the order of magnitude of millimeters. Naturally, the shutters could be made larger; but there would be a loss in the depth of focus, which is completely unacceptable in the case of endoscopes when the image recording is carried out by means of a CCD-camera.

OBJECT AND SUMMARY OF THE INVENTION

It is the primary object of the invention to improve known shutters, especially in connection with objectives, so that they are suitable particularly for CCD-cameras and so that the depth of focus as well as the resolution for image presentation can be increased by means of them.

This object is met in a shutter of the type described above in that the transmission function determining the shutter first drops off toward zero in a radial transition area which is a continuation of the central area mentioned above and which has a quantity n of cutouts which extend toward the radial outside and are spaced apart from one another at equal angles 360°/n in the circumferential direction, and the quantity n of cutouts has the value 5, 6 or 7. It is possible to use a shutter of this kind, according to the invention, in any type of optical beam path, for example, in the beam path of a laser, etc., also without an objective. However, the preferred use of the shutter in connection with an objective is referred to hereinafter.

First of all, it is surprising in terms of physics that this object can be met at all, since the shutter diameter was previously regarded as an insurmountable barrier to improvement of resolution. Heretofore, there has been no suggestion whatsoever for straying from circular shutters with a radial rectangular transmission function, since these were believed to have the best depth of focus and the loss of resolution was always taken for granted with the smaller diameter of the shutter because all of the familiar physics textbooks attributed the maximum attainable resolving capability exclusively to the very small lens diameter or shutter diameter.

Shutters of the type mentioned above always have a sharp edge, so that the diffraction pattern limiting the resolution can be represented mathematically essentially by a zero-order Bessel function. In contrast to this, however, the diffraction pattern of the shutter, according to the invention, for the objective is still a sum of different Bessel functions as a result of the transition area provided according to the invention. Through the selection of the shape of the shutter and/or the configuration of the transmission function, for the purpose of displaying the diffraction pattern, contributions of higher Bessel functions can be added which, because of a different phase relationship, can narrow the broad maximum of the zero-order Bessel function in the neighborhood of small radii. Particularly also due to the area which is provided according to the invention for the diffraction and which is widened by the transition area, the zero-order Bessel function contribution dominating the resolution is also scaled to smaller radii, so that, as a result, the diffraction pattern limiting the resolution is even substantially sharper in the neighborhood of zero. However, because of the higher light intensity in the central area, the depth of focus is essentially entirely determined thereby. Accordingly, with an improved depth of focus, an improved resolution is also possible in particular.

Surprisingly, it has been shown that a camera which is outfitted with a shutter of this type for the objective of the camera is also substantially more sensitive to light. In fact, this could be expected because the central area is somewhat enlarged by the transition area with respect to the transmissivity of the shutter. But at the same time it would have to have been expected that the depth of focus would decrease. However, with a suitable design of the shutter according to the invention, it was observed that the depth of focus did not decrease in spite of increased-light sensitivity.

Due to the cutouts which extend on the radial outside and are spaced at equal angles 360°/n in the circumferential direction and because of the resulting symmetry, the Bessel functions which additionally contribute to the diffraction and whose solution, as is well known, runs in periodicity with the circumferential angle are selected. Accordingly, this further development forces the occurrence of higher-order Bessel functions than the zero order, especially of an order of the whole number n of 5, 6 or 7, which also enables the selection of a suitable phase position of these contributions based on a suitable shape for a particularly favorable increase in the resolving capability.

Surprisingly, it has proven particularly advantageous when the number n has the value 5, 6 or 7. Since these findings were made through experimentation, a plausible explanation was even found. These Bessel functions have a maximum in the neighborhood of the drop-off of the zero-order Bessel function. When it is made possible, as a result of appropriate shaping of the shutter, to generate these contributions in reverse phase position to the zero-order Bessel function, the total drop-off of the diffraction patterns

in the area of the diffraction maximum is substantially steeper and the possible resolution is thus improved in a substantially more effective manner. A shape of this kind is shown later in an embodiment example.

The desired transmission function of the shutter could also be achieved through arrangements of holes in the shutter material in the radial transition area. However, such holes can cause new diffraction effects, so that the resolution by means of the provided transition area remains far from optimum. Accordingly, based on these considerations, a preferable shutter will have no closed cutouts and, above all, no circular cutouts in the transition area forming a continuation of the central area.

Based on these considerations, the shutter was further optimized. According to an advantageous further development in this respect, it has proven particularly favorable when the shutter is formed with a star-shaped transition area around a circular central area.

In particular, the following further developments of the invention have proven especially favorable for the design of the shutter, according to the invention, for an objective. In a first further development of the invention, it is provided in this connection that the radial transmission function drops off to 90% of the central value at a radius R_1 and to 10% of the central value at a radius R_2, wherein R_2-R_1 is greater than 0.1 R_1.

In another advantageous further development of the invention in this connection, it is provided that the radial transmission function drops off to 90% of the central value at a radius R_1 and to 10% of the central value at a radius R_2, and $(R_2-R_1)<R_1$.

It has been determined in particular that the above-mentioned advantageous results can be achieved in a simple manner when R_2/R_1 is fixed at 0.8 ± 0.1.

Due to the fact that the radial area continuing the central area is set at the order of magnitude of 10% to 100% of the radius of the central area, the contribution of larger proportions to the increased resolution is not too small to be effective on the one hand and, on the other hand, the continuation of the area up to twice the central area also leads to an approximate doubling of the resolving capability, so that a noticeable increase in resolution can be seen without a substantial worsening of the depth of focus. In particular, the indicated value of $R_2/R_1-1=0.8\pm0.1$ has proven particularly suitable for practical applications.

Based on the ideas expressed above which were formed by means of mathematical considerations, such a simple shutter shape would not have been expected. In particular, a shutter of this type can be manufactured in a simple manner. With regard to the further improvement of the shutter according to the invention, this was an additional unexpected result which was particularly advantageous for the use of these shutters.

In another further development of the invention, the shutter is vacuum-deposited on a lens as an opaque layer, especially as a metal layer.

Initially, no special improvement was anticipated with respect to this embodiment form either. However, it has been shown that a substantial increase in resolution can be achieved in this way compared, for example, to an individual shutter which is placed in front of a lens. This is due primarily to the fact that the light passing through the shutter is immediately conducted into the glass of the following lens, so that deviations in the light propagation direction based on Snell's law of refraction, whereby every change in angle is reduced with respect to the surface normal, are compensated. Therefore, diffraction effects due to proximity to a glass surface resulting from said lens can be kept small.

This advantage becomes apparent above all when the surface normal remains constant in the area of the shutter opening or varies only slightly over the shutter area, namely, when this lens is plane or flat. The above-mentioned advantages can be achieved in an extremely simple manner, for example, in a commercially available CCD-camera, when the shutter is vacuum-deposited on the foremost lens of the objective. The fact that common CCD-cameras with a plane first lens surface are commercially available and the possibility of vacuum-depositing the metal layer on these lenses without completely disassembling the camera advantageously simplifies the required modification in which a shutter according to the invention is used on the objective that is already provided for the camera.

Due to the somewhat elongated optics, it is extremely advantageous for a favorable arrangement of the camera, for endoscopy in particular, to record images from areas which lie at an angle to the optical axis of the CCD-camera. For this purpose, it is provided that a prism and/or an achromat and/or a negative individual lens are/is arranged in front of the shutter located on the front lens. The prism allows a recording of images at an angle to the optical axis of the objective. The achromat is provided, for example, in order to correct for chromatic aberrations caused by the prism.

As stated above, cameras of the type mentioned above can be used in a particularly advantageous manner for endoscopy and the abovementioned embodiment forms for the shutters which will be better understood from the following embodiment forms were optimized especially for the field of endoscopy. However, it has also been shown that the objectives outfitted with a shutter of this kind are also particularly suitable for other CCD-cameras and other objectives which can be used for imaging.

The invention is described more fully in the following with reference to the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

In the drawings:

FIG. **1** illustrates the resolving capability as a function of the shutter diameter;

FIG. **2** illustrates the transmission function of a shutter according to the invention which can be used particularly advantageously in an objective;

FIG. **3** shows a particularly advantageous construction of a shutter; and

FIG. **4** shows an objective unit for a CCD-camera which is especially suitable for endoscopy and which is outfitted with the shutter according to the invention shown in FIG. **3**.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

The known curve of a diffraction pattern in a shutter is shown schematically in FIG. **1** for purposes of illustration. In particular, FIG. **1** shows curves **1** and **3** of transmissions averaged about the circumference as a function of the radius R, the distance from the center of the shutter.

In a round shutter, the transmission function is essentially a box profile as is shown schematically, for example, in FIG. **1** by reference number **1**. Further, curve **2** shows schematically the amplitude of the associated diffraction pattern at a shutter as follows from the dimensions of the shutter and from the wavelength of the light passing through the objective. When the shutter diameter is increased as is shown in

dashed lines by curve **3**, the expected diffraction pattern is scaled based on the known law of diffraction with radius R and shifts within a narrow area as is shown schematically by curve **4**.

This means that the resolving capability improves as the size of the shutter in an objective increases. On the other hand, the depth of focus which depends in practice on the angular area comprehended by the objective decreases.

In comparison with the conventional circular shutter with the rectangular transmission function shown by curve **1**, a gentler transition from maximum to minimum transmission is suggested in this case as is shown by way of example by reference number **5** in FIG. **2**.

This function initially shows a flat area and then a gradual drop-off between R_1 and R_2 corresponding to 10% and 90% of the value in the central area.

Because of this smooth transition, even closer contributions in the diffraction pattern relative to the diffraction curve **2** expected in the box profile are added to the diffraction pattern of the shutter as can be seen, for example, in curve **4** in FIG. **1**, so that the resolution is already improved in this way.

Radii R_1 and R_2 which relate to the drop-off of 90% and 10% of the transmission curve are shown in FIG. **2** to define the desired transmission behavior. It has proven particularly advantageous for a shutter which limits the central beam path of an objective when $R_2-R_1>0.1\ R_1$, $R_2-R_1<R_1$ and $R_2/R_1-1=0.8\pm0.1$.

The transmission curve shown in FIG. **2** can be achieved, for example, with a round shutter which is formed by means of a darkened quartz plate which transmits in the central area and whose degree of darkness continuously increases toward the outside. However, it has been shown that it is also possible to realize this transmission function according to the invention by means of a nonuniform curve of the transmission function in the circumferential direction because the components contributing to the curve **2** which originate as a result of the transition area are essentially determined by a higher-order Bessel function which approaches zero in the neighborhood of R=0, but has a maximum which is offset from the zero point. With an appropriate phase position given by the shape of the shutter, this results in a path interference of a majority of the intensity in the wide flank of then diffraction curve and the resolution is further improved.

Accordingly, it is particularly advantageous for the resulting deviation from a uniform transmission in the circumferential direction when the shutter is constructed by means of an opaque material in which cutouts are provided in the transition area in the circumferential direction so as to be spaced apart at identical angles 360°/n. The chief effect brought about by this is that the lowest-order Bessel function which contributes to the increase in resolution through changed phases is of the nth kind. Particularly favorable increases in resolution have been shown in particular when n is set at a value 5, 6 or 7. In an embodiment form, the quantity n can be an integral multiple of the value 5, 6 or 7.

FIG. **3** shows a shutter **6** of the type mentioned above which is constructed as a star-shaped cutout **7** in an opaque material. This star-shaped shutter opening **7** has a six-sided symmetry, that is, it is constructed such that n=6.

This shutter was used in an objective according to FIG. **4**. The shutter structure **6** and **7** shown in FIG. **2** was vacuum-deposited on a plane surface of a front lens **8**. Aluminum has proven to be a particularly suitable material for this purpose as a metal layer.

The sectional view in FIG. **4** shows the front lens **8** in the objective followed by an expansion lens **9** which is followed in turn in the light propagation direction by a plurality of field lenses **10**, **11**. This type of objective is especially suited to CCD-cameras.

In order to be able to acquire CCD images at an angle to the optical axis, a prism **12** was used in the embodiment example, wherein an achromat **13** is provided in front of the prism to compensate for chromatic aberrations caused by the prism **12** in that its dispersion behavior is selected in such a way that it compensates for the dispersion given by the prism **12**. In this way, loss of resolution due to different wavelengths is limited to a great extent, so that an especially high resolution results on the whole with the shutter shown in FIG. **2** when this objective is used in a CCD-camera, wherein its diffraction propagation was less than the CCD-elements used for image recording. It is also possible to use a negative individual lens instead of a prism.

In the construction shown in FIG. **4**, the shutter **7** also limits to near-axis beams, so that the depth of focus in the objective according to FIG. **4** is also increased relative to shutters with a rectangular radial transmission function in which the shutter must always have a certain minimum size in order to prevent loss of resolution.

However, not only CCD-cameras can be outfitted with these objectives with the shutter shown in FIG. **3**, or also in general with a transmission characteristic such as that shown in FIG. **2**, but also photographic objectives, e.g., for microfilming, in which a high resolution is also wanted.

While the foregoing description and drawings represent the present invention, it will be obvious to those skilled in the art that various changes may be made therein without departing from the true spirit and scope of the present invention.

What is claimed is:

1. A shutter, for use on an objective, for improving the depth of focus in a camera, said shutter comprising:

in a central area, means for providing a radially uniform transmission function averaged over the circumferential angle, said radial transmission function first dropping off toward zero in a radial transition area which is a continuation of said central area and which has a quantity n of cutouts which extend toward the radial outside and are spaced apart from one another at equal angles 360°/n in the circumferential direction, and the quantity n of cutouts has the value 5, 6 or 7, and

wherein the radial transmission function drops off to 90% of the central value at a radius R_1 and to 10% of the central value at a radius R_2, wherein $(R_2-R_1)>0.1\ R_1$.

2. The shutter according to claim **1**, wherein the radial transmission function drops off to 90% of the central value at a radius R_1 and to 10% of the central value at a radius R_2, and $(R_2-R_1)<R_1$.

3. The shutter according to claim **1**, wherein $R_2/R_1-1=0.8\pm0.1$.

4. The shutter according to claim **1**, wherein the quantity n is a whole-number multiple of the value 5, 6 or 7.

5. The shutter according to claim **1**, wherein the shutter has a star-shaped transition area outside of a circular central area.

6. The shutter according to claim **1**, wherein the shutter is vacuum-deposited on a lens as an opaque layer.

7. The shutter of claim **6**, wherein the opaque layer is a metal.

8. The shutter according to claim **6**, wherein the shutter is vacuum-deposited on a front plane surface of the lens.

9. The shutter according to claim 6, wherein the shutter is arranged on the foremost lens of the objective.

10. The shutter according to claim 1, wherein the shutter is arranged behind a prism or an achromat or a negative individual lens.

11. A CCD-camera for an endoscope, having a shutter for use as an objective, for improving the depth of focus in a camera, said shutter comprising:

in a central area, means for providing a radially uniform transmission function averaged over the circumferential angle, said radial transmission function first dropping off toward zero in a radial transition area which is a continuation of said central area and which has a quantity n of cutouts which extend toward the radial outside and are spaced apart from one another at equal angles 360°/n in the circumferential direction, and the quantity n of cutouts has the value 5, 6 or 7, and

wherein the shutter is vacuum-deposited on a lens as an opaque layer.

12. A shutter, for use on an objective, for improving the depth of focus in a camera, said shutter comprising:

in a central area, means for providing a radially uniform transmission function averaged over the circumferential angle, said radial transmission function first dropping off toward zero in a radial transition area which is a continuation of said central area and which has a quantity n of cutouts which extend toward the radial outside and are spaced apart from one another at equal angles 360°/n in the circumferential direction, and the quantity n of cutouts has the value 5, 6 or 7, and

wherein the radial transmission function drops off to 90% of the central value at a radius R_1 and to 10% of the central value at a radius R_2, wherein $(R_2-R_1)<R_1$.

13. The shutter according to claim 12, wherein the radial transmission function drops off to 90% of the central value at a radius R_1 and to 10% of the central value at a radius R_2, wherein $(R_2-R_1)>0.1\ R_1$, and

wherein $R_2/R_1-1=0.8\pm0.1$.

14. The shutter according to claim 12, wherein the quantity n is a whole-number multiple of the value 5, 6 or 7.

15. The shutter according to claim 12, wherein the shutter has a star-shaped transition area outside of a circular central area.

16. The shutter according to claim 12, wherein the shutter is arranged behind a prism or an achromat or a negative individual lens.

17. A shutter, for use on an objective, for improving the depth of focus in a camera, said shutter comprising:

in a central area, means for providing a radially uniform transmission function averaged over the circumferential angle, said radial transmission function first dropping off toward zero in a radial transition area which is a continuation of said central area and which has a quantity n of cutouts which extend toward the radial outside and are spaced apart from one another at equal angles 360°/n in the circumferential direction, and the quantity n of cutouts has the value 5, 6 or 7, and

wherein the shutter is vacuum-deposited on a lens as an opaque layer.

18. The shutter of claim 17, wherein the opaque layer is a metal.

19. The shutter according to claim 17, wherein the shutter is a vacuum-deposited on a front plane surface of the lens.

20. The shutter according to claim 17, wherein the shutter is arranged on the foremost lens of the objective.

21. A CCD-camera for an endoscope, having a shutter for use as an objective, for improving the depth of focus in a camera, said shutter comprising:

in a central area, means for providing a radially uniform transmission function averaged over the circumferential angle, said radial transmission function first dropping off toward zero in a radial transition area which is a continuation of said central area and which has a quantity n of cutouts which extend toward the radial outside and are spaced apart from one another at equal angles 360°/n in the circumferential direction, and the quantity n of cutouts has the value 5, 6 or 7, and

wherein the radial transmission function drops off to 90% of the central value at a radius R_1 and to 10% of the central value at a radius R_2, wherein $(R_2-R_1)>0.1\ R_1$.

22. A CCD-camera for an endoscope, having a shutter for use as an objective, for improving the depth of focus in a camera, said shutter comprising:

in a central area, means for providing a radially uniform transmission function averaged over the circumferential angle, said radial transmission function first dropping off toward zero in a radial transition area which is a continuation of said central area and which has a quantity n of cutouts which extend toward the radial outside and are spaced apart from one another at equal angles 360°/n in the circumferential direction, and the quantity n of cutouts has the value 5, 6 or 7, and

wherein the radial transmission function drops off to 90% of the central value at a radius R_1 and to 10% of the central value at a radius R_2, wherein $(R_2-R_1)<R_1$.

(57) **ABSTRACT**

A microlithography reduction objective formed from six mirrors arranged in a light path between an object plane and an image plane is provided. The microlithography reduction objective is characterized by having an image-side numerical aperture NA≧0.15. In some embodiments, the mirror closest to the image plane, i.e., the fifth mirror is arranged such that an image-side optical free working distance is greater than or equal to a used diameter of a physical mirror surface of the fifth mirror, a physical mirror surface being the area of a mirror where light rays from the object impinge. The fifth mirror may be arranged such that an image-side optical free working distance is greater than or equal to the sum of one-third the used diameter of the physical mirror surface on the fifth mirror and a length between 20 mm and 30 mm. The fifth mirror may be arranged such that the image-side optical free working distance is at least 50 mm, as well. The image-side free working distance is the physical distance between the vertex of the surface of the fifth mirror and the image plane. Other embodiments are described.

MICROLITHOGRAPHY REDUCTION OBJECTIVE AND PROJECTION EXPOSURE APPARATUS

This is a Continuation-In-Part of U.S. application Ser. No. 09/503,640, filed Feb. 14, 2000, now U.S. Pat. No. 6,353,470.

FIELD OF THE INVENTION

The invention relates to a microlithography objective, a projection exposure apparatus containing the objective, and a method of manufacturing an integrated circuit using the same.

BACKGROUND OF THE INVENTION

Using a lithography system operating with wavelengths below 193 nm for imaging structures of below 130 nm resolution has been proposed. In fact, such lithography systems have been suggested for the extreme ultraviolet (EUV) range with wavelengths of λ=11 nm or λ=13 nm producing structures of below 100 nm. The resolution of a lithographic system is described by the following equation:

$$RES=k_1\cdot\lambda/NA$$

where k_1 is a specific parameter of the lithographic process, λ is the wavelength of the incident light, and NA is the image-side numerical aperture of the system. For example, if one assumes a numerical aperture of 0.2, then the imaging of 50 nm structures with 13 nm radiation requires a process with k_1=0.77. With k_1=0.64, the imaging of 35 nm structures is possible with 11 nm radiation.

For imaging systems in the EUV region, substantially reflective systems with multilayer coatings are available as optical components. Preferably multilayers of Mo/Be are used as multilayer coating systems for systems operating at λ=11 nm, whereas Mo/Si systems are used for λ=13 mm. Since the reflectivity of the multilayer coatings is approximating 70%, it is desirable to use as few optical components as possible in e.g. an EUV projection microlithography objective to achieve sufficient light intensity. Specifically, to achieve high light intensity and to allow for the correction of imaging errors, systems with six mirrors and a image side numerical aperture (NA)=0.20 have been used.

Six-mirror systems for microlithography have become known from the publications U.S. Pat. No. 5,686,728, EP 779,528 and U.S. Pat. No. 5,815,310. The projection lithography system according to U.S. Pat. No. 5,686,728 has a projection objective with six mirrors, where each of the reflective mirror surfaces has an aspherical form. The mirrors are arranged along a common optical axis in such a way that an obscuration-free light path is achieved. Since the projection objective known from U.S. Pat. No. 5,686,728 is used only for UV light with a wavelength of 100–300 nm, the mirrors of this projection objective have a very high asphericity of approximately ±50 μm as well as very large angles of incidence of approximately 38°. Even after reducing the image side aperture to NA=0.2, an asphericity of 25 μm from peak to peak remains, with a barely reduced angle of incidence. Such asphericities and angles of incidence are not practicable in the EUV region due to the high requirements for surface quality and reflectivity of the mirrors.

Another disadvantage of the objectives disclosed in U.S. Pat. No. 5,686,728, which precludes their use with wavelengths below 100 nm such as the 11 nm and 13 nm wavelengths desirable for EUV microlithography, is the short distance between the wafer and the mirror arranged next to the wafer. In the case of U.S. Pat. No. 5,686,728, due to this short distance between the wafer and the mirror next to the wafer, the mirrors could be made only very thin. Due to the extreme layer stress in the multilayer systems discussed for 11 nm or 13 nm wavelengths, such thin mirrors are very unstable.

A projection objective with six mirrors for use in EUV lithography, particularly also for wavelengths of 13 nm and 11 nm, has become known from EP 779,528. This projection objective also has the disadvantage that at least two of the six mirrors have very high asphericities of 26 and 18.5 μm. However, even in the EP 779,528 arrangement, the optical free working distance between the mirror next to the wafer and the wafer itself is so small that either instabilities occur or the mechanical free working distance is negative.

Thus, it is desirable to provide a projection objective for lithography with short wavelengths, preferably smaller than 100 nm, which does not have the disadvantages of the state of the art described above.

SUMMARY OF THE INVENTION

According to one aspect of the invention, the shortcomings of the prior art are overcome by a projection objective having an object plane and an image plane and a light path for a bundle of light rays from the object plane to the image plane. The six mirrors of the objective are arranged in the light path from the object plane to the image plane. According to the invention the mirror closest to the image plane where e.g. an object to be illuminated such as a wafer is situated is arranged in such a way that an image-side numerical aperture is NA≧0.15. In this application the image-side numerical aperture is understood to be the numerical aperture of the bundle of light rays impinging onto the image plane. Furthermore, the mirror arranged closest to the image plane of the objective is arranged in such a way that the image-side free working distance corresponds at least to the used diameter of the mirror next to the wafer. In a preferred embodiment the image-side free working distance is at least the sum of one-third of the used diameter of the mirror next to the image plane and a length between 20 and 30 mm. In an alternative embodiment the image-side free working distance is at least 50 mm. In a particularly preferred embodiment, the image-side free working distance is 60 mm. In this application the free working distance is defined as the distance of the vertex of the surface of the mirror next to the image plane and the image plane. All surfaces of the six mirrors in this application are rotational-symmetric about a principal axis (PA). The vertex of a surface of a mirror is the intersection point of the surface of a mirror with the principal axis (PA). Each mirror has a mirror surface. The mirror surface is the physical mirror surface upon which the bundle of light rays traveling through the objective from the object plane to the image plane impinge. The physical mirror surface or the used area of a mirror can be an off-axis or an on-axis mirror segment relative to the principal axis (PA).

According to another aspect of the invention, a projection objective that comprises six mirrors is characterized by an image-side numerical aperture, NA, greater than 0.15 and an arc-shaped field width, W, at the wafer in the range 1.0 mm≦W. The peak-to-valley deviation, A, of the aspheres are limited with respect to the best fitting sphere of the physical mirror surface of all mirrors by:

$$A\leqq 19\ \mu m-102\ \mu m\ (0.25-NA)-0.7\ \mu m/mm\ (2\ mm-W).$$

In a preferred embodiment, the peak-to-valley distance A of the aspheres is limited with respect to the best fitting sphere of the off-axis segments of all mirrors by:

$$A\leqq 12\ \mu m-64\ \mu m\ (0.25-NA)-0.3\ \mu m/mm\ (2\ mm-W).$$

According to yet another aspect of the invention, a projection objective that includes six mirrors is characterized by an image-side numerical aperture NA≧0.15 and an image-side width of the arc-shaped field W≧1 mm, and the angles of incidence AOI are limited for all rays of the light bundle impinging a physical mirror surface on all six mirrors **S1**, **S2**, **S3**, **S4**, **S5**, **S6** by:

$$AOI \leqq 23° - 35°(0.25 - NA) - 0.2°/mm(2\ mm - W)$$

wherein the angles of incidence AOI refer to the angle between the incident ray and the normal to the physical mirror surface at the point of incidence. The largest angle of any incident bundle of light rays occurring on any of the mirrors is always given by the angle of a bundle-limiting ray.

Preferably, an embodiment of the invention would encompass all three of the above aspects, e.g., an embodiment in which the free optical working distance would be more than 50 mm at NA=0.20 and the peak-to-valley deviation of the aspheres, as well as the angles of incidence, would lie in the regions defined above.

The asphericities herein refer to the peak-to-valley (PV) deviation, A, of the aspherical surfaces with respect to the best fitting sphere of the physical mirror surface of an specific mirror. The physical mirror surface of a specific mirror is also denoted as the used area of this specific mirror. The aspherical surfaces are approximated in the examples by using a sphere. The sphere has a center on the figure axis vertex of the mirror. The sphere intersects the asphere in the upper and lower endpoint of the used area in the meridian section. The data regarding the angles of incidence always refer to the angle between the incident ray and the normal to the physical mirror surface at the point of incidence. The largest angle of any incident bundle of light rays occurring on any of the physical mirror surfaces is always given by the angle of a bundle-limiting ray. The used diameter or the diameter of the physical mirror surface will be defined here and below as the envelope circle diameter of the physical mirror surface or the used area of a mirror, which is generally not circular.

In a preferred embodiment, the free working distance is 60 mm.

The objective can be used not only in the EUV, but also at other wavelengths, without deviating from the scope of the invention. In any respect, however, to avoid degradation of image quality, especially degradation due to central shading, the mirrors of the projection objectives should be arranged so that the light path of the bundle of light rays traveling from the object plane to the image plane is obscuration-free. Furthermore, to provide easy mounting and adjusting of the system, the physical mirror surfaces have a rotational symmetry to a principal axis (PA). Moreover, to have a compact design with an accessible aperture and to establish an obscuration-free light path of the bundle of light rays traveling from the object plane to the image plane, the projection objective device is designed in such a way that an intermediate image of the object situated in the object plane is formed after the fourth mirror. In such systems, it is possible that the aperture stop is situated in the front, low-aperture objective part, with a pupil plane conjugated to the aperture stop imaged in the focal plane of the last mirror. Such a system ensures telecentricity in the image plane.

In a preferred embodiment of the invention, the aperture stop is freely accessible and arranged in the light path from the object plane to the image plane between the second and third mirror. Good accessibility of the aperture stop is ensured when the ratio of the distance between the first and third mirror to the distance between the first and second mirror lies in the range of:

$$0.5 < S1S3/S1S2 < 2.$$

As defined for the free working distance in general a distance between two mirrors is the distance of the vertices of the surfaces of these mirrors.

Furthermore, in order to prevent vignetting of the light running from the third to the fourth mirror, by the aperture stop arranged between the second and third mirror, the ratio of the distance between the second mirror and aperture stop to the distance between the third mirror and the aperture stop lies in the range:

$$0.5 < S2\ \text{aperture}/(S3\ \text{aperture}) < 2.$$

In such a system, the angles of incidence on the physical mirror surfaces in the front part of the objective are reduced.

An aperture stop which physically lies between the second mirror, **S2**, and the first mirror, **S1**, must be formed at least partially as a narrow ring in order to avoid clipping of light moving from **S1** to **S2**. In such a design, there is a danger that undesirable direct light or light reflected on **S1** and **S2**, will pass outside the aperture ring and reach the image plane and thus the wafer. However, if the aperture stop is placed in the light path between the second and third mirror and physically close to the first mirror (which can be easily achieved mechanically), an efficient masking of this undesired light is possible. The aperture stop can be designed both as an opening in the first mirror or an opening which is arranged behind the first mirror.

In another embodiment of the invention, the aperture stop is arranged on or near the second mirror. Arrangement of the aperture on a mirror has the advantage that it is easier to manufacture.

In order to ensure an obscuration-free ray path with simultaneously low angles of incidence, the ratio of the distance between the first and third mirrors **(S1S3)** to the distance between the first and second mirrors **(S1S2)** lies in the range:

$$0.3 \leqq S1S3/S1S2 \leqq 2.0,$$

while the ratio of the distance between the second and third mirrors **(S2S3)** to the distance between the third and fourth mirrors **(S3S4)** lies in the range:

$$0.7 \leqq S2S3/S3S4 \leqq 1.4.$$

In order to be able to make the necessary corrections of imaging errors in the six-mirror systems, in a preferred embodiment, all six mirrors are designed to be aspherical. However, an alternative embodiment whereby at most five mirrors are aspherical can simplify the manufacturing, because it is then possible to design one mirror, preferably the largest mirror, i.e., the quaternary mirror, in the form of a spherical mirror. Moreover, it is preferred that the second to sixth mirror be in a concave-convex-concave-convex-concave sequence.

In order to achieve a resolution of at least 50 nm, the design part of the rms wavefront section of the system should be at most 0.07λ and preferably 0.03 λ.

Advantageously, in the embodiments of the invention, the objectives are always telecentric on the image-side.

In projection systems, which are operated with a reflection mask, a telecentric light path on the object-side is not possible without illumination through a beam splitter, which reduces the transmission strongly. One such device is known from JP 95 28 31 16.

In systems with transmission mask, the projection objective can be telecentric on the object side. In these embodiments, the first mirror is preferably concave.

The telecentericity error in the image plane, where the wafer is situated should not exceed 10 mrad and is typically between 5 mrad and 2 mrad, with 2 mrad being preferred. This ensures that changes of the imaging ratio remain within tolerable limits over the depth of focus.

In an preferred embodiments of the invention, the six mirror objective may include a field mirror, a reducing three-mirror subsystem and a two-mirror subsystem.

In addition to the projection objective according to the invention, the invention also makes available a projection exposure apparatus that includes at least a projection objective device. In a first embodiment, the projection exposure apparatus has a reflection mask, while, in an alternative embodiment, it has a transmission mask. Preferably, the projection exposure apparatus includes an illumination device for illuminating an off-axis arc-shaped field and the system is designed as an arc-shaped field scanner. Furthermore, the secant length of the scan slit is at least 26 mm and the ring width is greater than 0.5 mm.

The invention will be described below with the aid of the drawings as examples.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** illustrates the ring field in the object plane of the objective.

FIG. **2** illustrates an embodiment of the invention with an intermediate image, a freely accessible aperture stop between a second and third mirror, and a image side numerical aperture of 0.2.

FIG. **3** illustrates a prior art six-mirror objective arrangement for wavelengths>100 nm as disclosed in U.S. Pat. No. 5,686,728.

FIG. **4** illustrates a second embodiment of the invention with an aperture stop between the second and third mirror at the first mirror.

FIG. **5** illustrates a third embodiment of the invention with an aperture stop on the second mirror and a working distance of 59 mm.

FIG. **6** illustrates a fourth embodiment of the invention with an intermediate image, a image side numerical aperture NA of 0.28 as well as a free working distance on the image-side which is at least the sum of one-third of the useful diameter of the mirror nearest to the wafer and a length which lies between 20 and 30 mm.

FIG. **7** illustrates a fifth embodiment of the invention of a system with an intermediate image and a image side numerical aperture NA of 0.30.

FIGS. **8**A and **8**B show the used diameter for different physical mirror surfaces or used areas of a mirror

DESCRIPTION OF THE PREFERRED EMBODIMENTS

In FIG. **1** the object field **1100** of a projection exposure apparatus in the object plane of the projection objective according to the invention is shown. The object plane is imaged by means of the projection objective in an image plane, in which a light sensitive object, for example a wafer with a light sensitive material is arranged. The image field in the image plane has the same shape as the object field. The object (or the image) field **1100** has the configuration of a segment of a ring field, and the ring field has an axis of symmetry **1200**.

In addition the axis **1200** extending to the object plane, the x-axis and the y-axis are depicted. As can be seen from FIG. **1**, the axis of symmetry **1200** of the ring field runs in the direction of the y-axis. At the same time the y-axis coincides with the scanning direction of an projection exposure apparatus, which is designed as a ring field scanner. The x-direction is thus the direction that stands perpendicular to the scanning direction, within the object plane. The ring field has a so called ring field radius R, which is defined by the distance of the central field point **1500** of the image field from the principal axis (PA) of the projection objective. The arc-shaped field in the object plane as well as in the image plane has a arc shaped field width W, which is the extension of the field in scanning or y-direction and a secant length SL.

In FIGS. **2**, **4** and **5**, arrangements of the six-mirror projection objectives according to the invention are shown. Each embodiment has a free working distance that corresponds at least to the used diameter of the physical mirror surface or mirror segment next to the wafer. In contrast, FIG. **3** shows a prior art system for use with wavelengths>100 nm, such as the system of U.S. Pat. No. 5,686,728. In all embodiments below, the same reference numbers will be used for the same components and the following nomenclature will be employed:

first mirror (**S1**), second mirror (**S2**), third mirror (**S3**), fourth mirror (**S4**),

fifth mirror (**S5**), and sixth mirror (**S6**).

In particular, FIG. **2** shows a six-mirror projection objective with a ray path from the object plane **2**, i.e. reticle plane to the image plane **4**, i.e. wafer plane. The embodiment includes a field mirror **S1**, which forms a virtual image of an object with an imaging ratio $\beta>0$. A three-mirror system formed from **S2**, **S3** and **S4** is also provided and produces a real, reduced image of the virtual image as the intermediate image, Z. Lastly, a two-mirror system **S5**, **S6**, images the intermediate image Z in the wafer plane **4** while maintaining the requirements of telecentricity. The aberrations of the three-mirror and two-mirror subsystems are balanced against one another so that the total system has a high optical quality sufficient for integrated circuit fabrication applications.

The physical aperture stop B is arranged between the second mirror **S2** and the third mirror **S3**. And, as is clear from FIG. **2**, the aperture stop is accessible in the ray path between the second mirror **S2** and the third mirror **S3**. Furthermore, the distance between the vertex **V5** of the surface of the mirror next to the wafer, i.e., the surface of the fifth mirror **S5** in the present embodiment, and the image plane is greater than the used diameter of the physical mirror surface of mirror **S5**. The used diameter of a physical mirror surface is explained in more detail in the description of FIGS. **8**A and **8**B. In other words, the following condition is fulfilled:

> the physical distance from the vertex **V5** of the surface of mirror **S5** to the image plane **4** is greater than the used diameter of mirror **S5**.

Other distance requirements are also possible and may be used, such as the physical distance is (1) greater than the sum of one-third of the used diameter of the mirror next to the wafer, **S5**, and 20 mm, or (2) greater than 50 mm. In the preferred embodiment, the physical distance is 60 mm.

Such a physical distance guarantees a sufficiently free working distance A, and allows the use of optical components compatible for use with wavelengths<100 nm, and preferably wavelengths of 11 to 13 nm. Optical components in this range include, for example, Mo/Si or Mo/Be multi-

layer systems, where the typical multilayer systems for λ=13 nm is Mo/Si layer pairs and for λ=11 nm, is Mo/Be systems, both of approximately 70 layer pairs. Reflectivities attainable in such systems are approximately 70%. In the multilayer layer systems, layer stresses of above 350 MPa may occur. Stresses of such values may induce surface deformation, especially in the edge regions of the mirror.

The systems according to the invention, as they are shown, for example, in FIG. **1**, have:

$$RES=k_1\lambda/NA.$$

This results in a nominal resolution of at least 50 nm and 35 nm at a minimum numerical aperture of NA=0.2 for k_1=0.77 and λ=13 nm, and for k_1=0.64 and λ=11 nm, respectively, where k_1 is a parameter specific for the lithographic process.

Furthermore, the light path for a bundle of light rays running from the object plane to the image plane of the objective shown in FIG. **2** is obscuration-free. For example, in order to provide image formats of 26×34 mm^2 or 26×52 mm^2, the projection objectives according to the invention are preferably used in an arc-shaped field scan projection exposure apparatus, wherein the secant length of the scan slit is at least 26 mm.

Numerous masks can be used in the projection exposure apparatus. The masks or reticle are arranged in the object plane of the projection objective. The masks include transmission masks, stencil masks and reflection masks. The projection objective, which is telecentric on the image side, i.e. in the image plane, can be telecentric or non-telecentric on the object side, i.e. in the object plane depending on which mask is used. For example, if the bundle of light rays is telecentric on the object-side when using a reflection mask, a transmission-reducing beam splitter must be employed. If the bundle of light rays is non-telecentric on the object-side, unevennesses of the mask leads to dimensional errors in the image. Therefore, the angle of incidence of the chief ray of the bundle of light rays through the central field point **1500** in the object plane is preferably below 10°, so that the requirements for reticle evenness lies in an achievable range. Moreover, the system of FIG. **2** which is telecentric on the image side has an image-side error of telecentry at the wafer level of 1 mrad for a image side numerical aperture of 0.2.

Due to the high image-side telecentricity, the entrance pupil of the last mirror **S6** is at or near the focal plane of this mirror. Therefore, in systems with an intermediate image as described before, the aperture, B, is in the front, low-aperture objective part preferably in the light path between the first and third mirror **S1**, **S3**. Thus the pupil plane conjugated with the aperture stop will be imaged in the focal plane of the last mirror.

All mirrors **S1**–**S6** of FIG. **2** are designed to be aspherical, with a maximum asphericity of approximately 7.3 μm. The low asphericity of the embodiment shown in FIG. **2** is advantageous from a manufacturing point of view, since the technological difficulties in processing the surfaces of the multilayer mirrors increases proportionally with aspherical deviation and gradient of the asphere.

The highest angle of incidence of a ray impinging a mirror surface in the six-mirror objective shown in FIG. **2** occur on the fifth mirror **S5** and is approximately 18.4°. The maximum variation of the angles of incidence of the rays within a bundle of light rays impinging onto a mirror surface occurs on mirror surface of mirror **S5** and is approximately 14.7°. The wavefront error at λ=13 nm is better than 0.032λ; the centroid distortion of the point spread function is <3 mm; and the static, dimension-corrected distortion lies at 4 nm.

A freely accessible aperture stop between the second and third mirror as well as no vignetting of the bundle of light rays running from **S3** to **S4** by the aperture stop is achieved with small angles of incidence of the rays impinging onto the mirror surfaces when the following distance conditions are fulfilled:

$$0.5<S1S3/S1S2<2$$

and

$$0.5<S2 \text{ aperture}/(S3 \text{ aperture})<2.$$

Here, the abbreviation **S1S3** means the mechanical distance or physical distance between the vertices **V1** and **V3** of the surface of the mirrors **S1** and **S3**. And, "**S2** aperture" means the mechanical distance between the vertex **V2** of the surface of mirror **S2** and the aperture. Furthermore, in order to reduce the angles of incidence on the mirrors in any of the embodiments of FIGS. **2**, **4**, and **5**, the distance from the object plane, where for example the reticle is situated to the vertex of the surface of the mirror **S1**, is made smaller than the mechanical distance from the vertex of the surface of mirror **S2** to the vertex of the surface of mirror **S3**, i.e., the following applies:

$$\text{reticle } S1<S2S3.$$

To ensure a sufficient free working distance A not only on the image side but also on the object side the reticle is situated sufficiently far in front of the first mirror next to the object plane, which is in the present case the surface of the second mirror **S2**. In the present case, for example, the physical distance between the reticle and the vertex **V2** of the surface of mirror **S2** is 80 mm.

Furthermore, in the embodiments of FIGS. **2** and **4** to **6**, the physical distance between the mirrors **S3** and **S6** is chosen so that mirrors of sufficient thickness can be used. Thicker mirrors have sufficient strength and stability properties that can withstand the high layer tensions described above. In these systems, the following relationship is preferred:

$$0.3 \text{ (used diameter } S3+\text{used diameter } S6)<S3S6.$$

Here **S3S6** denotes the physical distance between the vertex **V3** of the surface of mirror **S3** and the vertex **V6** of the surface of the mirror **S6**.

In the following table, the parameters of the system represented in FIG. **2** are exemplarily shown in Code V(™) nomenclature. The objective is a 5× system with a 26×2 mm^2 arc-shaped field in the image plane, wherein 26 mm is the secant length of the arc-shaped field and 2 mm is the width W of the arc shaped field. Furthermore the numerical aperture is 0.2 on the image side. The mean image side radius of the system is approximately 26 mm.

Reference wavelength = 13 nm

FIG. **3** shows an arrangement of a projection objective for microlithography with a wavelength of $\lambda<100$ nm according to U.S. Pat. No. 5,686,728. By way of a simplified explanation and comparison only, components similar to those of FIG. **1** are provided with the same reference numbers. As is clear, the physical distance between the vertex **V5** of the surface of the mirror next to the image plane **S5** and the image plane, where the wafer is situated, is significantly smaller than the used diameter of the fifth mirror **S5**, lying mainly in the range of approximately 20 mm. This leads to strength and stability problems for the optics in the EUV region because of the extreme tensions in the layers. Furthermore, the system has very high asphericities of ±50 μm and a maximum angle of incidence of 38°. From a manufacturing and coating technology point of view, such asphericities and angles of incidence are incompatible for use in the EUV region.

FIG. **4** is an alternative embodiment of a six-mirror system in which the aperture stop is situated on the first mirror. The same components as in FIG. **2** again receive the same reference number in FIG. **4**. The free working distance A to the wafer is 60 mm in this embodiment, as it was in the embodiment of FIG. **2**, and thus it is greater than the used diameter of the mirror next to the wafer, **S5**. Similarly, as with FIG. **2**, the physical distance between the vertex **V2** of the surface of mirror **S2** and the vertex **V3** of the surface of mirror **S3** was increased significantly in comparison to that of U.S. Pat. No. 5,686,728, so that large angles of incidence can be avoided in the system.

One difference to the objective of FIG. **2**, is that in FIG. **4** the aperture stop B is placed on the first mirror **S1**. As a result of this position, a reduction in vignetting from the light reflected on **S2** is possible, whereas with the physical aperture stop positioned between **S1** and **S2** light of the bundle of light rays running thorough the objective could pass above the aperture stop which is designed as a narrow ring. In the embodiment shown in FIG. **4**, the aperture can be either an opening in the **S1** mirror or an aperture disposed behind SI close to this mirror.

Another advantage of this embodiment is the spherical design of mirror **S4**, which presents advantages especially from the point of view of manufacturing, because mirror **S4** is the largest mirror of the system. With such a design, the asphericity in the used range is increased slightly to 10.5 μm. The largest angle of incidence occurs on mirror **S5** and is approximately 18.6°. The wavefront error of the arrangement is 0.032 λ, within a 1.7 mm wide arc-shaped field at λ=13 nm. Furthermore, if the mirror **S4** is designed to be slightly aspherical with 0.4 μm, then the wavefront error can be kept to 0.031λ within a 1.8 mm wide arc-shaped field at λ=13 nm. Efficient masking of the undesirable light is obtained not only when the aperture stop is formed directly on mirror **S1**, but also when it is arranged behind, i.e., after, mirror **S1**. Preferably, the aperture stop is positioned such that the following relationship is obtained:

$$S2S1 \leq 0.9 \times S2 \text{ aperture.}$$

S2S1 denotes the mechanical distance of the vertex **V2** of the surface of mirror **S2** and the vertex **V1** of the surface of the mirror **S1**.

Table 2 shows the constructional data of the 5× objective according to FIG. **4** in Code V(™) nomenclature, where the fourth mirror **S4** is spherical. The mean radius of the 26×1.7 mm image field is approximately 26 mm.

Reference wavelength = 13 nm

Another embodiment is shown in FIG. **5**, where again the same reference numbers are used for the same components as in the previous figures. Here, the aperture stop B is placed optically and physically on the secondary mirror or second mirror **S2**. The ability to place the aperture stop on **S2** makes manufacturing easier. Therefore this arrangement is advantageous. The system of FIG. **5** is a 4× reduction system with a wavefront error of 0.021λ within a 2 mm wide image side arc-shaped field at λ=13 nm. The maximum asphericity in the used range lies at 11.2 μm, and the largest angle of incidence, which occurs at **S5**, is approximately 18.3°. The ring field radius R as defined in FIG. **1** of the arc-shaped field in the image plane is approximately 26 mm, as with the previous two embodiments. Furthermore, the distance between the image plane and the vertex **V5** of the surface of the mirror next to the image plane, **S5**, is greater than the used diameter of the mirror next to the wafer, **S5**, and lies at around 59 mm in this embodiment.

Table 3 shows the optical parameters of the embodiment of FIG. **5** in Code V(™) nomenclature.

FIG. **6** shows an embodiment of the invention which includes a field mirror **S1**, a first subsystem with the second to fourth mirror **S2**–**S4** and a second subsystem with the fifth and sixth mirror, **S5**, **S6**. The field mirror **S1** with imaging ratio,β, β>0 produces a virtual image of the object in the object plane **2**. The virtual image is then imaged by the first subsystem consisting of the second, third and fourth mirrors, **S2**, **S3**, **S4**, which has β<0, producing a real intermediate image Z in a plane conjugate to the object plane **2**. The real intermediate image Z is imaged as a real image into image plane **4** by the second subsystem, which consists of the fifth and sixth mirrors, **S5**, **S6**. The image side numerical aperture of the system is NA=0.28. The optical free working distance,s A, between the vertex of the surface of the last mirror **S5** and the image plane **4** corresponds to at least the sum of one-third of the used diameter of the mirror nearest to the image plane and a length which lies between 20 and 30 mm. The aperture stop B is situated on the second mirror **S2**.

Table 4 shows the optical parameters of the embodiment of FIG. **6** in Code V(™) nomenclature.

FIG. **7** shows a similar, yet alternative, embodiment to that of FIG. **6** with a six-mirror objective with field mirror **S1** as well as first and second subsystems as shown in FIG. **6**. The embodiment shown in FIG. **7** comprises as the embodiment in FIG. **6** an intermediate image Z. Furthermore the aperture B is formed on the second mirror **S2** similar and the numerical aperture on the image side is NA=0.30. The optical parameters of this alternative embodiment are shown in Table 5 in Code V(™) nomenclature.

Reference wavelength = 13 nm

FIGS. **8**A and **8**B define the used diameter D as used in the description of the above embodiments. As a first example, the illuminated field **100** on a mirror in FIG. **8**A is a rectangular field. The illuminated field corresponds to the area on a mirror onto which a bundle of light rays running through the objective from the object side to the image side impinge. The used diameter D according to FIG. **8**A is then the diameter of the envelope circle **102**, which encompasses the rectangle **100**, where the corners **104** of the rectangle **100** lie on the envelope circle **102**. A more realistic example is shown in FIG. **8**B. The illuminated field **100** has a kidney shape, which is expected for the physical mirror surfaces of the mirrors **S1**–**S6** or the so called used areas of the mirrors **S1**–**S6**, when the field in the image plane as well as the field in the object plane is an arc shaped field as depicted in FIG. **1**. The envelope circle **102** encompasses the kidney shape fully and it coincides with the edge **110** of the kidney shape at two points, **106**, **108**. The used diameter D of the physical mirror surface or the used area of the mirrors **S1**–**S6** is then given by the diameter of the envelope circle **102**.

Thus, the invention provides a six-mirror projection objective with an imaging scale of preferably 4×, 5× or 6× for use in an EUV projection system. Other uses may be employed, however. The six-mirror projection objective has the resolution required for the image field, which is e.g. arc-shaped and has a advantageous structural design, since the aspheres of the mirror surfaces are relatively low, the angles of incidence of the rays of the bundle of light rays impinging the mirror surfaces are small, and there is enough room for mounting the mirrors.

I claim:

1. A projection objective with an object plane and an image plane and a light path for a bundle of light rays from the object plane to the image plane for use in short wavelength microlithography, comprising;

six mirrors (a first mirror (**S1**), a second mirror (**S2**), a third mirror (**S3**), a fourth mirror (**S4**), a fifth mirror (**S5**) disposed closest to the image plane and a sixth mirror (**S6**)) arranged in the light path such that an image-side numerical aperture (NA) is NA≧0.15, wherein each mirror has a physical mirror surface and wherein said fifth mirror is positioned in the light path such that at least one of the following conditions is satisfied:

an image-side optical free working distance is greater than or equal to a used diameter D of a physical mirror surface of the fifth mirror;

the image-side optical free working distance is greater than or equal to a sum of one-third of the used diameter of the physical mirror surface of the fifth mirror and a length between 20 mm and 30 mm; and

the image-side optical free working distance is at least 50 mm;

wherein the image side free working distance is the physical distance between the vertex of the surface of the fifth mirror and the image plane and wherein the physical mirror surface of a mirror is the area of the surface of a mirror, where the rays of the bundle of light rays running from the object side to the image side impinge.

2. A projection objective with an object plane and an image plane and a light path for a bundle of light rays from the object plane to the image plane for use in short wavelength microlithography, comprising;

six mirrors (a first mirror (**S1**), a second mirror (**S2**), a third mirror (**S3**), a fourth mirror (**S4**), a fifth mirror (**S5**) disposed closest to the image plane, and a sixth mirror (**S6**)) arranged in the light path such that an image-side numerical aperture (NA) is NA≧0.15 and an image side arc-shaped field width (W) lies in the range of 1.0 mm≦W, and wherein each of said six mirrors has a physical mirror surface with a maximum aspherical peak-to-valley (PV) deviation (A) from a best-fitting sphere in the following range:

$$A \leqq 19\ \mu m - 102\ \mu m\ (0.25 - NA) - 0.7\ \mu m/mm\ (2\ mm - W)$$

wherein the physical mirror surface of a mirror is the area of the surface of a mirror where the rays of the bundle of light rays running from the object side to the image side impinge.

3. A projection objective with an object plane and an image plane and a light path for a bundle of light rays from the object plane to the image plane for use in short wavelength microlithography, comprising;

six mirrors (a first mirror (**S1**), a second mirror (**S2**), a third mirror (**S3**), a fourth mirror (**S4**), a fifth mirror (**S5**) disposed closest to the image plane, and a sixth mirror (**S6**)) arranged such that an image-side numerical aperture (NA) is NA≧0.15 and an image-side arc-shaped field width (W) lies in the range of 1.0 mm≦W, and wherein the rays of a bundle of light rays incident on each physical mirror surface of the six mirrors have angles of incidence (AOI) relative to the surface normal of said physical mirror surface that are lying in the range:

$$AOI \leqq 23° - 35°(0.25 - NA) - 0.2°/mm(2\ mm - W)$$

wherein the physical mirror surface of a mirror is the area of the surface of a mirror where the rays of the bundle of light rays running from the object side to the image side impinge.

4. A projection objective with an object plane and an image plane and a light path from the object plane to the image plane for use in short wavelength microlithography, comprising;

a field mirror (**S1**) with an imaging ratio $\beta_1 > 0$, wherein the field mirror produces a virtual image of an object in the object plane;

a first subsystem with a second mirror (**S2**), a third mirror (**S3**), and a fourth mirror (**S4**), wherein the first subsystem has an imaging ratio $\beta_2 < 0$, and wherein said first subsystem images the virtual image to a real intermediate image;

a second subsystem with a fifth mirror (**S5**) disposed closest to the image plane and a sixth mirror (**S6**), wherein the second subsystem images the intermediate image to a real image in the image plane; and

wherein the objective has an image-side numerical aperture (NA) and an arc-shaped field width (W) in the image plane, where an object to be illuminated is situated, and wherein each mirror has a physical mirror surface that is the area of the surface of the mirror where the rays of the bundle of light rays running from the object side to the image side impinge.

5. A projection objective according to any one of claims **1** to **4**, wherein the surface of the mirrors have a rotational symmetry with respect to a principal axis (PA).

6. A projection objective according to one of claims **1** to **4**, further comprising an aperture stop (B) in the light path positioned between the second mirror (**S2**) and the third mirror (**S3**).

7. A projection objective according to claim **6**, wherein a ratio of a physical distance between the vertex of the surface

of the first mirror and the vertex of the surface of the third mirror (S1S3) to a physical distance between the vertex of the surface of the first mirror and the vertex of the surface of the second mirror (S1S2) is in the range of:

$$0.5<S1S3/S1S2<2.$$

8. A projection objective according to claim **7**, wherein a ratio of a physical distance between the vertex of the surface of the second mirror and the vertex of the surface of the third mirror (S2S3) to a physical distance between the vertex of the surface of the third mirror and the vertex of the surface of the fourth mirror (S3S4) lies in the range:

$$0.7<S2S3/S3S4<1.4.$$

9. A projection objective according to any one of claims **1** to **4**, wherein all physical mirror surfaces are aspherical.

10. A projection objective according to any one of claims **1** to **4**, wherein at most five physical mirror surfaces are aspherical.

11. A projection objective according to any one of claims **1** to **4**, wherein the second mirror, third mirror, fourth mirror, fifth mirror, and sixth mirror are in a concave-convex-concave-convex-concave sequence.

12. A projection objective according to any one of claims **1** to **4**, wherein a physical distance between the vertex of the surface of the third mirror and the vertex of the surface of the sixth mirror (S3S6) satisfies the following relationship:

$$0.3\ (\text{used diameter of third mirror } S3+\text{used diameter of sixth mirror } S6)<S3S6.$$

13. A microlithography projection exposure apparatus comprising:

a projection objective according to one of the claims **1** to **4**; and

an illumination system comprising a radiation source providing a bundle of light rays illuminating an arc-shaped field in the object plane of the projection objective, wherein the projection objective images a mask located in the object plane into the image plane of the projection objective, where a light sensitive objective is situated.

14. A method for producing a microelectronic device with a microlithography exposure apparatus according to claim **13** wherein a mask with a structure in the object plane is illuminated and said mask is imaged onto a light sensitive object situated in the image plane.

(57) **ABSTRACT**

A wavefront sensor includes an afocal relay stage for magnifying an incoming wavefront reflected from a source plane. In an exemplary application, a retina of an eye reflects an impinging light beam thereon to form a series of wavefronts. A lenslet array is positioned at a reference plane of the afocal relay stage to receive the magnified wavefront. Further downstream is positioned a means for imaging and demagnifying a focal plane image of the lenslet array at a final image plane. This demagnified image then serves as input to an analyzer, such as a charge-coupled-device (CCD) camera.

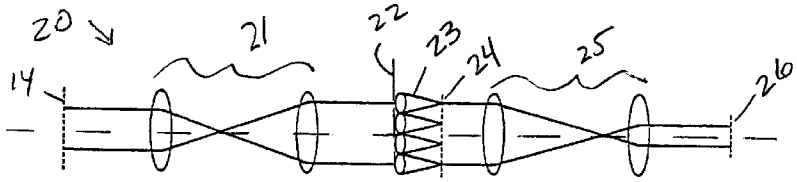

FIG. 2

WAVEFRONT SENSOR FOR OBJECTIVE MEASUREMENT OF AN OPTICAL SYSTEM AND ASSOCIATED METHODS

CROSS-REFERENCE TO RELATED APPLICATION

This application claims priority from provisional application Ser. No. 60/198,536, filed Apr. 19, 2000, "Wavefront Sensor with an Extended Dynamic Range and a Small-Format CCD Detector."

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to optical measurement systems and methods, and, more particularly, to such systems and methods for objective measurement of an eye.

2. Description of Related Art

Optical systems having a real image focus can receive collimated light and focus it at a point. Such optical systems can be found in nature, e.g., human and animal eyes, or can be manmade, e.g., laboratory systems, guidance systems, and the like. In either case, aberrations in the optical system can affect the system's performance. By way of example, the human eye will be used to explain this problem.

A perfect or ideal eye diffusely reflects an impinging light beam from its retina through the optics of the eye, which includes a lens and a cornea. For such an ideal eye in a relaxed state, i.e., not accommodating to provide near-field focus, reflected light exits the eye as a sequence of plane waves. However, an eye typically has aberrations that cause deformation or distortion of reflected light waves exiting the eye. An aberrated eye diffusely reflects an impinging light beam from its retina through its lens and cornea as a sequence of distorted wavefronts.

There are a number of technologies that attempt to provide the patient with improved visual acuity. Examples of such technologies include remodeling of the cornea using refractive laser surgery or intra-corneal implants, adding synthetic lenses to the optical system using intra-ocular lens implants, and precision-ground spectacles. In each case, the amount of corrective treatment is typically determined by placing spherical and/or cylindrical lenses of known refractive power at the spectacle plane (approximately 1.0–1.5 cms anterior to the cornea) and literally asking the patient which lens or lens combination provides the clearest vision. This is an imprecise measurement of true distortions in the reflected wavefront because (1) a single spherocylindrical compensation is applied across the entire wavefront; (2) vision is tested at discrete intervals (i.e., diopter units) of refractive correction; and (3) subjective determination by the patient is made in order to determine the optical correction. Thus conventional methodology for determining refractive errors in the eye is substantially less accurate than the techniques now available for correcting ocular aberrations.

One method of measuring ocular refractive errors is disclosed in U.S. Pat. No. 5,258,791 to Penney et al. for "Spatially Resolved Objective Autorefractometer," which teaches the use of an autorefractometer to measure the refraction of the eye at numerous discrete locations across the corneal surface. Penney '791 further teaches the use of autorefractometer measurements in determining an appropriate corneal surface reshaping to provide emmetropia, a condition of a normal eye when parallel beams or rays of light are focused exactly on the retina and vision is perfect.

By way of example, one method and system known in the art are disclosed by Junzhong Liang et al. in "Objective

Measurement Of Wave Aberrations of the Human Eye with the Use of a Hartmann-Shack Wave-Front Sensor"[*J. Opt. Soc. Am.* 11(7), July 1994, pp 1949–57]. Liang et al. teach the use of a Hartmann-Shack wavefront sensor to measure ocular aberrations by measuring the wavefront emerging from the eye by the retinal reflection of a focused laser light spot on the retina's fovea. The actual wavefront is reconstructed using wavefront estimation with Zernike polynomials. A parallel beam of laser light passes through beam splitters and a lens pair, which brings the beam to a focus point on the retina by the optics of the eye. Possible myopia or hyperopia of the tested eye is corrected by movement of a lens within the lens pair. The focused light on the fovea is then assumed to be diffusely reflected and acts as a point source located on the retina. The reflected light passes through the eye and forms a distorted wavefront in front of the eye that results from the ocular aberrations. The aberrated wavefront is then directed to the wavefront sensor.

The Hartmann-Shack wavefront sensor disclosed by Liang et al. includes two identical layers of cylindrical lenses with the layers arranged so that lenses in each layer are perpendicular to one another, as further disclosed in U.S. Pat. No. 5,062,702 to Bille. In this way, the two layers operate as a two-dimensional array of spherical lenslets that divide the incoming light wave into subapertures. The light through each subaperture is brought to focus in the focal plane of the lens array where a charge-coupled-device (CCD) image module resides.

The system of Liang et al. is calibrated by impinging an ideal plane wave of light on the lenslet array so that a reference or calibrating pattern of focus spots is imaged on the CCD. Since the ideal wavefront is planar, each spot related to the ideal wavefront is located on the optical axis of the corresponding lenslet. When a distorted wavefront passes through the lenslet array, the image spots on the CCD are shifted with respect to a reference pattern generated by the ideal wavefront. Each shift is proportional to a local slope, i.e., partial derivatives of the distorted wavefront, which partial derivatives are used to reconstruct the distorted wavefront, by means of modal wavefront estimation using Zernike polynomials.

However, the system disclosed by Liang et al. is effective only for eyes having fairly good vision. Eyes that exhibit considerable myopia (near-sightedness) cause the focus spots to overlap on the CCD, thereby making local slope determination practically impossible for eyes having this condition. Similarly, eyes that exhibit considerable hyperopia (farsightedness) deflect the focus spots such that they do not impinge on the CCD, thereby again making local slope determination practically impossible for eyes having this condition.

Various embodiments of a method and system for objectively measuring aberrations of optical systems by wavefront analysis have been disclosed in commonly owned application Ser. No. 09/566,668, "Apparatus and Method for Objective Measurement and Correction of Optical Systems Using Wavefront Analysis," filed May 8, 2000, which is hereby incorporated by reference herein. In this invention, an energy source generates a beam of radiation. Optics, disposed in the path of the beam, direct the beam through a focusing optical system (e.g., the eye) that has a rear portion (e.g., the retina) that provides a diffuse reflector. The beam is diffusely reflected back from the rear portion as a wavefront of radiation that passes through the focusing optical system to impinge on the optics. The optics project the wavefront to a wavefront analyzer in direct correspondence with the wavefront as it emerges from the focusing optical

system. A wavefront analyzer is disposed in the path of the wavefront projected from the optics and calculates distortions of the wavefront as an estimate of ocular aberrations of the focusing optical system. The wavefront analyzer includes a wavefront sensor coupled to a processor that analyzes the sensor data to reconstruct the wavefront to include the distortions thereof.

A perfectly collimated light beam (i.e., a bundle of parallel light rays, here a small-diameter, eye-safe laser beam) incident on a perfect, ideal emmetropic eye, focuses to a diffraction-limited small spot on the retina. This perfect focusing is true for all light rays passing through the entrance pupil, regardless of position. From the wavefront perspective, the collimated light represents a series of perfect plane waves striking the eye. The light emanates from an illuminated spot on the retina as wavefronts exiting as a series of perfect plane waves, which are directed onto a wavefront analyzer for measuring distortions from ideality.

In one embodiment, the radiation is optical radiation and the wavefront sensor is implemented using a plate and a planar array of light-sensitive cells. The plate is generally opaque but has an array of light-transmissive apertures that selectively let impinging light therethrough. The plate is disposed in the path of the wavefront so that portions of the wavefront pass through the light-transmissive apertures. The planar array of cells is arranged parallel to and spaced apart from the plate by a selected distance. Each portion of the wavefront passing through one of the light-transmissive apertures illuminates a geometric shape covering a unique plurality of cells.

The wavefront optical path relays the re-emitted wavefront from the corneal plane to an entrance face of a Hartman-Shack wavefront sensor. The wavefront incident on the sensor is received by a sensitive charged-coupled-device (CCD) camera and an optical plate containing an array of lenslets. The lenslet array is parallel to the CCD detector face, with a distance therebetween approximately equal to the focal length of each lens in the lenslet array. The lenslet array divides the incoming wavefront into a matching array of "wavelets," each of which focuses to a small spot on the CCD detector plane. The constellation of wavelet spots in the CCD is used to reconstruct the shape of the incident wavefront. Collimated light striking the lenslet at normal (perpendicular) incidence would focus to the spot on the CCD face where this optical axis intersects. The optics of the apparatus provides such collimated light to the wavefront sensor using a calibration optical path.

In the case of a reflected aberrated wavefront, light focuses to a spot displaced from the collimated reference point by a distance D_x. The distance from the lenslet face to the CCD surface, D_z, is precisely known. Therefore, dividing the measured displacement, D_x, by the known propagation distance, D_z, the slope of the wavefront at the location of this lens element is determined. The same calculation is applied in the y direction within the plane, and the entire process applied to every lenslet element irradiated by the wavefront. A mathematical algorithm is then applied to reconstruct the wavefront shape consistent with the calculated D_x/D_z and D_y/D_z slope data. Regardless of which wavefront sensor is used, the distance between the planar array of cells and the opaque plate, or the array of lenslets, can be varied to adjust the slope measurement gain of the wavefront sensor and thereby improve the dynamic range of the system.

Another measure of dynamic range enhancement is provided by the focusing optics. The focusing optics includes first and second lenses maintained in fixed positions in the path of the beam and wavefront. An arrangement of optical elements is disposed between the lenses in the path of the beam and the wavefront. The optical elements are adjustable to change the optical path length between the lenses. If an optical correction is desired, the distortions are converted to an optical correction, which, if placed in the path of the wavefront, causes the wavefront to appear approximately as a plane wave. The optical correction can be in the form of a lens or an amount of corneal material ablated from the eye.

One method for determining aberrations of an eye, herein described by way of example, includes directing a probe beam along a probe beam path toward an eye, directing a fixation image along a fixation image path toward the eye, directing a light source along a video image path toward the eye, generating a video image of the eye, directing a wavefront originating from the eye along a wavefront path, wherein the probe beam path, the fixation image path, the video image path, and the wavefront path are coincident at least along a portion of their respective paths, the probe beam path terminating at the retina of the eye and the probe beam reflecting from the retina of the eye as a wavefront, aligning the eye with the probe beam path based at least in part on the video image of the eye generated by the light source directed along the video image path, measuring the wavefront, and generating data representative of the aberrations of the eye based on the measurement of the wavefront. Further, the aligning of the eye with the probe beam path based at least in part on the video image of the eye generated by the light source directed along the video image path, may have the wavefront pass through a single microlens array.

SUMMARY OF THE INVENTION

It is an object of the present invention to provide a system and method for objectively measuring ocular aberrations using a wavefront analyzer of simple and inexpensive design.

It is a further object to provide such an apparatus and method that can employ a small-format camera.

It is an additional object to provide a method for constructing such a system.

These and other objects are achieved by the present invention, a wavefront sensor that comprises an afocal relay stage for magnifying an incoming wavefront reflected from a source plane. In an exemplary application, a retina of an eye reflects an impinging light beam thereon to form a series of wavefronts.

A lenslet array is positioned at a reference plane of the afocal relay stage to receive the magnified wavefront. Further downstream is positioned a means for imaging and demagnifying a focal plane image of the lenslet array at a final image plane. This demagnified image then serves as input to an analyzer, such as, but not intended to be limited to, a charge-coupled-device (CCD) camera.

The features that characterize the invention, both as to organization and method of operation, together with further objects and advantages thereof, will be better understood from the following description used in conjunction with the accompanying drawing. It is to be expressly understood that the drawing is for the purpose of illustration and description and is not intended as a definition of the limits of the invention. These and other objects attained, and advantages offered, by the present invention will become more fully apparent as the description that now follows is read in conjunction with the accompanying drawing.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** (prior art) is a schematic diagram of an apparatus for wavefront sensing.

FIG. **2** is a schematic diagram of the apparatus of the present invention for wavefront sensing.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

A description of the preferred embodiments of the present invention will now be presented with reference to FIGS. **1** and **2**.

The prior art apparatus **10** (FIG. **1**) includes a first **11** and a second **12** afocal relay stage within the optical axis **13**. The optical path through the first afocal relay stage **11** results in an image of the corneal plane **14** at a first image plane **15**, which serves as an insertion point for a spherical trial lens, as described in application Ser. No. 09/566,668.

The wavefront sensor comprises a microlens array plate and a charge-coupled-device (CCD) camera at the second image plane **16** separated by a fixed distance. The optical path **13** thus creates an image of the corneal plane **14** at the lenslet array, that is, at the entrance face of the actual wavefront sensor, which could be accomplished by a single afocal relay stage. Placing a spherical lens into the optical axis **13** at the first image plane **15**, in theory, could be used to remove the defocus wavefront error. This would potentially expand the dynamic range of the apparatus **10**. However, the trial lens approach is a moving mechanism that can position lenses at the first image plane **15** with tremendous accuracy and repeatability. It was therefore highly desirable that alternative means be developed to address dynamic range.

The present invention **20** (FIG. **2**) accomplishes this by magnifying the corneal plane **14** image with the first afocal stage **21**. Magnification of the wavefront reduces the wavefront slope, so that the displacement of the focused lights spots on the CCD is decreased. The prior art design **10** does include some magnification in the second afocal stage **12** for this reason. The chosen magnification factor used with that apparatus **10** at the second afocal stage **12** is approximately 1.2, which is insufficient to cover the desired range in refractive errors. A magnification factor in excess of 1.5 is desirable for expanding the use of the apparatus **10**. However, simply magnifying the corneal plane **14** has a drawback in that it necessitate a large-aperture wavefront sensor. That is, both the lens array and the CCD camera would preferably have large cross-sectional areas to encompass the magnified image of the point of plane. This is not a significant issue for the lens array plate; however, a large-format CCD camera is quite expensive, and such cameras are only available from a limited number of vendors.

The apparatus **20** of the present invention solves this difficulty. The corneal plane **14** is imaged at a reference plane **22** by the first afocal relay stage **21**. The first afocal relay stage **21** magnifies the corneal plane **14** by a predetermined amount. A lenslet array plate **23** is placed at reference plane **22**. Focused spots of light from an eye are produced at the lenslet array **23** focal plane **24**.

A second afocal relay stage **25** images the array focal plane **24** at a camera plane **26**, where the CCD is located. The second stage **25** may be other than an afocal design, but preferably should provide demagnification of the array focal plane **24**. This feature permits a small-active-area camera to be used as the light-recording element in the wavefront sensor. Specifics of the optical design are adjustable as desired to maximize performance for given camera and lenslet array specifications.

It may be appreciated by one skilled in the art that additional embodiments may be contemplated, including alternate optical elements to achieve similar functions.

In the foregoing description, certain terms have been used for brevity, clarity, and understanding, but no unnecessary limitations are to be implied therefrom beyond the requirements of the prior art, because such words are used for description purposes herein and are intended to be broadly construed. Moreover, the embodiments of the apparatus illustrated and described herein are by way of example, and the scope of the invention is not limited to the exact details of construction.

Having now described the invention, the construction, the operation and use of preferred embodiment thereof, and the advantageous new and useful results obtained thereby, the new and useful constructions, and reasonable mechanical equivalents thereof obvious to those skilled in the art, are set forth in the appended claims.

What is claimed is:

1. A wavefront sensor comprising:

an afocal relay stage for magnifying an incoming wavefront reflected from a source plane;

a lenslet array positioned at a reference plane of the afocal relay stage for receiving the magnified wavefront; and

means for imaging and demagnifying a focal plane image of the lenslet array at a final image plane, for serving as input to an analyzer.

2. The wavefront sensor recited in claim **1**, wherein the imaging and demagnifying means comprises a second afocal relay stage.

3. The wavefront sensor recited in claim **1**, wherein the source plane comprises a corneal plane.

4. The wavefront sensor recited in claim **1**, wherein the afocal relay stage comprises means for magnifying the incoming wavefront by a factor of at least 1.5.

5. The wavefront sensor recited in claim **1**, wherein the demagnifying means is adapted to reduce the lenslet array focal plane image to a dimension smaller than a dimension of the incoming wavefront.

6. A system for determining refractive aberrations of an eye comprising:

means for directing a beam of light onto a cornea of an eye;

an afocal relay stage for magnifying wavefronts of light reflected from a retina of the eye;

a lenslet array positioned at a reference plane of the afocal relay stage for receiving the magnified wavefront;

means for demagnifying a focal plane image of the lenslet array at a final image plane; and

means for imaging the final image plane for determining aberrations from planarity of the reflected wavefronts.

7. The system recited in claim **6**, wherein the directing means comprises a laser beam focused on a fovea of the eye.

8. The system recited in claim **6**, wherein the imaging and demagnifying means comprises a second afocal relay stage.

9. The system recited in claim **6**, wherein the afocal relay stage comprises means for magnifying the incoming wavefront by a factor of at least 1.5.

10. The system recited in claim **6**, wherein the demagnifying means is adapted to reduce the lenslet array focal plane image to a dimension smaller than a dimension of the incoming wavefront.

11. The system recited in claim 6, wherein the imaging means comprises a charge-coupled-device camera.

12. The system recited in claim 11, wherein the camera comprises a small active area camera.

13. A method of measuring refractive aberrations in an eye comprising the steps of:

directing a beam of light onto a cornea of an eye;

magnifying wavefronts of light reflected from a retina of the eye;

directing the magnified wavefronts to a lenslet array positioned at a reference plane of the magnified wavefronts;

demagnifying a focal plane image of the lenslet array at a final image plane; and

imaging the final image plane for determining aberrations from planarity of the reflected wavefronts.

14. The method recited in claim 13, wherein the directing step comprises focusing a laser beam on a fovea of the eye.

15. The method recited in claim 13, wherein the magnifying step comprises directing the reflected wavefronts to a first afocal relay stage.

16. The method recited in claim 13, wherein the demagnifying step comprises directing the focal plane image of the lenslet array to a second afocal relay stage.

17. The method recited in claim 13, wherein the first afocal relay stage comprises means for magnifying the reflected wavefronts by a factor of at least 1.5.

18. The method recited in claim 13, wherein the demagnifying step comprises reducing the lenslet array focal plane image to a dimension smaller than a dimension of the reflected wavefronts.

19. The method recited in claim 13, wherein the imaging step comprises using a charge-coupled-device camera to collect the final image plane.

20. A method for constructing a system for measuring refractive aberrations in an eye comprising the steps of:

providing means for directing a beam of light onto a cornea of an eye;

providing means for magnifying wavefronts of light reflected from a retina of the eye;

providing a lenslet array positioned at a reference plane of the magnified wavefronts;

providing means for demagnifying a focal plane image of the lenslet array at a final image plane; and

providing means for imaging the final image plane; and

providing means for determining aberrations from planarity of the reflected wavefronts.

(57) **ABSTRACT**

A reduction objective, a projection exposure apparatus with a reduction objective, and a method of use thereof are disclosed. The reduction objective has a first set of multilayer mirrors in centered arrangement with respect to a first optical axis, a second set of multilayer mirrors in centered arrangement with respect to a second optical axis, and an additional mirror disposed at grazing incidence, such that said additional mirror defines an angle between the first optical axis and said second optical axis. The reduction objective has an imaging reduction scale of approximately 4× for use in soft X-ray, i.e., EUV and UV, annular field projection applications, such as lithography

REDUCTION OBJECTIVE FOR EXTREME ULTRAVIOLET LITHOGRAPHY

This is a continuation-in-part of U.S. application Ser. No. 09/322,813, filed May 28, 1999, now U.S. Pat. No. 6,244,717.

FIELD OF THE INVENTION

The invention relates to a reduction objective, a projection exposure apparatus, and method of use thereof for exposing patterned information onto a reduced image plane for use in lithography applications, such as integrated circuit fabrication.

BACKGROUND OF THE INVENTION

The desirability of creating lithography systems which operate with incident light wavelengths below 193 nm to achieve imaging structures or patterns with resolution below 130 nm has been established. In fact, there has been a need for lithography systems using soft X-ray, or so called extreme ultraviolet (EUV), wavelength incident light, such as λ=11 nm or λ=13 nm light, to obtain image resolution in the below 100 nm range. The resolution of a lithography system is described by the following equation:

$$RES=k_1 \cdot /NA$$

where k_1 is a specific parameter of the lithography process, λ is the wavelength of the incident light and NA is the numerical aperture of the system on the image side. This equation can be used to establish design criteria for soft X-ray lithography systems. Thus, for a numerical aperture of 0.10, the imaging of 100 rim structures with 13 nm radiation requires a process with k_1=0.77. Alternatively, with k_1=0.64, which occurs with 11 nm radiation, imaging of 70 nm structures is possible with a numerical aperture of 0.10.

For lithography imaging systems in the soft X-ray region, multilayer coated reflective systems, such as Distributed Bragg Reflectors (DBRs) and mirrors, are used as optical components. These multilayer systems employ alternating layers of different indices of refraction. The particular multilayer reflective system depends on the wavelength of incident light used. For example, with incident light of λ=11 nm alternating layers of Mo/Be are preferred and with incident light of λ=13 nm Mo/Si layers are used. In the case of projection objectives used in soft X-ray or EUV microlithography, the reflectivity of these multilayer systems is approximately 70%. It is, therefore, desirable to use as few optical components in the projection objective as possible to ensure sufficient light intensity at the image. With high intensity light, four-mirror projection objective systems were found to be useful in correcting imaging errors at NA=0.10.

Other requirements for soft X-ray projection objectives, in addition to using a limited number of multilayer reflectors, relate to obscuration, image field curvature, distortion, telecentricity on both the image and the object side, free working distance, and aperture stop positioning and accessibility. Obscurations, for example the central obscuration apparent in Schwarzschild systems, create intolerable degradation in image quality. If an obscuration-free light path is required, then, in the case of centered systems, an off-axis image field must be used. In order to provide

image formats of 26×34 mm^2 or 26×52 mm^2, it is advantageous to design the projection objective system as an annular field scanner. In such systems, the useful secant length of the scanning slit should be at least 26 mm, and the annular width should lie in the range of 0.5 mm to 2 mm in order to make uniform illumination and illumination-control and dose-control possible.

Regarding distortion, a distinction between static and dynamic or scan distortion is made. Scan distortion is the effective distortion which is obtained by integration of the static distortion over the scanning path. The limits for magnification-corrected, static distortion follow essentially from the specifications for contrast and CD variation.

Image-side telecentricity is also desired in soft X-ray lithography systems. Whether telecentricity is possible on the object side depends on the type of projection application used. If the projection system uses a reflection mask, then a telecentric optical path on the object side is not possible. If transmission masks, for example stencil masks, are used then a telecentric optical path on the object side can be realized.

In order to enable clean limitations of the beam, the aperture stop should be physically accessible. The image-side telecentricity requirement, referred to above, means that the entrance pupil of the last mirror would lie in or near its focal point. In order to obtain a compact design and maintain an accessible aperture stop, it is recommended that a beam-limiting element be placed before the last mirror. This, preferably, results in the place of the beam-limiting element at the third mirror.

Four-mirror projection or reduction objectives have become known from the following publications:

U.S. Pat No. 5,315,629

EP 480,617

U.S. Pat. No. 5,063,586

EP 422,853

Donald W. Sweeney, Russ Hudyma, Henry N. Chapman, David Shafer, EUV optical Design for a 100 mm CD Imaging System, 23rd International Symposium of microlithography, SPIE, Santa Clara, Calif., Feb. 22–27, 1998, SPIE Vol. 3331, p. 2ff.

In U.S. Pat. No. 5,315,629, a four-mirror projection objective with NA=0.1, 4×31.25×0.5 mm^2 is claimed. The mirror sequence is concave, convex, concave, concave. From EP 480,617, two NA=0.1, 5×, 25×2 mm^2 systems have become known. The mirror sequence is concave, convex, arbitrary/convex, concave.

The systems according to U.S. Pat. No. 5,063,586 and EP 422,853 have a rectangular image field, for example, at least 5×5 mm^2, and use a mirror sequence of convex, concave, convex, concave. These generally decentered systems exhibit very high distortion values. Therefore, the objectives can only be used in steppers with distortion correction on the reticle. However, the high level of distortion makes such objectives impractical in the structural resolution regions discussed here ($\leqq$130 nm).

From U.S. Pat. No. 5,153,898, overall arbitrary three to five-multilayer mirror systems have become known. However, the disclosed embodiments all describe three-mirror systems with a rectangular field and small numerical aperture (NA<0.04). Therefore, the systems described therein can only image structures above 0.25 μm in length.

Furthermore, reference is made to T. Jewell: "Optical system design issues in development of projection camera for EUV lithography", Proc. SPIE 2437 (1995) and the citations given there, the entire disclosure of which is incorporated by reference.

In the known systems according to EP 480,617 as well as U.S. Pat. No. 5,315,629 and according to Sweeney, cited above, it was found to be disadvantageous that the outside-axially used part of the primary mirror conflicts with the wafer-side sensor structures of a projection exposure installation when not very large free mechanical working distances greater than 100 mm are realized. By using mirror segments which are placed "near the image field", these conflicts occur only at significantly lower distances (≈10 mm).

Six mirror projection or reduction objectives with all multilayer mirrors in centered arrangement to an optical axis have become known, e.g., from U.S. Pat. No. 6,033,079. The system according to U.S. Pat. No. 6,033,079 is telecentric on the image side. To provide small reflection angles at the object side, i.e., at the reticle, a long distance between the primary multilayer mirror and the reticle according to U.S. Pat. No. 6,033,079 is chosen. A disadvantage of this reduction objective is the extension, or lengthening, of the projection objective in the direction of the optical axis.

Thus, it is desired to provide a projection objective which is suitable for lithography with short wavelengths (at least below 193 nm and, preferably below 100 nm) which does not have the disadvantages of the prior art mentioned above, uses as few optical elements as possible and, yet, has a sufficiently large aperture and fulfills the telecentricity requirements as well as all other requirements for a projection system operating with incident light of wavelengths below 193 nm.

SUMMARY OF THE INVENTION

According to an aspect of the invention, the shortcomings of the prior art are overcome by using a reduction objective that includes four-mirrors (primary, secondary, tertiary, and quaternary). Using this four-mirror system, high transmission efficiency is achieved at wavelengths in the soft x-ray and EUV region with a multilayer mirror system of 70% reflectivity and an aperture in the range of NA≈0.10. The four-mirror objective according to the invention is thus characterized by high resolution, low manufacturing costs and high throughput. In another embodiment a system using six multilayer mirrors is provided.

In both systems a first set of multilayer mirrors is in centered arrangement with respect to a first optical axis and a second set of multilayer mirrors is in centered arrangement with respect to a second optical axis. At least one additional mirror is disposed at grazing incidence between said first and said second set of multilayer mirrors, wherein said additional mirror defines an angle between said first optical axis and said second optical axis.

In a preferred embodiment of the invention, it is provided that an aperture stop lies on or near a mirror, especially on the tertiary mirror. In this embodiment, the aperture stop is physically accessible and the reduction objective is compact and free from vignetting.

In another embodiment of the reduction objective of the invention, the secondary mirror and the quaternary mirror are concave. In still a further embodiment of a four-mirror-system, the four mirrors are arranged in the convex-concave-convex-concave sequence.

The asphericities discussed herein refer to the peak-to-peak or peak-to-valley (PV) deviation A of the aspherical surfaces in comparison to the best fitting sphere in the used region of the mirrors. In the embodiments of the invention discussed herein, these are approximated by a sphere, the center of which lies on the figure-axis of the mirror and the meridional plane of the aspherical element intersects in the upper and lower and point of the used region. The data on the angles of incidence, as provided below in Table II, refer to the angle between the particular incident radiation and the normal to the surface at the point of incidence. The largest angle of incidence of a ray is established by a rim-ray at one of the mirrors.

Preferably, the optically free working distance on the wafer side is 60 mm and the free working distance on the reticle side is at least 100 mm.

As will be appreciated from this disclosure by persons of ordinary skill in the art, the objectives described above can be used not only for soft X-ray lithography, but for other wavelengths, both in the EUV range and outside of this range, without deviation from the invention. Nonetheless, the invention is preferably used at soft X-ray and EUV wavelengths in the region of 193 nm and below. Wavelengths within this range can be generated using excimer lasers.

In order to achieve a diffraction-limited system, it is preferred that the design part of the rms wave front section of the system is at most 0.07λ. It is further preferred that the reduction objective is designed so that it is telecentric on the image side. In systems with a transmission mask, the projection objective is also designed to be telecentric on the object side. In projection systems which are operated with a reflection mask, a telecentric beam path without illumination over a beam splitter which reduces transmission greatly, such as is shown in JP-A-95/28 31 16, is not possible on the object side. Therefore, the chief ray angle in the reticle is chosen so that shading-free illumination, that is no obscuration, is possible. Overall, the telecentricity error on the wafer should not exceed 10 mrad, and preferably is in the 5 mrad to below 2 mrad range. This ensures that the change in the image scale or distortion lies within tolerable limits in the depth of field.

In a preferred embodiment of the invention, the first set of multilayer mirrors comprises four mirrors and the second set of multilayer mirrors comprises two mirrors. The grazing-incidence mirror is arranged in such a way that the first and the second optical axis are parallel to each other. Such an embodiment provides for a short projection objective in axial direction and for small reflection angles at the object side.

According to another aspect of the invention, the reduction objective is used with a mask and a soft X-ray or EUV exposure source, for example, in a projection exposure apparatus, such as those used in lithography for integrated circuit fabrication. In the embodiment, the projection exposure apparatus has a reflection mask and, in an alternative embodiment, it has a transmission mask.

The projection exposure apparatus is preferably designed as an annular-field scanner illuminating an off-axis annular field. 10Advantageously, it is provided that the secant length of the scanning slit is at least 26 mm and that the annular width is greater than 0.5 mm, so that uniform illumination is made possible.

Another advantage of the objective of the invention, is that the asphericity of the aspherical optical elements is small enough so that the system requirements of being "diffraction-limited" and having high reflectivity multilayer mirrors can be achieved, such that the resulting accuracy requirements on these surfaces in all spatial frequency regions from the free diameter of the mirror to atomic dimensions can be obeyed.

According to another aspect of the invention, a method of integrated circuit fabrication using a projection exposure apparatus including a reduction objective is provided. The method comprises the steps of providing a mask, providing a soft X-ray or EUV, illumination source, and providing four mirrors (primary, secondary, tertiary, and quaternary) in centered arrangement with respect to an optical axis, wherein the primary mirror is a convex mirror and the secondary mirror has a positive angular magnification.

Traditionally, approximately 40 pairs of alternating Mo/Si DBR layers are used to create mirrors with high reflectivity of 13 nm wavelength incident light. Similarly, high reflectivity of 11 nm wavelength radiation, requires approximately 70 pairs of Mo/Be alternating layers. By using large numbers of DBR layers, the acceptance angle of mirrors and thus their objective systems is only a few degrees and decreases with increasing angle of incidence. Furthermore, with this increasing angle of incidence, detrimental phase effects can occur. If the test-point-related mean angle of incidence varies greatly over a system surface, then layer packets with changing thickness must be applied. These disadvantages of existing multilayer mirror objective systems are reduced in the present invention in which the objectives have a low mean angle of incidence and a low surface-specific variation around the mean angle of incidence.

The invention will be explained below with the aid of drawings depicting the preferred embodiments.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a schematic representation of the system classification used in the invention.

FIG. **2** is a lens cross-section of a first four-mirror system (type-e system) according to the prior art.

FIG. **3** is a lens cross-section of a four-mirror system (type-f system) according to the invention.

FIG. **4** is a lens cross-section of another four-mirror system (type-g system) according to the invention.

FIG. **5** is a lens cross-section of type f with an introduced grazing incidence mirror according to the invention.

FIG. **6** is a lens cross-section of a system with six multilayer mirrors and a grazing incidence mirror.

FIG. **7** is a depiction of a four-mirror or six-mirror reduction objective that is telecentric on the object side and used with a transmission mask.

FIG. **8** is a depiction of a four-mirror or six-mirror reduction objective that is telecentric on the object side and used with a reflection mask.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

The practical examples identified in FIGS. **2** to **5** are centered reduction systems, telecentric on the image side, with an aperture stop (indicated by AS in FIG. **4**, for example) at the third mirror **M3**. In all systems, the same reference numbers are used for the same components and the following nomenclature is employed:

first (primary) mirror (**M1**), second (secondary) mirror (**M2**), third (tertiary) mirror (**M3**), fourth (quaternary) mirror (**M4**).

Reduction objectives used in lithography are classified by their primary mirror magnification m(**M1**), or convergence ratio $\nu(M1)=-1/m(M1)$, and their secondary-mirror chief ray angular magnification $\mu(M2)$. This nomenclature is taken from Dietrich Korsch, Reflective optics, Academic Press, 1991, p. 41 ff, which is incorporated herein by reference. For the different types of primary mirrors Table 1, below, summarizes the different convergence ratio and angular magnification values obtainable.

TABLE I

	M1	$\nu(M1)$	$\mu(M2)$
type-a	concave	$\epsilon]1,\infty[$	$<-\epsilon_4$
type-b	plane, concave	$\epsilon[-1,1]$	$<-\epsilon_4$
type-e	convex	$\epsilon]-\infty,-1[$	$<-\epsilon_4$
type-f	convex	$\epsilon]-\infty,-1[$	$\epsilon]\epsilon_4,1-\epsilon_2[$
type-g	convex	$\epsilon]-\infty,-1[$	$\epsilon]1+\epsilon_3,\infty[$

The following is true for these systems: $\epsilon_i>0$ increases with the numerical i6, 1aperture NA of the system, that is, $\epsilon_i=0\rightarrow$ NA=0. A schematic representation of the system classification as used below is shown in FIG. **1**.

The concept of the chief ray angular magnification or angular magnification refers to the tangents of the chief ray (see Korsch, Reflective Optics, incorporated by reference above). A positive angular magnification means that the slopes of the straight lines identifiable with the incident and reflected chief rays to the optical axis have the same sign, that is, that the entrance and exit pupils of the respective mirror lie on the same physical side of the mirror.

As shown in FIG. **1**, type-a, type-b and type-e are topologically connected components of the two-dimensional parameter space. Therefore type-a, type-b, and type-e objectives can be transformed continuously into each other. In contrast, this is not possible between each of the two other classes of the three systems shown in FIG. **1**. The class including types-a, -b, and -e, can not be continuously transformed into the type-f class (system) or the type-g class (system). FIG. **1** indicates the forbidden regions F in which, in the case of a finite NA, obscuration of the light beam by the mirror will occur and therefore the objectives will fail to image properly.

The particular topologically-connected component region is determined by $\mu(M2)$. The annular field systems disclosed in U.S. Pat. No. 5,315,629 and EP 480,617 are type-a systems. Type-b systems provide continuous transition to the type-e system which also include the system known from Donald W. Sweeney et al., 23rd International Symposium of Microlithography. Type-a, type-b, and type-e systems are known in the prior art.

Systems of type-f and type-g are not known from any of the publications referred to above. The systems according to type-f and type-g differ from the systems of U.S. Pat. No. 5,315,629 and EP 480,617 by having a convex primary mirror. The system disclosed in Donald W. Sweeney et al., 23rd International Symposium of Microlithography, loc. cit., has a convex primary mirror but it also has a different angular magnification μ at **M2** and thus a different optical path in the system, which does not overcome the prior art problems described above.

Systems of type-f with ν(**M 1**) above approximately −1.5 lead to large chief ray angles on the reticle and to large system diameters. As a result, sensible system design with a concave **M1**, i.e. ν(**M1**)≧1, is difficult.

In the following Table II, typical functional data are given for some of the embodiments of the various system categories. The distortion values follow from the magnification correction through the annular field. Objective systems belonging to the individual system classes are shown in FIGS. **2–5**.

TABLE II

	type-f (94)	type-g (68)
M1	convex	convex

Explanation of the abbreviations used in Table II are listed in Table III, below.

TABLE III

	Meaning
M1	form of the primary mirror
ν(M1)	"conversion ratio" according to Korsch
μ(M2)	"angular magnification" according to Korsch
NA	image-side numerical aperture
Red	reduction factor = −1/imaging scale
annular field [mm^2]	secant length × annular width in the image field
mean annular field radius [mm]	image field radius in the middle of the annular field
OO' [mm]	object-image distance
FWD [mm]	optically free working distance on the image side
CRAO [deg]	chief ray angle in the object space
CRA [mrad]	chief ray angle in the image space
max. asph. [μm]	maximum deviation of the asphere from the best fitting sphere with respect to the used region of the mirror
AOI max. [deg]	maximum angle of incidence
ΔAOI max. [deg]	variation of the angle of incidence over the mirror
WFE max. [λrms]	maximum rms wavefront error in units of λ
distortion [nmPV]	peak-to-peak value over the annular field scale-corrected chief ray distortion

Systems with a convex **M1**, i.e. primary mirror, show a significantly higher asphericity than the type-a designs with a concave **M1**.

FIG. **2** shows a cross-section of a type-e system from a reticle plane **2**, or mask, to a wafer plane **4**. The mirror nearest to the wafer is the first mirror **M1**. Type-e systems have the lowest AOI and ΔAOI on mirrors **M1**, **M2**, **M3**, **M4**, which favors the polarization-optical properties of the system. However, the high chief ray angles on the reticle plane **2** requires plane reticles. Conversely, type-g systems, as shown in cross-section in FIG. **4**, have relatively large AOI and ΔAOI on mirrors **M1**, **M2**, **M3**, **M4** with tolerable chief ray angles on the reticle.

As shown in FIG. **3**, type-f systems require the largest aspherical elements, but have favorable angular distributions on mirrors **M1**, **M2**, **M3**, **M4** and on the reticle **2**. The low distortion results in a relatively small image field. Although the constructional length, i.e. the physical length, of the system is larger than in the other systems, the long drift sections within the objective permit the optional use of additional components, such as an alignment system, deflecting mirror, etc. A chief ray CR and an optical axis HA are also shown in FIG. **3**.

The type-f and type-g systems, as shown in FIGS. **3** and **4**, respectively, can be realized with positive and negative chief ray angles on reticle **2**. Thus, an optimal geometry can be selected, especially a comparatively low free working distance to reticle **2**, for imaging the light when using a reflection mask. Furthermore, when using a transmission mask, a telecentric beam path can be realized.

The systems of type-a and type-f have relatively long "drift sections" before or within the actual image system. Therefore, it is possible to introduce grazing-incidence mirrors of high reflectivity as correction elements. These correction elements can include Schmidt corrector-type elements or an active optical correction system. Based on known values for molybdenum-coated mirrors; it is theoretically possible to achieve approximately 85% reflectivity of non-polarized incident light of wavelength 13.3 nm incident at an angle of 75°. Due to the grazing incidence of the beam, the illuminated part of the mirror can be made

very large in one direction, in comparison to that on the neighboring mirror, which facilitates the design of the correcting elements. Preferably, the individual mirrors are designed in a pair-wise manner with the normals to the surface being almost perpendicular to one another, in order to be able to manipulate the beams in all spatial directions with the same resolution. FIG. **5** shows such a design of type-f with an introduced grazing-incidence mirror GIM.

The parameters of the system according to FIG. **3** in the code V format are given in Table 1 below.

In FIG. **6** another embodiment of the invention is shown. The projection objective comprises reticle **2** in the object plane. The system is telecentric in the image plane, i.e., the wafer plane **4**. A first set of multilayer mirrors comprises the mirrors **M1**, **M2**, **M3** and **M4** in centered arrangement to a first optical axis **HA1**, and a second set of multilayer mirrors comprises the mirrors **M4** and **M5** in centered arrangement to a second optical axis **HA2**. The mirror **M4** has a positive chief ray angular magnification. The grazing incidence mirror GIM is arranged such that the first optical axis **HA1** is parallel to the second optical axis **HA2**. The projection objective system comprises an intermediate image **IM1** between the fourth and fifth mirror.

The grazing incidence mirror GIM is disposed near the intermediate image. Since near the intermediate image the ray bundle has only a small extension, the grazing incidence mirror can be chosen small in size.

Preferably the grazing incidence mirror is arranged in the system, such that the distance d_1 from the first optical axis **HA1** to the grazing incidence mirror is equal to the distance d_2 from the second optical axis **HA2** to the grazing incidence mirror.

Furthermore in FIG. **6** a system of coordinates is shown. The z-direction is parallel to the optical axes **HA1**, **HA2**. The y-direction is perpendicular to the z-direction and lies in the plane of the figure. The x-direction is perpendicular to the z- and the y-direction. In such a coordinate system the projection objective according to FIG. **6** has a positive linear magnification in the x-direction, and due to the grazing incidence mirror GIM, the system has negative linear magnification in y-direction.

The projection objective according to FIG. **6** provides for a large distance between the object plane and the first mirror and thus for small reflection angles in the object plane. The

data of the system according to FIG. **6** in Code-V-format are apparent from Table 4:

FIG. **7** shows the four-mirror or six-mirror reduction objective of FIGS. **3**, **4**, or **6** with the reticle plane **2** as a transmission mask. Thus, it can be seen from FIG. **6** that the reduction objective is telecentric on the object side of such a configuration.

Similarly, FIG. **8** shows the four-mirror or six mirror reduction objective of FIGS. **3**, **4**, or **6** with reticle plane **2** as a reflection mask. In such a configuration, a beam splitter may be used, for example, to ensure the reduction objective is also telecentric on the object side.

Thus, the invention provides for a reduction objective with an imaging reduction scale of approximately 4× for use in soft X-ray, i.e., EUV and UV, annular field projection applications, such as lithography. The reduction objection achieves the necessary resolution at the required image field and provides a structural design with optical elements of sufficiently mild asphericity, sufficiently small incident angles for the multilayered optics, and sufficiently large constructional space for the image carriers.

We claim:

1. A reduction objective with an image side and an object side, comprising:

a first set of multilayer mirrors in centered arrangement with respect to a first optical axis, and a second set of multilayer mirrors in centered arrangement with

respect to a second optical axis situated between the image side and the object side; and

an additional mirror disposed at grazing incidence such that said additional mirror defines an angle between said first optical axis and said second optical axis.

2. A reduction objective according to claim **1**, wherein the first set of multilayer mirrors comprises a primary multilayer mirror and a secondary multilayer mirror.

3. A reduction objective according to claim **2**, wherein the primary mirror is convex and the secondary mirror has positive chief ray angular magnification.

4. A reduction objective according to claim **2**, wherein the second set of multilayer mirrors comprises a tertiary multilayer mirror and a quaternary multilayer mirror.

5. A reduction objective according to claim **4**, wherein the primary mirror is convex and the secondary mirror has positive chief ray angular magnification.

6. A reduction objective according to claim **1**, wherein said angle is 75°.

7. A reduction objective according to claim **1**, wherein the first set of multilayer mirrors comprises a primary, a secondary, a tertiary and a quaternary multilayer mirror.

8. A reduction objective according to claim **7**, wherein the second set of multilayer mirrors comprise a fifth and a sixth multilayer mirror.

9. A reduction objective according to claim **8**, wherein the fifth mirror is convex and the sixth mirror is concave.

10. A reduction objective according to claim **8**, wherein the first and the second optical axis are parallel to each other and said angle is 0°.

11. A reduction objective according to claim **10**, wherein the grazing incidence mirror is disposed between the first optical axis and the second optical axis.

12. A reduction objective according to claim **10**, wherein the objective is telecentric at the object side.

13. A reduction objective according to claim **10**, wherein the objective is telecentric at the image side.

14. A reduction objective according to claim **8**, wherein the reduction objective comprises a plane conjugate to the object plane in which an intermediate image of the object lies.

15. A reduction objective according to claim **14**, wherein the grazing incidence mirror is disposed near the intermediate image of the object.

16. A reduction objective according to claim **8**, wherein the quaternary multilayer mirror has positive chief ray angular magnification.

17. A reduction objective according to claim **8**, wherein linear magnification of the reduction objective in an x-direction is positive and the linear magnification of the reduction objective in a y-direction is negative.

18. A projection exposure apparatus including a reduction objective with an image side and an object side for annular field scanning operation comprising:

a mask;

a first set of multilayer mirrors in centered arrangement with respect to a first optical axis and a second set of multilayer mirrors in centered arrangement with respect to a second optical axis situated between the image side and the object side; and

an additional mirror disposed at grazing incidence such that said additional mirror defines an angle between said first optical axis and said second optical axis.

19. A method for integrated circuit fabrication using a projection exposure apparatus including a reduction objective, with an image side and an object side, comprising the steps of:

providing a mask;

providing a first set of multilayer mirrors in centered arrangement with respect to a first optical axis and a second set of multilayer mirrors in centered arrangement with respect to a second optical axis situated between the image side and the object side; and

providing an additional mirror disposed at grazing incidence such that said additional mirror defines an angle between said first optical axis and said second optical axis.

(57) **ABSTRACT**

Average fringe contrast is determined by PSI measurements at each step of relatively large translations of the reference optics and mirror of a white-light Linnik interference objective and the resulting data are used to minimize the OPD between the reference and test beam paths of the instrument. Utilizing the same algorithms used in the art to perform conventional vertical scanning interferometry, the position of minimum OPD is determined by finding the position of maximum average fringe contrast. Furthermore, by automating the system with a precise translation mechanism, operator-to-operator variations are completely eliminated and the precision of the process of OPD minimization is greatly improved. In another embodiment of the invention, the optimal focal position of the reference mirror is found at the same time by calculating the average lateral variation of fringe contrast as a function of OPD and focal position. The optimal OPD and focal position correspond to the maximum average lateral variation of fringe contrast in the resulting three-dimensional space.

FIG. 12

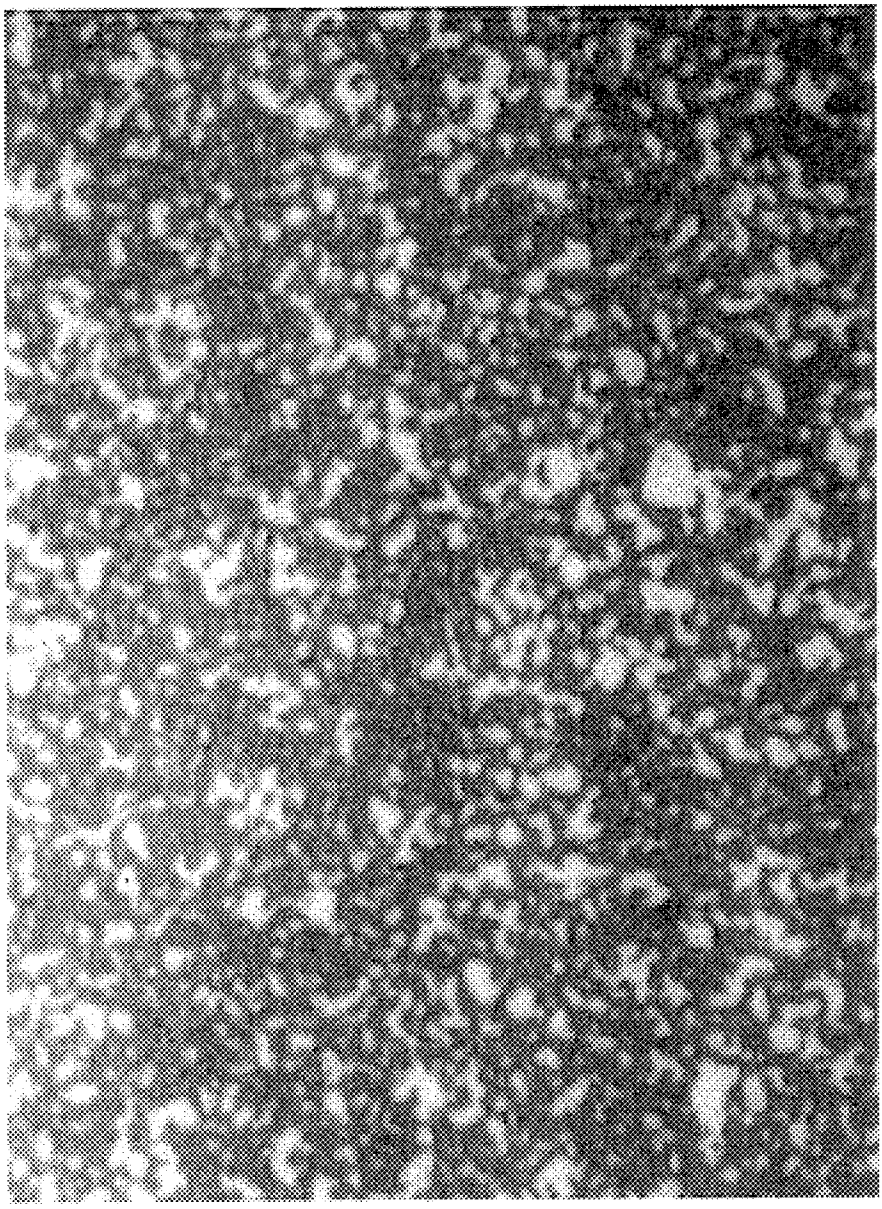

FIG. 13

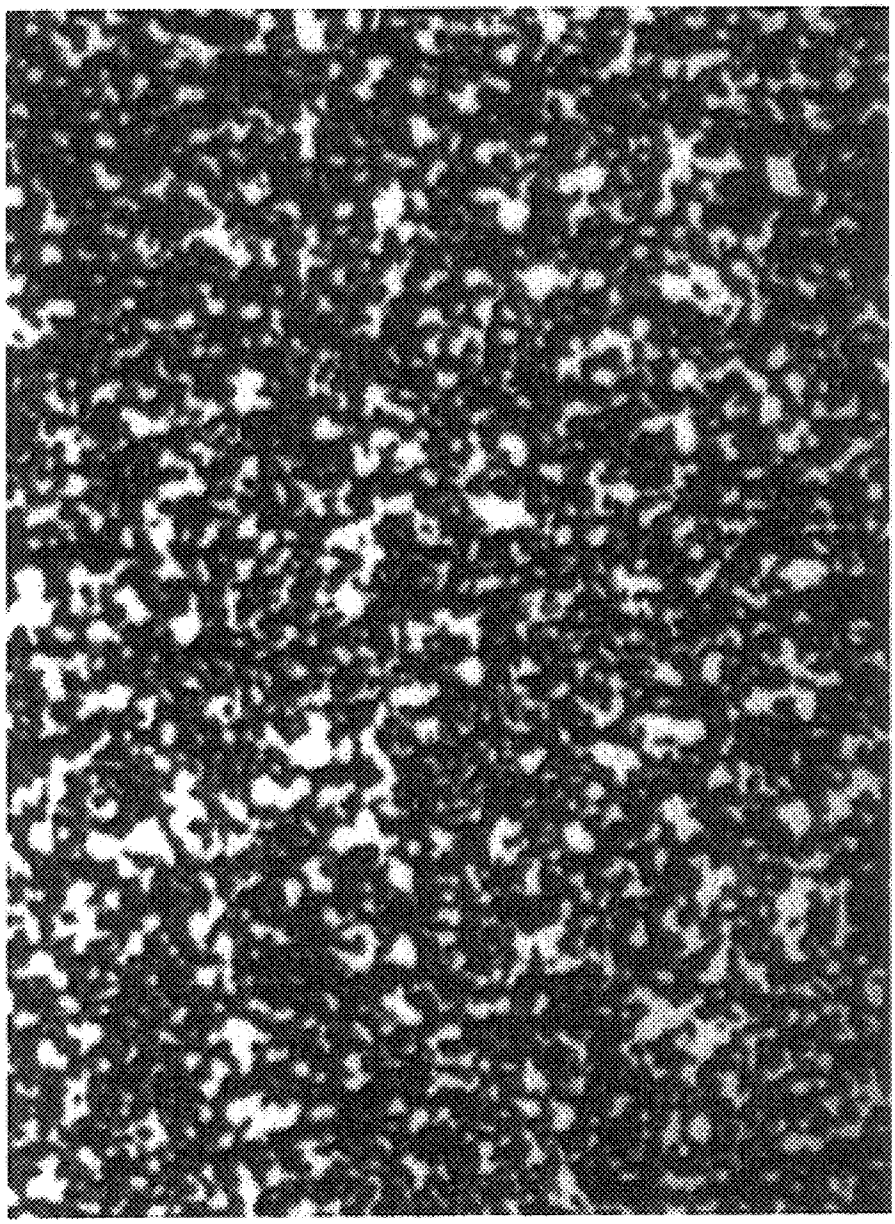

FIG. 14

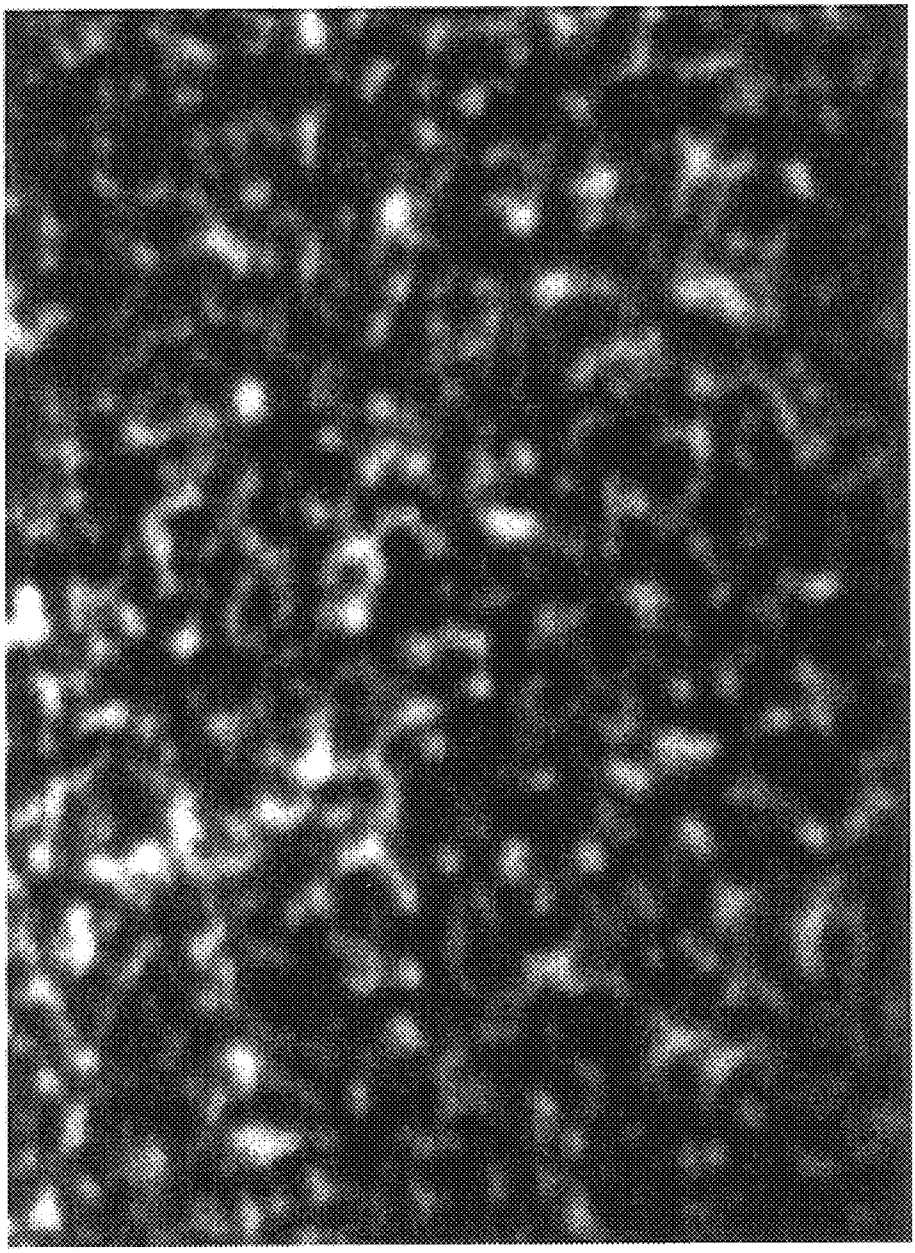

FIG. 15

AUTOMATED MINIMIZATION OF OPTICAL PATH DIFFERENCE AND REFERENCE MIRROR FOCUS IN WHITE-LIGHT INTERFERENCE MICROSCOPE OBJECTIVE

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention is related in general to the field of interferometry and, in particular, to an automated method and apparatus for minimizing the optical path difference between the reference and the test arms of a Linnik white-light interference objective.

2. Description of the Related Art

White-light interferometric devices typically utilize microscope objectives for simultaneously imaging a sample surface and a reference surface onto a detector in order to produce interference fringes representative of the height of the sample. As illustrated in simple schematic form in FIG. **1**, a typical Linnik interference microscope includes an objective **10** focused on a test surface S and incorporating an interferometer. The interferometer comprises a beam splitter **12** and a reference mirror R such that the light beam W directed to the sample surface S is split and also directed toward the reference mirror.

As is well understood by those skilled in the art, the light beams reflected from the reference mirror R and the test surface S (the reference and test beams, respectively) are combined to produce interference fringes as a result of the optical path difference (OPD) between the reference and test beams. The light reflected by the test surface S interferes with the light reflected at the reference mirror R and, according to the principle of superposition, bright interference fringes are produced corresponding to all points on the reference mirror where the optical path difference of the light is equal to a multiple of its wavelength. In order for discernible fringes to appear, the OPD must be within the coherence length of the light source. Spectral filtering may be used to increase the coherence length of the light.

The light from the reference and sample surfaces is typically passed back through the interferometric microscope **10** and appropriate imaging optics **14** toward an imaging array **16** positioned in a camera in coaxial alignment with the objective. The imaging array usually consists of individual charge-coupled-device (CCD) cells or other sensing apparatus adapted to record a two-dimensional array of signals corresponding to interference effects produced by the interferometer as a result of light reflected at individual x-y coordinates or pixels in the surface S and the reference mirror R and received at corresponding individual cells in the array. Appropriate electronic hardware (not shown) is also provided to process the signals generated by each cell and transmit them to a computer **18** for further processing. Thus, an interference-fringe map is generated by detecting the intensity of the light signal received in each cell of the array. The map may be displayed on a monitor **20** connected to the processing unit **18**. As mentioned, a filter **32** may be provided to optionally narrow the bandwidth of the light beam W to a predetermined value.

In a Linnik interferometer, a smooth test surface S is typically profiled by phase-shifting interferometry (PSI), typically by scanning the reference arm of the microscope objective **10**. A piezoelectric translator or equivalent device (not shown in FIG. **1**) is used in conventional manner to shift the reference optics **30** and mirror R together with respect to the sample surface S. Phase shifting is founded on the basic

concept of varying the phase difference between two interfering beams in some known manner, such as by changing the optical path difference in discrete steps or linearly with time. Under such conditions, three or more measurements of the light intensity at a pixel of a receiving sensor array can be used to determine the relative phase of the light reflected from the point on a test surface corresponding to that pixel, with respect to the other points on the test surface. Based on such measurements at each pixel of coordinates x and y, a phase distribution map $\Phi(x,y)$ can be determined for the test surface, from which very accurate height data $h(x,y)$ are calculated in relation to the wavelength λ of the light source used by the following general equation:

$$h(x, y) = \frac{\lambda}{4\pi}\Phi(x, y). \quad (1)$$

Phase-shifting interferometry provides a vertical resolution in the order of 1/100 of a wavelength or better. The technique is typically limited to measurements of smooth surfaces due to a height ambiguity encountered at phase steps greater than π.

Linnik interferometers are also used for vertical-scanning interferometry (VSI) of rough surfaces. VSI is a well-known technique where white light is used as the light source in an interferometer and the degree of modulation, or coherence, of interference fringes produced by the instrument is measured for various distances between the test surface and the reference surface of the interferometer (each corresponding to a different optical path difference) to determine surface height. The microscope objective is typically adapted for vertical movement (along the z coordinate). Thus, an interference-fringe map is generated by detecting the intensity of the light signal received in each cell of the light sensor as a function of the z-scan position. The position of the scanning mechanism corresponding to maximum interference at each pixel is determined and used, based on the distance from a reference point, to calculate the height of the surface at that pixel.

As shown in FIG. **1**, the Linnik configuration of a microscope objective includes a white light source **22** and imaging optics **24** providing an illumination beam W to the system through a beam splitter or equivalent device **26**. The illumination beam is then focused, ideally, in the entrance pupils E and E' of the reference and test imaging optics **30** and **28**, respectively. This is known as Kohler illumination, and produces approximately uniform illumination on the sample surface S and the reference surface R. By way of calibration, the reference mirror R is set at the focal point of the imaging optics **30** through a process based on a visual determination of best focus produced by axially shifting the reference mirror with respect to its imaging optics **30** along a distance F, as one skilled in the art would readily understand. This is often accomplished by the introduction of a field stop in the illuminator (not shown in FIG. **1**). When the diameter of the field stop is reduced sufficiently to bring its edges into the field of view, a sharp image of the edges is formed on the camera when the reference surface R is in focus. Copending application Ser. No. 09/452,334 discloses a mechanism for focusing the reference mirror R automatically, which provides an opportunity for periodic recalibration of the instrument.

Prior to carrying out surface profiling by PSI measurements, the distance between the sample surface S and its focusing optics **28** is also adjusted to produce a sharp, in-focus image of the sample. This is normally achieved by

moving the entire objective **10** vertically with respect to the sample stage (although the same result could obviously be achieved as well by moving the stage). The distance F' (FIG. **1**) between the lens **28** and the surface S is varied, either manually or automatically, until the sample surface is in focus. Typically, the optimal in-focus position of the sample surface is determined by visual observation of the best picture of the sample surface seen at the monitor **20**. Alternatively, an image of the field stop, as described above, can be used to set the optimal in-focus position. Similarly, for VSI measurements, fringes are present at a given scan position only for portions of the surface that are in focus.

When a light of short coherence length is used, such as produced by the white-light source **22**, interference between the return beams only occurs when the optical path difference between the test and the reference paths is within the coherence length of the system. The coherence length of a white-light source can be increased with spectral filtering. Therefore, it is necessary to minimize the OPD in order to obtain satisfactory fringe contrast for PSI and VSI measurements. In general, for optimum performance the OPD between the reference and test paths must be less than approximately one wavelength. If a 40 nm bandwidth red light source is used, the coherence length is about 9 μm and the OPD between the reference and test paths must be less than 0.6 μm.

If a narrower bandwidth is chosen to carry out the interferometric measurements, such as with the use of a laser light, the coherence length and hence the OPD can be much greater, but stricter operational requirements render the commercial use of this type of interferometer less desirable for many applications. Therefore, short coherence lengths are preferred in many cases and the sample and reference path length difference must then necessarily be placed within very close tolerances. Minute changes in the optical path difference between the reference and test surfaces are sufficient to cause degradation of the fringe quality seen at the sensor **16**.

Therefore, the quality of the phase-shifting and vertical-scanning measurements are also directly related to the degree to which the OPD is minimized.

A manual control is typically provided to adjust the length of the optical path of either the reference or the test beam. For example, a typical adjustment consists of manually translating the lens **30** and the reference mirror R together (thereby preserving the in-focus position of the reference mirror) with respect to the splitter **12** along a distance D (see FIG. **1**), so as to generate the best visual fringe contrast. This adjustment is performed prior to performing measurements of the test sample S. In phase-shifting, measurements are accomplished using a scanning mechanism, typically a piezoelectric element, that also shifts the lens **30** and mirror R together in the spatial dimension of the distance D, herein also referred to as the D direction. In vertical-scanning, measurements are made by varying the distance F', either by moving the objective **10** or the sample S. Obviously, the OPD adjustment is limited by the subjective nature of human measurements and by the relatively coarse ability of the human eye to discern degrees of contrast in an interferogram. This is particularly true in the case of nulled fringes, where a single, uniform fringe covers the entire field-of-view.

As interference microscopes have become standard quality-control tools in production environments, such as for testing the topography of magnetic heads, greater measurement precision and repeatability are required. Such interference microscopes are now capable of making measurements with sub-nanometer precision. Accordingly, the precise minimization of the OPD between the reference mirror and the test surface has become more and more critical. This is especially true with objectives of high numerical aperture and correspondingly short depth of focus. Even though it is possible to maximize the fringe contrast (minimum OPD) in the Linnik interferometer at a condition where the reference mirror is out of focus, this condition is known to degrade the measurement performance of interference microscopes, as detailed in U.S. Pat. No. 5,978,086.

It has therefore become necessary to obtain extremely tight levels of control over the length of the reference path with respect to the test path, encompassing distances D and F in FIG. **1**. In addition, it would be very desirable to have an automated method and apparatus for minimizing the OPD in white-light interference objectives in order to avoid the subjectivity and lack of precision of human measurements. The present invention is directed at improving the quality of the fringes generated by the interference between the reference and test beams by ensuring that the OPD between the two beams is optimally minimized. Two solutions are provided for optimizing the objective prior to performing phase-shifting or vertical-scanning interferometry. One solution is provided by maximizing the fringe contrast in the process of OPD minimization. It is suitable for general test surfaces, but requires separate optimization of reference mirror focus. The second solution entails maximizing the fringe modulation across the test surface. While it is suitable for a limited number of test surfaces with specific attributes, it allows for the simultaneous optimization of reference mirror focus and OPD, and can be employed in the critical measurement of magnetic heads.

BRIEF SUMMARY OF THE INVENTION

One primary object of this invention is a method for optimizing the process of minimization of the optical path difference between the reference and test beams of a white-light Linnik interferometer.

Another primary objective of the invention is a method for setting the in-focus position of the reference surface of an interferometric microscope objective.

Another object of the invention is a method that is suitable for automated implementation.

Still another objective is a method and corresponding implementing apparatus that are suitable for automated use while the interferometer is in service for quality control in an assembly line.

Another goal of the invention is a method and apparatus that are suitable for incorporation within existing instruments.

A final object is a procedure that can be implemented easily and economically according to the above stated criteria.

Therefore, according to these and other objectives, the present invention consists of incorporating a mechanism for producing relatively large translations of the reference optics and mirror in a white-light Linnik interference objective and carrying out PSI measurements while the OPD between the reference and test beams is varied. Utilizing the same algorithms used in the art to perform conventional phase shifting interferometry, the position of minimum OPD is determined by finding the corresponding position of maximum intensity contrast of the interference fringes resulting from the superposition of the reference and test beams as the OPD is varied. Alternatively, for a test surface with specific

characteristics, such as a magnetic head air bearing surface, the OPD is minimized and the reference mirror is simultaneously focused by maximizing the variation in fringe modulation across the test surface. By automating the system with a precise translation mechanism, operator-to-operator variations are completely eliminated and the precision of the process of OPD minimization and reference mirror focus are greatly improved.

Various other purposes and advantages of the invention will become clear from its description in the specification that follows and from the novel features particularly pointed out in the appended claims. Therefore, to the accomplishment of the objectives described above, this invention consists of the features hereinafter illustrated in the drawings, fully described in the detailed description of the preferred embodiment and particularly pointed out in the claims. However, such drawings and description disclose only one of the various ways in which the invention may be practiced.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a simplified schematic representation of a prior-art Linnik interferometric microscope.

FIG. **2** is a typical intensity signal obtained from a detector cell in the image plane of an interferometer as the OPD is varied by vertically scanning the objective or the test sample, or by varying the reference path length.

FIG. **3** is a schematic representation of the microscope objective of FIG. **1** incorporating a scanning mechanism for translating the reference optics and mirror with reference to the sample surface.

FIG. **4** is a partially cut-out view of an interference objective according to one preferred embodiment of the invention.

FIG. **5** is a view of the interference objective of FIG. **4** where the reference sleeve is shown in exaggerated extended position for clarity.

FIG. **6** shows the fringe modulation for an examplary PSI measurement as a function of optical path difference in a Linnik objective, where the spectral bandwidth of the light is approximately **40** nm with center wavelength of about 600 nm.

FIG. **7** is a diagram of the steps involved in the procedure of the invention for OPD minimization by fringe contrast maximization.

FIG. **8** shows the fringe modulation for a series of examplary trials, where the OPD was minimized with the automated algorithm of the invention and manually by two different operators.

FIG. **9** is a schematic representation of the microscope objective of FIG. **1** incorporating an alternative preferred embodiment of the invention, which includes a first scanning mechanism for translating the reference optics and mirror in relation to the sample surface as well as a second scanning mechanism for translating the reference mirror in relation to the reference optics.

FIG. **10** is a partially cut-out view of an interference objective according to the embodiment of FIG. **9**.

FIG. **11** is a three-dimensional plot of average fringe-modulation lateral variation as a function of both OPD and focal distance changes.

FIG. **12** is a diagram of the steps involved in producing minimum OPD and optimal reference-mirror focus by finding the peak of the average lateral variation of modulation as a function of OPD and focal position.

FIG. **13** shows an intensity image of an air bearing surface (ABS) found to be suitable for optimizing the OPD and focal position of an interferometric objective with the procedure outlined in FIG. **12**.

FIG. **14** is a modulation image of the air bearing surface of FIG. **13** produced at D and F positions optimized with the procedure outlined in FIG. **12**.

FIG. **15** is a modulation image of the air bearing surface of FIG. **13** produced at D and F positions that have not been optimized.

DESCRIPTION OF THE PREFERRED EMBODIMENT OF THE INVENTION

The present invention is based on the idea of maximizing fringe modulation or the spatial variation of fringe modulation in order to minimize the optical path difference between the reference path and the test path of a white-light interference objective in a white-light Linnik interferometer. The approach makes it possible to automate the process and optimize the quality of the resulting PSI or VSI profiling measurements. For the purposes of this disclosure, the term white light is intended to refer to any broad-bandwidth light such as produced by halogen lamps, arc lamps, and LEDs, which are often also filtered to reduce the bandwidth to a particular wavelength range of interest. In the examples described below, white light filtered to a 40-nm bandwidth with about 600-nm center wavelength was used. The reference symbols F, D, and F' are used to refer (as also defined above) to the distances between reference mirror and reference optics, reference optics and microscope splitter, and sample surface and microscope splitter, respectively, as well as to the spatial dimension or direction of these parameters.

The prior art discloses various ways by which VSI may be implemented to determine surface height by calculating the degree of fringe modulation, or coherence, of the interference fringes produced at the light detector for various OPDs between the test surface and the reference surface of the interferometer. These methods involve a determination of the scanning position corresponding to the peak of the modulation envelope of the intensity measurements collected during scanning. When white light is used as the source of illumination, the visibility of the fringes drops off rapidly from its maximum value at minimum OPD. FIG. **2** illustrates the modulation envelope E of a typical intensity signal I (irradiance) received at a detector cell in the image plane of the interferometer as the OPD is varied by vertically scanning the sample (or the objective). A measurement of relative surface height at the vertical-scanning point corresponding to the fringe-modulation peak Imax can thus be made. By simultaneously carrying out the procedure in parallel for each detector cell during vertical scanning, a three-dimensional height map can be obtained for the surface of the test sample. The point of maximum fringe visibility can be calculated from irradiance data using several known techniques. See, for example, the methods disclosed in U.S. Pat. No. 5,471,303 and U.S. Pat. No. 5,633,715.

According to the present invention, additional positioning mechanisms are incorporated into the conventional hardware of a Linnik interference objective. Referring to the drawings, wherein like parts are designated throughout with like numerals and symbols, FIG. **3** shows schematically a gear motor or equivalent device **40** rigidly coupled to a mounting structure **42** holding the lens **30** and the reference mirror R in fixed spatial relationship, so that the motor can translate both units together along the reference optical path of the objective **10**. The gear motor **40** is used to vary the distance D between the beam splitter **12** and the structure **42**

(i.e., the assembly containing the lens **30** and mirror R) in order to equalize the optical paths of the reference and test beams. Due to the relatively large adjustments that may be necessary to facilitate assembly of the objective **10** with typical mechanical components, the gear motor **40** is preferably selected with a range of about ½ mm, and in any event sufficient to translate the lens **30** and mirror R to a position in the D direction where the OPD is within the coherence length of the light source. Once adjusted to its nominal position, small, occasional motions in the position of lens **30** and mirror R to accommodate thermal, spectral, and other changes are required. A piezoelectric element **48**, also acting on the reference mirror R and lens **30** through the common support structure **42**, is provided to effect phase-shifting measurements after calibration.

In practice, the system of the invention is implemented by serially combining the gear motor or equivalent mechanism **40** used for minimizing OPD with the conventional piezoelectric mechanism used for conducting PSI profiling measurements. As illustrated in the partially cut-out view of FIG. **4**, the reference mirror R and lens **30** are fixedly assembled in an objective sleeve **44** mounted on the main body of the interference objective **10** by means of vertical flexures **46**. A piezoelectric actuator **48** causes the horizontal outward translation of the sleeve **44** against the flexures **46** that urge the sleeve toward the beam splitter **12** (not seen in FIG. **4**). The whole mechanism of the piezoelectric actuator **48** is coupled to the upper end of a pivoted lever arm **50**, and the lower end of the arm is coupled to the motor **40** of the invention. In the preferred embodiment of the invention, the output shaft of the motor **40** consists of a lead screw **52** threaded through a stationary lead nut **54** that engages the lever arm **50** by means of two lateral V-shaped ridges connected to conforming grooves in the lever arm. The screw **52** passes through the lever arm and is supported by a bearing **56** in the main body of the objective.

Thus, the series combination of the motor **40** and piezo actuator **48** provide a scanning mechanism capable of translating the objective sleeve **44** (and with it the reference optics **30** and mirror R) for the purpose of minimizing OPD as well as for performing phase-shifting measurements. FIG. **5** illustrates the extended position of the sleeve **44** with reference to the main body of the objective **10**. During OPD minimization, which may occur within the noted range of about ½ mm, the short-range actuator **48** functions as a coupling device to transmit the motion of the lever arm **50** to the sleeve **44** while the long-range motor **40** effects relatively large incremental steps. At each of these incremental positions during the long-range translation, the motor **40** is stopped and a measurement is made using the short-range piezoelectric actuator **48** and white light reduced in bandwidth and centered around an appropriate wavelength by the filter **32**. This measurement is referred herein as a PSI measurement because it is conducted in the same manner of conventional PSI measurements. Instead of measuring phase shift, though, the recorded frames of intensity data are used to produce average modulation data, which are then utilized as individual points to generate an average modulation curve tracking the long-range scan produced by the motor **40**. As well understood in the art, modulation (commonly also referred to as visibility or contrast) is defined as the ratio between the difference and the sum of the maximum and minimum intensities recorded over a predetermined scan range (i.e., modulation=$[I_{max}-I_{min}]/[I_{max}+I_{min}]$).

Each PSI measurement causes the signal at the detector to vary approximately sinusoidally, as illustrated in FIG. **2**. The average fringe modulation for the entire pixel array is recorded at each translation point by some averaging method (simple arithmetic averaging was used in testing the concept of the invention). Following long-range translation of the objective sleeve **44** through a predetermined range of motion, the translation location where the average fringe modulation is at a maximum is determined (i.e. the peak of the envelope, as illustrated in FIG. **6**, where incremental long-range steps of about ⅝ of a micron are shown for illustration), and the objective sleeve is returned to this position. If the peak fringe modulation is not found within the selected translation range, the range is increased and the procedure is repeated. Obviously, various known methods can be adopted to select the appropriate length of the long-range scan, its step size, and origin. For example, it may be advantageous to change the step size during a scan where modulation is measured for relatively large ranges, but the fundamental procedure is the same. The invention was tested by judiciously selecting initial values for these parameters, shifting the origin half the selected scan range in one direction from the current OPD position, and then scanning incrementally in the opposite direction over the selected range length.

When the point of minimum OPD is found, the calibration process is completed and normal PSI profilometric measurements may be carried out with white light (which may be appropriately filtered) in conventional manner using the piezoelectric actuator **48** while the motor **40** is inactive. It is noted that PSI measurements may also be carried out by varying the distance F or the distance F' (FIG. **3**), although this is generally inferior for PSI measurements at high numerical apertures because of the more non-collimated condition and corresponding error introduced by such lenses. During all phases of operation, the flexures **46** urge the objective sleeve **44** toward the splitter **12** (see FIG. **3**); that is, toward a direction of decreasing reference-beam path length.

In operation, the procedure of the invention is carried out advantageously in automatic fashion by first focusing the reference mirror R within the focal plane of the lens **30**; focusing the test surface S with respect to its optics **28**; and then minimizing the OPD between the reference and test optical paths by monitoring the average fringe modulation through short-range PSI measurements while scanning the reference arm of the objective with the long-range motorized mechanism, as described. These steps can be automated in relatively straightforward manner by adapting the same algorithms used for conventional VSI and PSI measurements. When the position of maximum average fringe modulation is found through the calibration process, the test surface S can be profiled by performing PSI after switching to the short-range piezoelectric scanner (illustrated by element **48**), or by VSI in the conventional manner (scanning the objective or the sample towards or away from each other). The procedure is outlined in FIG. **7**.

Thus, a new procedure and apparatus have been disclosed to improve the process of bringing the reference and test optical paths to within a small fraction of the coherence length of the light source. By utilizing a motorized implementation, the invention makes it possible to automate the procedure and optimize the process of minimization of the OPD between the test and reference beams. FIG. **8** illustrates the improvement provided by the invention in terms of consistency and repeatability in the process of OPD minimization. Over the course of seven trials conducted both automatically and manually by two separate operators, the range of peak average modulation corresponding to minimum OPD determined manually was three times as large, for both operators, as the range measured automatically.

As detailed in U.S. Pat. No. 5,978,086, it is critical to avoid shifts of the reference mirror R away from its best focus position. Therefore, it would be very advantageous if it were possible to reset the mirror's best-focus position as part of the same procedure by which the OPD is minimized. According to another aspect of the invention, we found that this can be accomplished if a test surface with specific characteristics is used.

In an effort to solve this problem, we investigated average fringe modulation as a function of changes of both the D and F distances (see FIG. **3**). We discovered that an average-modulation envelope such as shown in FIG. **2** can be observed and used advantageously from scanning in the OPD distance D even when the reference mirror R is away from its best focus position. That is, a poorly focused reference mirror still produces a significant peak in the average modulation curve obtained while scanning over the distance D (FIG. **3**) to minimize OPD. Therefore, the procedure outlined above to optimize OPD (FIG. **7**) is relatively insensitive to the focal position of the reference mirror. Unfortunately, this means that a single solution for maximum average fringe modulation as a function of D and F (i.e., in D,F space) does not exist.

In order to effectively determine both the D and F parameters at the same time, the functionality of the observed variable must provide a single-point peak in D,F space. We discovered that such an observable variable exists in the average lateral variation of modulation, rather than in the average modulation defined above. Average lateral variation of modulation is defined as the average change in modulation between proximate pixels, as further detailed below for the purposes of this disclosure. Accordingly, we selected a test surface S smooth enough for carrying out PSI measurements, but exhibiting sufficient nonuniformity in reflectivity to produce lateral variations in modulation. We found that we can use this fact, coupled with the physically smooth nature of the test surface, to optimize reference focus and OPD at the same time by noting that the average lateral variation in modulation will reach a maximum when both variables D and F are optimized.

Thus, there exists a three-dimensional solution space wherein the average lateral variation of fringe modulation can be plotted as a function of adjustment axes D and F. This is accomplished by varying both D and F and recording the average lateral variation of fringe modulation at each coordinate point in D,F space. The lateral variation of modulation V(x,y) is calculated at every detector-surface pixel location (x,y) by comparing the modulation M(x,y) at pixel (x,y) to its "lateral neighbors" as follows:

$$V(x,y)=abs(M(x,y)-[M(x+G_x,y)+M(x-G_x,y)+M(x,y+G_y)+M(x,y-G_y)]/4\}, \quad (2)$$

where G_x and G_y are the X and Y granularities, respectively. G_x and G_y represent the typical "grain size" in the modulation array, the grains being caused by dissimilar-material effects on the modulation, as well understood in standard image-processing techniques. For the purposes of the tests of the invention, we found that a G_x and a G_y equal to 10 (that is, comparing a pixel to neighbors ten steps removed) was optimal for the optical resolution provided by the system).

Thus, according to this aspect of the invention, an additional scanning mechanism **60** is required to translate the reference mirror R with respect to the lens **30**, as illustrated schematically in FIG. **9**. In practice, the mechanism **60** consists of a motor **60** adapted to rotate a collar **62** that supports the mirror R and is threaded onto the sleeve **44** holding the reference lens **30**, as shown in FIG. **10**. Therefore, as the collar **62** rotates, the distance F is varied (FIG. **9**).

An origin, two sets of scanning ranges, and related steps are selected, in similar manner as the procedure outlined above, to cover predetermined ranges for both D and F. At every point in (D,F) space, PSI measurements are conducted, by scanning preferably in the D dimension, but alternatively in the F (or F') dimension, to measure fringe modulation for every pixel in the detector array. The lateral variation of modulation is then calculated for each pixel using Equation (2) and an average V(x,y) for that D,F position, denoted by V_{avg}(D,F), is computed by some arbitrary criterion, such as simple arithmetic average. This average V(D,F) value represents a point on a three-dimensional (V_{avg},D,F) surface that we found to have a single maximum corresponding to optimal D and F values. Repeating the calculation of V_{avg}(D,F) at incremental D and F positions, this three-dimensional surface is generated and optimum focus and OPD positions are readily ascertained. As illustrated in FIG. **11**, the surface **64** is monotonic, which facilitates the process of finding its single maximum using conventional numerical methods. This occurs when the OPD is minimized and the reference mirror is simultaneously in best focus. It is noted that this procedure can be carried out advantageously using any known numerical algorithm for finding the maximum of a surface in three-dimensional space. During this scanning operation, the focal distance F' of the sample surface S may need adjustment to maintain the sample in the optimal in-focus position, as would be obvious to one skilled in the art. We found that automatic periodic refocusing of the surface S by conventional methods facilitates the process. The steps of the procedure are outlined in FIG. **12**.

We also discovered that a test surface S that is suitable for practicing this aspect of the invention is the air bearing surface (ABS) of a magnetic head. The ABS is a highly polished surface composed of multiple materials (typically aluminum oxide and titanium carbide). The reflectivity of these materials varies, such that, while the surface is smooth, an optical image of the surface exhibits bright and dark structural sections. This is illustrated in FIG. **13**, which is an intensity image of a region of an ABS.

A primary commercial application of interference microscopes is in the measurement of the topography of magnetic heads. Within these heads, the height of the poles and shields utilized in the process of writing and reading data is critical. These heights are typically measured with respect to the nearby air bearing surface. Thus, optimization of the properties of the interference objective used to measure these heights can be done very advantageously with the test surface itself, thereby eliminating the need for a separate calibration surface.

Those skilled in the art readily understand that theoretically the best conditions for performing a surface measurement by interferometry are achieved when maximum fringe contrast is produced, although practical considerations often warrant some additional adjustments. FIG. **14**, corresponding to the sample surface of FIG. **13**, is an example of the sharp fringe modulation produced when D and F are optimized according to the invention. In comparison, FIG. **15** is an example of the same modulation image produced when D and F have not been optimized.

Therefore, various changes in the details, steps and components that have been described may be made by those skilled in the art within the principles and scope of the

invention herein illustrated and defined in the appended claims. For example, various kinds of long-range, linear scanning mechanisms could be used with equivalent results. Similarly, various alternative VSI or PSI algorithms known in the art could be used to find the position of maximum fringe contrast and maximum variation of fringe contrast. Moreover, the invention has been described in terms of a white-light instrument used for conducting surface measurements by phase-shifting interferometry, but it should not be so limited because the same principles can be applied to any interferometer using broad-bandwidth light, whether for PSI or VSI measurements. Thus, while the present invention has been shown and described herein in what is believed to be the most practical and preferred embodiments, it is recognized that departures can be made therefrom within the scope of the invention, which is not to be limited to the details disclosed herein but is to be accorded the full scope of the claims so as to embrace any and all equivalent processes and products.

We claim:

1. A method for minimizing the optical path difference between a test beam path and a reference beam path produced in an interference microscope objective having a reference-arm assembly that comprises a reference lens and a reference mirror, and having first scanning means for carrying out interference measurements of a test surface, the method comprising the following steps:

(a) providing second scanning means for translating the reference-arm assembly along said reference beam path;

(b) translating the reference-arm assembly through a plurality of positions along the reference beam path using said second scanning means;

(c) measuring a fringe modulation at predetermined locations corresponding to said plurality of positions along the reference beam path;

(d) determining a location of the reference-arm assembly along the reference beam path corresponding to an optimal fringe modulation; and

(e) fixing said optimal-fringe-modulation location of the reference-arm assembly such that interferometric measurements of the test surface may be carried out by varying the optical path difference therefrom.

2. The method of claim **1**, wherein said step (c) is carried out by performing phase-shifting interferometric measurements at each of said plurality of positions.

3. The method of claim **1**, wherein said optimal fringe modulation is selected to correspond to a maximum fringe modulation and said step (d) is carried out by performing vertical-scanning interferometry analysis with the fringe modulation data produced by step (c) at each of said plurality of positions.

4. The method of claim **3**, wherein said fringe modulation at each of said plurality of positions along the reference beam path is an average of modulation components calculated for individual pixels of a light detector.

5. The method of claim **1**, wherein said second scanning means includes a gear motor.

6. The method of claim **1**, wherein said steps (b), (c), (d) and (e) are carried out automatically.

7. A method for minimizing the optical path difference between a test beam path and a reference beam path produced in an interference microscope objective having a reference-arm assembly that comprises a reference lens and a reference mirror, and for contemporaneously optimizing the focal position of the reference mirror, wherein the objective comprises first scanning means for carrying out interference measurements of a test surface, the method comprising the following steps:

(a) providing second scanning means for translating the reference-arm assembly in an OPD dimension along said reference beam path;

(b) providing third scanning means for translating the reference mirror with respect to the reference lens in a focal-distance dimension along said reference beam path;

(c) measuring a fringe modulation at predetermined locations corresponding to a plurality of OPD and focal-distance positions obtained using said second and third scanning means;

(d) calculating a lateral variation of fringe modulation for each of said predetermined locations;

(e) determining an optimal OPD position and an optimal focal-distance position corresponding to an optimal lateral variation of fringe modulation; and

(f) fixing the OPD and focal-distance positions at said optimal OPD and focal-distance positions such that interferometric measurements of the test surface may be carried out by varying the OPD therefrom.

8. The method of claim **7**, wherein said step (c) is carried out by performing phase-shifting interferometric measurements at each of said plurality of OPD and focal-distance positions.

9. The method of claim **7**, wherein said optimal lateral variation of fringe modulation is selected to correspond to a maximum lateral variation of fringe modulation and said step (e) is carried out by finding said maximum using the lateral variation of fringe modulation calculated for said predetermined locations.

10. The method of claim **9**, wherein said step (e) is carried out by performing vertical-scanning interferometry analysis with the later variation of fringe modulation data produced by step (d) at each of said plurality of positions.

11. The method of claim **9**, wherein said lateral variation of fringe modulation at each of said predetermined locations is an average of lateral variation of fringe modulation components calculated for individual pixels of a light detector.

12. The method of claim **7**, wherein each of said second and third scanning means includes a gear motor.

13. The method of claim **7**, wherein said steps (c), (d), (e) and (f) are carried out automatically.

14. An apparatus for minimizing the optical path difference between a test beam path and a reference beam path produced in an interference microscope objective having a reference-arm assembly that comprises a reference lens and a reference mirror and having first scanning means to carry out interference measurements of a test surface, comprising:

second scanning means to effect a translation of the reference-arm assembly along said reference beam path;

means for measuring a fringe modulation at a plurality of positions along the reference beam path scanned by said second scanning means;

means for determining a position of the reference-arm assembly along the reference beam path corresponding to an optimal fringe modulation; and

means for fixing said position of the reference-arm assembly such that interferometric measurements of the test surface may be carried out by translating the reference-arm assembly therefrom.

15. The apparatus of claim 14, wherein said optimal fringe modulation is selected to correspond substantially to maximum fringe modulation.

16. The apparatus of claim 15, wherein said means for determining a position of the reference-arm assembly along the reference beam path corresponding to maximum fringe modulation includes means for carrying out vertical-scanning interferometry analysis with the fringe modulation data measured at each of said plurality of positions.

17. The apparatus of claim 14, wherein said means for measuring a fringe modulation at a plurality of positions includes means for carrying out phase-shifting interferometric measurements at each of said plurality of positions.

18. The apparatus of claim 14, wherein said fringe modulation at each of said plurality of positions along the reference beam path is an average of fringe-modulation components calculated for individual pixels of a light detector.

19. The apparatus of claim 14, wherein said second scanning means includes a gear motor.

20. An apparatus for minimizing the optical path difference between a test beam path and a reference beam path produced in an interference microscope objective having a reference-arm assembly that comprises a reference lens and a reference mirror, and for contemporaneously optimizing the focal position of the reference mirror, the apparatus having first scanning means for carrying out interference measurements of a test surface, comprising:

second scanning means for translating the reference-arm assembly in an OPD dimension along said reference beam path;

third scanning means for translating the reference mirror with respect to the reference lens in a focal-distance dimension along said reference beam path;

means for measuring a fringe modulation at predetermined locations corresponding to a plurality of OPD and focal-distance positions obtained using said second and third scanning means;

means for calculating a lateral variation of fringe modulation for each of said predetermined locations;

means for determining an optimal OPD and focal-distance position corresponding to an optimal lateral variation of fringe modulation; and

means for fixing the OPD and focal-distance positions at said optimal OPD and focal-distance positions such that interferometric measurements of the test surface may be carried out by varying the OPD therefrom.

21. The apparatus of claim 20, wherein said optimal lateral variation of fringe modulation is selected to correspond substantially to a maximum lateral variation of fringe modulation.

22. The apparatus of claim 21, wherein said means for determining an optimal OPD and focal-distance position corresponding to a maximum lateral variation of fringe modulation includes means for carrying out vertical-scanning interferometry analysis with lateral variation of fringe modulation data calculated at said predetermined locations.

23. The apparatus of claim 20, wherein said means for measuring a fringe modulation at predetermined locations corresponding to a plurality of OPD and focal-distance positions includes means for carrying out phase-shifting interferometric measurements at each of said plurality of OPD and focal-distance positions.

24. The apparatus of claim 20, wherein said lateral variation of fringe modulation for each of said predetermined locations corresponding to said plurality of OPD and focal-distance positions is an average of lateral variation of fringe-modulation components calculated for individual pixels of a light detector.

25. The apparatus of claim 20, wherein each of said second and third scanning means include a gear motor.

(57) **ABSTRACT**

A portable TV telephone has an objective lens system configured to form an image of an object and an antenna configured to transmit and receive at least one of an image signal representing the image of the object, a dial signal and a voice signal carried by radio waves. A display unit is configured to display at least a dial number and the image of the object and a switch is configured to operate responsive to at least the dial number. The objective lens system includes a diffractive optical element configured to at least correct chromatic aberration produced by the objective lens system. The objective lens system includes, in order from an object side, a first negative lens unit and a second positive lens unit.

OBJECTIVE LENS SYSTEM

This is a division of application Ser. No. 09/455,362 filed Dec. 6, 1999, now U.S. Pat. No. 6,243,217, which is a divisional of application Ser. No. 08/713,069 filed Sep. 12, 1996, now U.S. Pat. No. 5,999,327, the entire contents of each being incorporated by reference.

BACKGROUND OF THE INVENTION

a) Field of the Invention

The present invention relates to an objective lens system which uses a radial type gradient index lens element.

b) Description of the Prior Art

As conventional examples of lens systems having relatively wide field angle and high optical performance which are used, for example, as objective lens systems for endoscopes, there are known many lens systems such as a lens system disclosed by Japanese Patent Kokoku Publication No. Sho 60-46410 shown in FIG. **1**. A conventional example shown in FIG. **1** is a lens system of the so-called retrofocus type which is composed, in order from the object side, of a front lens unit having negative refractive power, a stop and a rear lens unit having a positive refractive power. In this lens system, the front lens unit has a function to widen a field angle and another function to correct curvature of field by reducing a Petzval's sum of the lens system as a whole, the rear lens unit serves for suppressing production of spherical aberration and coma by distributing refractive powers among three positive lens elements and a cemented lens component, and the cemented lens component corrects lateral chromatic aberration which poses a problem, in particular, in a lens system which has a wide field angle. Though this conventional example favorably corrects aberrations, it is composed of lens elements in a number as large as six, thereby posing a problem of low producibility or a high manufacturing cost. Accordingly, it is expected to develop a retrofocus type objective lens system for endoscopes which is composed of an extremely small number of lens elements and has a high producibility. However, a lens system which favorably corrects aberrations and has high optical performance can hardly be composed of two homogenous spherical lens elements.

Further, an endoscope is generally equipped with a system for illuminating a location to be observed since it is used frequently for observing and photographing dark locations such as interiors of human bodies, aircraft engines, pipings and so on. In addition, an objective lens system for endoscopes has an NA which is not so large for obtaining a large depth of field. Accordingly, axial aberrations do not pose a serious problem, but a wide field angle and a negative-positive asymmetrical composition as shown in FIG. **1** make it difficult to correct offaxial aberrations. When an objective lens system is to be composed of two negative and positive lens elements, it is impossible to use a cemented lens component as in the objective lens system disclosed by Japanese Patent Kokoku Publication No. Sho 60-46410 mentioned above as the conventional example, whereby lateral chromatic aberration can hardly be corrected and offaxial imaging performance is remarkably degraded. It is therefore difficult to favorably correct offaxial aberrations with two homogenous lens elements so as to obtain favorable offaxial imaging performance.

It is therefore conceivable to use a radial type gradient index lens element which is characterized in that it corrects chromatic aberration in particular more favorably than a homogenous lens element. As a conventional example of an objective lens system for endoscopes which uses a radial type gradient index lens element and is composed of two lens elements, there is known a lens system disclosed by Japanese Patent Kokai Publication No. Sho 52-29238. However, this conventional example has a field angle as narrow as 72° which is insufficient for use as an objective lens system for endoscopes.

Further, a lens system disclosed by Japanese Patent Kokai Publication No. Hei 5-107471, for example, is known as a conventional example of an objective lens system having a wide field angle obtained with two lens elements. Though this example uses a radial type gradient index lens element, it does not effectively make use of the chromatic aberration correcting capability of the radial type gradient index lens element and does not sufficiently correct lateral chromatic aberration which poses a problem in a lens system having a wide field angle in particular.

SUMMARY OF THE INVENTION

A primary object of the present invention is to provide an objective lens system which is composed of lens elements in a number on the order of 2, that favorably corrects aberrations and has a wide field angle.

The objective lens system according to the present invention is characterized in that it comprises, in order from the object side, a first lens unit having a negative refractive power and a second lens unit having a positive refractive power, that at least the first lens unit comprises a radial gradient index lens element which has a refractive index distribution in a radial direction of the lens element; and that the first lens unit satisfies that following condition (1):

$$1/V_{10}<1/V_{00} \tag{1}$$

wherein the reference symbols V_{00} and V_{10} represent parameters expressing a dispersing power of the radial type gradient index lens element which are given by the following formula (b) and (c) respectively:

$$V_{00}=(N_{00d}-1)/(N_{00F}-N_{00C}) \tag{b}$$

$$V_{10}=N_{10d}/(N_{10F}-N_{10C}) \tag{c}$$

wherein the reference symbols N_{00d}, N_{00F}, and N_{00C} represent refractive indices of the radial type gradient index lens element for the d-line, F-line and C-line respectively, and the reference symbols N_{10d}, N_{10F}, and N_{10C}) designate values of a coefficient of a term r^2 for the d-line, F-line and C-line respectively when a refractive indices of the radial type gradient index lens element is expressed in a form of a poly-nominal. In embodiments of the present invention which are to be described later, refractive indices of radial type gradient index lens element are given by the following formula (a):

$$n(r)=N_{00}+N_{10}r^2+N_{20}r^4+\ldots \tag{a}$$

wherein the reference symbol r represent a distance as measured from an optical axis in a radial direction of the radial type gradient index element and the reference symbol n(r) designates a refractive index of a portion of the radial type gradient index lens element located at the distance r.

Further, the objective lens system according to the present invention is characterized in: that it is composed, in order from the object side, of a first lens unit having a negative refractive power, and a second lens unit having a positive refractive power, that at least the second lens unit comprises a radial type gradient index lens element having a refractive

index distribution in a radial direction of the lens element, and that the second lens unit satisfies the following conditions (1) and (3):

$$1/V_{10}<1V_{00} \quad (1)$$

$$0.05<\phi_{2m}/\phi<1.0 \quad (3)$$

wherein the reference symbols ϕ_{2m} represents a refractive index of a medium of the radial type gradient lens element used in the second lens unit.

Further, it is desirable that the objective lens system according to the present invention described above satisfies the following condition (2):

$$-0.5<\phi_{1m}/\phi<-0.02 \quad (2)$$

wherein the reference symbol ϕ_{1m} represent a refractive power of a medium of the radial type gradient index lens element used in the first lens unit and the reference symbol ϕ designates a refractive power of the objective lens system as a whole.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** shows a sectional view illustrating a composition of a conventional objective lens system;

FIG. **2** shows a diagram schematically showing a fundamental composition of the objective lens system according to the present invention;

FIG. **3** shows a diagram schematically showing the fundamental composition of the objective lens system according to the present invention wherein an image surface is positioned in parallel with an optical axis;

FIGS. **4** through **15** show sectional views illustrating compositions of first through twelfth embodiments of the objective lens system according to the present invention;

FIGS. **16**A and **16**B show views illustrating a composition of a thirteenth embodiment of the objective lens system according to the present invention;

FIGS. **17** through **21** show sectional views illustrating composition of fourteenth through eighteenth embodiments of the objective lens system according to the present invention;

FIGS. **22**A, **22**B and **22**C show diagrams exemplifying a shape, before working, of a lens element which is to be used in the objective lens system according to the present invention;

FIGS. **23**A, **23**B and **23**C show diagrams exemplifying a shape, after working, of the lens system which is to be used in the objective lens system according to the present invention;

FIG. **24** is a diagram showing an example of a stop which is to be disposed in the objective lens system according to the present invention;

FIG. **25** is a diagram showing another example of a stop which is to be disposed in the objective lens system according to the present invention;

FIGS. **26** through **31** show sectional views illustrating compositions of nineteenth through twenty-fourth embodiments of the objective lens system according to the present invention;

FIG. **32** shows a perspective view illustrating an endoscope which uses the objective lens system according to the present invention;

FIG. **33** shows a side view of a non-flexible endoscope which uses the objective lens system according to the present invention;

FIG. **34** shows a perspective view illustrating a video camera which uses the objective lens system according to the present invention;

FIG. **35** shows a perspective view illustrating a portable TV telephone which uses the objective lens system according to the present invention; and

FIG. **36** shows a perspective view illustrating a portable data input unit which uses the objective lens system according to the present invention.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

It is desirable that an objective lens system which has a relatively wide field angle for use in endoscopes, for example, is configured as the so-called retrofocus type composed, in order from the object side, of a first lens unit having a negative refractive power and a second lens unit having a positive refractive power.

Further, it is desirable that endoscopes, for example, which are inserted into human bodies and pipings for observing interiors thereof use objective lens systems having small diameters. When the lens system according to the present invention is to be used as an objective lens system for endoscopes, it is desirable for reducing a diameter of the lens system to compose it by disposing a stop between a negative lens unit and a positive lens unit. By selecting such a composition, it is possible to lower heights of rays passing through a first lens unit or a second lens unit, thereby reducing the diameter of the lens system. When the lens system has an asymmetrical composition, or is composed of a positive lens unit and a negative lens unit disposed on both sides of a top, however, offaxial aberrations are apt to be produced in large amounts in the lens system as a whole, or it is difficult to favorably correct lateral chromatic aberration in particular. For favorably correcting lateral chromatic aberration, it is desirable to use a radial type gradient index lens element which has a more excellent characteristic for correcting chromatic aberration than a homogenous lens element.

It is known that lateral chromatic aberration LTC produced by a thin radial type gradient index lens element is expressed by the following formula (d):

$$LTD=K(\phi_s/V_{00}+\phi_m/V_{10}) \quad (d)$$

wherein the reference symbol K represents a constant determined dependently on a height of an offaxial ray and an angle of a final axial ray, the reference symbol (ϕ_s designates a refractive power of a surface of the radial type gradient index lens element and the reference symbol (ϕ_m denotes a refractive power of a medium of the radial type gradient index lens element which is known to be approximated by the following formula (e):

$$\phi_m=31\ 2N_{10}d_G \quad (e)$$

wherein the reference symbol d_G represents thickness of the radial type gradient index lens element.

As is apparent from the formula (d), it is possible to control an amount of chromatic aberration to a desired value by varying V_{10} in the second term of the formula.

Since the objective lens system according to the present invention has an asymmetrical composition, like the model of thin lens elements shown in FIG. **2**, wherein a first negative lens unit L_1 and a second positive lens unit L_2 are disposed in that order from the object side and on both side of a stop S, each of the lens units refracts a ray RO coming

from an offaxial object point, unlike a ray RA coming from an axial object point, in a direction which is the same as a refracted direction (downward in FIG. **2**) of an incident light bundle. Accordingly, lateral chromatic aberration is produced in a very large amount in the objective lens system according to the present invention, thereby making it difficult to compose the objective lens system, in order from the object side, of a negative lens unit and a positive lens unit which consist of two homogenous lens elements.

For solving this problem or favorably correcting lateral chromatic aberration by adopting a radial type gradient index lens element, it is conceivable to select either of two cases: one where the radial index lens element is used in the first negative lens unit and the other where the radial gradient lens element is used in the second positive lens unit.

Description will be made of a first composition of the objective lens system according to the present invention where a radial gradient index element is used in the first negative lens unit.

For allowing a radial type gradient index lens element to produce chromatic aberration in an amount smaller than that of chromatic aberration produced by a homogenous lens element which has the same refractive power as that of the radial type gradient index lens element, it is necessary to form the formula (d) to satisfy the following relationship:

$$\phi_s/V_{00}+\phi_m/V_{10}<\phi_1/V_{00}$$

wherein the reference symbol ϕ_t represents a refractive power of the homogenous lens element on an assumption that it has an Abbe's number which is equal to that on the optical axis of the radial type gradient index lens element.

Since the radial type gradient index lens element and the homogenous lens element which are compared with each other have the same refractive power, we obtain:

$$\phi_t=\phi_2+\phi_m$$

From the two formulae mentioned above, there establishes the following relationship:

$$\phi_2/V_{00}+\phi_m/V_{10}<\phi_s/V_{00}+\phi_m/V_{00}$$

The above-mentioned condition (1) is obtained from this formula.

For favorably correcting lateral chromatic aberration in the objective lens system according to the present invention, it is desirable to use a radial type gradient index lens element satisfying the condition (1) as the first lens unit which has the negative refractive power as described above. The condition (1) is required for allowing a radial type gradient index lens element to produce chromatic aberration in an amount smaller than that of chromatic aberration produced by a homogenous lens element which has the same refractive power as that of the radial type gradient index lens element. If the condition (1) is not satisfied, a radial type gradient index lens element cannot correct lateral chromatic aberration more favorably than a homogenous lens element which has the same refractive power as that of the radial type gradient index lens element.

When a radial type gradient index lens element is to be used for correcting lateral chromatic aberration, it is necessary, as apparent from the formula (d), to take into sufficient consideration not only a value of V_{10} but also refractive powers of a surface and a medium. For reducing an amount of lateral chromatic aberration to be produced by the first lens unit in the objective lens system according to the present invention, it is desirable from the formula (d) to meet the following equation:

$$\phi_s/V_{00}+\phi_m/V_{10}=0$$

By using a total refractive power of a surface and a medium ϕ_G ($=\phi_s+\phi_m$) in this formula and developing it, we obtain:

$$\phi_m=\phi_G\times V_{10}/(V_{10}-V_{00})$$

Since the Abbe's number V_{00} of a radial type gradient index lens element ordinarily has a value on the order of 30 to 80 on an optical axis and the first lens unit has the negative refractive power, the condition (1) required for correcting chromatic aberration can be transformed as follows:

$$\phi_G\times V_{10}/(V_{10}-V_{00})<0$$

It is desirable as understood from this formula that a medium has a negative refractive power. Taking into consideration this fact and the requirement to correct lateral chromatic aberration favorably in the objective lens system as a whole, it is desirable that a radial type gradient index lens element which is to be used in the objective optical system according to the present invention is made of a medium having a refractive power ϕ_{1m} satisfying the above-mentioned condition (2).

When a ratio of a refractive power of a medium of the first lens unit relative to a refractive power of the objective lens system satisfies the condition (2), it is possible to correct lateral chromatic aberration favorably in the objective lens system as a whole. If the upper limit of −0.02 of the condition (2) is exceeded, a medium of the radial type gradient index lens element will have a weak refractive power, thereby undesirably making it difficult to correct lateral chromatic aberration favorably in the objective lens system as a whole. If the lower limit of −0.5 of the condition (2) is not satisfied, in contrast, a medium will have too strong a refractive power, thereby overcorrecting lateral chromatic aberration.

The objective lens system according to the present invention which has a second composition is composed of a first lens unit having a negative refractive power and a second lens unit having a positive refractive power; a radial type gradient index lens element being used in the second lens unit having the positive refractive power; and the radial type gradient index lens element used in the second lens unit having a refractive index expressed by the above-mentioned formula (a) and satisfying the following conditions (1) and (3):

$$1/V_{10}<1/V_{00} \quad (1)$$

$$0.05<\phi_{2m}/\phi<1.0 \quad (3)$$

wherein the reference symbol ϕ_{2m} represents a refractive power of the gradient index lens element which is used in the second lens unit and the reference symbol ϕ designates a refractive power of the objective lens system as a whole.

Since lateral chromatic aberration is produced in a very large amount in the objective lens system as a whole as described above, it is difficult to compose the lens system, in order from the object side, of two negative and positive homogenous lens elements. When a radial type gradient index lens element is to be used in the second lens unit for solving this problem or favorably correcting lateral chromatic aberration, it is desirable to configure this lens element so as to satisfy the condition (1) mentioned above.

The condition (1) is required for allowing the radial type gradient index lens element to produce chromatic aberration in an amount smaller than that of chromatic aberration produced by a homogenous lens element which has the same refractive power as that of the radial type gradient index lens element.

If the condition (1) is not satisfied, the radial type gradient index lens element cannot correct chromatic aberration more favorably than the homogenous lens element having the same refractive power as that of the radial type gradient index lens element.

When a radial type gradient index lens element is to be used for correcting lateral chromatic aberration, it is necessary to take into consideration not only a value of V_{10} but also refractive powers of a surface and a medium as described above. When lateral chromatic aberration produced by the second lens unit is to be reduced in the objective lens system according to the present invention, the formula (d) is transformed, as in the case where a radial type gradient index lens element is used in the first lens unit, into the following formula:

$$\phi_m = \phi_G \times V_{10}/(V_{10}-V_{00})$$

Since the second lens unit has a positive refractive power, it is desirable that ϕ_m has a positive value. When a radial type gradient index lens element is to be used in the second lens unit for correcting lateral chromatic aberration favorably in the objective lens system as a whole, it is desirable that the refractive power ϕ_m of a medium satisfies the above-mentioned condition (3).

When a ratio of a refractive power of medium relative to a refractive power of the objective lens system as a whole satisfies the condition (3), it is possible to correct lateral chromatic aberration favorably in the objective lens system as a whole.

If the lower limit of 0.05 of the condition (3) is not satisfied, a medium of the radial type gradient index lens element will have a weak refractive power, thereby undesirably making it difficult to correct lateral chromatic aberration favorably in the objective lens system as a whole. If the upper limit of 1.0 of the condition (3) is exceeded, in contrast, a refractive power of medium will be too strong, thereby undesirably overcorrecting lateral chromatic aberration.

The condition (3) is required also for favorably correcting not only chromatic aberration but also the other aberrations.

The objective optical system according to the present invention which has a wide field angle produces a positive Petzval's sum in the lens system as a whole, thereby tending to tilt an image surface toward the object side. For favorably correcting this Petzval's sum, it is desirable to use a radial type gradient index lens element in the second lens unit which has a large positive Petzval'sum.

A Petzval's sum PTZ of a radial type gradient index lens element is expressed by the following formula (f):

$$PTZ = \phi_s/N_{00} + \phi_m/N_{00}^2 \quad (f)$$

As is apparent from the formula (f) in which the denominator of the second term on the right side is squared, it is possible to configure a radial type gradient index lens element so as to have a Petzval's sum which is smaller than of a homogenous lens element having the same refractive power as that of the radial type gradient index lens element.

For reducing a Petzval's sum of the objective lens system with a radial type gradient index lens element, it is desirable from the formula (f) that the radial type gradient index lens element satisfies the following formula:

$$\phi_s/N_{00} + \phi_m/N_{00}^2 = 0$$

The formula shown below can be derived by using a total refractive power of surface and medium ϕ_G ($=\phi_2+\phi_m$) in the above formula and developing it.

$$\phi_m = \phi_G \times N_{00}/(N_{00}-1$$

Since refractive indices N_{00} on an optical axis of radial gradient index lens elements ordinarily have values larger than 1, or on the order of 1.45 to 1.85, it is desirable for favorably correcting a Petzval's sum to use a radial type gradient index lens element which has a positive refractive power of medium when it is to be used in the second lens unit having the positive refractive power. If a radial type gradient index lens element which has a negative refractive power of medium is used in the second lens unit, the positive Petzval's sum will be further enlarged, hereby undesirably tilting an image surface toward the object side.

For correcting the Petzval's sum in the objective lens system according to the present invention, it is desirable from the formula (f) that a refractive power of medium is strong to a certain degree or refractive power of medium ϕ_m satisfies the condition (3). When a ratio of the refractive power of medium relative to a refractive power of the objective lens system as a whole satisfies the condition (3), it is possible to favorably correct the Petzval's sum in the objective lens system as a whole. If the lower limit of 0.05 of the condition (3) is not satisfied, a refractive power of medium will be weak, thereby making it difficult to correct the Petzval's sum favorably in the objective lens system as a whole. If the upper limit of 1.0 of the condition (3) is exceeded, in contrast, a refractive power of medium will be too strong and the Petzval's sum will be overcorrected, thereby undesirably tilting an image surface in a direction away from the object side.

As understood from the foregoing description, the condition (3) is required for favorably correcting lateral chromatic aberration and Petzval's sum at the same time in the objective lens system according to the present invention (which has the second composition).

Further, an objective lens system for endoscopes is generally used in combination with a solid-state image pickup device such as CCD or an end surface of the so-called image guide composed of an optical fiber bundle which is disposed on an image surface. When a objective lens system is to be combined not with a silver salt photographic film but with a solid-state image pickup device or an image guide, it is desirable for enhancing a light condensing efficiency to configure the objective lens system so as to be telecentric on the image side so that incident rays are as perpendicular as possible to an image surface. For configuring the objective lens system according to the present invention so as to meet this requirement, the second lens unit having the positive refractive power must have an image side surface which has a positive refractive power stronger than that of an object side surface thereof. When the image side surface of the second lens unit on which offaxial rays are relatively high has a strengthened refractive power in the objective lens system according to the present invention having a wide field angle, however, this surface will produce coma in a large amount and it will be difficult to correct this coma favorably with a homogenous lens element.

Accordingly, it was conceived to correct coma favorably in the objective lens system according to the present invention with a radial type gradient index lens element used in the second lens unit. For correcting this aberration, it is desirable that the radial type gradient index lens element has such a refractive index distribution as to progressively lower refractive indices from the optical axis toward a marginal portion. An amount of coma to be produced by the image side surface of the second lens unit can be reduced by configuring the radial type gradient index lens element to be used in the second lens unit so as to have such a refractive

index distribution. Therefore, the condition (3) serves for favorable correction of coma in addition to favorable correction of lateral chromatic aberration. When the condition (3) is satisfied, the radial type gradient index lens element has a refractive index distribution wherein refractive indices are progressively lowered from the optical axis toward the marginal portion, thereby being capable of favorably correcting coma. If the lower limit of 0.05 of the condition (3) is not satisfied, it will be difficult to favorably correct coma with the radial type gradient index lens element. If the upper limit of 1.0 of the condition (3) is exceeded, in contrast, coma will undesirably be overcorrected.

Since the objective lens system according to the present invention has a wide field angle and the asymmetrical composition which is negative-positive in order from the object side, it tends to produce remarkable barrel form distortion which can hardly be corrected favorably with two homogenous lens elements. For correcting the barrel form distortion favorably in the objective lens system according to the present invention, it is desirable to use, in the second lens unit having the positive refractive power, a radial type gradient index lens element which has a refractive index distribution wherein refractive indices are progressively lowered from the optical axis toward the marginal portion. Distortion to be produced by the second lens unit can be reduced by using a radial type gradient index lens element having such a refractive index distribution. Accordingly, the condition (3) serves for favorable correction of distortion in addition to favorable correction of lateral chromatic aberration. When the condition (3) is satisfied, refractive indices are progressively lowered from the optical axis toward the marginal portion, thereby enabling to favorably correct distortion. If the lower limit of 0.05 of the condition (3) is not satisfied, it will be difficult to favorably correct distortion with a radial type gradient index lens element. If the upper limit of 1.0 of the condition (3) is exceeded, in contrast, aberrations other than distortion will undesirably be overcorrected.

The objective lens system according to the present invention which has a third composition is characterized in: that it is composed, in order from the object side, of a first lens unit having a negative refractive power and a second lens unit having a positive refractive power; that it uses at least one radial type gradient index lens element having a refractive index distribution in a radial direction from an optical axis which is expressed by the formula (a); and that at least one the of surfaces of lens elements including the radial type gradient index lens element composing the lens system is configured as an aspherical surface which has such a shape as to weaken a refractive power of the lens element having the aspherical surface from the optical axis toward the marginal portion.

Since the objective lens system according to the present invention has a wide field angle and an asymmetrical composition which is negative-positive in order from the object side, it tends to produce remarkable distortion in addition to lateral chromatic aberration. Though distortion can be corrected to a certain degree by using a radial type gradient index lens element in the second lens unit as described above, it is desirable for correcting distortion more favorably to configure the objective optical system according to the present invention so as to comprise at least one surface of at least one lens element which is configured as an aspherical surface having such a shape as to weaken a refractive power of the lens element having the aspherical surface from the optical axis toward the marginal portion. In the objective lens system according to the present invention, barrel form distortion is produced by both the first lens unit having the negative refractive power and the second lens unit having the positive refractive power. When an aspherical surface is to be used in either of the lens units in the objective lens system, it is therefore desirable to configure the aspherical surface so as to have such a shape as to weaken a refractive power from the optical axis toward the marginal portion of the lens element using the aspherical surface. When the second lens unit uses a radial type gradient index lens element, for example, it is desirable to use an aspherical surface in the first lens unit having the negative refractive power and configure the aspherical surface so as to have such a shape as to weaken the negative refractive power from the optical axis toward the marginal portion. Though distortion produced by the second lens unit can be corrected to a certain degree by using a radial type gradient index lens element in the second lens unit as described above, distortion can be corrected more favorably by using an aspherical surface in the first lens unit.

When a radial type gradient index lens element is used in the first lens unit, it is desirable to use, in the second lens unit having a positive refractive power, an aspherical surface which has such a shape as to weaken the positive refractive power toward the optical axis to a marginal portion.

If an aspherical surface has such a shape as to strengthen the refractive power of a lens unit which comprises this aspherical surface, it will undesirably make barrel form distortion more remarkable in the objective lens system as a whole.

It is needless to say that an effect similar to that described above can be obtained by configuring a surface of a radial type gradient index lens element as an aspherical surface.

For correcting lateral chromatic aberration in the objective lens system according to the present invention which has the third composition, it is desirable to configure the radial type gradient index lens element so as to satisfy the condition (1). If the condition (1) is not satisfied, lateral chromatic aberration will undesirably be more remarkable in the objective lens system according to the present invention.

It is needless to say that lateral chromatic aberration can be corrected more favorably by using two radial type gradient index lens elements when the objective lens system according to the present invention is to be composed of two negative and positive lens elements.

It is also needless to say that distortion can be corrected more favorably by using an aspherical surface on each of the lens elements when the objective lens system is to be composed of two negative and positive lens elements.

The objective lens system according to the present invention which has a fourth composition is characterized in that it is composed, in order from the object side, of a first lens unit having a negative refractive power and a second lens unit having a positive refractive power. The second lens unit comprises at least one radial type gradient index lens element which has a refractive index distribution in a radial direction expressed by the formula (a), or wherein refractive indices are progressively lowered from an optical axis toward a marginal portion. The radial type gradient index lens element has a shape of a positive lens element. The radial type gradient index lens element satisfies the condition (1).

When a radial type gradient index lens element is to be used in the second lens unit, it is desirable for correcting lateral chromatic aberration to configure it so as to satisfy the condition (1) as described above, and it is desirable for correcting a Petzval's sum, coma or distortion that this lens element has a refractive index distribution wherein refrac-

tive indices are lowered from the optical axis toward the marginal portion. When not only correction of aberrations but also manufacturing facility are taken into consideration, it is desirable that the radial type gradient index lens element has a shape of a positive lens element.

Since the objective lens system according to the present invention has a wide field angle, it is necessary that the second lens unit has a strong positive refractive power. When a radial type gradient index lens element is to be used in the second lens unit, it is therefore desirable that the radial type gradient index lens element also has a strongly positive refractive power. However, it is undesirable that the radial type gradient index lens element has an extremely strong positive refractive power of medium for a reason described below. As apparent from the formula (e), it is sufficient for strengthening a refractive power of medium of a radial type gradient index lens element to enlarge an absolute value of the refractive index distribution coefficient of the second order N_{10} or thickness d_G of the radial type gradient index lens element. However, an absolute value of the refractive index distribution coefficient of the second order can be enlarged only within a range limited by preparation of materials and enlargement of thickness d_G makes it difficult to configure the objective lens system compactly, thereby making it unusable as an objective lens system for endoscopes, for example, which are desired to be compact. Accordingly, it is desirable not to impart an extremely strong positive refractive power to a medium but to impart refractive powers to both the medium and surfaces, or configure the radial type gradient index lens element so as to have a shape of a positive lens element.

The objective lens system according to the present invention which has a fifth composition is characterized in that it is composed, in order from the object side, of a first lens unit having a negative refractive power and a second lens unit having a positive refractive power; that it uses at least one lens element which is configured as a radial type gradient index lens element having a refractive index distribution in the radial direction from an optical axis expressed by the formula (a); and that a lens unit comprising the radial type gradient index lens element or at least one optical element disposed in the objective lens system has a function to shield components having specific wavelengths.

By using a radial type gradient index lens element, it is possible to obtain an objective lens system which favorably corrects chromatic aberration in particular and has high imaging performance. An objective lens system for endoscopes which comprises a solid-state image pickup device such as a CCD, for example, may use an infrared cut filter for cutting off rays in the infrared region since the image pickup device has high sensitivity at wavelengths in the infrared region. Further, such an optical system may use a low pass filter made, for example, of quartz for eliminating noise components produced due to moire. Furthermore, such an objective lens system may use a band cut filter for cutting off components having specific wavelengths since endoscopes may be used not only for observing interiors of human bodies but also for cutting off diseased portions of patients with laser knives. It is therefore desirable that the objective lens system according to the present invention uses not only a radial type gradient index lens element but also filters of the kinds mentioned above so that it can exhibit high imaging performance when it is used in optical systems for endoscopes which use, for example, solid-state image pickup devices such as CCD's.

It is desirable that these filters are disposed at locations between a lens element disposes on the image side and an image surface at which offaxial rays, in particular, are nearly in parallel with the optical axis. By disposing the filters as described above, it is possible to prepare approximately equal optical path lengths for axial and offaxial rays, thereby allowing the filters to exhibit their effects uniformly over the entire image pickup surface.

Endoscopes which are to be inserted into human bodies must be compact and require compacter optical systems. When importance is laid on compactness rather than optical performance, it is effective to dispose filters between the first lens unit and the second lens unit. Further, for obtaining an objective lens system which is compact and can be manufactured at a low cost, is is effective to impart filter functions to at least one of the lens elements including a radial type gradient index lens element.

The objective lens system according to the present invention which has a sixth embodiment is characterized in that it is composed, in order from the object side, of a first lens unit having a negative refractive power and a second lens unit having a positive refractive power, that it uses at least one radial type gradient index lens element which has a refractive index distribution in a radial direction expressed by the formula (a); and that it uses a reflecting surface for at least a single reflection disposed on the image side of the second lens unit.

Resolution of an optical system for endoscopes which uses a solid-state image pickup device such as a CCD, for example, can be enhanced by reducing the size of picture elements and arranging these picture elements in a larger number at a higher density on the image pickup device. However, the size of a picture element can be reduced only within a certain manufacturing limit and it is therefore conceivable to enhance resolution by enlarging an image pickup surface. However, it is desirable that endoscopes which may be inserted into human bodies have smaller diameters, or it is undesirable to enlarge image pickup surfaces, thereby enlarging diameters of endoscopes.

For allowing solid-state image pickup devices having larger image pickup surfaces to be used without enlarging diameters of endoscopes, the objective lens system according to the present invention uses a reflecting surface for at least one reflection on the image side of the second lens unit which makes it possible to dispose a solid-state image pickup device not in parallel with a radial direction of the endoscope but in a position inclined with regard thereto. FIG. **3** shows a conceptional diagram of the objective lens system according to the present invention which has the sixth composition. In FIG. **3**, the reference symbol L_1 represents the first negative lens unit, the reference symbol L_2designates the second positive lens unit, the reference symbol RA denotes an axial ray, the reference symbol RO represents an offaxial ray, the reference symbol R designates the reflecting surface and the reference numeral **10** denotes the image pickup device disposed on an image pickup plane. The reflecting surface R disposed on the image side of the second lens unit makes it possible to arrange the solid-state image pickup device which has a large image pickup surface nearly parallel to the optical axis. Though a system for a single reflection is illustrated in FIG. **3**, it is possible, needless to say, to obtain a similar effect by using a larger number of reflecting surfaces for a plurality of reflections.

When a solid-state image pickup device having a large image pickup surface is used, an image height can be enhanced in a lens system for obtaining a lens system having a wide field angle. However, it is desired for an objective lens system to correct aberrations more favorably over a range from a center to a marginal portion of an image plane.

For an objective lens system having a wide field angle in particular, it is desired to favorably correct lateral chromatic aberration.

An objective lens system which has high imaging performance for axial and offaxial rays can therefore be obtained by using a radial gradient index lens element which has high capability to correct chromatic aberration in particular. It is possible to obtain an objective lens system having higher performance by combining an objective lens system which uses a radial type gradient index lens element with a reflection system shown in FIG. **3** which permits enlarging an image pickup surface.

When a radial type gradient index lens element is used in the second lens unit in each of the compositions (first through sixth composition) of the objective lens system according to the present invention, it is desirable for more favorable correction of lateral chromatic aberration, coma and distortion to satisfy the following condition (4)

$$-0.5<N_{10p}\cdot f^2<-0.01 \tag{4}$$

wherein the reference symbol N_{10p} represents a refractive index distribution coefficient of the second order when a radial type gradient index lens element is used in the second lens unit and the reference symbol f designates a focal length of the objective lens system as a whole.

When the condition (4) is satisfied, a refractive power of medium of the radial type gradient index lens element has a sufficiently large value, thereby making it possible to correct lateral chromatic aberration favorably. Further, refractive indices are progressively lowered from the optical axis toward a marginal portion and a difference in refractive index (Δn) is large between the optical axis and the marginal portion, thereby making it possible to favorably correct coma produced by an image side surface of the second lens unit and barrel form distortion which poses a problem in the objective lens system as a whole.

If the upper limit of −0.01 of the condition (4) is exceeded, the radial type gradient index lens element will have a weak refractive power of medium, thereby making it difficult to correct lateral chromatic aberration favorably in the objective lens system as a whole, and the difference in refractive indices will be small between the optical axis and the marginal portion, thereby making it difficult to correct coma and distortion. If the lower limit of −0.5 of the condition (4) is not satisfied, in contrast, the radial type gradient index lens element will have a large refractive index difference Δn, thereby undesirably making it difficult to prepare a material for the radial type gradient index lens element.

When a radial type gradient index lens element is used in the first lens unit in the objective lens system according to the present invention which has one of the compositions described above, it is desirable for correcting lateral chromatic aberration more favorably to satisfy the following condition (5):

$$0.01<N_{10n}\cdot f^2<0.6 \tag{5}$$

wherein the reference symbol N_{10n} represents the refractive index distribution coefficient of the second order of a gradient index lens element when the radial type gradient index lens element is used in the first lens unit and the reference symbol f designates a focal length of the objective lens system as a whole.

When the condition (5) is satisfied, a refractive power of medium of the radial type gradient index lens element has a sufficiently large value, thereby making it possible to correct lateral chromatic aberration favorably.

If the lower limit of 0.01 of the condition (5) is not satisfied, the radial type gradient index lens element will have a weak refractive power of medium, thereby making it difficult to correct lateral chromatic aberration favorably in the objective lens system as a whole. If the upper limit of 0.6 of the condition (5) is exceeded, the radial type gradient index lens element will have a large refractive index difference Δn, thereby making it difficult to prepare a material for the radial type gradient index lens element.

When the radial type gradient index lens element is used in the first lens unit or the second lens unit of the objective lens system according to the present invention, it is desirable for correcting lateral chromatic aberration more favorably in the lens system to satisfy the following condition (6):

$$1/V10<0.01 \tag{6}$$

The objective lens system which satisfies the condition (6) can favorably correct lateral chromatic aberration. Since radial type gradient index lens elements have Abbe's numbers on the order of 30 to 80 as described above, it is desirable from the formula (d), for allowing a radial type gradient index lens element to exhibit a sufficient function for correction chromatic aberration to satisfy the condition (6). If the condition (6) is not satisfied, it will undesirably be impossible to sufficiently correct lateral chromatic aberration.

When a radial type gradient index lens element is used in the first lens unit of the objective lens system according to the present invention which has any one of the first through sixth compositions, it is desirable for correcting lateral chromatic aberration more favorably to satisfy the following condition (7):

$$0.05<d_{Gn}/f_{Gn}<1.2 \tag{7}$$

wherein the reference symbol d_{Gn} represents thickness of the radial type gradient index lens element used in the first lens unit and the reference symbol f_{Gn} designates a focal length of the radial type gradient index lens element used in the first lens unit.

A radial type gradient index lens element can exhibit its effect to connect chromatic aberration when it has refractive power of medium ϕ_m having a value which is large to a certain degree as described above. When a radial type gradient index lens element has extremely small thickness, for example, the refractive power of medium ϕ_m is weak as judged from the formula (e), thereby making it difficult to favorably correct chromatic aberration. It is therefore desirable that the objective lens system according to the present invention satisfies the condition (7) when a radial type gradient index lens element is used in the first lens unit.

If the lower limit of 0.05 of the condition (7) is not satisfied, the refractive power of medium will be weak, thereby undesirably making it difficult to favorably correct lateral chromatic aberration. If the upper limit of 1.2 of the condition (7) is exceeded, in contrast, the radial type gradient index lens element will have large thickness, thereby undesirably prolonging a total length of the objective lens system.

When a radial type gradient index lens element is used in the second lens unit of the objective lens system according to the present invention which has any one of the composition described above, it is desirable for correcting lateral

chromatic aberration more favorably to satisfy the following condition (8).

$$0.3<d_{Gp}/f_{Gp}<4.0 \quad (8)$$

wherein the reference symbol d_{Gp} represents the thickness of the radial type gradient index lens element used in the second lens unit and the reference symbol f_{Gp} designates a focal length of the radial type gradient index lens element used in the second lens unit.

When a radial type gradient index lens element has extremely small thickness as described above, for example, the refractive power of medium ϕ_m is weak, thereby making it difficult to correct chromatic aberration favorably. When a radial type gradient index lens element is to be used in the second lens unit of the objective lens system according to the present invention, the lens system is therefore configured so as to satisfy the condition (8).

If the lower limit of 0.3 of the condition (8) is exceeded, a refractive power of medium will be weak, thereby undesirably making it difficult to favorably correct lateral chromatic aberration. If the upper limit of 4.0 of the condition (8) is exceeded, a radial type gradient index lens element will have large thickness, thereby undesirably enlarging the objective lens system.

When the first lens unit is to be composed of a single negative lens element in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable for favorably correcting aberrations to satisfy the following condition (9)

$$0.1<1H/r_2<1.7 \quad (9)$$

wherein the reference symbol 1H represents an image height and the reference symbol r_2 designates a radius of curvature on an image side surface of the first lens unit having the negative refractive power.

If the lower limit of 0.1 of the condition (9) is not satisfied, the image side surface of the first lens unit will have a weak refractive power and it will be necessary to strengthen a negative refractive power of an object side surface of the first lens unit on which off axial rays are relatively high, whereby the object side surface will undesirably produce distortion, astigmatism, etc. in larger amounts. If the upper limit of 1.7 of the condition (9) is exceeded, in contrast, the image side surface of the first lens unit will have a strong negative refractive power, thereby undesirably overcorrecting spherical aberration in the objective lens system as a whole.

When the second lens unit is to be composed of a single positive lens element in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable for favorably correcting aberrations to satisfy the following condition (10)

$$-1.5<IH/r_3<0.8 \quad (10)$$

wherein the reference symbol IH represents an image height and the reference symbol r_3 designates a radius of curvature on an object side surface of the second lens unit having the positive refractive power.

If the lower limit of −1.5 of the condition (10) is not satisfied, the object side surface of the second lens unit will have a strong negative refractive power, thereby undesirably overcorrecting spherical aberration in the objective lens system as a whole. If the upper limit of 0.8 of the condition (10) is exceeded, in contrast, the object side surface will undesirably produce spherical aberration, etc. in larger amounts.

When the, second lens unit is to be composed of a single positive lens element in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable for favorably correcting aberrations to satisfy the following condition (11):

$$-1.0<IH/r_4<-0.2 \quad (11)$$

wherein the reference symbol IH represents an image height and the reference symbol r_4 designates a radius of curvature on an image side surface of the second lens unit having the positive refractive power.

If the lower limit of −1.0 of the condition (11) is not satisfied, the image side surface of the second lens unit will have a strong positive refractive power, thereby undesirably aggravating astigmatism and distortion in the objective lens system as a whole. If the upper limit of −0.1 of the condition (11) is exceeded, in contrast, it will be necessary to strengthen a positive refractive power of the object side surface of the second lens unit, whereby the object side surface will undesirably produce astigmatism and distortion in large amounts.

When a radial type gradient index element is to be used in the first lens unit in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable for correcting lateral chromatic aberration more favorably to satisfy the following condition (12):

$$0.05<N_{10n}\cdot f_{Gn}^{\ 2}<1.2 \quad (12)$$

wherein the reference symbol f_{Gn} represents a focal length of the radial type gradient index lens element to be used in the first lens unit.

When the condition (12) is satisfied, the refractive power of medium of the radial type gradient index lens element will have a value which is sufficiently large relative to its total refractive power and can favorably correct lateral chromatic aberration. If the lower limit of 0.05 of the condition (12) is not satisfied, the refractive power of medium will be weak, thereby undesirably making it difficult to correct lateral chromatic aberration favorably with the radial type gradient index lens element. IF the upper limit of 1.2 of the condition (12) is exceeded, refractive index difference Δn will be large, thereby undesirably making it difficult to prepare a material for the radial type gradient index lens element.

When a radial type gradient index lens element is to be used in the second lens element in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable for correcting lateral chromatic aberration, a Petzval's sum, coma or distortion more favorably to satisfy the following condition (13):

$$-0.8<N_{10p}\cdot f_{Gp}^{\ 2}<-0.05 \quad (13)$$

wherein the reference symbol f_{Gp} d represents a focal length of the radial type gradient index lens element to be used in the second lens unit.

When the condition (13) is satisfied, the refractive power of medium of the radial type gradient index lens will have a value which is sufficiently large relative to its total refractive power and can favorably correct lateral chromatic aberration. If the upper limit of −0.05 of the condition (13) is exceeded, the refractive power of medium will be weak, thereby undesirably making it difficult to correct lateral

chromatic aberration favorably with the radial type gradient index lens element. If the lower limit of −0.8 of the condition (13) is not satisfied, in contrast, refractive index difference Δn will be large, thereby undesirably making it difficult to prepare a material for the radial type gradient index lens element.

When a radial type gradient index lens element is to be used in the second lens unit in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable, for facilitating preparation of a material in addition to correction of lateral chromatic aberration, to satisfy the following condition (14):

$$0.1<\phi_{2m}/\phi<0.8 \quad (14)$$

When the condition (14) is satisfied, the radial type gradient index lens element will have a strong refractive power of medium and can correct lateral chromatic aberration favorably. If the lower limit of 0.1 of the condition (14) is not reached, the radial type gradient index lens element will have a weak refractive power of medium and can hardly correct lateral chromatic aberration favorably in the objective lens system as a whole, and a difference in refractive indices will be small between a portion of the radial type gradient index lens element located on the optical axis and a marginal portion thereof, thereby making it difficult to correct coma and distortion. If the upper limit of 0.8 of the condition (14) is exceeded, in contrast, the radial type gradient index lens element will have a large refractive index difference Δn or large thickness, thereby undesirably making it difficult to prepare a material for the radial type gradient index lens element in the former case or undesirably enhancing a manufacturing cost and prolonging a total length of the objective lens system in the latter case.

When a radial type index lens element is to be used in the first lens unit in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable, for facilitating manufacturing of the radial type gradient index lens element in addition to correction of lateral chromatic aberration, to satisfy the following condition (15):

$$-0.25<\phi_{1m}/\phi<-0.05 \quad (15)$$

When the condition (15) is satisfied, the radial type gradient index lens element will have a strong refractive power of medium and can favorably correct lateral chromatic aberration. If the upper limit of −0.05 of the condition (15) is not reached, the radial type gradient index lens element will undesirably have a weak refractive power of medium and can hardly correct lateral chromatic aberration favorably. If the lower limit of −0.25 of the condition (15) is exceeded, the radial type gradient index lens element will undesirably have a large refractive index difference Δn, whereby it can hardly be manufactured or it will be thickner and more expensive to manufacture.

When a radial type gradient index lens element is to be used in the first lens unit in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable, for facilitating manufacturing of the radial type gradient index lens element in addition to correction of lateral chromatic aberration, to satisfy the following condition (16)

$$0.02<N_{10n}\cdot f^2<0.4 \quad (16)$$

When the condition (16) is satisfied, a marginal portion of the radial type gradient index lens element used in the first lens unit may have a refractive index higher than that of a portion thereof on the optical axis, whereby the radial type gradient index lens element has a sufficiently strong refractive power of medium and can correct lateral chromatic aberration favorably.

If the lower limit of 0.02 of the condition (16) is not satisfied, the radial type gradient index lens element will have a weak refractive power of medium, thereby making it difficult to correct lateral chromatic aberration favorably in the objective lens system as a whole. If the upper limit of 0.4 of the condition (16) is exceeded, the radial type gradient index lens element will have a large refractive index difference Δn, thereby undesirable making it difficult to prepare a material therefor.

When a radial type gradient index lens element is to be used in the second lens unit of the objective lens system according to the present invention which has any one of the compositions described above, it is desirable, for facilitating manufacturing of the radial type gradient index lens element in addition to correction of lateral chromatic aberration, to satisfy the following condition (17):

$$-0.25<N_{10p}\cdot f2<-0.04 \quad (17)$$

When the condition (17) is satisfied, the radial type gradient index lens element has a sufficiently strong refractive power of medium and can favorably correct lateral chromatic aberration.

If the upper limit of −0.04 of the condition (17) is exceeded, the radial type gradient index lens element will have a weak refractive power of medium, thereby making it difficult to correct lateral chromatic aberration favorably in the objective lens system as a whole. If the lower limit of −0.25 of the condition (17) is not satisfied, in contrast, the radial type gradient index lens element will have a large refractive index difference Δn, thereby making it difficult to prepare a material therefor.

For correcting lateral chromatic aberration more favorably in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable to configure a radial type gradient index lens element so as to satisfy the following condition (18):

$$1/V_{10}<0 \quad (18)$$

When the condition (18) is satisfied, the radial type gradient index lens element produces chromatic aberration in a direction opposite to that of chromatic aberration produced by a homogeneous lens element having a refractive power which is the same as that of the radial type gradient index lens element. That is to say, when a radial type gradient index lens element is used in the first lens unit or the second lens unit of the objective lens system according to the present invention satisfies the condition (18), lateral chromatic aberration is overcorrected independently by the radial type gradient index lens element, but this overcorrected chromatic aberration cancels lateral chromatic aberration produced by the other lens element, thereby correcting chromatic aberration favorably in the objective lens system as a whole.

When a radial type gradient index lens element is to be used in the first lens unit of the objective lens system according to the present invention which has any one of the compositions described above, it is desirable, for facilitating manufacturing of the radial type gradient index lens element

in addition to correction of lateral chromatic aberration, to satisfy the following condition (19)

$$0.1<d_{Gn}/f_{Gn}<0.9 \quad (19)$$

If the lower limit of 0.1 of the condition (19) is exceeded, the radial type gradient index lens element will undesirably have a weak refractive power of medium, thereby undesirably making it difficult to correct lateral chromatic aberration favorably. If the upper limit of 0.9 of the condition (19) is exceeded, in contrast, the radial type gradient index lens element will be thick, thereby undesirably increasing the manufacturing cost of the objective lens system.

When a radial type gradient index lens element is to be used in the first lens unit of the objective lens system according to the present invention which has any one of the composition described above, it is desirable, for facilitating manufacturing of the radial type gradient index lens element in addition to correction of lateral chromatic aberration, to satisfy the following condition (20)

$$0.7<d_{Gp}/f_{Gp}<2.8 \quad (20)$$

When a radial type gradient index lens element has extremely small thickness for example, it has a weak refractive power of medium ϕm and can hardly correct chromatic aberration favorably. When a radial type gradient index lens element is to be used in the second lens unit of the objective lens system according to the present invention, it is therefore desirable to configure the radial type gradient index lens element so as to satisfy the condition (20).

If the lower limit of 0.7 of the condition (20) is exceeded, the radial type gradient index lens element will undesirably have a weak refractive power of medium, thereby undesirably making it difficult to correct lateral chromatic aberration favorably. IF the upper limit of 2.8 of the condition (20) is exceeded, in contrast, the radial type gradient index lens element will have large thickness, thereby undesirably increasing the manufacturing cost of the objective lens system.

When the first lens unit is to be composed of a single negative lens element in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable for more favorable correction of aberrations to configure it so as to satisfy the following condition (21):

$$0.25<IH/r_2<1.4 \quad (21)$$

If the lower limit of 0.25 of the condition (21) is not satisfied, an image side surface of the first lens unit will have a weak negative refractive power and it will be necessary to strengthen a negative refractive power of an object side surface of the first lens unit on which off axial rays are relatively high, whereby the object side surface will undesirably produce distortion, astigmatism, etc. in large amounts. If the upper limit of 1.4 of the condition (21) is exceeded, in contrast, the image side surface of the first lens unit will have a strong negative refractive power, thereby undesirably overcorrecting spherical aberration in the objective lens system as a whole.

When the second lens unit is to be composed of a single positive lens element in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable for favorably correcting aberrations to satisfy the following condition (22):

$$-0.9<IH/r_3<0.6 \quad (22)$$

If the lower limit of −0.9 of the condition (22) is not reached, an object side surface of the second lens unit will have a strong negative refractive power, thereby undesirably overcorrecting spherical aberration in the objective lens system as a whole. IF the upper limit of 0.6 of the condition (22) is exceeded, in contrast, the object side surface will undesirably produce astigmatism, distortion, etc. in large amounts.

When the second lens unit is to be composed of a single positive lens element in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable for favorable correction of aberrations to satisfy the following condition (23):

$$-0.8<IH/r_4<-0.2 \quad (23)$$

If the lower limit of −0.8 of the condition (23) is not reached, the image side surface of the second lens unit will have a strong negative refractive power, thereby undesirably aggravating astigmatism and distortion in the objective lens system as a whole. If the upper limit of −0.2 of the condition (23) is exceeded, in contrast, it will be necessary to strengthen the positive refractive power of the object side surface of the second lens unit, whereby the object side surface will undesirably produce spherical aberrations, etc. in large amounts.

When a radial type gradient index lens element is to be used as the first lens unit of the objective lens system according to the present invention which has any one of the compositions described above, it is desirable, for facilitating manufacturing of the radial type gradient index lens element in addition to correction of lateral chromatic aberration, to satisfy the following condition (24)

$$0.121N_{10n}\cdot f_{Gn}^2<0.85 \quad (24)$$

When the condition (24) is satisfied, a refractive power of medium of the radial type gradient index lens element has a value sufficiently large relative to a total refractive power thereof, thereby making it possible to correct lateral chromatic aberration favorably. If the lower limit of 0.1 of the condition (24) is exceeded, the radial type gradient index lens element will undesirably have a weak refractive power of medium and can hardly correct lateral chromatic aberration favorably. If the upper limit of 0.85 of the condition (24) is not satisfied, in contrast, a refractive index difference Δn will undesirably be large, thereby making it difficult to prepare a material for the radial type gradient index lens element.

When a radial type gradient index lens element is to be used as the second lens element of the objective lens system according to the present invention which has any one of the compositions described above, it is desirable, for facilitating manufacturing of the radial type gradient index lens element in addition to correction of lateral chromatic aberration, to satisfy the following condition (25):

$$-0.3<N_{10p}\cdot f_{Gp}^2<-0.1 \quad (25)$$

When the condition (25) is satisfied, a refractive power of medium of the radial type gradient index lens element has a

value sufficiently large relative to a total refractive power thereof, whereby the radial type gradient index lens element can correct lateral chromatic aberration favorably. If the upper limit of −0.1 of the condition (25) is not reached, the refractive power of medium will undesirably be weakened, thereby undesirably making it difficult to correct lateral chromatic aberration with the radial type gradient index lens element. If the lower limit of −0.3 of the condition (25) is exceeded, in contrast, the refractive index difference Δn will undesirably be large, thereby making it difficult to prepare a material for the radial type gradient index lens element.

Though it is desirable to satisfy the condition (18) for correcting lateral chromatic aberration more favorably in the objective lens system according to the present invention which has any one of the compositions described above, lateral chromatic aberration is overcorrected when $1/V_{10}$ has a negative value which is too large. Therefore, it is further desirable to satisfy the following condition (26):

$$-0.5<1/V_{10}<0 \quad (26)$$

When the condition (26) is satisfied, it is possible to correct lateral chromatic aberration favorably. If the upper limit of 0 of the condition (26) is exceeded, lateral chromatic aberration will undesirably be under-corrected. IF the lower limit of −0.5 of the condition (26) is not reached, lateral chromatic aberration will undesirably be over-corrected.

From a viewpoint of reducing a manufacturing cost of the objective lens system according to the present invention, it is desirable that a radial type gradient index lens element has a planar surface on one side or planar surfaces on both sides.

The objective lens system according to the present invention which has a seventh composition uses a diffraction type optical element as an optical element which is disposed in the lens system.

The objective lens system according to the present invention which has the seventh composition is composed, for example, of a first lens unit having a negative refractive power, a stop and a second lens unit having a positive refractive power: the first lens unit being composed of a diffractive optical element and the second lens unit being composed of a refractive optical element (lens).

Further, an objective lens system which can accomplish the object of the present invention can be obtained by composing a lens system of a positive lens unit and a positive lens unit: the positive lens unit disposed on the object side being composed of a radial type gradient index lens element and the lens unit disposed on the image side being composed of a diffractive optical element.

The objective lens system which has each of the compositions described above is composed of a small number of optical elements, has a compact size and exhibits favorable optical performance. It is therefore suited for use as an objective lens system for endoscopes, non-flexible endoscopes and video cameras.

Accordingly, endoscopes, non-flexible endoscopes, video cameras, portable TV telephones, portable data input units, etc. which use the objective lens system according to the present invention having the compositions described above are included within the scope of the present invention.

Now, embodiments of the objective lens system according to the present invention will be described below:

EMBODIMENT 1

wherein the reference symbols r_1, r_2, . . . represent radii of curvature on surfaces of respective lens elements, the reference symbols d_1, d_2, . . . designate thicknesses of the respective lens elements and airspaces reserved therebetween, the reference symbols n_1 n_2, . . . denote refractive indices of the respective lens elements, and the reference symbols ν_1, ν_2, . . . represent Abbe's numbers of the respective lens elements.

The first embodiment of the objective lens system according to the present invention has a composition illustrated in FIG. **4**. Speaking concretely, it is composed of two lens units, i.e., in order from the object side, a first lens unit consisting of a negative lens element, a stop and a second lens unit consisting of a positive lens element. The second lens unit having the positive refractive power is configured as a radial type gradient index lens element. The first lens unit is composed of a homogenous lens element which has a planar surface on the object side and a concave surface on the image side, whereas the second lens unit is composed of a radial type gradient index lens element having a meniscus shape which has a concave surface on the object side.

Though it is ordinarily difficult to favorably correct lateral chromatic aberration in particular with two lens elements, the lens system preferred as the first embodiment is capable of favorably correcting lateral chromatic aberration by using the radial type gradient index lens element as the second lens unit.

Further, distortion and coma produced by the second lens unit are favorably corrected by the radial type gradient index lens element used as the second lens unit which has a refractive index distribution wherein refractive indices are progressively lowered from an optical axis toward a marginal portion.

In the first embodiment, lateral chromatic aberration in particular is corrected favorably by configuring the radial type gradient index lens element used as the second lens unit so as to satisfy the condition (18).

Furthermore, the object side planar surface of the first lens unit is effective for lowering a cost required for polishing the lens element.

Though the first embodiment is composed only of the two lens elements, it favorably corrects aberrations and has high optical performance.

The second embodiment of the present invention is an objective lens system which has a composition illustrated in

FIG. **5**. Speaking concretely, it is composed of two lens elements, i.e., in order from the object side, a first lens unit composed of a negative lens element, a stop and a second lens unit composed of a positive lens element. The second lens unit having the positive refractive power is configured as a radial type gradient index lens element.

The second embodiment is an example in which the objective lens system is configured so as to have a total length that is shorter than that of the first embodiment. In the second embodiment also, lateral chromatic aberration in particular is favorably corrected by using the radial type gradient index lens element as the second lens unit.

The radial type gradient index lens element has a meniscus shape which has a concave surface on the object side. When a radial type gradient index lens element has such a meniscus shape, its refractive power of surface and refractive power of medium which are weaker and stronger respectively than a refractive power of surface and a refractive power of medium of a radial type gradient index lens element having a biconvex shape and a refractive power which is the same as that of the radial type gradient index lens element. When a radial type gradient index lens element has a strong refractive power of medium, its effect for correcting chromatic aberration can be effectively utilized as seen from the formula (d). For effectively utilizing the effect of a radial type gradient index lens element, the second embodiment adopts the radial type gradient index lens element which has the meniscus shape. The meniscus shape which has the concave surface on the object side is effective in particular for preventing offaxial aberrations from being aggravated.

In the second embodiment, the outer circumferential portion located outside an effective diameter of the first lens unit and the second lens unit is configured as a nearly planar surfaces on which both the lens units are cemented or kept in contact with each other. By cementing these two lens units into an integrated part, it is possible to simplify a structure of a lens barrel and facilitate assembly of the objective lens system.

The second embodiment also has high optical performance though it is composed only of the two lens elements.

The third embodiment of the present invention is an objective lens system which has a composition illustrated in FIG. **6**. That is to say, the objective lens system is composed of two lens unit, in order from the object side, of a first lens unit composed of a negative lens element, a stop, and a second lens unit composed of a positive lens element. The second lens unit having the positive refractive power is configured as a radial type gradient index lens element. The first lens unit is composed of a homogenous lens element having a biconcave shape, whereas the second lens unit is composed of a radial type gradient index lens element having a meniscus shape which has a concave surface on the object side.

Though it is ordinarily difficult to favorably correct lateral chromatic aberration with two lens elements, the objective lens system according to the present invention is capable of favorably correcting lateral chromatic aberration by using the radial type gradient index lens element as the second lens unit.

The third embodiment is an example wherein amounts of aberrations to be produced by the first lens unit are reduced by selecting the biconcave surface for the first lens unit so that a power of this lens unit is shared between the surfaces.

Though $1/V_{10}$ of the radial type gradient index lens element has a positive value, lateral chromatic aberration is favorably corrected by satisfying the condition (1).

The objective lens system preferred as the third embodiment also has high optical performance though it is composed only of the two lens elements.

The fourth embodiment of the present invention is an objective lens system which has a composition shown in FIG. **7**. Concretely, it is composed of two lens units, in order from the object side, a first lens unit composed of a negative lens element, a stop and a second lens unit composed of a positive lens element. The second lens unit having the positive refractive power is configured as a radial type gradient index lens element. The first lens unit has a planar surface on the object side and a concave surface on the image side configured as an aspherical surface which weakens a negative refractive power as portions of the aspherical surface are farther from an optical axis toward a marginal portion. The second lens unit is composed of a radial type gradient index lens element which has a biconvex shape.

The aspherical surface used in this embodiment has a shape expressed by the following formula:

wherein a direction along the optical axis is taken as the x axis, a direction perpendicular to the optical axis is taken as the y axis, the reference symbol r represents a radius of curvature on the optical axis, the reference symbol p designates a conical constant and the reference symbol A_{2i} denotes an aspherical surface coefficient.

In the fourth embodiment, the aspherical surface used in the first lens unit is capable of favorably correcting mainly barrel form distortion produced in the lens system as a whole.

Though the first lens unit has the planar surface on the object side in the fourth embodiment, a similar effect can be obtained by using an aspherical surface as the object side surface of the first lens unit.

The fourth embodiment is an example wherein the second lens unit is configured as the biconvex radial type gradient index lens element which has a weakened refractive power of medium and a strengthened refractive power of surface. Accordingly, the radial type gradient index lens element can have a small refractive index difference Δn contributing to a refractive power of medium, thereby enhancing productibility or shortening a time required for imparting a refractive index distribution at a stage to prepare a material for the radial type gradient index lens element.

In spite of the fact that the fourth embodiment is composed only of the two lens elements, it has high optical performance.

It is possible to obtain a similar effect by using, in place of the aspherical surface disposed in the first lens unit, an axial type gradient index lens element having a refractive index continuously varying in the direction along the optical axis.

The fifth embodiment of the present invention is an objective lens system which has a composition illustrated in FIG. **8**. That is to say, it is composed of two lens elements, in order from the object side, a first lens unit composed of a negative lens element, a stop and a second lens unit composed of a positive lens element configured as a radial type gradient index lens element. The first lens unit has a planar surface on the object side and a concave surface on the image side which is configured as an aspherical surface which has such a shape as to weaken a negative refractive power as portions of the aspherical surface are farther from the optical axis toward a marginal portion, whereas the second lens unit is configured as a radial type gradient index lens element having a biconvex shape. The aspherical surface used in the first lens unit is capable of favorably

correcting barrel form distortion which is produced in the objective lens system as a whole as in the fourth embodiment.

For configuring compactly a tip of an endoscope which is to comprise the objective lens system according to the present invention, an outer circumferential portion of the radial type gradient index lens element used as the second lens unit is cut off as shown in FIG. **8**. A tip of the objective lens system can be made thinner since the lens barrel or the like can be disposed, for example, as a slashed location **3** on the cut portion **2**.

The fifth embodiment is an example wherein the objective lens system has a total length that is shorter than that of the fourth embodiment. Though the fifth embodiment is composed only of the two lens elements, it has high optical performance.

The sixth embodiment of the present invention has a composition shown in FIG. **9**. Speaking concretely, it is composed of two lens units, in order from the object side, a first lens unit composed of a negative lens element, a stop and a second lens unit composed of a positive lens element. The first lens unit having the negative refractive power is configured as a radial type gradient index lens element. The first lens unit is a radial type gradient index lens element which has a planar surface on the object side and a concave surface on the image side, whereas the second lens unit is a biconvex homogenous lens element.

Unlike the first through fifth embodiments, the sixth embodiment uses the radial type gradient index lens element as the first lens unit for favorably correcting lateral chromatic aberration which poses a problem in particular in the objective lens system according to the present invention.

The planar surface adopted as the object side surface of the first lens unit makes it possible to reduce the cost required for polishing the lens element.

Further, aberrations are reduced by selecting the biconvex shape for the second lens unit so that its power is shared between the two surfaces.

Furthermore, the image side surface of the second lens unit has a refractive power of surface which is stronger than that of the object side surface thereof so that offaxial rays are incident on an image surface nearly at telecentric angles.

The sixth embodiment also has high optical performance though it is composed only of the two lens elements.

The seventh embodiment of the present invention has a composition illustrated in FIG. **10**. That is to say, an objective lens system preferred as the seventh embodiment is composed of two lens units, in order from the object side, a first lens unit composed of a negative lens element, stop and a second lens unit composed of a positive lens element. The first lens unit having the positive refractive power is configured as a radial type gradient index lens element. The first lens unit is a radial type gradient index lens element which has a planar surface on the object side and a concave surface on the image side, whereas the second lens unit is a homogeneous lens element which has a biconvex shape.

This embodiment also has high optical performance though it is composed only of the two lens elements.

The eighth embodiment of the present invention is an objective lens system which has a composition shown in FIG. **11**. This lens system is composed of two lens units, in order from the object side, a first lens unit composed of a negative lens element, a stop and a second lens unit composed of a positive lens element. The first lens unit having the positive refractive power is configured as a radial type gradient index lens element. The first lens unit is a radial type gradient index lens element having a meniscus shape which has a concave surface on the image side, whereas the second lens unit is a homogeneous lens element which has a biconvex shape.

The composition of the eighth embodiment, in which the radial type gradient index lens element has the meniscus shape which has a concave surface on the image side is advantageous for correcting offaxial aberrations in particular.

The eighth embodiment also has high optical performance in spite of the face that it is composed only of the two lens elements.

The ninth embodiments of the present invention is an objective lens system which has a composition illustrated in FIG. **12**. Speaking concretely, this lens system is composed of two lens elements, in order from the object side, a first lens unit composed of a negative lens units, a stop and a second lens unit composed of a positive lens element. The first lens unit having the negative refractive power is configured as a radial type gradient index lens element. The first lens unit is a radial type gradient index lens element having a meniscus shape which has a planar surface on the object side and a concave surface on the image side, whereas the second lens unit has aspherical surfaces on both sides.

Owing to a fact that an image side surface of the second lens unit on which offaxial rays are relatively high is configured as an aspherical surface having such a shape as to weaken a positive refractive power as portions of the aspherical surface are farther from an optical axis toward a marginal portion, the ninth embodiment is capable of favorably correcting barrel form distortion produced in the lens system as a whole.

Though the ninth embodiment uses the aspherical surfaces on both sides of the second lens unit, a similar effect can be obtained by using an aspherical surface only on one side.

The ninth embodiment also exhibits high optical performance though it consists only of the two lens elements.

Further, a similar effect can be obtained by adopting, the place of the aspherical surfaces used in the second lens unit, an axial type gradient index lens element which continuously varies a refractive index in a direction along the optical axis.

The tenth embodiment of the present invention is an objective lens system which has a composition shown in FIG. **13**. This lens system consists of two lens units, in order from the object side, a first lens unit composed of negative lens element, a stop and a second lens unit composed of a positive lens element. The first lens unit having the negative refractive power and the second lens unit having the positive refractive power are configured as radial type gradient index lens elements. The first lens unit is a radial type gradient index lens element which has a planar surface on the object side and a concave surface on the image side, whereas the second lens unit is a radial type gradient index lens element which has a biconvex shape.

The tenth embodiment is an example wherein lateral chromatic aberration produced in the lens system as a whole is favorably corrected by using radial type gradient index lens elements in both the lens units. In other words, lateral chromatic aberration is favorably corrected by configuring the radial type gradient index lens element used in the first lens unit to satisfy the condition (1) and the condition (2), and designing the radial type gradient index lens element used in the second embodiment to satisfy the condition (1) and the condition (3).

Though the tenth embodiment consists only of the two lens elements, it has high optical performance.

Preferred as an eleventh embodiment of the present invention is an objective lens system which has a composition illustrated in FIG. **14**. This lens system comprises two lens units, or is composed, in order from the object side, a first lens unit composed of a negative lens element, a stop, a second lens unit composed of a positive lens element and filters F disposed on the image side of the second positive lens unit. The first lens unit is configured as a homogenous lens element which has a planar surface on the object side and a concave surface on the image side, whereas the second lens unit is configured as a biconcave radial type gradient index lens element which has an object side surface having a weak positive refractive power.

When the objective lens system according to the present invention is used in a video scope or the like which uses a solid-state image pickup device such as a CCD, a low pass filter and an infrared cut filter composed, for example, of quartz or diffraction gratings may be disposed on the object side of an image surface as exemplified in FIG. **14**. The eleventh embodiment is an example comprising such filters. In the objective lens system according to the present invention, the above-mentioned filters can be disposed between the negative lens element and the positive lens element.

Preferred as the twelfth embodiment of the present invention is an objective lens system which has a composition shown in FIG. **15**. Like the eleventh embodiment, the twelfth embodiment comprises two lens units, or is composed, in order from the object side, of a first lens unit composed of a negative lens element, a stop, a second lens unit composed of a positive lens element, and filters which are disposed between the two lens elements and on the image side of the positive lens element. The first lens unit is configured as a homogenous lens element which has a planar surface on the object side and a concave surface on the image side, whereas the second lens unit is configured as a radial type gradient index lens element which has a biconvex shape.

The thirteenth embodiment of the present invention has a composition illustrated in FIGS. **16**A and **16**B: FIG. **16**A being a sectional view showing the thirteenth embodiment as a whole and FIG. **16**B being a diagram illustrating only a portion B on an enlarged scale. The thirteenth embodiment is composed, in order from the object side, of a first lens unit composed of a negative lens element, a stop and a second lens unit composed of a positive lens element. A radial type gradient index lens element is used as the second lens unit. The first lens unit has a planar surface on the object side and a concave surface on the image side, whereas the second lens unit has a planar surface on the object side and a convex surface on the image side.

The thirteenth embodiment is an example wherein aberrations are favorably corrected by using a radial type gradient index lens element and a large number of planar surfaces are adopted for reducing a cost required for polishing lens elements, or the object side surface of the first lens unit and the object side surface of the second lens unit are configured to be planar.

Further, for preventing eccentricities of lens elements, in directions along an optical axis and perpendicular thereto in particular, which pose a problem at a stage of assembly, an outer circumferential portion **4** is obliquely chamfered as shown in FIG. **16**B so that a chamfered portion **4** is limited at a location **6** of a lens barrel **5**. Since a radial type gradient index lens element which has a refractive power of medium requires a manufacturing precision stricter than that for a homogenous lens element, the thirteenth embodiment provides effective assembling convenience. A similar effect can, needless to say, be obtained by assembling the first lens unit having the negative refractive power in a similar manner.

Though the thirteenth embodiment uses a large number of planar surfaces, it has high optical performance.

The fourteenth embodiment of the present invention is an objective lens system which has a composition illustrated in FIG. **17**. That is to say, the fourteenth embodiment is composed, in order from the object side, of a first lens unit consisting of a negative lens element, a stop and a second lens unit consisting of a positive lens element which is configured as a radial type gradient index lens element. The first lens unit has a planar surface on the object side and a concave surface on the image side, whereas the second lens unit has a meniscus shape which has a concave surface on the object side.

When a radial type gradient index lens element is used as the second lens unit, it is desirable for correcting aberrations such as spherical aberration that the term of the fourth order N_{20} of a refractive index distribution has a positive value.

The fifteenth embodiment of the present invention has a composition shown in FIG. **18**. Speaking concretely, the fifteenth embodiment is composed, in order from the object side, of a first lens unit consisting of a negative lens element, a second lens unit consisting of a positive lens element and a reflecting optical element. A radial type gradient index lens element is used as the second lens unit. In this embodiment, a light bundle emerging from the second lens unit is reflected by a reflecting surface **7** of a reflecting optical element P made, for example, of a mirror or a prism so that it is imaged onto a solid-state image pickup device **10** which is disposed nearly parallel to the optical axis. This reflecting surface makes it possible to dispose a solid-state image pickup device such as a CCD that is not parallel to a radial direction of the lens elements, but oblique. Though a solid-state image pickup device **10** is disposed nearly parallel to the optical axis in the fifteenth embodiment, the image pickup device can be disposed more obliquely by selecting an adequate inclination angle for the reflecting surface **7** relative to the optical axis. Though the fifteenth embodiment is configured to reflect the light bundle only once, it is possible to reflect the light bundle twice, three times or more times by adopting a larger number of reflecting surfaces.

The sixteenth embodiment of the present invention is an objective lens system which has a composition shown in FIG. **19**. That is to say, the sixteenth embodiment is composed, in order from the object side, of a first lens unit composed of a negative lens element, a second lens unit composed of a positive lens element and a solid-state image pickup device. A radial type gradient index lens element is used ass the second lens unit. In this embodiment, the radial type gradient index lens element has a nearly planar image side surface which is cemented or kept in close contact to or with a solid-state image pickup device **10** such as a CCD. Further, disposed in the second lens unit, is a member which extends from an outer circumference toward an optical axis for shielding a light bundle passing through the lens unit or functioning as an aperture stop of the objective lens system. Such a shielding member can be constituted, for example, by forming a cut **8** from the outer circumference toward the optical axis. For preventing the cut from producing flare, it is desirable to color the cut **8**. Further, it is possible to cut the second lens unit along a dashed line **9** shown in FIG. **25** into a front portion La and a rear portion Lb, attach a stop S to a cut surface of the front portion La and cementing the two portions to each other or bringing them into close contact with each other. A similar effect can be obtained by attaching

the stop S to the rear portion Lb in place of the front portion La. As means for attaching the stop, it is conceivable to utilize deposition, printing or bonding a stop plate. This means can be utilized for manufacturing not only an aperture stop but also a flare stop.

In the sixteenth embodiment, the aperture stop is disposed at a location 1 mm apart from an object side surface of the second lens unit toward an image surface.

It is needless to say that an aperture stop, a flare stop or the like can be manufactured by the means described above in each of the embodiments.

The seventeenth embodiment of the present invention has a composition illustrated in FIG. **20**. That is to say, the seventeenth embodiment is composed, in order from the object side, of a first lens unit composed of a negative lens element, a second lens unit composed of a positive lens element, an optical filter F and a solid-state image pickup device **10**. A radial type gradient index lens element is used as the second lens unit. In the seventeenth embodiment, the second lens unit has planar surfaces on both sides for reducing the cost for polishing the lens unit. The seventeenth embodiment is an example wherein the second lens unit is cemented to the optical filter F for simplifying a structure of a lens barrel and assembly of the objective lens system. Further, the optical filter F is cemented or kept in close contact to or with the solidstate image pickup device **10**. Furthermore, the first lens unit and the second lens unit are cemented or kept in close contact to or with each other on outer circumferences thereof outside an effective diameter thereof.

In the seventeenth embodiment, an aperture stop is disposed at a location 1 mm apart from an object side surface of the second lens unit toward an image surface.

The eighteenth embodiment of the present invention has a composition shown in FIG. **21**. That is to say, the eighteenth embodiment is composed, in order from the object side, of a first lens unit composed of a negative lens element, a regularly reflecting optical element and a second lens unit composed of a positive lens element. The second lens unit which is disposed on the image side is configured as a radial type gradient index lens element.

Certain endoscopes are specified for oblique observation in direction inclined relative to the optical axis. When the objective lens system according to the present invention is used in an endoscope for oblique observation, a reflecting optical element P composed of a mirror or a prism is disposed between the first lens unit and the second lens unit as shown in FIG. **21** so that a light bundle emerging from the first lens unit is reflecting by a reflecting surface **7** of the reflecting optical element and led to the second lens unit.

Though a lens element ordinarily has a circular sectional shape, it may have a different sectional shape. FIGS. **22**A, **22**B, **22**C, **23**A, **23**B and **23**C exemplify lens elements which have external shapes cut or worked in accordance with shapes of image pickup devices for configuring objective lens systems compactly. FIGS. **22**A, **22**B and **22**C schematically show the second lens unit which is used in the first through eighteenth embodiments before being shaped. FIG. **22**A shows a sectional view taken in a direction from an object, FIG. **22**B is a sectional view taken in a direction in parallel with the optical axis, and FIG. **22**C illustrates an image circle **11** of the objective lens system and an image pickup surface **12** of an image pickup device. FIGS. **23**A, **23**B and **23**C schematically show the lens element illustrated in FIGS. **22**A, **22**B and **22**C in another condition after it is shaped. Since a solid-state image pickup device such as CCD may have a rectangular shape and a lens element ordinarily has a circular shape as shown in FIG. **22**A, there is produced, as slashed in FIG. **22**C, a region which serves for image formation but is not used for image pickup. Since it is desired to configure an objective lens system for endoscopes compacter, it is conceivable to cut off the region of the lens element which is not used for image pickup. The eighteenth embodiment is an example wherein lens portion through which rays to be condensed outside an image pickup surface of an image pickup device are cut off as exemplified by FIGS. **23**A and **23**B so that an image formation range of the lens element is nearly coincident with the image pickup surface of the image pickup device. It is possible to obtain a compacter objective lens system or endoscopes by configuring a lens element so as to occupy a narrower space.

Though the second lens unit is worked for narrowing a lens space in the example descried above, it is needless to say that a similar effect can be obtained by working other lens element or optical element, for example, the first lens unit or the reflecting optical element.

The nineteenth embodiment has a composition illustrated in FIG. **26**. Speaking concretely, the nineteenth embodiment is a retrofocus type objective lens system which is composed, in order from the object side, of a first negative lens unit, a second positive lens unit and a third positive lens unit. A stop is disposed between the second lens unit and the third lens unit. The nineteenth embodiment is an objective lens system which has a wide field angle and is usable for endoscopes, video cameras, etc. Though the nineteenth embodiment has a wide field angle which makes it rather hard to contact lateral chromatic aberration, it corrects lateral chromatic aberration with a radial type gradient index lens element. In the nineteenth embodiment, the first lens unit has a plano-concave shape and a function to widen a field angle, the second lens unit has a plano-convex shape and a function to correct mainly lateral chromatic aberration produced by the first lens unit, and the third lens unit has a biconvex shape and a main imaging function, and is configured as a radial type gradient index lens element.

Though it is rather hard in the nineteenth embodiment to correct coma which is produced by the third lens unit disposed on the image side of a stop, coma is corrected by configuring the third lens unit as a radial type gradient index lens element which has such a characteristic as to progressively lower a refractive index in a radial direction from an optical axis. In other words, coma is corrected by imparting a positive refractive power to a medium of the radial type gradient index lens element. The composition described above is capable of correcting not only coma but also distortion.

For correcting coma with a medium of a radial type gradient index lens element, it is desirable that terms of high orders of a refractive index distribution satisfy the following condition (27):

$$-0.05 < \sum_{i=2}^{n} N_{iod} e^{2i} < 0.2 \tag{27}$$

wherein the reference symbol e represents an effective diameter of the lens element.

If the lower limit of −0.05 of the condition (27) is not reached, coma will be undercorrected. If the upper limit of 0.2 of the condition (27) is exceeded, in contrast, coma will be overcorrected.

It is desirable for more favorable correction of coma to satisfy the following condition (28):

$$0 < \sum_{i=2}^{n} N_{iod} e^{2i} < 0.1 \quad (28)$$

If the lower limit of 0 of the condition (28) is not reached, coma will be undercorrected. If the upper limit of 0.1 of the condition (28) is exceeded, in contrast, coma will be overcorrected. Either of these cases is undesirable for more favorable correction of coma.

Further, a planar surface used as an object side surface of the lens element disposed on the image side in the nineteenth embodiment has an effect for preventing adhesion of foreign matter such as dust.

In this embodiment, at least one lens element can have a function to cut off components having specific wavelengths, or a radial type gradient index lens element can have such a function.

When an image pickup device such as a CCD which has high sensitivity in the infrared wavelength region is to be disposed on an image pickup surface, for example, it is desirable to provide a function to cut off components having wavelengths in the infrared region. Accordingly, it is desirable that at least one lens element has a function to cut off components having specific wavelenghts such as those in the infrared region.

The function to cut off components having specific wavelengths can be obtained by forming, on a flat portion of a lens element or a flat plate, an interference film which cuts off the components having specific wavelengths.

A stop can be manufactured from a thin plate.

Further, amounts of aberrations produced can be reduced by configuring a radial type gradient index lens element so as to have a biconvex shape, thereby sharing a refractive power between the two surfaces.

Use of a radial type gradient index lens element makes it possible to obtain an optical system which is compact and composed of a small number of lens elements, and has a wide field angle and favorably corrected aberrations such as chromatic aberration and coma. Accordingly, it is effective to use an optical system such as an optical system for image input units for portable TV telephones and portable data input units such as those shown in FIGS. **35** and **36**.

The twentieth embodiment is an optical system which has a composition illustrated in FIG. **17**. It is a retrofocus type optical system which is composed, in order from the object side, of a first lens unit having a negative refractive power, a second lens unit having a positive refractive power and a third lens unit having a positive refractive power. A stop is disposed between the second lens unit and the third lens unit.

The twentieth embodiment is an optical system which has a wide field angle and is usable as an objective lens system for endoscopes or a lens system for video cameras, etc. Though the twentieth embodiment also has a wide field angle and hardly allows correction of lateral chromatic aberration in particular, aberrations are favorably corrected in this embodiment by using a radial type gradient index lens element.

In the twentieth embodiment, the first lens unit is a plano-concave lens element having a function to widen a field angle, the second lens unit is a radial type gradient index lens element having planar surfaces on both sides and a function to correct lateral chromatic aberration produced by the first lens unit, and the third lens unit has a biconvex shape and a main imaging function. The twentieth embodiment favorably corrects lateral chromatic aberration in particular by using, as the second lens unit disposed on the object side of the stop, a radial type gradient index lens element made of a medium which has a positive refractive power and a relatively strong dispersing power. The medium having the positive refractive power favorably corrects a Petzval's sum.

For correcting lateral chromatic aberration by disposing a radial type gradient index lens element on a stop, it is desirable to satisfy the following condition (29).

$$0.01<1V_{10}<0.5 \quad (29)$$

If the lower limit of 0.01 of the condition (29) is not reached, lateral chromatic aberration will be undercorrected. If the upper limit of 0.5 of the condition (29) is exceeded, in contrast, lateral chromatic aberration will be overcorrected.

For correcting lateral chromatic aberration more favorably by disposing a radial type gradient index lens element on the object side of the stop, it is desirable to satisfy the following condition (30):

$$0.015<1/V_{10}<0.1 \quad (30)$$

If the lower limit of 0.015 of the condition (30) is not reached, lateral chromatic aberration will be undercorrected. If the upper limit of 0.1 of the condition (30) is exceeded, lateral chromatic aberration will be overcorrected. Either of these cases is undesirable for correcting lateral chromatic aberration extremely favorably.

When preparation of a material for a radial type gradient index lens element is taken into consideration, it is desirable that $1/V_{10}$ has a value not exceeding 0.05. From viewpoints of manufacturing convenience and cost, it is desirable to configure a radial type gradient index lens element so as to have planar surfaces on both sides. When durability of a radial type gradient index lens element is taken into consideration, it is desirable to make it entirely of a glass material.

The twenty-first embodiment has a composition illustrated in FIG. **28**, or is a retrofocus type optical system which is composed, in order from the object side, of a first lens unit having a negative refractive power and a second lens unit having a positive refractive power. A stop is disposed between the first lens unit and the second lens unit. The twenty-first embodiment which is an optical system having a wide field angle is usable as an objective lens system for endoscopes or video cameras and so on. Though this optical system also has a wide field angle and hardly allows correction of lateral chromatic aberration in particular, lateral chromatic aberration is favorably corrected by using a radial type gradient index lens element.

In the optical system preferred as the twenty-first embodiment, the first lens unit has a negative meniscus shape which has a concave surface on the image side, and the second lens unit has a biconvex shape and a main imaging function. A radial type gradient index lens element is used as the first lens unit.

Offaxial aberrations can be corrected favorably by configuring the radial type gradient index lens element used as the first lens unit so as to have the meniscus shape which has the concave surface on the side of the stop. Lateral chromatic aberration is favorably corrected in particular owing to a fact that the radial type gradient index lens element has a positive refractive power of medium and is configured so as to satisfy the condition (29).

Further, coma is corrected favorably by using an aspherical surface on the lens element disposed on the object side of the stop. This aspherical surface has such a shape as to weaken a positive refractive power as portions of the aspherical surface are farther from an optical axis toward a marginal portion. Owing to this aspherical surface, the twenty-first embodiment is configured as an optical system which is compact and composed of a small number of lens elements, has a wide field angle and favorably corrects aberrations such as coma. It is therefore effective to apply the twenty-first embodiment as an optical system for image intake devices for portable TV telephones and portable date input units.

The twenty-second embodiment has a composition shown in FIG. **29**, or is an optical system composed of a single radial type gradient index lens element. The radial type gradient index lens element has a meniscus shape which has a concave surface on the object side and a positive power of medium. A stop is disposed at a location 0.9471 mm apart from an object side surface of the lens element toward the image side.

The twenty-second embodiment has a wide field angle, and is usable as an objective lens system for endoscopes or a lens system for video camera and so on. Though the twenty-second embodiment which has a wide field angle hardly allows correction of chromatic aberration, it is corrected with the radial type gradient index element. A flat glass plate is disposed on the object side as a cover glass plate. A stop is disposed in the radial type gradient index lens element for obtaining highly symmetrical refractive power of medium, thereby favorably correcting offaxial aberrations. The radial type gradient index lens element satisfies the condition (29) for correcting lateral chromatic aberration produced by an object side concave or convex surface with a medium located on the object side of the stop.

For reducing chromatic aberration to be produced by surfaces of the radial type gradient index lens element, it is desirable that V_{00} has a value of at least 30, or more desirably, at least 40. For reducing aberrations to be produced by the surfaces of the radial type gradient index lens element, it is desirable that N_{00} has a value of at least 1.55, or more desirably, at least 1.6.

The twenty-third embodiment has a composition shown in FIG. **30**, or is composed of two lens units, in order from the object side, a first positive lens unit and a second positive lens unit. The twenty-third embodiment is an example wherein aberrations are corrected favorably by composing an optical system of a radial type gradient index element and a diffraction type optical element (DOE). Speaking more concretely, the twenty-third embodiment is composed, in order from the object side, of a first lens unit composed of a radial type gradient index lens element and a second lens unit composed of a diffraction type optical element.

A diffraction type optical element is equivalent to a lens element which has a very high imaginary refractive index as described in literature SPIE, Vol. 126, P46 (1997). For this reason, the diffractive optical element is assumed to be a lens element which is optically equivalent to the optical element including aberrations to be produced thereby, and radii of curvature, thickness, a refractive index, an Abbe's number and aspherical surface coefficients of the lens element are described in the numerical data of the twenty-third embodiment. In the twenty-third embodiment, a stop is disposed on the object side of the optical system (the first lens unit).

In the twenty-third embodiment, the first lens unit composed of the radial type gradient index lens element has a main imaging function and the second lens unit composed of the diffraction type optical element favorably corrects lateral chromatic aberration. The twenty-third embodiment is an example of an optical system which is composed of a small number of optical elements and has a wide field angle, and favorably corrects lateral chromatic aberration with a diffractive optical element disposed on the image side of a stop. The diffraction type optical element has a positive refractive power, is disposed on the image side of the radial type gradient index lens element and has a function to favorably correct lateral chromatic aberration produced by a convex surface of the radial type gradient index lens element. Further, the radial type gradient index lens element has another function to favorably correct a Petzval's sum.

The twenty-third embodiment is usable as described above, as an objective lens system for endoscopes or an optical system for video cameras and so on. Since the twenty-third embodiment is an optical system which is compact and is composed of a small number of lens elements, and favorably corrects aberrations such as chromatic aberration owing to the fact that it uses the diffraction type optical element, it is effective to apply it as an optical system for image intake devices for portable TV telephones and portable data input units.

The twenty-fourth embodiment has a composition illustrated in FIG. **31**, or is composed, in order from the object side, of a first lens unit having a negative refractive power and a second lens unit having a positive refractive power. A stop is disposed between the first lens unit and the second lens unit. In the twenty-fourth embodiment, the first lens unit having the negative refractive power serves mainly for widening a field angle and the second lens unit having the positive refractive power functions mainly for imaging.

The twenty-fourth embodiment favorably corrects aberrations by using the diffraction type optical element in that place of the radial type gradient index lens element adopted for the twenty-first embodiment.

The twenty-fourth embodiment hardly allows correction of offaxial aberrations since it has an asymmetrical refractive power distribution wherein a negative refractive power is disposed on the object side of the stop and a positive refractive power is disposed on the image side of the stop. For this reason, lateral chromatic aberration is corrected favorably by disposing the diffraction type optical element on the object side of the stop an imparting a negative refractive power to this optical element. Coma and distortion in particular can be corrected favorably by using an aspherical surface on a positive lens unit disposed on the image side of the stop and configuring this aspherical surface so as to have such a shape as to weaken a positive refractive power in a radial direction from an optical axis. The negative lens unit has a meniscus shape which has a concave surface on the side of the stop for reducing amounts of offaxial aberrations in particular. Further, the positive lens unit has a biconvex shape so that amounts of aberrations are reduced by sharing a refractive power between two surfaces. Furthermore, the diffraction type optical element is disposed on a surface which is concave toward the stop so that differences between angles of incidence of paraxial rays and offaxial rays are reduced, thereby enhancing a diffraction efficiency.

FIG. **32** is a perspective view illustrating an endoscope according to the present invention which uses an objective lens system such as the embodiment described above. The reference numeral **21** represents the objective lens system.

FIG. **33** is a side view of a non-flexible endoscope according to the present invention which uses an objective lens system such as the embodiment described above. The reference numeral **21** represents the objective lens system.

FIG. **34** shows a video camera according to the present invention which uses an objective lens system such as the embodiment described above. The reference numeral **21** represents the objective lens system.

FIG. **35** shows a perspective view illustrating a portable TV telephone according to the present invention which uses an objective lens system such as the embodiment described above. The reference numeral **21** represents the objective lens system, the reference numeral **22** designates an antenna for transmission and reception, the reference numeral **23** denotes a display, and the reference numeral **24** represents switches.

Further, FIG. **36** shows a perspective view illustrating a portable data input unit according to the present invention which uses an objective lens system such as the embodiment described above. The reference numeral **21** represents the objective lens system, the reference numeral **22** **22** designates an antenna for transmission and reception, the reference numeral **23** denotes a display, and the reference numeral **24** represents switches.

As understood from the foregoing description, the objective lens system for endoscopes according to the present invention is composed of lens elements in a number on the order of 2, and is nevertheless an optical system which favorably corrects aberrations, lateral chromatic aberration in particular, and has high optical performance.

What is claimed is:

1. A portable TV telephone, comprising:

an objective lens constructed and arranged to form an image of an object;

an antenna constructed and arranged to transmit and receive at least one of an image signal representing said image of the object, a dial signal and a voice signal carried by radio waves;

a display unit which displays at least a dial number and said image of the object; and

a switch which operates responsive to at least the dial number,

wherein said objective lens system includes a diffractive optical element configured to at least correct chromatic aberration produced by said objective lens system,

wherein said objective lens system has a stop,

wherein said diffractive optical element has a negative refractive power and

wherein said diffractive optical element is disposed on an object side of said stop.

2. A portable TV telephone comprising:

an objective lens system arranged to form an image of an object;

an antenna constructed and arranged to transmit and receive at least one of an image signal representing said image of the object, a dial signal and a voice signal carried by radio waves;

a display unit constructed and arranged to display at least a dial number and said image of the object; and

a switch constructed and arranged to operate responsive to at least the dial number,

wherein said objective lens system includes a diffractive optical element configured to at least correct chromatic aberration produced by said objective lens system, wherein said objective lens system comprises, in order from an object side, a first negative lens unit and a second positive lens unit, and wherein said first lens unit consists only of a negative lens element and said second lens unit consists only of a positive lens element.

3. A portable TV telephone comprising:

an objective lens system arranged to form an image of an object;

an antenna constructed and arranged to transmit and receive at least one of an image signal representing said image of the object, a dial signal and a voice signal carried by radio waves;

a display unit constructed and arranged to display at least a dial number and said image of the object; and

a switch constructed and arranged to operate responsive to at least the dial number,

wherein said objective lens system includes a diffractive optical element configured to at least correct chromatic aberration produced by said objective lens system, wherein said objective lens system comprises, in order from an object side, a first negative lens unit and a second positive lens unit, and wherein said diffractive optical element is cemented to a surface of said first negative lens unit.

4. A portable TV telephone comprising:

an objective lens system arranged to form an image of an object;

an antenna constructed and arranged to transmit and receive at least one of an image signal representing said image of the object, a dial signal and a voice signal carried by radio waves;

a display unit constructed and arranged to display at least a dial number and said image of the object; and

a switch constructed and arranged to operate responsive to at least the dial number,

wherein said objective lens system includes a diffractive optical element configured to at least correct chromatic aberration produced by said objective lens system, wherein said objective lens system comprises, in order from an object side, a first negative lens unit and a second positive lens unit, wherein said objective optical system comprises a stop which is disposed between said first negative lens unit and said second positive lens unit, and wherein said diffractive optical element is disposed on the object side of said stop.

5. The portable TV telephone according to claim **1**, **2**, **3** or **4**, wherein said objective lens system is disposed on a surface on which said image display unit is disposed.

6. The portable TV telephone according to claim **1**, **2**, **3** or **4**, wherein said objective lens system is disposed on a surface on which said switch is disposed.

(57) **ABSTRACT**

An apparatus for determining aberrations of an eye includes a patient head rest allowing for positioning adjustment. The patient head rest is operable with an optical table having a base. The base includes a probe beam generating apparatus, probe beam directing optics which itself comprises a beam splitter; a mirror; and a lens. The probe beam directing optics is capable of directing a probe beam toward an eye of a patient positioned on the patient head rest. Video image components are provided and comprise a light source, a mirror; and a video camera. The video image components are capable of generating an image of an eye of a patient positioned on the patient head rest. Eye fixation components generate a target that the eye of a patient positioned on the patient head rest can view. The eye fixation components comprise a fixation target, a light source, a lens, and a mirror. Wavefront directing and analyzing components measure a wavefront emanating from the eye of a patient positioned on the patient head rest and determine aberrations of the eye that range from at least about + or −1 diopters to at least about + or −6 diopters. The wavefront directing and analyzing components include a lens; a mirror, a microlens array, a camera, and a data processor.

APPARATUS AND METHOD FOR OBJECTIVE MEASUREMENT OF OPTICAL SYSTEMS USING WAVEFRONT ANALYSIS

This application is a continuation of U.S. patent application Ser. No. 09/566,409, filed May 8, 2000 now U.S. Pat. No. 6,460,997.

FIELD OF THE INVENTION

The invention relates generally to optical aberration measurement and analysis, and more particularly to an objective measurement of optical systems, such as systems of a human eye.

BACKGROUND OF THE INVENTION

Optical systems having a real image focus can receive collimated light and focus it at a point. Such optical systems can be found in nature, e.g., human and animal eyes, or can be man-made, e.g., laboratory systems, guidance systems, and the like. In either case, aberrations in the optical system can affect the system's performance. By way of example, the human eye will be used to explain this problem.

A perfect or ideal eye diffusely reflects an impinging light beam from its retina through optics of the eye which includes a lens and a cornea. For such an ideal eye in a relaxed state, i.e., not accommodating to provide near-field focus, reflected light exits the eye as a sequence of plane waves. However, an eye typically has aberrations that cause deformation or distortion of reflected light waves exiting the eye. An aberrated eye diffusely reflects an impinging light beam from its retina through its lens and cornea as a sequence of distorted wavefronts.

There are a number of technologies that attempt to provide the patient with improved visual acuity. Typically, treatment is determined by placing spherical and/or cylindrical lenses of known refractive power at the spectacle plane (approximately 1.0–1.5 centimeters anterior to cornea) and literally asking the patient which lens or lens combination provides the clearest vision. This is an imprecise measurement of true distortions in the reflected wavefront because 1) a single spherocylindrical compensation is applied across the entire wavefront, 2) vision is tested at discrete intervals (i.e., diopter units) of refractive values, and 3) subjective determination by the patient is employed. Thus, conventional methodology for determining refractive errors in the eye is substantially less accurate than the techniques now available for measuring the ocular aberrations.

One method of measuring ocular refractive errors is disclosed in U.S. Pat. No. 5,258,791 to Penney et al. for "Spatially Resolved Objective Autorefractometer," which teaches the use of an autorefractometer to measure the refraction of the eye at numerous discrete locations across the corneal surface. The autorefractometer is designed to deliver a narrow beam of optical radiation to the surface of the eye, and to determine where that beam strikes the retina using a retinal imaging system. Both the angle of the beam's propagation direction with respect to the optical axis of the system and the approximate location at which the beam strikes the corneal surface of the eye are independently adjustable. However, a small uncertainty or error in the location of the beam's point of incidence on the cornea exists due to the curved corneal surface. For each point of incidence across the corneal surface, the refraction of the eye corresponding to that surface point can be determined by adjusting the angle at which the beam strikes the cornea until the beam refracted on to the iris strikes the fovea centralis. Adjustment of the beam angle of propagation can be accomplished either manually by the patient or automatically by the autorefractometer, if a feedback loop involving a retinal imaging component is incorporated.

Penney '791 further teaches the use of the autorefractometer measurements in determining the appropriate corneal surface reshaping to provide emmetropia, a condition of a normal eye when parallel beams or rays of light are focused exactly on the retina and vision is perfect. This is accomplished by first obtaining an accurate measurement of corneal surface topography using a separate commercially available device. A mathematical analysis is then performed using an initial corneal topography at each surface reference point, the measured refraction at each surface point, and Snell's law of refraction, to determine a desired change in surface contour at each reference point.

A major limitation to the approach described by Penney '791 is that a separate measurement of corneal topography is desired to perform the Snell's Law analysis of needed refraction change. This adds significantly to the time and cost of a complete and desirable diagnostic evaluation. Further, the accuracy of the refraction change analysis will be dependent upon the accuracy of the topographic measurement and the accuracy of the autorefractometer measurement. In addition, any error in the spatial orientation of a topography map with respect to a refraction map will degrade the accuracy of the measured profile. Yet another limitation to known approaches such as described in Penney '791, by way of example, is that test points on the corneal surface are examined sequentially. Eye motion during the examination, either voluntary or involuntary, could introduce substantial errors in the refraction measurement. Penney '791 teaches detection of such eye movement by deliberately including measurement points outside the pupil, i.e., in the corneal region overlying the iris, where the return from the retina will obviously be zero at specific intervals in the examination sequence. However, this approach may still allow substantial undetected eye movement error between such iris reference points.

By way of example, one method and system known in the art, are disclosed by Junzhong Liang et al. in "Objective Measurement Of Wave Aberrations Of The Human Eye With The Use Of A Hartmann-Shack Wave-Front Sensor," published in the Journal of the Optical Society of America, Volume 11, No. 7, July 1994, pages 1949–1957. Liang et al. teach the use of a Hartmann-Shack wavefront sensor to measure ocular aberrations by measuring the wavefront emerging from the eye by the retinal reflection of a focused laser light spot on the retina's fovea. The actual wavefront is reconstructed using wavefront-estimation with Zernike polynomials.

The imprecise measurement technique of placing lenses of known refractive power anterior to the cornea and asking a patient which lens or lens combination provides the clearest vision has been improved with the use of autorefractometers, as described in Penny '79, or with the use of wavefront sensors as described by Liang et al. Spatially resolved refraction data, in combination with measured existing surface contour of the anterior surface of the eye, enable a calculation of a detailed spatially resolved new contour. However, it would be an improvement in this art if such vision measurements could be made without the need for this contour data, and further without the need for feedback from the patient regarding an appropriate lens. Liang et al. discloses the use of a Hartmann-Shack wavefront sensor to measure ocular aberrations by measuring the

wavefront emerging from the eye by retinal reflection of a focused laser light spot on the retina's fovea. A parallel beam of laser light passes through beam splitters and a lens pair which brings the beam to a focus point on the retina by the optics of the eye. Possible myopia or hyperopia of the tested eye is determined by movement of a lens within the lens pair. The focused light on the fovea is then assumed to be diffusely reflected and acts as a point source located on the retina. The reflected light passes through the eye and forms a distorted wavefront in front of the eye that results from the ocular aberrations. The aberrated wavefront is then directed to the wavefront sensor.

A point source of radiation on the retina would be ideal for such measurements. However, when the perfect eye receives a collimated beam of light, the best possible image on the retina is a diffraction limited spot. As illustrated by way of example, with Penny et al. and Liang et al., discussed above, and typical for those of skill in the art, parallel or collimated beams are used with the optics of the eye being measured to achieve this diffraction limited spot for such objective measurements. To do so, a setup for each patient includes a lens or lens combination and adjustments thereto for accommodating that patient's specific visual acuity. Providing a lens combination, as well as setting up for their use becomes cumbersome, time consuming, and at an additional expense. Eliminating the need for such optics is desirable and eliminates a variable within optical measurement systems that typically include many variables. Further, there is a need for providing optical characteristics of an eye without requiring feedback from the patient. By way of example, the patient may be a wild or domestic animal, living or dead.

The Hartmann-Shack wavefront sensor disclosed by Liang et al. includes two identical layers of cylindrical lenses with the layers arranged so that lenses in each layer are perpendicular to one another, as further disclosed in U.S. Pat. No. 5,062,702 to Bille. In this way, the two layers operate as a two-dimensional array of spherical lenslets that divide the incoming light wave into sub-apertures. The light through each sub-aperture is brought to focus in the focal plane of the lens array where a charge coupled device (CCD) image module resides.

The system of Liang et al. is calibrated by impinging an ideal plane wave of light on the lenslet array so that a reference or calibrating pattern of focus spots is imaged on the CCD. Since the ideal wavefront is planar, each spot related to the ideal wavefront is located on the optical axis of the corresponding lenslet. When a distorted wavefront passes through the lenslet array, the image spots on the CCD are shifted with respect to a reference pattern generated by the ideal wavefront. Each shift is proportional a local slope, i.e., partial derivatives of the distorted wavefront, which partial derivatives are used to reconstruct the distorted wavefront, by means of modal wavefront estimation using Zernike polynomials.

However, the system disclosed by Liang et al. is effective only for eyes having fairly good vision. Eyes that exhibit considerable myopia (near-sightedness) would cause the focus spots to overlap on the CCD, thereby making local slope determination practically impossible for eyes having this condition. Similarly, eyes that exhibit considerable hyperopia (farsightedness) deflect the focus spots such that they do not impinge on the CCD thereby again making local slope determination practically impossible for eyes having this condition.

SUMMARY OF THE INVENTION

In general, an embodiment of the present invention provides a method and system for objectively measuring aberrations of optical systems by wavefront analysis. Another embodiment further provides for the objective measurement of ocular aberrations having a dynamic range that can cope with large amounts of such aberrations so as to be useful in practical applications. Still another embodiment of the present invention provides a method and system for objectively measuring ocular aberrations using a wavefront analyzer of simple and inexpensive design.

One embodiment of the present invention provides an apparatus and method for making objective and detailed measurements of aberrations present in human eyes. Aberrations measured by the apparatus include "higher order" phenomena, such as spherical aberration and coma, in addition to the traditional myopia/hyperopia and astigmatism.

In accordance with an embodiment of the present invention, an energy source generates a beam of radiation. Optics, disposed in the path of the beam, direct the beam through a focusing optical system that has a rear portion which provides a diffuse reflector. The beam is diffusely reflected back from the rear portion as a wavefront of radiation that passes through the focusing optical system to impinge on the optics. The optics project the wavefront to a wavefront analyzer in direct correspondence with the wavefront as it emerges from the focusing optical system. A wavefront analyzer is disposed in the path of the wavefront projected from the optics and calculates distortions of the wavefront as an estimate of ocular aberrations of the focusing optical system. The wavefront analyzer includes a wavefront sensor coupled to a processor that analyzes the sensor data to reconstruct the wavefront to include the distortions thereof.

One embodiment of the present invention, herein described by way of example, utilizes wavefront sensing to measure the aberrations of the eye. When one considers the perfect or ideal eye as earlier described, a perfectly collimated light beam (i.e., a bundle of parallel light rays) incident on the perfect, ideal emmetropic eye, focuses to a diffraction-limited small spot on the retina. This perfect focusing is true for all light rays passing through the entrance pupil, regardless of position. From the wavefront perspective, the collimated light represents a series of perfect plane waves striking the eye. Due to the reversible nature of light ray propagation, the light emanates from an illuminated spot created on the retina as wavefronts exiting the ideal eye as a series of perfect plane waves. The apparatus of the present invention achieves this ray reversal effect using a probe beam optical path for projecting a small diameter, eye-safe laser beam into the eye and onto the fovea. The light scattered from the irradiated retina serves as a secondary source for a re-emitted wavefront. The probe laser beam strikes the retina at an appropriate foveal location to illuminate a sufficiently small spot. A fixation optical path is provided which includes a reference target aligned to an optical axis. This allows a patient to fixate on a target. A video path provides a video image of the eye plane, centered on the optical axis. A video image of the eye allows a clinical operator to assist in orienting the eye for the wavefront measurement.

Embodiments of the present invention, herein described, provide a refraction measurement system that easily accommodates the measurement of vision characteristics of the eye, even in the presence of finite refractive errors. The time for a patient to be in a fixed position during examination is reduced, while at the same time providing a useful source of light on the retina of the eye to be measured regardless of the characteristics of the eye of that patient or other patients to

be examined. Desirably, measurements are made without requiring patient or operator feedback. One method aspect of the invention for measuring optical characteristics of an optical system, such as the eye, includes focusing an optical beam onto an anterior surface of the eye for providing a finite source of secondary radiation on the retina of the eye, which secondary radiation is emitted from the retina as a reflected wavefront of radiation that passes through the eye. The reflected wavefront is directed onto a wavefront analyzer for measuring distortions associated with the reflected wavefront.

In one embodiment, the radiation is optical radiation and the wavefront sensor is implemented using a plate and a planar array of light-sensitive cells. The plate is generally opaque but that has an array of light transmissive apertures that selectively let impinging light therethrough. The plate is disposed in the path of the wavefront so that portions of the wavefront pass through the light transmissive apertures. The planar array of cells is arranged parallel to and spaced apart from the plate by a selected distance. Each portion of the wavefront passing through one of the light transmissive apertures illuminates a geometric shape covering a unique plurality of cells.

As herein described, by way of example, the wavefront optical path of the present invention relays the re-emitted wavefront from the corneal plane to an entrance face of a Hartman-Shack wavefront sensor. The wavefront incident on the sensor is received by a sensitive charged-coupled device (CCD) camera and an optical plate containing an array of lenslets. The lenslet array is parallel to the CCD detector face with a distance therebetween approximately equal to the focal length of each lens in the lenslet array. The lenslet array divides the incoming wavefront into a matching array of "wavelets," each of which focuses to a small spot on the CCD detector plane. The constellation of wavelet spots in the CCD is used to reconstruct the shape of the incident wavefront. Collimated light striking the lenslet at normal (perpendicular) incidence would focus to the spot on the CCD face where this optical axis intersects. The optics of the apparatus provides such collimated light to the wavefront sensor using a calibration optical path. Collimated light CCD images are routinely obtained as part of a daily calibration process and used for reference in analyzing experimental data.

However, in the case of a reflected aberrated wave front, light focuses to a spot displaced from the collimated reference point by a distance Dx. The distance from the lenslet face to the CCD surface, Dz, is precisely known. Therefore, dividing the measured displacement, Dx, by the known propagation distance, Dz, the slope of the wavefront at the location of this lens element is determined. The same calculation is applied in the y direction within the plane, and the entire process applied to every lenslet element irradiated by the wavefront. A mathematical algorithm is then applied to reconstruct the wavefront shape consistent with the calculated Dx/Dz and Dy/Dz slope data. Regardless of which wavefront sensor is used, the distance between the planar array of cells and the opaque plate, or the array of lenslets, can be varied to adjust the slope measurement gain of the wavefront sensor and thereby improve the dynamic range of the system.

Another measure of dynamic range enhancement is provided by the focusing optics. The focusing optics includes first and second lenses maintained in fixed positions in the path of the beam and wavefront. An arrangement of optical elements is disposed between the lenses in the path of the beam and the wavefront. The optical elements are adjustable to change the optical path length between the lenses.

A method aspect of the present invention, as herein described, determines aberrations of an eye requiring greater than a + or −3 diopter change, and includes directing an optical beam onto a retina of an eye, reflecting the optical beam from the retina of the eye, determining characteristics of a wavefront in a reflected optical beam, and generating data based on the characteristics of the wavefront, which data quantifies the aberrations of the eye. The data may further be generated based on refractive indices of media through which the optical beam passes. Yet further, data based on the characteristics of the wavefront, which data quantifies the aberrations of the eye for a discrete section of the eye may also be generated.

One method for determining aberrations of an eye, herein described by way of example, includes directing a probe beam along a probe beam path toward an eye, directing a fixation image along a fixation image path toward the eye, directing a light source along a video image path toward the eye, generating a video image of the eye, directing a wavefront originating from the eye along a wavefront path, wherein the probe beam path, the fixation image path, the video image path, and the wavefront path are coincident at least along a portion of their respective paths, the probe beam path terminating at the retina of the eye and the probe beam reflecting from the retina of the eye as a wavefront, aligning the eye with the probe beam path based at least in part on the video image of the eye generated by the light source directed along the video image path, measuring the wavefront, and generating data representative of the aberrations of the eye based on the measurement of the wavefront. Further, the aligning of the eye with the probe beam path based at least in part on the video image of the eye generated by the light source directed along the video image path, may have the wavefront pass through a single microlens array.

One apparatus for determining the aberrations of an eye comprises a patient head rest comprising vertical adjustment, the patient head rest associated with an optical table having a base. The base carries a probe beam generating apparatus, probe beam directing optics, the probe beam directing optics comprising a beam splitter; a mirror; and a lens, the probe beam directing optics being capable of directing a probe beam toward an eye of a patient positioned on the patient head rest, video image components, the video image components comprising a light source, a mirror, and a video camera, the video image components being capable of generating an image of an eye of a patient positioned on the patient head rest, eye fixation components, the eye fixation component comprising a fixation target; a light source; a lens; and a mirror, the fixation components being capable of generating a target that the eye of a patient positioned on the patient head rest can view, and wavefront directing and analyzing components, the wavefront directing and analyzing components comprising a lens, a mirror, a microlens array, a camera, and a data processor. The wavefront directing and analyzing components are capable of measuring the wavefront emanating from the eye of a patient positioned on the patient head rest and determining aberrations of said eye that range from at least about + or −1 diopters to at least about + or −6 diopters.

BRIEF DESCRIPTION OF THE DRAWINGS

Embodiments of the invention are described by way of example with reference to the accompanying drawings in which:

FIG. **1A** is a schematic view of the ideal eye reflecting light from its retina as a planar wavefront;

FIG. **1**B is a schematic view of an aberrated eye reflecting light from its retina as a deformed wavefront;

FIG. **1**C is a schematic view of the distorted wavefront relative to a reference plane to show the wavefront error or optical path difference as a function of transverse distance in the propagation direction;

FIG. **1**D is a schematic view illustrating use of a reference plane;

FIG. **2** is a simplified schematic of the system for determining ocular aberrations in accordance with the essential features of the present invention;

FIG. **3** is a schematic of one embodiment of a Hartmann-Shack wavefront analyzer used in the present invention;

FIG. **4** is a perspective view of a portion of the pinhole imaging plate and planar array of light-sensitive cells comprising the wavefront sensor from the embodiment of FIG. **3** where the deflection of a wavefront piece associated with an aberrated eye is shown in comparison with a wavefront piece associated with a calibration or planar wavefront;

FIG. **5** is a plan view of a designated area on the planar array of light-sensitive cells associated with a corresponding hole;

FIG. **6** is a schematic of another embodiment of a wavefront analyzer used in the present invention;

FIG. **7** is a schematic view of an eye to be measured by the present invention;

FIG. **8** is a schematic view of an eye to be measured by the present invention;

FIG. **9** is a side elevation view of one embodiment of the present invention illustrating a patient positioning for measurement;

FIG. **10** is an end elevation view of the embodiment of FIG. **9**;

FIG. **11** is an enlarged perspective view of an patient positioning portion of the embodiment of FIG. **9**;

FIG. **12** is a top plan view of optical elements of the embodiment of FIG. **9**;

FIG. **12**A illustrates a fixation target optical path of FIG. **12**;

FIG. **12**B illustrates a video image optical path of FIG. **12**;

FIG. **12**C illustrates a probe laser optical path of FIG. **12**;

FIG. **12**D illustrates a re-emitted wavefront optical path of FIG. **12**;

FIG. **12**E illustrates a calibration wavefront optical path of FIG. **12**;

FIGS. **12**F and **12**G are front elevation and top plan views of a trial lens holder useful with embodiments of the present invention herein described;

FIG. **13** is a block diagram illustrating electrical components of the embodiment of FIG. **9**;

FIG. **14** is an enlarged image of an eye illustrating a centration image;

FIG. **15** is a block diagram illustrating an operable flow of steps used in one embodiment of the present invention;

FIG. **16** is an enlarged image of an eye illustrating a pre-measurement eye alignment;

FIG. **17** is an enlarged image of an eye illustrating a pre-measurement eye alignment checking thereof;

FIG. **18** is a line diagram illustrating an eye registration pattern;

FIG. **19** illustrates a rejected CCD image;

FIG. **20** illustrates a CCD image including centroids;

FIG. **21** is an enlarged image of a centroid;

FIG. **22** illustrates an image available to an operator of a measured and reference centroid;

FIG. **23**A illustrates a spacial filter operable in one embodiment of the present invention;

FIG. **23**B illustrates a noisy CCD image before filtering to provide an image as illustrated with reference to FIG. **20**;

FIG. **24**A is a three dimensional plot of a wavefront reconstruction in accordance with the present invention;

FIG. **24**B illustrates a higher order aberration for the wavefront of FIG. **23**;

FIG. **25** illustrates a geometric effect of a curved corneal surface on a wavefront measurement;

FIG. **26**A is a pictorial line drawing illustrating magnification modification to the embodiment of FIG. **12**; and

FIG. **26**B is a pictorial line drawing illustrating optical elements of the present invention.

DETAILED DESCRIPTION OF THE INVENTION

The present invention will now be described more fully hereinafter with reference to the accompanying drawings, in which embodiments of the present invention are shown by way of illustration and example. This invention may, however, be embodied in many forms and should not be construed as limited to the embodiments set forth herein. Rather, these embodiments are provided so that this disclosure will be thorough and complete, and will fully convey the scope of the invention to those skilled in the art. Like numbers refer to like elements throughout.

By way of illustrative example, the present invention will be described with respect to diagnosing a human eye. However, it is to be understood that the teachings of the present invention are applicable to any optical system having a real image focus that can be, or can be adapted to diffusely reflect a focused spot of radiation from a rear portion of the optical system back through the optical system as a wavefront of radiation. Thus, the present invention can be used with human or animal eyes of patients that may be alive or dead, or any man-made optical system.

The method of using wavefront analysis will be introduced with reference to the eye example and the aid of the schematic drawings of FIGS. **1**A, **1**B, and **1**C. As earlier described with reference to an ideal eye, and with reference now to FIG. **1**A, the ideal emmetropic or perfect eye **100** diffusely reflects an impinging light beam (not shown for sake of clarity) from the back of its retina **102** (i.e., the fovea centralis **103**) through the eye's optics which includes lens **104** and cornea **106**. For such an ideal eye **100** in a relaxed state, i.e., not accommodating to provide near-field focus, the reflected light (represented by arrows **108**) exits the eye **100** as a sequence of plane waves, one of which is represented by straight line **110**. However, as illustrated with reference to FIG. **1**B, a typical eye **120** normally has aberrations that cause deformation or distortion of a reflected wave exiting the eye, where the aberrated eye **120** diffusely reflects an impinging light beam (again not shown for sake of clarity) from the back of its retina **122** of the fovea centralis **123** through lens **124** and cornea **126**. For the aberrated eye **120**, the reflected light **128** exits the eye **120** as a sequence of distorted wavefronts, one of which is represented by wavy line **130**.

With reference now to FIG. **1**C, a coordinate system is defined for convenience, where positive x is upward in the plane of the figure, positive y is outward from the plane of

the figure, and positive z is to the right along a propagation direction. The distorted wavefront **130** is herein described mathematically as W(x,y). One method of measuring distortions in the wavefront **130** is by determining a spatial separation Δz between a reference plane **131** (by way of example, a plane analogous to the ideal wavefront **110**) at a known distance Z_0 from the eye **120** at each (x,y) point of the distorted wavefront **130** as the leading edge of the wavefront **130** traverses the distance Z_0. This is described mathematically as:

$$\Delta z(x,y)=z_0-W(w,y) \tag{1}$$

These Δz measurements define optical path differences due to aberrations in the eye **120** being tested, by way of example.

Depending on the desired therapy (for example, synthetic lens addition), the material thickness at each (x, y) coordinate can be calculated directly if the refractive index of the material in question is known. For many procedures, such as intra-ocular lens implantation, a wavefront analysis may be performed repetitively during a procedure to provide feedback information as to the appropriate endpoint of the procedure.

In terms of the illustrative example, the differences Δz(x, y) between the distorted wavefront **130** and the ideal wavefront **110** are the consequence of the aberrations in the eye. Measuring these aberrations consists of introducing an optical path difference at the reference plane **131** of negative Δz(x,y). If the treatment approach, by way of example, consists of adding material to the cornea **126**, then one choice for the location of reference plane **131** is tangential to the surface of cornea **126** (i.e. at z=0). This is illustrated schematically with reference to FIG. **1**D, where the curvature of the cornea **126** is greatly exaggerated for clarity of illustration.

The appropriate corneal addition at any (x,y) transverse coordinate is, to within a small error, given by:

$$\Delta z(x,y)/(n_c-1) \tag{2}$$

where n_c is the refractive index of corneal tissue or 1.3775. The method described in detail below calculates Δz(x,y) by first measuring the local slopes in wavefront **130**, i.e. ∂W(x, y)/∂x and ∂W(x,y)/∂y, at a number of points in the transverse x and y directions in reference plane **131** and then generating a mathematical description of W(x,y) having slopes in best possible agreement with the experimentally determined values. One such slope ∂W(x, y)/∂x is illustrated with reference again to FIG. **1**D. In doing this, a small error is introduced due to the fact that distorted wavefront **130** is measured at the reference plane **131** while wavefront **130** emerged from a curved corneal surface just posterior to reference plane **131**. By way of example, an error $E_x(x,y)$ is the lateral displacement in the x-direction at each (x,y) location at the measurement plane (i.e., reference plane **131**) to the curved corneal surface. A similar error will be manifest for any measurements involving curved optical surfaces. The error will generally increase with both (x,y) displacement from the point of tangency and local wavefront error.

The magnitude of error $E_x(x,y)$ can be found for each measurement location (x,y) measured at an arbitrary coordinate, e.g., (x_0,y_0) by projecting that location back to the point of origin on the cornea **126**. This is explained mathematically with reference again to FIG. **1**D, where by way of example, it is assumed that the error is in the plane of the figure, i.e., the plane defined by $y=y_0$, although it is quite straightforward mathematically to extend the analysis to include errors in the y-dimension. The quantification of a line L tracing the propagation of the wavefront **131** measured at (x_0,y_0) in the z_0 reference plane from the corneal surface to the reference plane is:

$$L(x) = z_0 - \frac{(x - x_0)}{\partial W(x_0, y_0)/\partial x} \tag{3}$$

If the corneal surface in the plane of the figure is described by the expression $S(x_0,v_0)$, then the point of origin for the wavefront **131** in question can be found by finding the point of intersection between L(x) and S(x, y_0). Mathematically, one finds the value x', that satisfies $L(x')=S(x_0,y_0)$. The error $E_x(x_0,y_0)$ is then given as $Ex(x_0,Y_0)=x'-x_0$. Extending the analysis to consider errors in the y-direction would yield a similar expression for E_y where $E_y(x_0, y_0)=y'-y_0$. If significant, these transverse errors can be compensated for by laterally displacing the aberration calculated at each (x,y) coordinate by the amounts $E_x(x,y)$ and $E_y(x,y)$.

In the case of human corneas, the transverse error under most circumstances will be negligible. The error will be zero at the origin where the corneal tissue and reference plane **131** are tangent. For human corneas, the tissue is approximately spherical with a radius of curvature of approximately 7.5–8.0 mm. The treatment radius is typically no more than 3 mm, and local wavefront radius of curvature will almost never exceed 50 mm (a 20 diopter refractive error). The transverse error E at a 3 mm treatment radius for a local wavefront radius of curvature of 50 mm is less than 40 μm.

For certain ophthalmic procedures, wavefront analysis can also be used repetitively during the procedure to provide useful feedback information. One example of such use would be following placement of an intra-ocular lens implant (IOL). The analysis helps to identify whether the appropriate refractive power IOL has been inserted, or whether a different refractive power IOL should be used.

In order to perform wavefront analysis in a manner compatible with procedures such as those described above, the amount of spatial separation of component portions of wavefront **130** relative to the corresponding component portions of the planar or ideal wavefront **110** is measured. It is the system and method of the present invention that allows such separation to be objectively and accurately measured for even substantially aberrated eyes **120** including those exhibiting severe defects such as severe myopia or hyperopia.

For the evaluation or measurement portion of the present invention, the patient's pupil should ideally be dilated to approximately 6 mm or more, i.e., the typical size of a human pupil in low light. Smaller amounts of dilation or no dilation at all may also evaluated or measured. In this way, the eye is evaluated while it is using the greatest area of the cornea so that any measurement takes into account the largest usable corneal area of the patient's eye. A lesser amount of the cornea is used in daylight where the pupil is considerable smaller, e.g., on the order of 3 millimeters. Dilation can be brought about naturally by implementing the measurement portion of the present invention in a low light environment such as a dimly lit room. Dilation can also be induced through the use of pharmacologic agents.

Referring now to FIG. **2**, a simplified schematic of one exemplary embodiment of the apparatus **10** of the present invention is illustrated. The apparatus **10** includes a laser **12** for generating optical radiation used to produce a small-diameter laser beam **14**. The laser **12** generates a collimated laser light beam (represented by dashed lines for the beam **14**) of a wavelength and power that is eye safe. For oph-

thalmic applications, appropriate wavelengths would include the entire visible spectrum and the near infrared spectrum. By way of example, appropriate wavelengths may be in a range of from approximately 400 to 1000 nanometers, including 550, 650, 850 useful wavelengths. While operation in the visible spectrum is generally desired, since these are the conditions in which the eye operates, the near infrared spectrum may offer advantages in certain applications. For example, the patient's eye may be more relaxed if the patient does not know measurement is taking place. Regardless of the wavelength of the optical radiation, power should be restricted in ophthalmic applications to eye safe levels. For laser radiation, appropriate eye-safe exposure levels can be found in the U.S. Federal Performance Standard for Laser Products. If the analysis is to be performed on an optical system other than the eye, the examination wavelength range logically should incorporate the intended performance range of the system.

To select a small-diameter collimated core of laser light beam **14**, an iris diaphragm **16** is used to block all of laser light beam **14** except for the laser beam **18** of a size desired for use. In terms of the present invention, the laser beam **18** will have a diameter in the range of approximately 0.5–4.5 millimeters with 1–3 millimeters being typical, by way of example. A badly aberrated eye uses a smaller diameter beam while an eye with only slight aberrations can be evaluated with a larger diameter beam. Depending on the output divergence of the laser **12**, a lens, as will be later described, can be positioned in the beam path to optimize collimating of the beam.

Laser beam **18**, as herein described by way of example, is a polarized beam that is passed through a polarization sensitive beam splitter **20** for routing to a focusing optical train **22** which optical train operates to focus the laser beam **18** through the optics of the eye **120** (e.g., the cornea **126**, pupil **125** and the lens **124**) to the retina **122**. It is to be understood that the lens **124** may not be present for a patient that has undergone a cataract procedure. However, this does not affect the present invention. In the illustrated example of FIG. **2**, the optical train **22** images the laser beam **18** as a small spot of light at or near the eye's fovea centralis **123** where the eye's vision is most acute. Note that the small spot of light could be reflected off another portion of retina **122** in order to determine aberrations related to another aspect of one's vision. For example, if the spot of light were reflected off the area of the retina **122** surrounding the fovea centralis **123**, aberrations specifically related to one's peripheral vision could then be evaluated. In all cases, the spot of light may be sized to form a near-diffraction limited image on the retina **122**. Thus, the spot of light produced by laser beam **18** at fovea centralis **123** does not exceed approximately 100 micrometers in diameter and, typically, is on the order of 10 micrometers.

The diffuse reflection of the laser beam **18** back from the retina **122** is represented in FIG. **2** by solid lines **24** indicative of radiation that passes back through the eye **120**. The wavefront **24**, earlier described with reference to FIG. **1**B as distorted wavefront **130** impinges on and is passed through the optical train **22** and on to the polarization sensitive beam splitter **20**. The wavefront **24** is depolarized relative to the laser beam **18** due to reflection and refraction as the wavefront **24** emanates from the retina **122**. Accordingly, the wavefront **24** is turned at the polarization sensitive beam splitter **20** and directed to a wavefront analyzer **26** such as a Hartmann-Shack (H-S) wavefront analyzer. In general, the wavefront analyzer **26** measures the slopes of wavefront **24**, i.e., the partial derivatives with respect to x and y, at a number of (x,y) transverse coordinates, as earlier described with reference to FIGS. **1**C and **1**D. This partial derivative information is then used to reconstruct or approximate the original wavefront with a mathematical expression such as a weighted series of Zernike polynomials.

The polarization states for the incident laser beam **18** and the beam splitter **20** minimizes the amount of stray laser radiation reaching the sensor portion of the wavefront analyzer **26**. In some situations, stray radiation may be sufficiently small when compared to the radiation returning from the desired target (e.g., the retina **122**) so that the polarization specifications are unnecessary.

The present invention is able to adapt to a wide range of vision defects and as such achieves a new level of dynamic range in terms of measuring ocular aberrations. Dynamic range enhancement is accomplished with the optical train **22** and/or a wavefront sensor portion of the wavefront analyzer **26**. With continued reference to FIG. **2**, the optical train **22** includes a first lens **220**, a flat mirror **221**, a Porro mirror **222** and a second lens **224** all of which lie along the path of laser beam **18** and the wavefront **24**. The first lens **220** and the second lens **224** are identical lenses maintained in fixed positions. The Porro mirror **222** is capable of linear movement as indicated by arrow **223** to change the optical path length between the lenses **220** and **224**. However, it is to be understood that the present invention is not limited to the particular arrangement of the flat mirror **221** and the Porro mirror **222** and that other optical arrangements, as will herein be described by way of example, will be used without departing from the teachings and benefits of the present invention.

A "zero position" of the Porro mirror **222** is identified by replacing the eye **120** illustrated with reference again to FIG. **2**, by a calibration source, as will be described later by way of further example, of collimated light to provide a reference wavefront such as the perfect plane wave **110**, earlier described with reference to FIG. **1**A. Such a source could be realized by a laser beam expanded by a beam telescope to the diameter that will cover the imaging plane of wavefront analyzer **26** and adjustment of the Porro mirror **222** until the wavefront analyzer **26** detects the light as being collimated. Note that the changes in optical path length brought about by the Porro mirror **222** can be calibrated in diopters to provide an approximate spherical dioptric measurement, as will be explained further below.

The dynamic range of the apparatus **10** is further improved by providing an improved wavefront sensor arrangement **28** as illustrated with reference to FIGS. **3** and **4**. The wavefront analyzer **26** includes an opaque imaging plate **32** having an array of holes **34** passing therethrough, a planar array **36** of light-sensitive cells such as charge coupled device (CCD) cells **38**, and a processor **40** operable with the planar array **36** of the CCD cells **38**. The combination of the plate **32** and the planar array **36** provides one embodiment of the present invention. The plate **32** is held parallel to and spaced from the planar array **36** by a separation distance F. As will be explained further below, the separation distance F can be varied to adjust for signal gain. To do this, the planar array **36** is coupled to a positioning apparatus **42**, e.g., a conventional motorized linear positioner having precise movement capability, that adjusts the position of planar array **36** relative to the plate **32** for changing the separation distance F as indicated by arrow **43**. With respect to the array of holes **34**, each of the holes **34** are of equal size and shape with a circle being typical owing to its ease of manufacture. As herein described by way of

example, a square array geometry is used for the array of holes **34**, although other array geometries will be used without departing from the teachings of the present invention.

As illustrated with reference to FIG. **4**, when the wavefront **24** impinges on the plate **32**, a portion of the wavefront **24**, indicated by arrow **25**, passes through the hole **34** to illuminate planar array **36**. To a first order, the resulting image formed by each such wavefront portion **25** is a positive shadow of the respective hole **34**. However, diffraction occurs as determined by the diameter D of each hole **34**, the wavelength A of the light source (e.g. the wavefront **24**) and the separation distance F between the plate **32** and the planar array **36**. The value of F is varied by the positioning apparatus **42** to adjust the gain based on the particular patient as will be explained further below.

Note that performance of the plate **32** with holes **34** may also be accomplished using a solid plate or film made from a light-sensitive material such as a photolithographic film. In such a case, the array of holes **34** would be replaced by an array of shaped light transmissive apertures through which light passes when impinging thereon. The remainder of such a plate or film would be impervious to light. Such an embodiment permits the light transmissive apertures to be easily made to conform to any desired shape.

Regardless of how each wavefront portion **25** is generated, the present invention measures the amount of angular deflection of each wavefront portion **25** relative to a wavefront portion **112** that results from a calibration wavefront such as the planar wavefront earlier described. The calibration or planar wavefront of light results in the wavefront portion **112** impinging at a normal or perpendicular to plate **32** and illuminates a geometric spot **114** on the planar array **36**. In contrast, continuing with the wavefront **24** representing a distorted wavefront as described above, the wavefront portion **25** will exhibit an amount of angular deflection relative to the calibration wavefront portion **112**. The angular deflection causes the wavefront portion **25** to illuminate a geometric spot **27** on the planar array **36** that is offset from the spot **114**. In terms of the present invention, the amount of offset is measured relative to centroids **116** and **29** of spots **114** and **27**, respectively. In the two dimensions of the planar array **36**, the centroid **29** is typically deflected in both the x and y directions of the array **36**. Thus, the angular deflection in each of the x and y directions is given by $\Delta x/F$ and $\Delta y/F$, respectively.

With reference again to FIG. **2**, the lenses **220** and **224** in one embodiment are identical as mentioned above. However, in certain applications it may be desirable to magnify or minify the wavefront at the wavefront sensor. This can be accomplished by using lenses **220** and **224** of different focal lengths and adjusting dimensions of the apparatus **10** accordingly. For ophthalmic evaluation, the object plane of the apparatus should ideally be tangent to the corneal surface which can be achieved by a variety of means. Thus, each point at the object plane of the optical train **22** very nearly corresponds to the same point on the cornea **126**. However, since the cornea **126** is curved, there will be a slight lateral displacement. The plate **32** described earlier with reference to FIG. **4** of the wavefront analyzer **26**, or an imaging plane of any wavefront sensor portion, is positioned at the focal plane of lens **220**. In this way, the object plane is always imaged on the plate **32** in direct correspondence with the wavefront image emerging from cornea **126**. This will be true regardless of the optical path length between the lenses **220** and **224**. There are several advantages to this structure, one of which is that there are very good planar arrays of light-sensitive cells that are commercially available to image an area corresponding to the 6 millimeter central circular region of the cornea.

The plate **32** (or the imaging plane of any wavefront sensor portion of a wavefront analyzer) breaks the wavefront **24** into wavefront pieces that can each be measured independently in terms of propagation direction at the planar array **36**. Since in an embodiment herein described by way of example, the optical train **22** does not magnify or reduce the image in the object plane, a point at the object plane corresponds to the same point at the image plane of the optical train. With the Porro mirror **222** set at its zero position, the direction each portion of the wavefront **24** is traveling toward the object plane is reproduced exactly at the image plane of wavefront analyzer **26**. By way of example, if one wavefront portion at a location in the object plane was traveling away from the optical axis at an angle of 20° with respect to the optical axis that is perpendicular to the object plane, the wavefront portion at the same location in the image plane will also be traveling away from the optical axis at an angle of 20°.

Note that a person who is myopic will produce a wavefront such that the wavefront portions/pieces isolated by the plate **32** will converge toward the center of planar array **36**. A hyperopic person will produce a wavefront such that the wavefront pieces isolated by the plate **32** diverge. Thus, a person with a significant vision error becomes difficult to evaluate because wavefront portions can either overlap (myopia) at the planar array **36** or spill off (hyperopia) the planar array.

In the present invention, five ways of compensating for such severe aberrations are herein described by way of example. The first way is to utilize a wavefront sensor with sufficiently small light sensitive cells **38** and sufficiently large holes **34** (or any other transmissive aperture). In this way, measurement of each wavefront piece can be performed to an acceptable accuracy using a small value for F. A second way is to move planar array **36** along the optical axis to change the separation distance F to the plate **32**. For a person with a severe aberration, the planar array **36** is positioned close to the plate **32** to keep the projected wavefront portions well separated and on the planar array. For a mild aberration, the planar array **36** is moved to increase the separation distance F to the plate **32** to make a more accurate measurement. The advantage of moving the planar array **36** to change the separation distance F to the plate **32** is that the wavefront analysis is easily achieved for any position. Yet another way of compensating for severe aberrations using the present invention is to change the optical path length between lenses **220** and **224**. Moving the Porro mirror **222** will not affect where the wavefront hits the plate **32**, but will change the angular deflections at which the projected wavefront portions pass through the plate **32**, i.e., $\Delta x/F$ and $\Delta y/F$. Decreasing the optical path length between lenses **220** and **224** will tend to pull the wavefront portions toward the center of planar array **36** thereby compensating for hyperopia. Increasing the optical path length between lenses **220** and **224** will tend to spread the wavefront portions toward the edges of the planar array **36** thereby compensating for myopia. The degree to which the angular deflection associated with each wavefront piece is altered is a linear function of its distance off the optical axis and the movement of the Porro mirror **222** from its zero position. A fourth way of compensating for severe aberrations is to insert one or more trial lenses of specified sphero-cylindrical power at the location of the intermediate focal plane, as will be discussed in detail later in this section. This serves to

reduce or remove low order aberrations from the wavefront so that displacement of spots at the CCD cells **38** is minimized and accurate evaluation can proceed. The effect of the specified lens addition is then included in the final wavefront reconstruction. A fifth way is to increase the magnification of the wavefront at the wavefront sensor relative to that at the eye.

This is accomplished by an appropriate choice of lenses in the relay optic design. Magnification will reduce the slope of the wavefront uniformly, thereby reducing the displacement of each spot at the CCD.

By way of example, to accurately determine the centroid **29** of the spot **27** of light impinging on the planar array **36**, a fine structure of cells **38** relative to a spot size is provided. Each spot covers a plurality of cells **38**. One method used to determine the centroid **29** of each spot **27** unambiguously with respect to a spot caused by another one of the holes **34**, assigns a unique number of cells **38** to each hole **34**. The "assigned areas" are designated, as illustrated with reference to FIG. **5**, by way of example, with the heavy grid lines **39**. It is to be understood that the grid lines **39** are not actual physical boundaries between cells **38** but are shown simply to illustrate the unique designated areas containing a plurality of the cells **38**. It is anticipated that other centroid strategies will be utilized that do not necessitate such partitioning of the array **36** given the teachings of the present invention. An alternative method for identifying and correlating centroids is later described in this section.

By way of example, the present invention could also be practiced with a wavefront analyzer that replaces plate **32** described with reference to FIG. **3**, with a two dimensional array of identical spherical lenslets **33**, as illustrated with reference to FIG. **6**. In such an embodiment, the lenslet array **33** may be operable by the positioning apparatus **42** such that separation distance F is independent of the focal length f that defines the focal plane of the lenslet array **33** which is represented by dashed line **35**. Each wavefront portion **37** passed through a sub-aperture of the lenslet array **33** is reduced in size (e.g., diameter) but is not necessarily brought to a minimum focus at the planar array **36** as it would be if separation distance F were equal to focal length f. In the operation of this embodiment configuration, the lenslet array **33** is positioned to concentrate the light in each wavefront portion of an area for providing sufficient intensity onto the planar array **36**, yet still illuminating a substantial plurality of cells **38** for greatest accuracy in determining the deflection of the centroids **29**.

Regardless of the structure of the wavefront sensor, the processor **40** computes each two-dimensional centroid **29** of each spot **27** generated by the wavefront **24**. The amount of two dimensional centroid shift relative to the centroid of the calibrating spot for each designated area associated with a corresponding hole **34** (or sub-aperture of lenslet array **33**) is divided by the separation distance F to generate a matrix of local slopes of the wavefront, i.e., $\partial W(x,y)/\partial x$ and $\partial W(x,y)/\partial y$ at the (x,y) coordinates of the centers of holes **34**. For simplicity of discussion, these will be indicated by $P(x,y)=\partial W(x,y)/\partial x$ and $Q(x,y)=\partial W(x,y)/\partial y$, respectively.

Numerous methods exist for using the partial derivative data to calculate the distorted wavefront **130** and **24** as described above with reference to FIGS. **1**B and **2**. One acceptable approach is that described by Liang et al. in the aforementioned Journal of the Optical Society of America paper, where the wavefront is approximated using Zernike polynomials. This is a standard analytic technique described in numerous optics texts such as "Principles of Optics, 11 by M. Born and E. Wolf, Pergamon Press, Oxford, England, 1964. By way of example, the Zernike polynomial approach will be discussed herein. However, it is to be understood that other mathematical approaches can be used in approximating the distorted wavefront. By way of example, such approaches may include the use of Fourier series and Taylor series.

$$W(x,y)=\sum_{i=0}^{n} C_i Z_i(x,y) \tag{4}$$

Briefly, the wavefront W(x,y) is expressed as a weighted sum of the individual polynomials where Ci are the weighting coefficients, and $Z_i(x,y)$ are the Zernike polynomials up to some order. The upper limit n of the summation is a function of the number of Zernike polynomials, i.e., the highest order, used to approximate the true wavefront. If m is the highest order used, then

$$n=(m+1)(m+2)/2 \tag{5}$$

Derivation of the Zernike polynomials up to an arbitrary order n is described in numerous optical texts such as the aforementioned book by Born and Wolf. One possible method of determining the centroid **29**, **116** of a spot **27**, **114**, respectively, as earlier described with reference to FIGS. **4** and **5**, and calculation of the Zernike weighting coefficients will now be explained. The directions of the unit normals at the center of each hole **34** are based on the centroids of the spots on cells **38**.

Since each spot will illuminate a plurality of cells varying intensity, a standard amplitude-weighted centroid calculation can be used to find the center of each spot. In order to clearly delineate each centroid from background noise, by way of example, resulting from spurious light reaching the CCD surface between valid spots, standard mathematical techniques such as a matched spatial filter can be applied to the CCD data prior to centroid identification.

An alternative method is herein described for identifying individual spots and correlating their geometry. The apparatus is configured such that the optical axis is aligned to the center of a particular aperture at the entrance face of the wavefront sensor. This aperture is located at or near the center of the entrance face. If the probe beam entering the eye is also aligned to the system optical axis, then due to the reversible nature of light rays, a light spot will always be seen directly behind the aligned aperture. That is, a spot will always be seen on the CCD sensor at this location, regardless of the wavefront aberrations, and will always correspond to the overlying aperture. Immediately adjacent spots will be minimally displaced from their "zero slope" locations. As one moves further from the central reference spot, generally greater spot displacements will occur. Using this knowledge, it is a relatively straight forward process to identify all the spots in the CCD pattern and establish their geometric relationships.

The displacement of the centroid from that of a perfectly collimated light beam, corresponding to ideal and emmetropic vision, is then calculated and used to determine the wavefront slope at each sample location. The location of the centroids for a collimated light beam may either be directly measured in a calibration step prior to the patient exam, or taken from a calculated reference pattern based on the wavefront sensor construction.

Multiple exposures may be used to check for improper eye alignment or eye movement during individual exposures. If eye movement during exposures cannot be analyzed successfully by acquiring multiple exposures, then the appa-

ratus **10** can be augmented by the addition of an eye tracker **25**, illustrated with reference again to FIG. **2**. One possible placement of the eye tracker **25** is herein illustrated. However, it is to be understood that the eye tracker **25** could be placed elsewhere within the apparatus **10**. In this way, wavefront analysis is performed even during a limited amount of eye motion.

A one-time calibration exposure can also be used to determine the relative sensitivities of the individual cells. This is made in uniform collimated light with plate **32** removed. The responses of individual cells are then recorded. For each light transmissive aperture (e.g., hole **34**), the centroid in the collimated case serves as a dedicated origin for the particular hole. The shift from the "origin" for each hole to the centroid caused by the wavefront **24** (as observed in this coordinate system) is determined by the direction of the wave surface corresponding to that hole. If Δx(m,n) is the x-component of the (m,n)th centroid and F is the plate separation, then the P-value for the (m,n)th centroid is:

$$P(m,n)=\partial x(m,n)/\partial z=\Delta x(m,n)/F \tag{6}$$

The corresponding expression for Q is:

$$Q(m,n)=\partial y(m,n)/\partial z=\Delta y(m,n)/F \tag{7}$$

Thus, each P(m,n) and Q(m,n) represents the partial derivatives of W(x,y) with respect to x and y for the (x,y) coordinates of each hole **34**. For an m-order Zernike approximation of the original wavefront, the experimentally determined P's and Q's are then used in the following equations to calculate the appropriate C_i weighting coefficients as follows:

$$P(m,n)=\frac{\partial W(x,y)}{\partial x}=\sum_{i=0}^{n} C_i \frac{\partial Z_i(x,y)}{\partial x} \tag{8}$$

$$Q(m,n)=\frac{\partial W(x,y)}{\partial x}=\sum_{i=0}^{n} C_i \frac{\partial Z_i(x,y)}{\partial x} \tag{9}$$

By using a least-squares approx(m,n)/∂zach to minimize the error between the actual wavefront slopes on the left hand side in the above equations and the Zernike approximations on the right hand side, optimal values for the weighting coefficients can be obtained.

In one possible approach to calculating a centroid $(x_{c'}y_{c'})$, each hole **34** is assigned its dedicated area of the array **36** or $(i_{m,n}\pm\Delta i,j_{m,n}\pm\Delta j)$. This square of many light-sensitive cells is large enough that neighboring hole images never encroach, and all illumination from this hole is contained. The square contains 4Δi*Δj cells.

If array **36** is designated $C_{k,1}=(x_c(i,j), y_{c'}(i,j))$, k, 1=0 . . . 2Δ1, 2Δj, and the spacing on centers is Δx=Δy=d, the measured cell responses are V(k, 1) and the relative responsivities are R(k,I), then the x-component $x_{c'}$ a function of i, j is represented by

$$x_c(i,j)=[\Sigma_{k,1}V(k,1)*R(k,1)*d*k]/[\Sigma_{k,1}V(k,1)*R(k,1)] \tag{10}$$

and the y-component $y_{c'}$ as a function of i,j is represented by

$$y_c(i,j)=[\Sigma_{k,1}V(k,1)*R(k,1)*d*I]/[\Sigma_{k,1}V(k,1)*R(k,1)] \tag{11}$$

Then, if $(x_{c0}(i,j), y_{c0}(i,j))$ is the "origin centroid" for the (i, j) hole, i.e., made in perpendicular collimated light, and $(x_{cw}(i,j), y_{cw}(i,j))$ is the corresponding centroid found for the wavefront to be measured, then the relative centroid shift $(x_{cr}(i,,j)), Y_{cr}(i,j))$ is found as

$$x_{cr}(i,j)=x_{cw}(i,j)-x_{c0}(i,j) \tag{12}$$

$$y_{cr}(i,j)=y_{cw}(i,j)-y_{c0}(i,j) \tag{13}$$

The values P(i,j) and Q(i,j) are determined from

$$P(i,j)=x_{cr}(i,j)/F \tag{14}$$

and

$$Q(i,j)=y_{cr}(i,j)/F \tag{15}$$

The surface partial derivatives P(i,j) and Q(i,j) for the array of hole centers of plate **32** are next used to calculate the appropriate Zernike polynomial weighting coefficients to describe the original wavefront W(x,y). This will now be explained by way of illustration for a 7×7 square array of holes **34**. However, it is to be understood that other sizes and shapes of hole arrays could be used.

First, a 1×98 matrix (i.e., column vector) PQ(k) is formed as

$$PQ(k)=P(7i+j),\ j=0\ldots 6,\ i=0\ldots 6,\ k=0\ldots 48 \tag{16}$$

$$PQ(k)=Q(7i+j),\ j=0\ldots 6,\ i=0\ldots 6,\ k=49\ldots 98 \tag{17}$$

with j cycling for each i, i.e., PQ(18)=P(2,5).

The matrix PQ is multiplied from the left with a transition matrix TM to get the matrix C as follows

$$C=TM*PQ \tag{18}$$

where TM is a 98 wide by 14 high matrix and C is a 1 wide by 14 high matrix or column vector. C is the matrix C_k k=1, . . . , 14 such that, to a least square error,

$$W(x,y)=\Sigma_k C_k*Z_k(x,y) \tag{19}$$

and TM is calculated for a given aperture, e.g., a 6 millimeter pupil aperture. The functions $Z_k(x,y)$ in equation (19) are the Zernike polynomials. There is no standard convention as to their sequence. Thus, for consistency, it is important that the same sequence is used to produce the set C_k that was chosen for deriving the matrix TM. They occur in groups of the same order, which is the highest exponent in the group, with the total number of members in an order increasing with the order. For example, in a fourth order analysis, orders up to and including 4 are used (less Z_0—the single member of order 0 that is the constant 1 which describes the reference position of the group in the z direction). Since wavefront **24** is moving along z (at the velocity of light), this "piston term" describes only an arbitrary offset in Z, and this term may be ignored. The first 5 orders (0, 1, . . . ,4) contain 15 functions including the piston term.

Thus, in the illustrated example, 14 values of C_k are calculated as coefficients of 14 Zernike polynomials. By way of example, one such order used to calculate TM is herein illustrated, and includes both the Zernike functions and their partial derivatives.

Z(14)	$+y^4 - 6x^2y^2 + x^4$
dZ(14)/dx	$-12xy^2 + 4x^3$
dZ(14)/dy	$+4y^3 - 12x^2y$

The choice of sequencing the Zernike polynomials dictates the interpretations of the C_k in equation (19) and therefore the order of terms in the TM matrix. Hence, the TM matrix is calculated after the choice is made. The development of the TM matrix for the illustrated example will be explained below.

Note that the fourth order analysis is only an example and is not the only possibility. A Zernike analysis can be done to any order. In general, the higher the order, the more accurate the result over the tested points. However, an exact polynomial fit over the tested points is not necessarily desirable. Such fits have the typical disturbing property that, unless the surface itself happens to be an exact polynomial of order no higher than that used for the surface fit, forcing an exact fit at separated points often causes wild swings between fitted points. That is, in polynomial surface fitting, an exact fit at a finite number of points can yield a poor average fit for a general function.

Calculation of the $\Delta z(x,y)$ optical path difference information from the Zernike reconstruction of the wavefront is accomplished simply by subtracting a constant from the Zernike approximation. The value of the constant will depend on the desired characteristics of $\Delta z(x,y)$. Depending on the method chosen to compensate for the aberrations (e.g., lens addition, etc.) it may, for example, be desirable to set either the maximum, mean or minimum value in $\Delta z(x,y)$ equal to zero.

The development of the transition matrix TM will now be explained for the illustrated example of a 7×7 array of holes in plate **32**. At each point (x_i,y_j), the tangents of the components of the normal are $P(x_i,y_j)$ and $Q(x_i,y_j)$ where

$$P(x_i,y_j)=\partial W(x_i,y_j)/\partial x \tag{20}$$

and

$$Q(x_i,y_j)=\partial W(x_i,y_j)/\partial y \tag{21}$$

Combining these with equation (11),

$$P(x_i,y_j)=\Sigma_k C_k \partial W(x_i,y_j)/\partial x \tag{22}$$

and

$$Q(x_i,y_j)=\Sigma_k C_k \partial W(x_i,y_j)/\partial y \tag{23}$$

each applicable to 49(i,j) combinations. These are combined into a single column vector PQ that is 98 elements high, i.e., a 98×1 matrix. Defining two matrices C_k (14 high×1 wide) and $M_{k,(i,j)}$ (14 wide×98 high)

$$(M_{k,(i,j)})=\partial Z_k(x_i,y_j)/\partial x;\ \partial Z_k(x_i,y_j)/\partial y \tag{24}$$

where the x-derivatives are the first 49 rows and the y-derivatives are the last 49 rows. Then, equation (19) can be rewritten as the matrix equation

$$(PQ)=(M)(C) \tag{25}$$

where the top 49 rows of M are the $\partial W(x_i, y_j)/\partial y$.

The expression in equation (25) gives the normal components in terms of the Zernike coefficients for a surface described by the array of 14 C's. These are exact, but it is not guaranteed that the actual total surface can be described by such an array of coefficients. Accordingly, if it is assumed that the description is within an acceptable tolerance, i.e., tolerating the errors that remain after least square error determination, then equation (26) can be considered to define the column vector C implicitly in terms of the mathematical matrix M and the measured vector PQ, both of which are known. The method of effecting the solution under the minimization condition is as follows. First, equation (25) is multiplied on the left by M^T, the transpose of M such that

$$(M^T)(PQ)=(M^T)(M)(C)=(S)(C) \tag{26}$$

where

$$S \equiv M^T M \tag{27}$$

is a square and symmetric matrix, e.g., of dimensions 14×14 (with each element the sum of 98 products). Such a matrix has an inverse unless the determinant of its coefficients is zero. Since this is based on the Zernike polynomials alone, and they are all independent of each other, the determinant is non-zero, so that an inverse S^{-1} is defined. Next, equation (25) is multiplied on the left by S^{-1} to yield

$$(S^{-1})(M^T)(PQ)=(S^{-1})(S)(C)=(I)(C)=C \tag{28}$$

Then, the mathematical transition matrix (independent of measurement) is

$$(TM)=(S^{-1})(M^{T}) \tag{29}$$

and the "best fit" array of C's from the measured PQ's can be produced by the simple matrix multiplication

$$(C)=(TM)(PQ) \tag{30}$$

To evaluate the eye unambiguously, all spots illuminating the planar array **36** due to a wavefront **24** are incident on the planar array simultaneously. If it is desired to reduce effects of eye movement, a pulsing or shuttering laser source may be used, or an eye tracker.

With reference again to FIGS. **7** and **8**, a beam of linearly polarized light (S-component) is emitted from a diode laser (670 nm, 3 mW by way of example), which beam of light passes through an electro-mechanical shutter, which controls the duration of light exposure on the eye **14** of the patient, and in particular, the exposure of the retina **18** of the eye **14** illustrated with reference again to FIGS. **7** and **8**. It is expected that alternate sources of light, for example, non-coherent and non-polarized, as well as alternate light transmitting techniques will come to the mind of those skilled in the art. When the shutter is open, the projected beam, collimated light from the diode laser, is directed by a long focal length lens for focusing on the anterior surface **22** of the cornea **24** of the eye **14**, as illustrated with reference to FIG. **7**, passing through the pupil **72** and lens **28** of the eye **14**, and onto the retina **18** as the small measurable spot **16**. In an alternate embodiment, the lens comprises a zoom lens for varying the focus and moving the focus location as desired. By focusing on the cornea **24**, the measurement is minimally dependent on the curvature of the cornea. However, other locations proximate the corneal surface are acceptable.

It is typical in the art of eye measurements to form a collimated beam and attempt to focus the collimated beam onto the retina, using lenses and lens combinations with the optics of the eye to produce the smallest possible spot **36**, as earlier described with reference to FIG. **8**. Lenses and focusing techniques typically take valuable time and include multiple attempts to focus a spot on the retina using various lenses and lens combinations to accommodate each unique vision of each patient being measured. With this technique, and the understanding that most of the blurring results from the curvature of the cornea, the technique eliminates the need to find lenses or lens combinations to minimize the size of the spot on the retina that is used as the secondary source of radiation.

With reference now to FIGS. **9–11**, an exemplary embodiment of the apparatus **10** will be herein described beginning with series **300**, which improved apparatus **300** is constructed as a patient examination station which allows the patient **302** to be comfortably positioned for the measurement of the eye **120**, as earlier described. For convenience to the technician operating the apparatus **300**, a computer monitor, mouse, and keyboard are located on a separate cart for this embodiment of the present invention, herein described. The apparatus **300** includes a housing **304** having a platform **306** which is carried by a rigid frame **308**. The frame **308** includes wheels **310** to facilitate shipping and installation at the clinical site, as well as locking and leveling feet **312** for securing the apparatus to the supporting floor **314**. Once the apparatus is positioned, the integrated leveling feet **312** are deployed to provide a stable stationary frame **308**, and thus platform **306**.

As illustrated, by way of example with reference again to FIGS. **9–11**, the patient **302** sits at a patient end **316** of the apparatus **300**, with his or her head resting in a headrest **318**, which headrest is adjustable in directions left/right (X-direction), up/down (Y-direction), or toward/away (Z-direction) relative to the platform **306**, using adjustment assembly **320**. The headrest **318** is attached to the lower surface of the platform **306** which forms an optical table for mounting optical components thereon, as illustrated with reference to FIG. **12**, and as will herein be described in further detail. The housing **304** includes a removable optical table cover **322** which protects the optical components carried within the housing. The optical table cover **322** is secured to the platform **306** with keyed locks to prevent unauthorized access to the optical components. The platform **306** is bolted to the rigid frame at four locations **307**, as illustrated with reference again to FIGS. **9** and **10**. The frame **308** also carries electronics **324** and a computer **326** which includes the processor **40** earlier described with reference to FIG. **6**, as well as a connector plate for a computer keyboard, monitor and mouse. The frame **308** also includes an upper bay **328** housing electronics controlling optical components carried by the platform **306**, and a lower bay **330** housing an uninterruptible power supply (UPS) and an isolation transformer.

As illustrated with reference again to FIGS. **9–12**, three ports are positioned within the cover **322**, and include an examination port **332** to allow the wavefront measurement of the eye **120** to take place, and two eye illumination ports **334** which allow lamps **336** carried within the housing **304** to illuminate the eye for visualization by an internal video camera **338**. In addition, the adjustment assembly **320** includes a position sensor **321** which senses an x-direction displacement for detecting a position of the headrest **318** to the left or to the right of a reference center line location **3191**. A signal indicative of the sensed displacement is provided to the computer **326** for automatically recording the appropriate eye **120** (e.g. left or right) being measured.

As illustrated with reference again to FIG. **12**, the platform **306** provides an optical table with the patient positioning the eye **120** for measurement by the apparatus **300**. The platform surface measures approximately two feet by four feet, with the optical components fixed to the surface using a combination of commercial and customized precision hardware mounts. All transmissive optical elements have surface anti-reflection coating optimized for the selected probe beam wavelength. The optical layout includes five distinct optical pathways which share the optical elements as will herein be described, by way of example. With reference again to FIG. **12**, a first optical path **340**, a fixation target image optical path illustrated in isolation in FIG. **12A** for convenience to the reader, displays a fixation target image to the patient seated at the apparatus **300**. The patient aligns his/her visual axis to the optical axis **342** by looking at the center of a target reticle **344** having a grid pattern. With reference again to FIG. **12**, a second optical path **346**, a video image optical path illustrated in isolation in FIG. **12B** for convenience to the reader, captures a video image of the corneal plane. This allows the technician to assist in aligning the eye **120** for examination, and to record the exact location of the eye during each measurement using software reticles superimposed on a video image. With reference again to FIG. **12**, a third optical path **348**, a probe laser optical path illustrated in isolation in FIG. **12C** for convenience to the reader, sends a probe laser beam **360** into the eye **120** along the optical axis **342**. As earlier described with reference to FIGS. **2** and **7**, the probe laser beam **14**, herein referred to

with numeral **350** is attenuated to an eye-safe intensity and linearly polarized before being focused onto the corneal surface. With reference again to FIG. **12**, a fourth optical path **352**, a re-emitted wavefront optical path illustrated in isolation in FIG. **12**D for convenience to the reader, conveys the reflected wavefront **24** of FIG. **2**, and herein described with numeral **364** re-emitted from the eye **120** and directed towards a wavefront sensor **356**. To accomplish this, first and second afocal relay stages **358**, **360** transfer the reflected wavefront **354** from the corneal plane of the eye **120** to the entrance face of the wavefront sensor **356**. Finally, with reference again to FIG. **12**, a fifth optical path **362**, a calibration wavefront optical path illustrated in isolation in FIG. **12**E for convenience to the reader, injects collimated laser light into the wavefront transfer path leading to the sensor **356**. Software operable within the computer **326**, described earlier with reference to FIG. **9**, uses collimated light wavefront sensor output data to calibrate the apparatus **300** prior to patient measurement.

With continued reference to FIGS. **12**, and **12**A, the first optical path **340** is herein described as a fixation path which provides a reference image to the patient, such that the eye **120** is property aligned when the patient is fixating on the reticle **344** of a reference target **366**. A target illumination lamp **368** back-lights the fixation target **366**, which fixation target image reaches the patient eye **120** by transmission through a 50/50 beam splitter **370**, lenses **372**, reflection in 50/50 beam splitters **374**, **376**, and transmission through lens combinations of afocal relay stage **358**, as well as through polarizing beam splitter **378**. In addition, a spectral filter is placed over the target illumination lamp **368** to remove radiation over the 620–790 nm wavelength range that might otherwise interfere with a wavefront measurement at 670 nm. The lens combinations in the first relay stage **358** contain identical lens elements mounted in reverse order. Each consists of two meniscus lens elements, with an interposed achromatic doublet. The lens combinations work in tandem as a unity magnification afocal relay stage.

The optical elements including the polarizing beam splitter **378**, the lenses of the first afocal stage **358**, the beam splitters **374**, **376**, and one lens **380** of the lenses **372** are mechanically fixed in place on the surface of the platform **306**. The optical elements including a lens pair **382** of the lenses **372**, the beam splitter **370**, the fixation target **366**, and the illumination lamp **368** are all mounted on one precision linear translation stage, capable of movement along the optical axis **342** of this pathway. Translation of these optical elements focuses the fixation target **366** for the patient's view, compensating for any myopia/hyperopia present in the eye **120**. During patient examination the focus translation stage is adjusted to place the target optically just beyond the eye's infinity focal plane. This allows the patient to see a relatively distinct reticle pattern without stimulating accommodation by the eye **120**. The beam splitters **378**, **376**, **374** serve as interfaces between other optical pathways within the optical axis **342**, as will herein be described in further detail. By way of example, the beam splitter **370** is included for alignment purposes. A photo-detector **384** attached to the center of the left edge of beam splitter **370** senses light transmitted toward the fixation target along the optical axis.

With reference again to FIGS. **12** and **12**B, the second optical path **346** captures video images of the eye **120** at an examination plane. This allows the clinical operator/technician to assist in patient alignment, and to measure actual eye displacement during the wavefront measurement. As earlier described, the illumination lamps **336** illuminate the eye **120**. The image of the eye is conveyed to the video camera **338** by transmission through the polarizing beam splitter **378** and the lens combinations **358**, reflection in the 50/50 beam splitter **376**, transmission through the 50/50 beam splitter **374**, reflection off mirror **386**, and transmission through lens **388**. All these optical elements are fixed in place on the surface of the platform **306**. By way of example, this second path **346** provides a video field of view approximately 22 mm in diameter at the eye plane, with a limiting resolution of ~64 mm. As earlier described, a number of filters are placed in front of each eye illumination lamp **336** to reduce the spectral bandwidth of the radiation reaching the eye **120**. By way of example, these will includes a blue filter to remove light at wavelengths below ~455 nm (for eye safety), an infrared filter to remove light at wavelengths above ~920 nm (for eye safety), and a rejection filter to remove light over the wavelength range 620 nm–790 nm (to prevent interference with the wavefront measurement at 670 nm).

With continued reference to FIGS. **12** and **12**C, the third optical path **348** irradiates a small spot on the patient's retina with eye safe laser radiation, as earlier described with reference to FIGS. **1**A–**1**D. The irradiated retinal spot on the fovea centralis **123** of the retina **122** is, as herein described, the origin of the re-emitted wavefront **130** measured by the sensor **356**. The output beam, probe laser beam **350** from diode laser **390** reaches the patient eye **120** by transmission through a linear polarizer and attenuator **392**, lens **394**, shutter **396**, and reflection off mirror **398** and in the polarizing beam splitter **378**. All these elements are fixed in position.

In one embodiment of the present invention, output of the diode laser **390** is essentially collimated and is focused onto a corneal surface of the eye **120** by lens **394**. The projected probe laser beam **350**, collimated light from the diode laser **390**, is directed by a long focal length lens **394** for focusing on the anterior surface of the cornea **126** of the eye **120**, as illustrated by way of example with reference again to FIG. **1**B, passing through the pupil and lens **124** of the eye **120**, and onto the retina **122** as a small measurable spot on the fovea centralis **123**. As earlier described with reference to FIG. **7**, in one embodiment, the lens **394** illustrated with reference again to FIG. **12**, comprises a zoom lens for varying the focus and moving the focus location as desired. By focusing on the cornea **126**, the measurement is minimally dependent on the curvature of the cornea. However, other locations proximate the corneal surface are acceptable.

While diffraction and various aberrations are present, the present invention avoids the aberration effects from the cornea which typically dominate. The lens of the eye **120** contributes a relatively small aberration effect when compared to that of the cornea **126**. Further, and with regard to the selection of the lens **394**, selecting a lens with a short focal length would provide a relatively large incident angle of the beam **350**, a well focused point on the surface of the cornea **126**, and less aberration effects from the cornea . A small incident angle provides a larger focus point on the cornea **126**, but a more desirable smaller spot on the retina **122**, which spot size will depend on the wavelength and starting point size and focal length of the lens **394** selected. Embodiments of the present invention including lenses of approximate one half meter and 100 mm, by way of example, haves been effectively used.

The polarizer **392** linearly polarizes the probe beam **350** into an s-state (by way of example, out of the plane of the drawing of FIG. **12**). The angled interior interface of the polarizing beam splitter **378** reflects s-polarized light, so that light entering the eye **120** is s-polarized. A linear polarizer

400 is angled with respect to the polarizer 392 and works in conjunction with the attenuator to attenuate probe beam power delivered to the eye 120 to less than 10 μW, by way of example. The diode laser 390 is triggered by an external electrical trigger signal 402. A nominal illumination duration for eye measurement is 700 ms. The shutter 396 is included as an additional safeguard against overexposure of the eye 120 to the probe laser beam 350. The shutter 396 is normally closed and is opened by an independent electrical trigger signal 404 synchronized to the laser trigger signal 402.

By way of example, one retinal exposure for each illumination by the probe beam is 10 μW×0.7 s=7 μJ. Up to 10 repeat measurements may be obtained during a single patient examination session. Such exposures are well within the safety limits defined in the American National Standard for Safe Use of Lasers (ANSI Z136.1-1993, American National Standards Institute, New York, N.Y.). In that reference, the maximum permissible exposure (MPE) for "intrabeam" viewing a laser beam in the 400–700 nm wavelength range and the 18×10^{-6} to 10 second pulse duration range is $1.8*t^{3/4}$ mJ/cm^2. (t is the pulse duration in seconds). A limiting aperture for the eye is identified as approximately 7 mm in diameter. As a result, an allowable single-pulse energy is $0.6927*t^{3/4}$ mJ. For a single 0.7 second pulse the MPE is 530 μJ, almost two orders of magnitude larger than a delivered energy per pulse, for the apparatus herein described. An additional calculation is performed to assess the safety of the repetitive exposures. The relevant calculation in the Standard multiplies the single pulse MPE by $n^{-¼}$, where n is the total number of pulses in the exposure duration T_{max}. For the apparatus of the present invention, the 10-pulse safety limit is $530\ \mu J/pulse\times10^{-0.25}$= 298 μJ/pulse, still a factor of 40 larger than the actual pulse energy focused into the eye.

As illustrated with reference again to FIGS. 12 and 12D, the fourth optical path 352 conveys the wavefront 354, earlier identified by numeral 130 with reference to FIG. 1B, emerging from the eye 120 to the wavefront sensor 356, herein described using a Hartman-Shack sensor by way of example for the wavefront analysis. The wavefront 354 re-emitted by the eye 120 in response to the probe beam 350 irradiation is conveyed to a CCD camera 406 by transmission through the polarizing beam splitter 378, the first afocal relay stage 358 lens combination, the 50/50 beam splitter 376, a trial lens holder 408, the second afocal relay stage 360 lens combination, reflection off mirror 410, and transmission through microlens array 412, as earlier described with numeral 33 with reference to FIG. 6. With the exception of the changeable trial lens holder 408, illustrated with reference to FIGS. 12F and 12G, all these optical elements are fixed in place on the surface of the platform 306.

The polarizing beam splitter 378 transmits only linearly polarized light in a p-state. The radiation of the probe beam 350 reflected from the corneal surface of the eye 120 will retain the incident s-state polarization and will not be appreciably transmitted by the beam splitter 378. In contrast, light that has been scattered off the retina of eye 120, light forming the wavefront 354 of interest, will be largely depolarized. The p-polarized fraction of this light will be transmitted by the beam splitter 378. Thus the beam splitter 378 selectively suppresses the corneal surface reflection that could otherwise complicate the wavefront measurement. A wavefront originating at the corneal plane of eye 120 is transferred to a plane of the trial lens holder 408 with unity magnification. This plane of the trial lens holder 408 provides an intermediate pupil plane and is included for placing an ideal N-diopter lens 409, see FIGS. 12F and 12G, at the trial lens plane to change the spherical curvature of the wavefront 354 by N-diopters, without altering other aberration content. The capability to reduce/remove the general wavefront curvature in a preselected manner significantly extends the dynamic range in wavefront measurement, without degrading the measurement accuracy. Trial lenses 409*a*–409*m*, by way of example and herein described of varying spherical powers, ranging from −16 diopters to +8 diopters in two-diopter increments, are mounted on a rotating wheel 407 of the holder 408. The wheel's axis of rotation is parallel to but offset from the optical axis 342. Turning the wheel places one of a plurality of preselected trial lenses at the trial lens plane. The wheel has precision mechanical detents that register the selected lens properly in the optical path.

A narrow band-pass optical filter is also placed at trial lens holder 408 location just anterior to the lens position. This filter has maximum transmission for 670 nm wavelength radiation (the probe beam wavelength), and a bandwidth of approximately 10 nm (full-width-half-maximum). This filter is used to reject spurious light (from the fixation target illumination, the eye illumination, and the like) from the wavefront path.

In one embodiment, as herein described by way of example, each of the lenses of the second afocal relay stage 360 consists of three lens elements, two meniscus lenses and an interposed achromatic doublet. However, they are not identical, and their combined action serves to magnify the passing wavefront 130. The wavefront 354 at the trial lens holder 408 location is imaged onto the surface of the microlens array 412 with a magnification of 1.22. Magnification of the wavefront image by this defined factor of 1.22 reduces the wavefront slope at each point in the image plane by the same 1.22 factor. This extends the measurement dynamic range of the device, again without decreasing accuracy. In addition, this magnification distributes the wavefront 130 over more elements, CCD cells 38 as earlier described with reference to FIG. 6, in the microlens array 412, thus increasing the number of slope measurements provided by the wavefront sensor 356. The mirror 410 is included to fit elements of the apparatus 300 within the dimensions of the platform 306. In addition, the mirror 410 also allows optical alignment adjustment for the microlens array 412 and the CCD camera 406 combination. As earlier described, by way of example, with reference to FIGS. 3–6, the microlens array contains a square array of microlenses which divide the incident wavefront into a transverse array of secondary "wavelets." These wavelets are focused onto a detector surface of the CCD camera, which is positioned parallel to the microlens array and one focal length posterior thereto. The pattern of focused wavelets in the CCD image is used to calculate the shape of the incident wavefront.

As illustrated with reference again to FIGS. 12 and 12E, the calibration beam path 362 provides the collimated beam 364 to the Hartman Shack wavefront sensor 356. Wavefront data for the collimated beam 364 is used as a reference in reconstructing the aberrated wavefront 354 from the real eye measurement. The source for the collimated reference beam 364 consists of a diode laser 414 coupled to a beam expander 416. In one embodiment of the invention herein described, the diode laser 414 used for reference is identical to the diode laser 390 used for the probe beam path 348. The collimated reference beam 364 is conveyed to the CCD camera 406 by transmission through polarizer/attenuator 418, negative lens and aperture 420, aperture and positive lens 422, reflection off mirror 424, transmission through aperture 426, reflection in the polarizing beam splitter 378,

transmission through the first afocal relay stage **358**, the 50/50 beam splitter **376**, the trial lens holder **408**, the second afocal relay stage **360**, reflection off the mirror **410**, and finally transmission through the microlens array **412**. Except for trial lens holder **408**, all these optical elements may be fixed in position on the surface of the platform **306**.

The optical element of the polarizer and attenuator **418** contains two linear polarizers and a neutral density filter. The linear polarizer furthest from the diode laser **414** polarizes the laser radiation in the s-state for maximum reflection in the polarizing beam splitter **378**. The linear polarizer closest to the diode laser **414** is partially "crossed" with respect to the polarizer **378** to attenuate the laser power. The neutral density filter further attenuates the beam, such that the laser power reaching the CCD Camera **406** is optimal for calibration of the sensor **356**. The negative lens and positive lens of elements **418**, **420** expand the diode laser output and form the collimated reference beam **364**. Intervening apertures of elements **418**, **420** transmit only the central portion of the expanding beam with the most uniform intensity. The mirror **424** is included to reduce the overall dimensions of the apparatus **300**. The aperture **426** is conjugate to the corneal plane, and is included so that the collimated reference beam **364** illuminates approximately the same area on the microlens array **412** as would the wavefront **354** re-emitted by a maximally dilated eye.

By way of illustration, optical components suitable for use with embodiments of the present invention herein described by way of example, are provided with reference to Table 1. An electrical component layout of the apparatus **300** is illustrated with reference to FIG. **13**, wherein a dashed box **428** indicates the platform **306** with the heretofore described element carried thereon. Except for the computer monitor, keyboard, and mouse all other electrical components are located within the frame under the optical table. Switches in the diagram are all located on a front panel **430** of the electronics **324** for ease in operator/technician access, as described earlier with reference to FIG. **9**. Electrical power from the clinical facility is drawn by an isolation transformer, which in turn supplies power to an uninterruptible power supply (UPS). The UPS delivers power to three power strips carried in the frame **308**. The host computer **326** has a self contained On/Off switch, as do the three power strips. One power strip **432** supplies power to the shutter controller **434**, which commands the probe laser shutter **396** through the signal **404**, two dual power supplies **436**, each capable of providing both 5 VDC and 9–15 VDC output, the host computer **326**, a computer monitor **438**, and a third power strip **440**. One dual power supply supplies 5 VDC power to the two patient illumination lamps **336**, and 9 VDC power to the target illumination lamp **368**. A second dual power supply supplies 5 VDC power to both diode lasers **390**, **414**. A user-accessible 3-position switch **442** allows the system operator/technician to provide power to either the probe laser **390** or the calibration laser **414**, with a center switch position being the "off" state.

A third power strip **444** supplies power to the CCD electronics controller **446**. The power strip **440** also supplies power to cooling fans **448** located on the platform and within the frame.

By way of example and for illustration purposes, operation of the apparatus **300** may generally proceed with the operator/technician first activating each of the electrical elements, with the CCD electronics controller **434** being last to be enabled. The operator then activates the calibration laser **414** via the 3-position switch **442**. The operator then instructs the computer **326** to acquire a calibration wavefront measurement. The computer **326** relays this command to the CCD controller electronics **446**, which activates the CCD camera **406** to take a predefined exposure. The CCD controller electronics **446** also sends trigger signals **402**, **404** described earlier with reference to FIG. **12**, to the probe laser **390** and the probe laser shutter **396**. However, since the probe laser **390** is not powered at this point, no probe beam **350** is delivered. Calibration CCD data are transferred to the CPU of the computer **326**, and stored for later analysis. The calibration laser **414** is switched off at the end of the calibration procedure.

The technician/operator then proceeds to patient measurements. The output switch **442** at the dual voltage power supply **436** is positioned to a probe laser setting. The probe laser **390** is now in a "ready" state awaiting an additional trigger signal to operate. The operator then positions the patient appropriately in the apparatus **300** as earlier described with reference to FIGS. **9–11**, with the assistance of an image from the video camera **338** displayed on the computer monitor, by way of example. With the patient situated, the operator instructs the computer **326** to obtain wavefront data, as earlier described with reference to FIGS. **2–7**. The computer **326** relays appropriate commands to the CCD electronics controller **446**, which triggers the probe laser **396** to fire, triggers the shutter controller **434** to open the probe laser shutter **396**, and exposes the CCD camera **406**. CCD camera image data is transferred back to the computer **326**. The computer **326** includes software that analyzes the patient and calibration data to calculate the patient wavefront profile for use. At the end of the data collection, the operator shuts down the electronics, starting with the CCD electronics controller **446**. The software integrated into the apparatus **300** may be described, by way of example, as including: A graphical user interface (GUI) to allow the technician to perform all desired operations to enter and save patient information and perform the desired measurements; database and file system interfaces to allow for the saving and tracking of patient information, measurement, and hardware details; control of the electro-optical and electro-mechanical components as necessary in order to be able to accurately and safely perform the desired measurements; and processing of the measurement data to generate mathematical descriptions of the aberrations (the optical path difference) measured in the subject eye.

By way of further example, patient measurement and apparatus configuration information is stored in multiple tables in a Microsoft Access™ 7.0 database. The interface to this within the code is based upon the Microsoft Foundation Classes (MFC) wrapper to the Microsoft Jet Engine. The framework generates a Structured Query Language (SQL) to create, retrieve and update records in the database. Use of the Microsoft Access application to access the data is not needed. In one embodiment of the present invention, the following data may be stored in the database: patient information—name, address, medical record number, and the like; measurement Information—geometry, time of measurement, and the like; and system Information—hardware serial numbers and key hardware parameters.

Additionally, the software may be developed with two operating levels—password-protected and not-password-protected. From within the password-protected-mode, the technician/operator has access to system configuration information and features necessary for system setup and maintenance that are not accessible from the not-password-protected mode. All patient entry and measurement capabilities are available from the not-password-protected mode. All patient information desired in order to be able to

uniquely identify and track the patient is entered via the graphical user interface (GUI) and stored in the Microsoft Access database. Selecting the "Patient Data" menu item brings up a patient information data information screen, from which the technician can enter new patient data as well as being able to review and edit existing information. The patient data that can be stored and retrieved, typically includes: name, address, medical record number, data of birth, phone number, sex, manifest and cycloplegic refractions and vertex distance as well as centration information.

Centration information that is measured via a centration process and stored as part of the patient record describes the position of the center of the constricted pupil with respect to the center of the limbus. This information is used in aligning the patient for the measurement where the goal is to align the visual axis of the eve with the optical axis **342** of the apparatus **300**. When the centration procedure is invoked a list is displayed of all patients that have been entered into a database operable with the apparatus **300** but have not yet had the centration steps performed. The monitor displays all patient information including a review of centration information, or alternatively, for just those patients entered for a given time period. In order to perform centration for a given patient and eye, that patient is selected from this list by clicking on the desired patient/eye with the mouse. An example of the centration process is illustrated with reference to FIG. **14**. Once a patient has been selected, the patient is instructed to look into the apparatus **300** and at the fixation target **366**, as earlier described with reference to FIG. **12**.

By way of further disclosure, the fixation target **366** is, as earlier described, included so that the patient **302** can stare along the optical axis **342** of the apparatus **300**. For best fixation, the target should be clearly visible to the patient. However, care should be taken to see that the patient does not attempt to accommodate when fixating on the target. This would occur if the target were optically closer than the patient's infinity focal plane. If the patient did accommodate, i.e., if the lens in the eye changed shape to provide increased focusing, then the eye would appear excessively myopic during the wavefront measurement. To avoid this, the fixation target optics are adjusted so that the target appears to lie optically just beyond the patient's far-field focus. Thus for each patient the target will appear relatively clear, but not in sharp focus. The patient may initially try to accommodate to improve the sharpness of the image, but will eventually find that the clearest image is seen for the most relaxed (non-accommodative) state. This technique is known as "fogging," and is routinely performed by optometrists when doing clinical evaluations. The eye drops used to dilate the eye for the measurement also reduce the lens' ability to accommodate, thereby further ensuring valid wavefront measurement.

With reference again to FIG. **14**, an image of the patients eye **120** is frozen. Two reticles **450**, **452** are then used to locate the centers **454**, **456** of the constricted pupil and limbus, respectively. Each reticle **450**, **452** can be moved and sized—one reticle **450** is positioned over the perimeter of the constricted pupil **458** and the other reticle **452** over the limbus **460**. Once they have been located, the information is saved to the database. This can be performed for as many patients as is desired and the centration procedure is then exited.

For illustration, a sequence of events followed in measuring the refractive errors in an eye and computing the corresponding optical path difference (OPD) is illustrated with reference to FIG. **15**. By way of example, steps include performing a reference measurement **462**. To provide a reference with which to compare the measurement of the eye **120** and also to check the alignment of the apparatus **300**, a reference measurement is made using the collimated laser light **364**, as earlier described with reference to FIG. **12**. The software forces the operator to make at least one such measurement at the start of each day and an additional one at the end of each day. More reference measurements can be performed as desired by the operator. When patient measurements are performed, the measurement records in the database identify which reference measurements correspond to each measurement, i.e., which reference image was the latest one done prior to the measurement. A "Perform Reference Measurement" screen may be provided for viewing a sample reference image.

A next step includes selecting a patient and eye to measure **464**. The patient and eye to be measured may be selected from a "Patient Select" dialog screen. It is desired that all patients are displayed along with a check mark to show whether or not centration has been performed for that patient. If a patient is selected that has not yet had centration performed then the operator is informed of this and no measurement can be performed. Once a valid patient/eye has been selected to be measured then the perform measurement dialog is displayed which includes GUI buttons necessary in order for the operator to perform and check the measurement.

A next step includes aligning the eye using the video camera and reticles **466**. The apparatus **300** is operated with the visual axis of the eye aligned, as close as is practically possible, to the optical axis **342** before performing a measurement. The center of the constricted pupil **454** is used as the approximate anatomical landmark for the visual axis. Given that the eye **120** is dilated when the measurement is performed, it is not possible to directly determine this center. However, the centration procedure performed on each patient defines the center of the constricted pupil **454** with respect to the limbus **460** and thus it is possible to use the position of the limbus to place the eye **120** in a desired location.

As illustrated with reference to FIG. **16**, a reticle **468** is displayed on screen that is offset from the optical axis by the appropriate amount such that when the limbus **460** of the eye **120** is aligned to this reticle **468**, the eye **120** is positioned as desired. Prior to taking the measurement, it is the operator's responsibility to ensure that the patient is positioned appropriately such that the limbus **460** is aligned with the reticle **468** while the patient is looking at the fixation target **366**.

A measurement is then performed **470**. Once the eye **120** is aligned, the operator presses an "acquire" button to perform the wavefront measurement of the patients eye. The system response to the acquire command is as follows:

1. Video image is frozen
2. Probe beam laser is activated
3. External shutter is opened so that the probe beam can reach the eye
4. CCD shutter opens and the CCD is exposed to the re-emitted wavefront (1–4 generally performed simultaneously)
5. CCD shutter closes and the exposure is completed
6. CCD data is transmitted to the computer
7. External shutter closes and the probe beam turns off.

The software continually checks the status of the CCD electronics and the temperature of the camera and only allows measurements to be taken when everything is working nominally.

A review of eye and apparatus geometry is accepted or rejected **472**. Although it is not necessary for the eye **120** to be perfectly aligned with respect to the optical axis **342** (the software compensates for minor misalignments), it is desirable for it to be close. The eye **120** will have been aligned prior to the measurement but uncontrollable eye motion (e.g. saccades and loss-of-fixation) may make the alignment sub-optimal at the time of the exposure. To check that the alignment is acceptable, the video image of the eye is frozen at the time the measurement is taken. The operator then aligns a reticle to the limbus ring and presses a "check geometry" button on the GUI. If the software determines that the alignment is not acceptable, the operator is informed of this and a new exposure is made as desired. By way of example, and with reference to FIG. **17**, optimal measurement as herein described, would have the limbus **460** aligned to circle B. In actuality, the eye **120** was offset during the exposure and the limbus **460** was aligned to circle A. The difference between these two states is shown by the line A'B'. The software determines whether or not the image is acceptable based on the length of A'B'.

It is also at this point that the operator records the rotational state of the eye. Prior to the wavefront measurement, a pattern of four line segments **474** arranged in an "X" pattern **476**, as illustrated with reference to FIG. **18**, around the periphery of the cornea are applied to the eye using a mechanical instrument The pattern **476** consists of two pairs of collinear line segments **474** angled at 45° with respect to each other. Each line segment **474** is 4 mm long, and collinear segments are separated by 7 mm. At the same time the limbus ring reticle is aligned with the actual limbus in the frozen video image, an X reticle that matches this pattern is aligned to the applied eye marks in the frozen image. The orientation information is then saved by the software along with the limbus position data.

As a next step in the process, the CCD image is processed, accepted and saved, or rejected **478**, as illustrated with reference again to FIG. **15**. If the geometry of the measurement is acceptable, it is then probable that the quality of the CCD image will be high. It is desirable, however, to check that this is so. The software processes the image and then presents an auto-scaled image to the operator to review. If the software determines that the image is unacceptable then the operator will be informed of this and a new exposure made. If the user decides that the image is unacceptable for whatever reason then the image can be manually rejected at this stage. An example of an unacceptable image is illustrated with reference to FIG. **19**. In this example, a significant portion **479** of the image is obscured in some manner, resulting in wavefront data for only part of the pupil. By unacceptable, it is meant that such an image is not believed to result in the accuracy and precision of measurement that is desired for surgical procedures which are obtained by the present invention. It does not mean that such as illustrated may not be usable in any sense.

Once a valid measurement has been made the next step **480** is to measure the local slopes of the wavefront **130**, as earlier described with reference to equations herein presented. As described with reference to FIGS. **4–6**, it is necessary for the software to compute the centroids **116** of the clusters of light on the CCD array **38** and then determine the distances of each of these centroids **116** from the corresponding reference centroids **29**. The centroids are determined by first computing which pixels should be processed and grouping them together into clusters. The intensity-weighted centroid of each cluster is then computed. As illustrated with reference to FIG. **20**, an example of an image from a myopic eye with the computed centroids **482** of cluster **484** marked by "X"s is shown. FIG. **21** illustrates a close-up of one of the clusters **484** and displays not only the centroid **482** but also the pixels **486** used in the centroiding calculation for the cluster **484**. CCD pixels **488** processed in the centroiding algorithm are marked by dots. This algorithm, by way of example, isolates centroids by use of a spacial filter which removes stray light signals that create noise for the CCD image. Such filtering may be desirable before calculation of light cluster positions.

Without filtering, computation of the cluster centroids may be made difficult as a result of noise on the Image such that individual pixels with no actual data content may be brighter than pixels containing relevant data, speckle in the image may result in valid data clusters having irregular profiles with significant variation in intensity of adjacent pixels, haze or background noise may be high relative to the actual data or may be non-uniform across the image, intensity of valid data may be non-uniform across the image, scatter from different parts of the eye may result in spurious signals on the image, and high aberrations in the eye may significantly distort the clusters of valid data, by way of examples. The spatial filter permits a re-computation of the brightness of each pixel in a bitmap using a weighted averaging technique that considers surrounding pixels. In a particular application herein described for illustration and by way of example, the spatial filter is designed to yield a maximum value when centered on valid data, reduce an effect of individual bright pixels or small groups thereof, normalize background levels, smooth valid data profiles, and simplify the task of extracting the valid data from background noise or haze. One filter employed in one embodiment of the present invention is square (n×n) and includes real values (positive and negative) assigned to each pixel. The filter is designed to be optimally matched to images obtained from eyes with high, yet measurable, levels of aberration. By wave example, a cross-section through the filter is illustrated with reference to FIG. **23**A. An effect of applying such a filter improves an image such as illustrated with reference to FIG. **23**B to the image illustrated with reference again to FIG. **20**, by way of example, a cleaner image and one that is easily processed for identification and computation of cluster centroids. By applying the filter, images that would otherwise be deemed to noisy or of insufficient quality to process, can now be processed and desired wavefront information computed.

The center of each centroid is calculated using a standard center of mass algorithm based on light intensity. The clusters and centroids illustrated with reference to FIG. **22** are illustrated with the locations of the corresponding reference centroids **490** also visible. The open circles in this figure indicate the locations of the reference centroids. Lines connect these with the associated sample centroids **482**. From the distances between the reference and measurement centroids **490**, **482** respectively, and the distance between the lens array **33** and the CCD plane **36**, described with reference to FIG. **6**, the local slopes are calculated. Given these local slopes and information about the apparatus setup, including any and all magnification factors, it is then possible to determine the local slopes at the pupil plane and, from these, and compute the optical path difference of the eye being measured.

A description of the wavefront is then made **492**. As earlier described, the reconstructed wavefront is described via a set of Zernike polynomials. The number of locations on the eye **120** at which the local slopes are determined (i.e. the number of sample points) greatly exceeds the number of

terms in the polynomials that will describe the wavefront. A least-squares-fit calculation is done to find the coefficients that best describe the surface. The order of the polynomial used is sufficient to describe not only the spherical and cylindrical refractive powers (2^{nd} order) but also the levels of coma (3^{rd} order) and spherical aberration (4^{th} order) present.

An example of the computed Zernike coefficients for an eye and the corresponding wavefront reconstruction **493** is illustrated with reference to FIG. **24**A. By way of example, for the wavefront illustrated with reference to FIG. **24**A, the spherical and cylindrical powers computed from the wavefront are −1.60/−1.13×150.4. The corresponding values obtained by an optometrist performing a phoropter examination (converted to the corneal plane) were −1.47/−1.19×150. The standard measurements of spherical and cylindrical powers agree well with the computation of spherical and cylindrical powers, but there are also higher order aberrations present. By way of further example, FIG. **24**B illustrates just these higher order aberrations **495** on the same scale as the plot of FIG. **24**A.

With regard to the optical path difference (OPD), scaling an optical path difference profile, OPD(x,y), by a refractive index difference (cornea to air) is not the only step. This wavefront measurement is made at a plane tangent to the cornea, as illustrated with reference to FIG. **25**, which is exaggerated to illustrate the effect. The image plane of the wavefront path is the lenslet array plate. The object plane of the wavefront path is the reference plane **494**. In this highly-exaggerated myopic case, herein described by way of example, one light ray **496** emerging from the eye **120** at transverse location a is detected at a transverse location b. The wavefront reconstructed from sensor data will have the slope of this ray at location b. Although this is true of the wavefront at the reference plane **494**, simple scaling of this wavefront would suggest a measurement at corneal location b that may not be entirely accurate. In actuality this effect is small. The radius of curvature of the cornea is typically on the order of 7.5 mm. (a range of 7–8 mm encompasses most eyes.) At a transverse location 3 mm from the corneal apex, the distance from the corneal surface to the reference plane is only ~0.63 μm. For a 10 diopter myope, a light ray exiting the cornea at a=3.0 mm will cross the reference plane at b=2.98 mm. The difference between a and b in this example is only 20 μm. Although small this geometric effect is systematic, having progressively greater impact on the measurement with increasing radial distance from the corneal apex. To increase accuracy, compensating for the curved geometry may be performed in the following manner:

1. Wavefront slopes are calculated at each measurement point in the reference plane.
2. The cornea is assumed to have a nominal radius of curvature (~7.5 mm).
3. The wavefront slopes measured at the reference plane is projected back onto the nominally curved cornea. The wavefront is measured to have a certain slope at b in the reference plane, described above. It is a straightforward mathematical process to calculate the point a where this ray exited the cornea.
4. The wavefront is reconstructed based on the measured slopes at the calculated corneal locations.

As above described, it is desirable to obtain the best information with a wavefront measurement having patient positioned at the apparatus **300**. The eye **120** being measured is at the desired location and looking in the appropriate direction. Based on analysis of the allowable eye-positioning tolerances, the apparatus **300** of this embodiment of the present invention provides the following patient position information:

The capability for ensuring that the subject eye is at the right location along the longitudinal (z) axis of the apparatus with an accuracy of +/−1 mm.

The capability for ensuring that the subject eye is properly positioned laterally with respect to the apparatus (i.e., in x-y) with an accuracy of +/−1 mm.

The capability for ensuring that the subject eye is desirably positioned in angle with respect to the apparatus (i.e., the difference between the visual axis and the optical axis of the system) with an accuracy of +/−0.5 degrees.

The capability for aligning an on-screen reticule to a set of marks applied to the eye outside the limbus to record the rotational orientation of the eye (i.e., about z) with respect to the apparatus with an accuracy of +/−one degree.

Once in position, the patient's eye can be successfully examined by the wavefront sensing technique. This embodiment of the apparatus includes a sufficient dynamic range to measure eyes over the expected scope of refractive errors.

The following list provides range and accuracy parameters, by way of example, for clinical wavefront measurements that can be obtained by this embodiment of the apparatus. This list is provided by way of illustration and does not limit the scope of the present invention.

1. capable of measuring wavefronts with spherical refractive powers in the range +6 to −15 diopters and cylindrical powers in the range 0 to −6 diopters.
2. capable of measuring coma and spherical aberration.
3. capable of measuring refractive errors over a pupil zone of up to 8 mm in diameter.
4. able to measure the refractive errors within the specified ranges to an accuracy of 0.042 μm RMS in air.

With reference again to FIG. **6**, and by way of further example, the output from wavefront analyzer **26**, e.g., the Zernike expansion of equation (19), can be used in a variety of ways. For example, the output may be used to continually or periodically monitor the progress or effects of an ophthalmic procedure, with such stored on disc or transmitted via e-mail, and the like. The output of the wavefront analyzer **26** is input to a processor **90** which converts the Zernike expansion of equation (19) into a form suitable for subsequent use as desired. Alternatively, the processor **90** may also be implemented at the processor **40** of the wavefront analyzer **26**, described earlier with reference to FIG. **6**.

By way of further example, the processor **90** can be used with preselected Zernike coefficients from the expansion of equation (19) to generate a standard sphero-cylindrical specification for a lens grinder **92** to produce a convectional optical lens, e.g., a lens for glasses, a contact lens, and the like.

As described earlier with reference to FIG. **12**, the apparatus **300** of the present venture includes first and second afocal relays stages **358**, **360**. To retain the benefit of wavefront magnification, as a means of increasing the dynamic range of the wavefront sensor **356** to accommodate patients with large refractive errors, while at the same time allowing for incorporation of a small format, inexpensive camera to record the wavefront slope data, a modification **500** to the apparatus **300** as illustrated with reference to FIG. **26**A is provided.

By way of example, a lens array may also be positioned and configured as illustrated with reference to FIG. **26**B, wherein a portion of the apparatus **300** of FIG. **12** includes the first and second afocal stages **358**, **360** within the optical axis **342**, and the wavefront sensor **356** consist of the microlens array and CCD camera separated by a fixed

distant, as earlier described with reference to FIG. **6**. This optical path through the afocal relay stages results in an image of the corneal plane **502** at the lenslet array, i.e. at the entrance face of the actual wave front sensor **356**. This can be accomplished by a single afocal stage. As earlier described with reference to FIG. **12**, the apparatus **300** includes an intermediate image plane as insertion point, the holder **408**, for a trial lens. Placing a spherical lens into the optical axis **342** at the first image plane, in theory, could be used to remove the defocus wavefront error. This would potentially expand the dynamic range of the apparatus **300**. However, the trial lens approach s a moving mechanism that can position lenses at the first image plane with tremendous accuracy in repeatability. It is highly desirable that alternative means be developed to address dynamic range.

One way to accomplish this is to magnify the corneal plane image at the lenslet array with the afocal stage **360**, earlier described. Magnification of the wavefront reduces the wavefront slope, so that the displacement of the focused lights spots on the CCD is decreased. The chosen magnification factor used with the apparatus **300** second afocal stage **360** is approximately 1.2 which is sufficient to cover the desired range in refractive errors. A magnification factor in excess of 1.5 is desirable for expanding the use of the apparatus **300**. However, simply magnifying the corneal plane has a drawback in that it necessitate a large aperture wavefront sensor. That is, both the lens array and the CCD camera preferably have large cross-sectional areas to encompass the magnified image of the point of plane. This is not a significant issue for the lens array. However, a large format CCD camera is quite expensive and such cameras are only available from a limited number of vendors.

To resolve such concerns, the modification **500** illustrated with reference again to FIG. **26**A is provided. The corneal plane **502** is imaged at a reference plane **504** by an afocal relay stage **506**, which magnifies the corneal plane by a preselected amount. The lenslet array **412** is placed at the reference plane **504**. Focused spots of light from the eye **120** are produced at the lenslet array focal plane **504**. Rather than place the CCD detector face at the reference plane **504**, an optical train **508** is inserted to image the array focal plane **413** at yet another plane, a final image plane **510**, at which plane the CCD detector face is positioned. The afocal relay stages **358**, **360** described earlier with reference to FIGS. **12** and **26**B, may or may not be included, as desired. However, the magnification of the array focal plane at the final image plane **510** is provided. This allows a small, relatively inexpensive, active area camera to be used as the light recording element in the wavefront sensor. Details of optical design including magnification specifics can be adjusted to maximize performance for a given camera and lens array plate specification.

The advantages of the present invention are numerous. A totally objective approach is presented for measuring ocular aberrations. The approach is effective for a wide range of vision defects. Accordingly, the present invention will be of great utility in a wide variety of clinical applications. For example, the calculated Zernike coefficients can be used to develop a completely objective lens prescription. In addition, each of the wavefront sensor embodiments provides for a greater degree of accuracy over the prior art with respect to measuring wavefront deflections. Further, the present wavefront sensor can be adjusted in terms of gain simply by adjusting the separation distance between the imaging plane of the sensor and the planar array of light-sensitive cells.

The objective measurement of the present invention will also find great utility for a large variety of applications where the "patient" is unable to provide feedback as d by conventional eye diagnosis. For example, the present invention could be used to evaluate the eyes of any patient not possessed of demonstrative communicative skills, e.g., babies, animals, dead specimens, as well as any constructed optical system, since the present invention is an objective analysis not requiring any assessment from the "subject". All that is necessary is for the subject's eye to be properly positioned so that proper optical access to the eye can be obtained.

The present invention will also be used in the area of identification should it be determined that each eye's Zernike coefficients are unique. Then, the present invention would find great utility in the fields of law enforcement, credit card/bank security, or any other field where positive identification would be beneficial.

Although the invention has been described relative to a specific embodiment thereof, there are numerous variations and modifications that will be readily apparent to those skilled in the art in light of the above teachings. It is therefore to be understood that, within the scope of the appended claims, the invention may be practiced other than as specifically described.

That which is claimed is:

1. A method for determining higher order aberrations of an eye requiring a correction of greater than +3 or −3 diopters, the method comprising:

directing an optical beam onto a retina of an eye;

reflecting the optical beam from the retina of the eye;

determining characteristics of a wavefront in the reflected optical beam; and

generating data based on the characteristics of the wavefront, which data quantifies at least one higher order aberration of the eye.

2. A method according to claim **1**, wherein the correction is made for an eye having myopia of greater than −3 diopters.

3. A method according to claim **1**, wherein the correction is made for an eye having hyperopia of greater than +3 diopters.

4. A method for determining higher order aberrations of an eye requiring a correction of greater than +3 or −3 diopters, the method comprising:

directing an optical beam onto a retina of an eye;

reflecting the optical beam from the retina of the eye;

determining characteristics of a wavefront in the reflected optical beam; and

generating data based on the characteristics of the wavefront and refractive indices of media through which the optical beam passes, which data quantifies at least one higher order aberration of the eye.

5. A method for determining higher order aberrations of an eye requiring a correction of greater than +3 or −3 diopters, the method comprising:

directing an optical beam onto a retina of an eye;

reflecting the optical beam from the retina of the eye;

determining characteristics of a wavefront in the reflected optical beam for a discrete section of the eye; and

generating data based on the characteristics of the wavefront, which data quantifies at least one higher order aberration of the eye for the discrete section.

6. A method for determining aberrations of an eye comprising:

directing a probe beam along a probe beam path toward an eye;

directing a fixation image along a fixation image path toward the eye;

directing a light source along a video image path toward the eye;

generating a video image of the eye;

directing a wavefront originating from the eye along a wavefront path, wherein the probe beam path, the fixation image path, the video image path, and the wavefront path being coincident at least along a portion of their respective paths, the probe beam path terminating at a retina of the eye and the probe beam reflecting from the retina of the eye as a wavefront;

aligning the eye with the probe beam path based at least in part on the video image of the eye generated by the light source directed along the video image path;

measuring the wavefront; and

generating data representative of aberrations of the eye based on the measurement of the wavefront.

7. A method for determining aberrations of an eye comprising:

directing a probe beam along a probe beam path toward an eye;

directing a fixation image along a fixation image path toward the eye;

directing a light source along a video image path toward the eye;

generating a video image of the eye;

directing a wavefront originating from the eye along a wavefront path, the probe beam path, the fixation image path, the video image path, and the wavefront path being coincident at least along a portion of their respective paths, the probe beam path terminating at a retina of the eye and the probe beam reflecting from the retina of the eye as a wavefront;

aligning the eye with the probe beam path based at least in part on the video image of the eye generated by the light source directed along the video image path, the wavefront passing through a single microlens array;

measuring the wavefront; and

generating data representative of aberrations of the eye based on the measurement of the wavefront.

(57) **ABSTRACT**

The invention is concerned with a microlithography projection objective device for short wavelength microlithography, preferably <100 nm, with a first mirror (**S1**), a second mirror (**S2**), a third mirror (**S3**), a fourth mirror (**S4**) and a fifth mirror (**S5**). The invention is characterized by the fact that the image-side numerical aperture (NA) is greater than or equal to 0.10 and that the mirror closest to the object to be illuminated, preferably the wafer, is arranged in such a way that the image-side optical free working distance corresponds at least to the used diameter (D) of the mirror closest to the wafer; the image-side optical free working distance is at least the sum of one-third of the used diameter (D) of the mirror closest to the wafer and a length which lies between 20 mm and 30 mm; and/or the image-side optical free working distance is at least 50 mm, preferably 60 mm.

MICROLITHOGRAPHY PROJECTION OBJECTIVE AND PROJECTION EXPOSURE APPARATUS

FIELD OF THE INVENTION

The invention relates to a microlithography objective, a projection exposure apparatus containing the objective, and a method of manufacturing an integrated circuit using the same.

BACKGROUND OF THE INVENTION

Using a lithography system operating with wavelengths below 193 nm for imaging structures of below 130 nm resolution has been proposed. In fact, such lithography systems have been suggested for the extreme ultraviolet (EUV) range with wavelengths of λ=11 nm or λ=13 nm producing structures of below 100 nm. The resolution of a lithographic system is described by the following equation:

$$RES=k_1\cdot\lambda/NA,$$

where k_1 is a specific parameter of the lithographic process, λ is the wavelength of the incident light, and NA is the image-side numerical aperture of the system. For example, if one assumes a numerical aperture of 0.2, then the imaging of 50 nm structures with 13 nm radiation requires a process with k_1=0.77. With k_1=0.64, the imaging of 35 nm structures is possible with 11 nm radiation.

For imaging systems in the EUV region, substantially reflective systems with multilayer coatings are available as optical components. Preferably multiple layers of Mo/Be are used as multilayer coating systems for systems operating at λ=11 nm, whereas Mo/Si systems are used for λ=13 mm. With the reflectivity of the multilayer coatings approximating 70%, it is desirable to use as few optical components as possible in applications such as EUV projection objective microlithography to achieve sufficient light intensity. Specifically, to achieve high light intensity and to allow for the correction of imaging errors, systems with six mirrors and a numerical aperture (NA)=0.20 have been used.

The six-mirror systems for microlithography have become known from the publications U.S. Pat. No. 5,686,728, EP 779,528 and U.S. Pat. No. 5,815,310. The projection lithography system according to U.S. Pat. No. 5,686,728 has a projection objective with six mirrors, where each of the reflective mirror surfaces has an aspherical form. The mirrors are arranged along a common optical axis in such a way that an obscuration-free light path is achieved. Since the projection objective known from U.S. Pat. No. 5,686,728 is used only for UV light with a wavelength of 100–300 nm, the mirrors of this projection objective have a very high asphericity of approximately ±50 μm as well as very large angles of incidence of approximately 38°. Even after reducing the numerical aperture to NA=0.2, an asphericity of 25 μm from peak to valley remains, with little reduction in the the angle of incidence. Such asphericities and angles of incidence are not practicable in the EUV region according to the present state of the art because of the higher requirements on surface quality and reflectivity of the mirrors in these latter systems.

Another disadvantage of the objectives disclosed in U.S. Pat. No. 5,686,728, which precludes their use with wavelengths below 100 nm such as the 11 nm and 13 nm wavelengths desirable for EUV microlithography, is the short distance between the wafer and the mirror lying closest to the wafer. This short distance allows only very thin

mirrors to be used in the U.S. Pat. No. 5,686,728 apparatus. Because of the extreme stresses on the coatings of the multilayer systems suitable for the 11 nm and 13 nm wavelengths in question, such thin mirrors are very unstable.

A projection objective with six mirrors for use in EUV lithography, even at wavelengths of 13 nm and 11 nm, has become known from EP 779,528. This projection objective also has the disadvantage, however, that at least two of the six mirrors have very high asphericities of 26 and 18.5 μm. Furthermore, in the EP 779,528 arrangement, the optical free working distance between the mirror next to the wafer and the wafer is so small that either instabilities occur or a negative mechanical free working distance is obtained.

Four-mirror projection objectives have become known from the following publications:

U.S. Pat. No. 5,315,629

EP 480,617

U.S. Pat. No. 5,063,586

EP 422,853

In U.S. Pat. No. 5,315,629, a four-mirror projection objective with NA=0.1, 4×, 31.25×0.5 mm^2 is claimed. From EP 480,617, two NA=0.1, 5×, 25×2 mm^2 systems have become known. The system according to U.S. Pat. No. 5,063,586 and EP 422,853 have a rectangular image field of at least 5×5 mm^2. These generally decentered systems exhibit very high distortion values. Therefore, the objectives can only be used in steppers with distortion correction on the reticle. However, the high level of distortion makes such objectives impractical at wavelengths below 100 nm.

From U.S. Pat. No. 5,153,898, overall arbitrary three to five-multilayer mirror systems have become known. The disclosed embodiments, however, all describe three-mirror systems with a rectangular field and small numerical aperture (NA<0.04). Therefore, the systems described therein can only image structures above 0.25 μm in length. The distortion of most examples lies in the μm range.

Furthermore, reference is made to T. Jewell: "Optical system design issues in development of projection camera for EUV lithography", Proc. SPIE 2437 (1995) and the citations given there, the entire disclosure of which is incorporated by reference.

Thus, it is desirable to provide a projection objective suitable for lithography with short wavelengths, preferably smaller than 100 nm, which does not have the disadvantages of the state of the art mentioned above, and which has as few optical elements as possible and a sufficiently large numerical aperture.

SUMMARY OF THE INVENTION

According to the invention, the short comings of the prior art are overcome by using a projection objective device which has five mirrors. By omitting a mirror from the known six-mirror systems—according to the five-mirror system of the invention—one can achieve a transmission which is at least 30% higher at wavelengths in the EUV region, if a reflectivity of the multilayer coating system of 70% is assumed for this radiation. In addition, numerical apertures of NA>0.10 can be realized. The five-mirror objective according to the invention is thus characterized by high resolution, low manufacturing costs and high throughput.

In a first embodiment of the invention, the mirror closest to the wafer is arranged in such a way that the image-side numerical aperture NA is greater than or equal to 0.10. Furthermore, the mirror closest to the wafer is arranged such that (1) the image-side free optical working distance corresponds at least to the used diameter of the mirror closest to

the wafer, (2) the image-side optical free working distance is at least the sum of one-third of the used diameter of the mirror closest the wafer and a length which lies between 20 and 30 mm, and/or (3) the image-side optical free working distance is at least 50 mm. Preferably, the optical free working distance is 60 mm.

In a second embodiment of the invention, the image-side numerical aperture NA is greater than or equal to 0.10, the annular field width W at the wafer lies in the region 1.0 mm≦W, and the peak-to-valley deviation, A, of the aspheres is limited with respect to the best-fitting sphere in the useful region on all mirrors, by:

$$A \leqq 24\ \mu m - 129\ \mu m(0.20 - NA) - 2.1\ \mu m/mm(2\ mm - W).$$

In a preferred embodiment, the peak-to-valley deviation A of the aspheres on all mirrors is limited by:

$$A \leqq 9\ \mu m - 50\ \mu m(0.20 - NA) - 0.4\ \mu m/mm(2\ mm - W).$$

In a third embodiment of the invention, with a numerical aperture in the range NA≧0.10 and an image-side width of the annular field in the range W≧1 mm, the angles of incidence, AOI, on all mirrors, relative to the normal of the surface of a given mirror, is limited by:

$$AOI \leqq 22° - 2°(0.20 - NA) - 0.3°/mm(2\ mm - W).$$

Combinations of the above may also be used according to the invention. For example, in a preferred embodiment, all three conditions are fulfilled, i.e., the free optical working distance is more than 50 mm at NA greater than 0.10 and the peak-to-valley deviation of the aspheres as well as the angles of incidence in the region defined above.

The asphericities herein refer to the peak-to-valley (PV) deviation, A, of the aspherical surfaces with respect to the best fitting sphere in the used area. The aspherical surfaces are approximated in the examples by using a sphere with center on the figure axis vertex of the mirror and which intersects the asphere in the upper and lower endpoint of the used area in the meridian section. The data regarding the angles of incidence always refer to the angle between the incident rays and the normal to the surface at the points of incidence. The largest angle of any incident light ray occurring on any of the mirrors is always given, i.e., the angle of a bundle-limiting ray. The used diameter will be defined here and below as the envelope circle diameter of the used area, which is generally not circular.

Preferably, the wafer-side optical free working distance is 60 mm.

The objective can be used not only in the EUV, but also at other wavelengths, without deviating from the scope of the invention. In any respect, however, to avoid degradation of image quality, especially degradation due to central shading, the mirrors of the projection objectives should be arranged so that the light path is obscuration-free. Furthermore, to provide easy mounting and adjusting of the system, the mirror surfaces should be designed on a surface which shows rotational symmetry to a principal axis (PA). Moreover, to have a compact design with an accessible aperture stop and to establish an obscuration-free path, the projection objective devices are designed to produce an intermediate image. It is preferred that the system include of a first and second subsystem, where a real intermediate image is formed by the first subsystem (with an imaging ratio in the range of $\beta<0$), and that the second subsystem images the intermediate image to a real system image in the wafer plane. In such structures, it is possible to have the plane for the object to be imaged located within the structural space of the entire mirror system, including the first, second, third, fourth and fifth mirrors.

In an embodiment of the invention, the aperture stop B lies on the first mirror. Alternatively, the freely accessible aperture stop can lie, both optically and physically, between the second and third mirrors.

In order to be able to make the necessary corrections of the imaging errors in the five-mirror systems, in a preferred embodiment, all five mirrors are aspherical. However, an alternative embodiment whereby at most four mirrors are aspherical, thus simplifying the manufacturing process, can be achieved. Then it is possible to make at least one mirror spherical, preferably the largest mirror.

In order to reach a resolution of at least 50 nm, the design part of the rms wave front part of the system should be at most 0.07 λ and preferably 0.03 λ.

Advantageously, in the examples of the invention, the objectives are always designed to be telecentric on the image-side. In projection systems which are operated with a reflection mask, a telecentric beam path on the object-side is not possible without illumination through a beam splitter which reduces transmission strongly such as known, for example, from JP-A-95 28 31 16. Therefore, the chief ray angles on the reticle are chosen so that vignetting-free illumination is possible. Alternatively, in systems with transmission masks, the projection objective can be telecentric on the object-side. Overall, the telecentricity error on the wafer should not exceed 10 mrad and typically is between 5 mrad and 2 mrad, with 2 mrad being preferred. This ensures that changes of the imaging ratio remain within tolerable limits over the focus.

In the embodiments of the invention, the projection objective is divided into two subsystems. The first subsystem is a reducing three-mirror system, preferably with imaging ratio (β) in range of $-0.5>\beta>-1.0$, and the second subsystem is a two-mirror subsystem.

In addition to the projection objective, the invention also provides a projection exposure apparatus, including at least one projection objective. In a first embodiment, the projection exposure apparatus has a reflection mask, while in an alternative embodiment, it has a transmission mask.

Furthermore, in a preferred embodiment, the projection exposure apparatus is an arc-shaped field scanner, and includes an illumination device for illuminating an off-axis arc-shaped field. Advantageously, the secant length of the scan slit is at least 26 mm and that the arc width is greater than 0.5 mm, so that homogenous illumination becomes possible.

The invention will be described below with the aid of drawings as examples.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a first embodiment of the invention with a real intermediate image between the first and second subsystem.

FIG. **2** is a second embodiment of the invention in which the aperture stop lies between the first and second mirror;

FIGS. **3**A and **3**B show the used diameter for differently illuminated light fields.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

In FIGS. **1** and **2**, preferred arrangements of the five-mirror projection objectives according to the invention are shown. Each has an optical free working distance that corresponds at least to the used diameter of the mirror

closest to the wafer or object to be illuminated. In all embodiments below, the same reference numbers are used for the same components with the following nomenclature employed:

first mirror (S1), second mirror (S2), third mirror (S3), fourth mirror (S4), and fifth mirror (S5).

In particular, FIG. 1 shows a five-mirror projection objective with a beam path from the reticle plane 2 to the wafer plane 4. The embodiment can be considered as a series circuit with (1) a three-mirror system consisting of S1, S2 and S3, that produces a real, reduced image of the object, as the intermediate-image Z and (2) a two-mirror system S4, S5, which images the intermediate image Z in the wafer plane 4 while maintaining the telecentricity requirements. The aberrations of the subsystems are balanced against one another in such a way that the total system has sufficient quality for the application.

A physical aperture stop B is arranged on the first mirror S1. To block light from passing above the aperture stop B, a narrow ring is used to block the light reflected toward S2 from S1. In the embodiment shown in FIG. 1, the aperture is realized as an opening at the S1 mirror. The aperture stop can also be positioned between the mirror S1 and the mirror S2.

In the system according to FIG. 1, the optical free working distance D between the mirror next to the wafer plane 4, the fourth mirror S4 in the present embodiment, and the wafer plane 4 is greater than the used diameter of mirror S4, that is, the following condition is fulfilled:

optical distance from S4 to the wafer plane 4> used diameter S4. Other distance conditions are possible, for example, that the optical free working distance is greater than the sum of one-third of the used diameter of the mirror S4 nearest to the wafer plane 4 plus 20 mm or that the optical free working distance can be greater than 50 mm. In the embodiment of FIG. 1, the free optical working distance is 60 mm. Such an optical working distance guarantees sufficient free mechanical working distance, which is greater than 0, as well as the use of optical components with sufficient strength properties to be used at wavelengths <100 nm and preferably of 11 or 13 nm.

The optical components for a wavelength of λ=13 nm and λ=11 nm include, for example, Mo/Si and Mo/Be multilayer coating systems, respectively, where the typical multilayer coating systems for λ=13 nm are 40 Mo/Si layer pairs, while the Mo/Be systems that are suitable for λ11 nm have approximately 70 layer pairs. Reflectivities of such systems lie in the range of approximately 70%. In the multilayer coating systems, layer stresses of above 350 MPa and more may occur. Stresses of such values may induce surface deformation, especially in the edge regions of the mirror.

The systems according to the invention, as shown as an example in FIG. 1, have:

$$RES=k_1\lambda/NA.$$

This results in a nominal resolution of at least 50 nm and 35 nm at a minimum numerical aperture of NA=0.15 for k_1=0.57 and λ=13 nm, and k_1=0.47 and λ=11 nm, respectively, where k_1 is a parameter specific for the lithographic process.

Furthermore, the beam path of the objective shown in FIG. 1 is obscuration-free. For example, in order to produce image formats of 26×34 mm^2 or 26×52 mm^2, the projection objectives according to the invention are preferably used in an arc-shaped field scan projection exposure apparatus, where the secant length of the scan slit is at least 26 mm.

Numerous types of mask can be used in the projection exposure apparatus, including transmission masks, stencil masks, and reflection masks, and the system, which is telecentric on the image-side can be telecentric or not telecentric on the object-side. For example, to form a telecentric beam path on the object-side, when using a reflection mask, a transmission-reducing beam splitter must be employed. With a beam path not telecentric on the object-side, unevenness of the mask will not lead to scaling errors in the image. The main beam angles at the reticle plane 2 are therefore preferably less than 10°, so that the requirements for reticle evenness lie in technologically realizable range. Moreover, the system according to FIG. 1 has an image-side telecentering error on the wafer plane 4 of 3±0.1 mrad at a numerical aperture of 0.15.

In the embodiment shown, all mirrors S1–S5 are aspherical, and the maximum asphericity in the used area lies at 14 μm. The maximum asphericity occurs on mirror S3. The low asphericity of the arrangement is advantageous from a manufacturing point of view, since the technological difficulties in producing of the surfaces of the multilayer mirror increase with the aspherical deviation and increasing gradient of the asphere.

The highest angle of incidence in the arrangement according to FIG. 1 occurs at S2 and is 18.9°. The wavefront error of the arrangement is better than 0.023 λ in the 2 mm wide arc-shaped field at λ=13 nm.

With the embodiments shown in FIGS. 1 and 2, the disadvantage of a mirror system with an odd number of mirrors, namely that a stretched structure reticle-projection optics-wafer can no longer be realized, is overcome. This disadvantage results from the fact that the reticle plane and the wafer plane were illuminated from the same direction especially in the case of systems with near normal incidence. This condition led to the reticle plane and the wafer plane lying on the same side of the objective.

According to FIG. 1 or 2, the reticle plane 2 is placed within the projection system. The mirror arrangement is chosen so that, in the direction of the optical axis, the structural space provided for the reticle stage, within the projection system, is as large as possible, preferably 400 mm. In addition, the plane of the object, i.e., the reticle, has a sufficiently large distance to the light bundles traveling in the objective. This ensures that a sufficiently large object, i.e., reticle, can be scanned in an annular field scanning operation. In a preferred example, approximately 200 mm can be scanned on the reticle, corresponding to 50 mm on the wafer.

In the embodiment shown in FIG. 1, the two mirrors of the two-mirror subsystem (S4, S5) have approximately the same radii R, within a few percent, and the distance between the two of the two oblate ellipsoidal mirrors is approximately R/$\sqrt{2}$. The three-mirror subsystem near the reticle plane 2 consists of three almost concentric mirrors (S1, S2, S3) of which the primary (S1) and the tertiary mirror (S3) have similar radii. The subsystem near the reticle plane 2 differs from a disturbed Offner system mainly by the position of the aperture stop B on the primary mirror and the non-telecentric beam path on the reticle.

A real intermediate image Z is produced between the two subsystems. The chief-ray angle inclination on the reticle plane 2 permits a vignetting-free illumination of a reflection mask. Furthermore, in the embodiments according to FIGS. 1 and 2, the distances between the mirrors are chosen to have a value such that the mirrors can be sufficiently thick so that the required strength properties are still obtained at the high layer stresses that occur.

The parameters of the systems shown in FIG. 1 are given in Table 1 in Code V (™) nomenclature. The objective is a 4× system with a 26×2 mm^2 arc-shaped field and a numerical aperture NA of 0.15. The mean image-side radius of the system is approximately 26 mm.

FIG. **2** shows an alternative embodiment of the invention of a five-mirror system in which the aperture stop B is between the first mirror and the second mirror. The same components as in FIG. **1** are assigned the same reference numbers.

The optical free working distance at the wafer plane **4** is approximately 60 mm in this embodiment, and thus it is larger than the used diameter of the mirror **S4**, which is closest to the wafer plane **4**. In contrast to the embodiment according to FIG. **1**, in FIG. **2** the aperture stop B is placed physically between the first and second mirrors so that it is freely accessible. The wavefront error is 0.024 λ, within the 1.7 mm wide arc-shaped field at λ=13 nm.

Table 2 shows the constructional data of the 4× objective according to FIG. **2** in Code V (™) nomenclature. The mean radius of the 26×1.7 mm^2 is again 26 mm and the aperture NA=0.15.

FIGS. **3**A and **3**B illustrate the meaning of the used diameter D in the present application. As an example, let the illuminated field **100** on a mirror in FIG. **3**A be a rectangular field. The used diameter D is then the diameter of the envelope circle **102**, which encompasses the rectangle **100**, where the corners **104** of the rectangle **100** lie on the envelope circle **102**.

FIG. **3**B shows a second example. The illuminated field **100** has a kidney shape, as expected for the useful range when using the objective according to the invention in a microlithography projection exposure apparatus. The envelope circle **102** encompasses the kidney shape fully and coincides with the edge **110** of the kidney shape at two points **106**, **108**. The used diameter D is then the diameter of the envelope circle **102**.

Thus, with the invention, a five-mirror projection objective is given for the first time, with an imaging scale of preferably 4×, 5× as well as 6× for preferred use in an EUV arc-shaped projection system. The projection objection has the necessary resolution for the required image field and provides conditions that make functional structural design possible, since the aspheres are sufficiently mild, the angles are sufficiently small for the layers and the structural spaces for the mirror carriers are sufficiently large.

What I claim is:

1. A projection objective for use in short wavelength microlithography to image an object onto a wafer plane, comprising:

a first mirror (**S1**), a second mirror (**S2**), a third mirror (**S3**), a fourth mirror (**S4**), and a fifth mirror (**S5**) such that the projection objective comprises a first subsystem and a second subsystem and wherein the object is imaged by a first subsystem, formed of the first mirror, the second mirror, and the third mirror (**S1**, **S2**, **S3**) with an imaging ratio (β) less than 0, into a real intermediate image (Z), and wherein a second subsystem, formed of the fourth mirror and the fifth mirror (**S4**, **S5**), images the intermediate image as a real system image in the wafer plane.

2. The projection objective of claim **1**, wherein

the first mirror (**S1**), the second mirror (**S2**), the third mirror (**S3**), the fourth mirror (**S4**), and the fifth mirror (**S5**) are arranged such that the image-side numerical aperture (NA) is

$$NA \geqq 0.10,$$

the arc-shaped field width (W) at the wafer plane lies in the range of

$$W \geqq 1.0 \text{ mm},$$

and the peak-to-valley deviation (A) of the aspheres in comparison to the best-fitting sphere in the used area is limited on all mirrors by

$$A \leqq 24\ \mu m - 129\ \mu m(0.20 - NA) - 2.1\ [\mu m/mm](2\ mm - W).$$

3. The projection objective of claim **1**, wherein

the first mirror (**S1**), the second mirror (**S2**), the third mirror (**S3**), the fourth mirror (**S4**), and the fifth mirror (**S5**) are arranged such that the image-side numerical aperture (NA) is at least 0.10, the image-side width of the arc-shaped field (W) at the wafer plane is at least 1.0 mm, and the angle of incidence (AOI) on all mirrors are in the range:

$$AOI \leqq 22° - 2°(0.20 - NA) - [0.3°/mm](2\ mm - W),$$

where the angle of incidence is measured for any given mirror relative to the surface normal of that mirror.

4. The projection objective of claim 1, wherein

the first mirror (S1), the second mirror (S2), the third mirror (S3), the fourth mirror (S4), and the fifth mirror (S5) are arranged such that the image-side numerical aperture (NA) is at least 0.10, and an object plane, where the object is located, is within the structural space of a mirror system consisting of the first mirror, second mirror, third mirror, fourth mirror and fifth mirror.

5. The projection objective according to claim 1, wherein the first subsystem is disposed near the object and that the second subsystem is disposed near the wafer plane.

6. The projection objective according to claim 4, wherein the mirrors are arranged in such a way that there is sufficient lateral structural space provided for a scan of the object plane so that an obscuration-free beam path is achieved.

7. The projection objective according to claim 4, wherein the mirrors are arranged in such a way that there is sufficient axial structural space for a scan of the object plane so that an obscuration-free beam path is achieved.

8. The projection objective according to claim 1, wherein the fourth mirror and the fifth mirror have substantially the same radii (R).

9. The projection objective according to claim 8, wherein the distance between the fourth mirror and the fifth mirror is approximately $\frac{R}{\sqrt{2}}$.

10. The projection objective according to claim 1, wherein the mirror surfaces are arranged on surfaces which exhibit rotational symmetry with respect to a principal axis (PA).

11. The projection objective according to claim 1, further comprising an aperture stop (B) arranged on the body of the first mirror (S1).

12. The projection objective according to claim 1, wherein the aperture stop lies between the first mirror and second mirror so that it is freely accessible.

13. The projection objective according to claim 1, wherein at least four mirrors are aspherical.

14. The projection objective according to claim 13, wherein all mirrors are aspherical.

15. The projection objective according to claim 1, wherein the imaging ratio (β) of the first subsystem is between −0.5 and −1.0.

16. The projection objective according to claim 1, wherein the rms wavefront error of the objective is at most 0.07 λ over an entire image field.

17. The projection exposure apparatus with a microlithography projection objective according to claim 1, further comprising an illumination device for illuminating an arc-shaped field.

(57) **ABSTRACT**

An apparatus for determining aberrations of an eye includes a patient head rest allowing for positioning adjustment. The patient head rest is operable with an optical table having a base. The base includes a probe beam generating apparatus, probe beam directing optics which itself comprises a beam splitter; a mirror; and a lens. The probe beam directing optics is capable of directing a probe beam toward an eye of a patient positioned on the patient head rest. Video image components are provided and comprise a light source, a mirror; and a video camera. The video image components are capable of generating an image of an eye of a patient positioned on the patient head rest. Eye fixation components generate a target that the eye of a patient positioned on the patient head rest can view. The eye fixation components comprise a fixation target, a light source, a lens, and a mirror. Wavefront directing and analyzing components measure a wavefront emanating from the eye of a patient positioned on the patient head rest and determine aberrations of the eye that range from at least about + or − 1 diopters to at least about + or − 6 diopters. The wavefront directing and analyzing components include a lens; a mirror, a microlens array, a camera, and a data processor.

APPARATUS AND METHOD FOR OBJECTIVE MEASUREMENTS OF OPTICAL SYSTEMS USING WAVEFRONT ANALYSIS

FIELD OF THE INVENTION

The invention relates generally to optical aberration measurement and analysis, and more particularly to an objective measurement of optical systems, such as systems of a human eye.

BACKGROUND OF THE INVENTION

Optical systems having a real image focus can receive collimated light and focus it at a point. Such optical systems can be found in nature, e.g., human and animal eyes, or can be man-made, e.g., laboratory systems, guidance systems, and the like. In either case, aberrations in the optical system can affect the system's performance. By way of example, the human eye will be used to explain this problem.

A perfect or ideal eye diffusely reflects an impinging light beam from its retina through optics of the eye which includes a lens and a cornea. For such an ideal eye in a relaxed state, i.e., not accommodating to provide near-field focus, reflected light exits the eye as a sequence of plane waves. However, an eye typically has aberrations that cause deformation or distortion of reflected light waves exiting the eye. An aberrated eye diffusely reflects an impinging light beam from its retina through its lens and cornea as a sequence of distorted wavefronts.

There are a number of technologies that attempt to provide the patient with improved visual acuity. Typically, treatment is determined by placing spherical and/or cylindrical lenses of known refractive power at the spectacle plane (approximately 1.0–1.5 centimeters anterior to cornea) and literally asking the patient which lens or lens combination provides the clearest vision. This is an imprecise measurement of true distortions in the reflected wavefront because 1) a single spherocylindrical compensation is applied across the entire wavefront, 2) vision is tested at discrete intervals (i.e., diopter units) of refractive values, and 3) subjective determination by the patient is employed. Thus, conventional methodology for determining refractive errors in the eye is substantially less accurate than the techniques now available for measuring the ocular aberrations.

One method of measuring ocular refractive errors is disclosed in U.S. Pat. No. 5,258,791 to Penney et al. for "Spatially Resolved Objective Autorefractometer," which teaches the use of an autorefractometer to measure the refraction of the eye at numerous discrete locations across the corneal surface. The autorefractometer is designed to deliver a narrow beam of optical radiation to the surface of the eye, and to determine where that beam strikes the retina using a retinal imaging system. Both the angle of the beam's propagation direction with respect to the optical axis of the system and the approximate location at which the beam strikes the corneal surface of the eye are independently adjustable. However, a small uncertainty or error in the location of the beam's point of incidence on the cornea exists due to the curved corneal surface. For each point of incidence across the corneal surface, the refraction of the eye corresponding to that surface point can be determined by adjusting the angle at which the beam strikes the cornea until the beam refracted on to the iris strikes the fovea centralis. Adjustment of the beam angle of propagation can be accomplished either manually by the patient or automatically by the autorefractometer, if a feedback loop involving a retinal imaging component is incorporated.

Penney '791 further teaches the use of the autorefractometer measurements in determining the appropriate corneal surface reshaping to provide emmetropia, a condition of a normal eye when parallel beams or rays of light are focused exactly on the retina and vision is perfect. This is accomplished by first obtaining an accurate measurement of corneal surface topography using a separate commercially available device. A mathematical analysis is then performed using an initial corneal topography at each surface reference point, the measured refraction at each surface point, and Snell's law of refraction, to determine a desired change in surface contour at each reference point.

A major limitation to the approach described by Penney '791 is that a separate measurement of corneal topography is desired to perform the Snell's Law analysis of needed refraction change. This adds significantly to the time and cost of a complete and desirable diagnostic evaluation. Further, the accuracy of the refraction change analysis will be dependent upon the accuracy of the topographic measurement and the accuracy of the autorefractometer measurement. In addition, any error in the spatial orientation of a topography map with respect to a refraction map will degrade the accuracy of the measured profile. Yet another limitation to known approaches such as described in Penney '791, by way of example, is that test points on the corneal surface are examined sequentially. Eye motion during the examination, either voluntary or involuntary, could introduce substantial errors in the refraction measurement. Penney '791 teaches detection of such eye movement by deliberately including measurement points outside the pupil, i.e., in the corneal region overlying the iris, where the return from the retina will obviously be zero at specific intervals in the examination sequence. However, this approach may still allow substantial undetected eye movement error between such iris reference points.

By way of example, one method and system known in the art, are disclosed by Junzhong Liang et al. in "Objective Measurement Of Wave Aberrations Of The Human Eye With The Use Of A Hartmann-Shack Wave-Front Sensor," published in the Journal of the Optical Society of America, Volume 11, No. 7, July 1994, pages 1949–1957. Liang et al. teach the use of a Hartmann-Shack wavefront sensor to measure ocular aberrations by measuring the wavefront emerging from the eye by the retinal reflection of a focused laser light spot on the retina's fovea. The actual wavefront is reconstructed using wavefront-estimation with Zernike polynomials.

The imprecise measurement technique of placing lenses of known refractive power anterior to the cornea and asking a patient which lens or lens combination provides the clearest vision has been improved with the use of autorefractometers, as described in Penny '79, or with the use of wavefront sensors as described by Liang et al. Spatially resolved refraction data, in combination with measured existing surface contour of the anterior surface of the eye, enable a calculation of a detailed spatially resolved new contour. However, it would be an improvement in this art if such vision measurements could be made without the need for this contour data, and further without the need for feedback from the patient regarding an appropriate lens. Liang et al. discloses the use of a Hartmann-Shack wavefront sensor to measure ocular aberrations by measuring the wavefront emerging from the eye by retinal reflection of a focused laser light spot on the retina's fovea. A parallel beam of laser light passes through beam splitters and a lens pair which brings the beam to a focus point on the retina by the optics of the eye. Possible myopia or hyperopia of the tested

eye is determined by movement of a lens within the lens pair. The focused light on the fovea is then assumed to be diffusely reflected and acts as a point source located on the retina. The reflected light passes through the eye and forms a distorted wavefront in front of the eye that results from the ocular aberrations. The aberrated wavefront is then directed to the wavefront sensor.

A point source of radiation on the retina would be ideal for such measurements. However, when the perfect eye receives a collimated beam of light, the best possible image on the retina is a diffraction limited spot. As illustrated by way of example, with Penny et al. and Liang et al., discussed above, and typical for those of skill in the art, parallel or collimated beams are used with the optics of the eye being measured to achieve this diffraction limited spot for such objective measurements. To do so, a setup for each patient includes a lens or lens combination and adjustments thereto for accommodating that patient's specific visual acuity. Providing a lens combination, as well as setting up for their use becomes cumbersome, time consuming, and at an additional expense. Eliminating the need for such optics is desirable and eliminates a variable within optical measurement systems that typically include many variables. Further, there is a need for providing optical characteristics of an eye without requiring feedback from the patient. By way of example, the patient may be a wild or domestic animal, living or dead.

The Hartmann-Shack wavefront sensor disclosed by Liang et al. includes two identical layers of cylindrical lenses with the layers arranged so that lenses in each layer are perpendicular to one another, as further disclosed in U.S. Pat. No. 5,062,702 to Bille. In this way, the two layers operate as a two-dimensional array of spherical lenslets that divide the incoming light wave into sub-apertures. The light through each sub-aperture is brought to focus in the focal plane of the lens array where a charge coupled device (CCD) image module resides.

The system of Liang et al. is calibrated by impinging an ideal plane wave of light on the lenslet array so that a reference or calibrating pattern of focus spots is imaged on the CCD. Since the ideal wavefront is planar, each spot related to the ideal wavefront is located on the optical axis of the corresponding lenslet. When a distorted wavefront passes through the lenslet array, the image spots on the CCD are shifted with respect to a reference pattern generated by the ideal wavefront. Each shift is proportional a local slope, i.e., partial derivatives of the distorted wavefront, which partial derivatives are used to reconstruct the distorted wavefront, by means of modal wavefront estimation using Zernike polynomials.

However, the system disclosed by Liang et al. is effective only for eyes having fairly good vision. Eyes that exhibit considerable myopia (nearsightedness) would cause the focus spots to overlap on the CCD, thereby making local slope determination practically impossible for eyes having this condition. Similarly, eyes that exhibit considerable hyperopia (farsightedness) deflect the focus spots such that they do not impinge on the CCD thereby again making local slope determination practically impossible for eyes having this condition.

SUMMARY OF THE INVENTION

In general, an embodiment of the present invention provides a method and system for objectively measuring aberrations of optical systems by wavefront analysis. Another embodiment further provides for the objective measurement of ocular aberrations having a dynamic range that can cope with large amounts of such aberrations so as to be useful in practical applications. Still another embodiment of the present invention provides a method and system for objectively measuring ocular aberrations using a wavefront analyzer of simple and inexpensive design.

One embodiment of the present invention provides an apparatus and method for making objective and detailed measurements of aberrations present in human eyes.

Aberrations measured by the apparatus include "higher order" phenomena, such as spherical aberration and coma, in addition to the traditional myopia/hyperopia and astigmatism.

In accordance with an embodiment of the present invention, an energy source generates a beam of radiation. Optics, disposed in the path of the beam, direct the beam through a focusing optical system that has a rear portion which provides a diffuse reflector. The beam is diffusely reflected back from the rear portion as a wavefront of radiation that passes through the focusing optical system to impinge on the optics. The optics project the wavefront to a wavefront analyzer in direct correspondence with the wavefront as it emerges from the focusing optical system. A wavefront analyzer is disposed in the path of the wavefront projected from the optics and calculates distortions of the wavefront as an estimate of ocular aberrations of the focusing optical system. The wavefront analyzer includes a wavefront sensor coupled to a processor that analyzes the sensor data to reconstruct the wavefront to include the distortions thereof.

One embodiment of the present invention, herein described by way of example, utilizes wavefront sensing to measure the aberrations of the eye. When one considers the perfect or ideal eye as earlier described, a perfectly collimated light beam (i.e., a bundle of parallel light rays) incident on the perfect, ideal emmetropic eye, focuses to a diffraction-limited small spot on the retina. This perfect focusing is true for all light rays passing through the entrance pupil, regardless of position. From the wavefront perspective, the collimated light represents a series of perfect plane waves striking the eye. Due to the reversible nature of light ray propagation, the light emanates from an illuminated spot created on the retina as wavefronts exiting the ideal eye as a series of perfect plane waves. The apparatus of the present invention achieves this ray reversal effect using a probe beam optical path for projecting a small diameter, eye-safe laser beam into the eye and onto the fovea. The light scattered from the irradiated retina serves as a secondary source for a re-emitted wavefront. The probe laser beam strikes the retina at an appropriate foveal location to illuminate a sufficiently small spot. A fixation optical path is provided which includes a reference target aligned to an optical axis. This allows a patient to fixate on a target. A video path provides a video image of the eye plane, centered on the optical axis. A video image of the eye allows a clinical operator to assist in orienting the eye for the wavefront measurement.

Embodiments of the present invention, herein described, provide a refraction measurement system that easily accommodates the measurement of vision characteristics of the eye, even in the presence of finite refractive errors. The time for a patient to be in a fixed position during examination is reduced, while at the same time providing a useful source of light on the retina of the eye to be measured regardless of the characteristics of the eye of that patient or other patients to be examined. Desirably, measurements are made without requiring patient or operator feedback. One method aspect of

the invention for measuring optical characteristics of an optical system, such as the eye, includes focusing an optical beam onto an anterior surface of the eye for providing a finite source of secondary radiation on the retina of the eye, which secondary radiation is emitted from the retina as a reflected wavefront of radiation that passes through the eye. The reflected wavefront is directed onto a wavefront analyzer for measuring distortions associated with the reflected wavefront.

In one embodiment, the radiation is optical radiation and the wavefront sensor is implemented using a plate and a planar array of light-sensitive cells. The plate is generally opaque but that has an array of light transmissive apertures that selectively let impinging light therethrough. The plate is disposed in the path of the wavefront so that portions of the wavefront pass through the light transmissive apertures. The planar array of cells is arranged parallel to and spaced apart from the plate by a selected distance. Each portion of the wavefront passing through one of the light transmissive apertures illuminates a geometric shape covering a unique plurality of cells.

As herein described, by way of example, the wavefront optical path of the present invention relays the re-emitted wavefront from the corneal plane to an entrance face of a Hartman-Shack wavefront sensor. The wavefront incident on the sensor is received by a sensitive charged-coupled device (CCD) camera and an optical plate containing an array of lenslets. The lenslet array is parallel to the CCD detector face with a distance therebetween approximately equal to the focal length of each lens in the lenslet array. The lenslet array divides the incoming wavefront into a matching array of "wavelets," each of which focuses to a small spot on the CCD detector plane. The constellation of wavelet spots in the CCD is used to reconstruct the shape of the incident wavefront. Collimated light striking the lenslet at normal (perpendicular) incidence would focus to the spot on the CCD face where this optical axis intersects. The optics of the apparatus provides such collimated light to the wavefront sensor using a calibration optical path. Collimated light CCD images are routinely obtained as part of a daily calibration process and used for reference in analyzing experimental data.

However, in the case of a reflected aberrated wave front, light focuses to a spot displaced from the collimated reference point by a distance Dx. The distance from the lenslet face to the CCD surface, Dz, is precisely known. Therefore, dividing the measured displacement, Dx, by the known propagation distance, Dz, the slope of the wavefront at the location of this lens element is determined. The same calculation is applied in the y direction within the plane, and the entire process applied to every lenslet element irradiated by the wavefront. A mathematical algorithm is then applied to reconstruct the wavefront shape consistent with the calculated Dx/Dz and Dy/Dz slope data. Regardless of which wavefront sensor is used, the distance between the planar array of cells and the opaque plate, or the array of lenslets, can be varied to adjust the slope measurement gain of the wavefront sensor and thereby improve the dynamic range of the system.

Another measure of dynamic range enhancement is provided by the focusing optics. The focusing optics includes first and second lenses maintained in fixed positions in the path of the beam and wavefront. An arrangement of optical elements is disposed between the lenses in the path of the beam and the wavefront. The optical elements are adjustable to change the optical path length between the lenses.

A method aspect of the present invention, as herein described, determines aberrations of an eye requiring greater than a + or −3 diopter change, and includes directing an optical beam onto a retina of an eye, reflecting the optical beam from the retina of the eye, determining characteristics of a wavefront in a reflected optical beam, and generating data based on the characteristics of the wavefront, which data quantifies the aberrations of the eye. The data may further be generated based on refractive indices of media through which the optical beam passes. Yet further, data based on the characteristics of the wavefront, which data quantifies the aberrations of the eye for a discrete section of the eye may also be generated.

One method for determining aberrations of an eye, herein described by way of example, includes directing a probe beam along a probe beam path toward an eye, directing a fixation image along a fixation image path toward the eye, directing a light source along a video image path toward the eye, generating a video image of the eye, directing a wavefront originating from the eye along a wavefront path, wherein the probe beam path, the fixation image path, the video image path, and the wavefront path are coincident at least along a portion of their respective paths, the probe beam path terminating at the retina of the eye and the probe beam reflecting from the retina of the eye as a wavefront, aligning the eye with the probe beam path based at least in part on the video image of the eye generated by the light source directed along the video image path, measuring the wavefront, and generating data representative of the aberrations of the eye based on the measurement of the wavefront. Further, the aligning of the eye with the probe beam path based at least in part on the video image of the eye generated by the light source directed along the video image path, may have the wavefront pass through a single microlens array.

One apparatus for determining the aberrations of an eye comprises a patient head rest comprising vertical adjustment, the patient head rest associated with an optical table having a base. The base carries a probe beam generating apparatus, probe beam directing optics, the probe beam directing optics comprising a beam splitter; a mirror; and a lens, the probe beam directing optics being capable of directing a probe beam toward an eye of a patient positioned on the patient head rest, video image components, the video image components comprising a light source, a mirror, and a video camera, the video image components being capable of generating an image of an eye of a patient positioned on the patient head rest, eye fixation components, the eye fixation component comprising a fixation target; a light source; a lens; and a mirror, the fixation components being capable of generating a target that the eye of a patient positioned on the patient head rest can view, and wavefront directing and analyzing components, the wavefront directing and analyzing components comprising a lens, a mirror, a microlens array, a camera, and a data processor. The wavefront directing and analyzing components are capable of measuring the wavefront emanating from the eye of a patient positioned on the patient head rest and determining aberrations of said eye that range from at least about + or −1 diopters to at least about + or −6 diopters.

BRIEF DESCRIPTION OF THE DRAWINGS

Embodiments of the invention are described by way of example with reference to the accompanying drawings in which:

FIG. **1A** is a schematic view of the ideal eye reflecting light from its retina as a planar wavefront;

FIG. **1B** is a schematic view of an aberrated eye reflecting light from its retina as a deformed wavefront;

FIG. **1**C is a schematic view of the distorted wavefront relative to a reference plane to show the wavefront error or optical path difference as a function of transverse distance in the propagation direction;

FIG. **1**D is a schematic view illustrating use of a reference plane;

FIG. **2** is a simplified schematic of the system for determining ocular aberrations in accordance with the essential features of the present invention;

FIG. **3** is a schematic of one embodiment of a Hartmann-Shack wavefront analyzer used in the present invention;

FIG. **4** is a perspective view of a portion of the pinhole imaging plate and planar array of light-sensitive cells comprising the wavefront sensor from the embodiment of FIG. **3** where the deflection of a wavefront piece associated with an aberrated eye is shown in comparison with a wavefront piece associated with a calibration or planar wavefront;

FIG. **5** is a plan view of a designated area on the planar array of light-sensitive cells associated with a corresponding hole;

FIG. **6** is a schematic of another embodiment of a wavefront analyzer used in the present invention;

FIG. **7** is a schematic view of an eye to be measured by the present invention;

FIG. **8** is a schematic view of an eye to be measured by the present invention;

FIG. **9** is a side elevation view of one embodiment of the present invention illustrating a patient positioning for measurement;

FIG. **10** is an end elevation view of the embodiment of FIG. **9**;

FIG. **11** is an enlarged perspective view of an patient positioning portion of the embodiment of FIG. **9**;

FIG. **12** is a top plan view of optical elements of the embodiment of FIG. **9**;

FIG. **12**A illustrates a fixation target optical path of FIG. **12**;

FIG. **12**B illustrates a video image optical path of FIG. **12**;

FIG. **12**C illustrates a probe laser optical path of FIG. **12**;

FIG. **12**D illustrates a re-emitted wavefront optical path of FIG. **12**;

FIG. **12**E illustrates a calibration wavefront optical path of FIG. **12**;

FIGS. **12**F and **12**G are front elevation and top plan views of a trial lens holder useful with embodiments of the present invention herein described;

FIG. **13** is a block diagram illustrating electrical components of the embodiment of FIG. **9**;

FIG. **14** is an enlarged image of an eye illustrating a centration image;

FIG. **15** is a block diagram illustrating an operable flow of steps used in one embodiment of the present invention;

FIG. **16** is an enlarged image of an eye illustrating a pre-measurement eye alignment;

FIG. **17** is an enlarged image of an eye illustrating a pre-measurement eye alignment checking thereof;

FIG. **18** is a line diagram illustrating an eye registration pattern;

FIG. **19** illustrates a rejected CCD image;

FIG. **20** illustrates a CCD image including centroids;

FIG. **21** is an enlarged image of a centroid;

FIG. **22** illustrates an image available to an operator of a measured and reference centroid;

FIG. **23**A illustrates a spacial filter operable in one embodiment of the present invention;

FIG. **23**B illustrates a noisy CCD image before filtering to provide an image as illustrated with reference to FIG. **20**;

FIG. **24**A is a three dimensional plot of a wavefront reconstruction in accordance with the present invention;

FIG. **24**B illustrates a higher order aberration for the wavefront of FIG. **23**;

FIG. **25** illustrates a geometric effect of a curved corneal surface on a wavefront measurement;

FIG. **26**A is a pictorial line drawing illustrating magnification modification to the embodiment of FIG. **12**; and

FIG. **26**B is a pictorial line drawing illustrating optical elements of the present invention.

DETAILED DESCRIPTION OF THE INVENTION

The present invention will now be described more fully hereinafter with reference to the accompanying drawings, in which embodiments of the present invention are shown by way of illustration and example. This invention may, however, be embodied in many forms and should not be construed as limited to the embodiments set forth herein. Rather, these embodiments are provided so that this disclosure will be thorough and complete, and will fully convey the scope of the invention to those skilled in the art. Like numbers refer to like elements throughout.

By way of illustrative example, the present invention will be described with respect to diagnosing a human eye. However, it is to be understood that the teachings of the present invention are applicable to any optical system having a real image focus that can be, or can be adapted to diffusely reflect a focused spot of radiation from a rear portion of the optical system back through the optical system as a wavefront of radiation. Thus, the present invention can be used with human or animal eyes of patients that may be alive or dead, or any man-made optical system.

The method of using wavefront analysis will be introduced with reference to the eye example and the aid of the schematic drawings of FIGS. **1**A, **1**B, and **1**C. As earlier described with reference to an ideal eye, and with reference now to FIG. **1**A, the ideal emmetropic or perfect eye **100** diffusely reflects an impinging light beam (not shown for sake of clarity) from the back of its retina **102** (i.e., the fovea centralis **103**) through the eye's optics which includes lens **104** and cornea **106**. For such an ideal eye **100** in a relaxed state, i.e., not accommodating to provide near-field focus, the reflected light (represented by arrows **108**) exits the eye **100** as a sequence of plane waves, one of which is represented by straight line **110**. However, as illustrated with reference to FIG. **1**B, a typical eye **120** normally has aberrations that cause deformation or distortion of a reflected wave exiting the eye, where the aberrated eye **120** diffusely reflects an impinging light beam (again not shown for sake of clarity) from the back of its retina **122** of the fovea centralis **123** through lens **124** and cornea **126**. For the aberrated eye **120**, the reflected light **128** exits the eye **120** as a sequence of distorted wavefronts, one of which is represented by wavy line **130**.

With reference now to FIG. **1**C, a coordinate system is defined for convenience, where positive x is upward in the plane of the figure, positive y is outward from the plane of the figure, and positive z is to the right along a propagation direction. The distorted wavefront **130** is herein described mathematically as W(x,y). One method of measuring dis-

tortions in the wavefront **130** is by determining a spatial separation Δz between a reference plane 131 (by way of example, a plane analogous to the ideal wavefront **110**) at a known distance Z_0 from the eye **120** at each (x,y) point of the distorted wavefront **130** as the leading edge of the wavefront **130** traverses the distance z_0. This is described mathematically as:

$$\Delta z(x,y)=z_0-W(w,y) \quad (1)$$

These Δz measurements define optical path differences due to aberrations in the eye **120** being tested, by way of example.

Depending on the desired therapy (for example, synthetic lens addition), the material thickness at each (x,y) coordinate can be calculated directly if the refractive index of the material in question is known. For many procedures, such as intra-ocular lens implantation, a wavefront analysis may be performed repetitively during a procedure to provide feedback information as to the appropriate endpoint of the procedure.

In terms of the illustrative example, the differences Δz(x, y) between the distorted wavefront **130** and the ideal wavefront **110** are the consequence of the aberrations in the eye. Measuring these aberrations consists of introducing an optical path difference at the reference plane **131** of negative Δz(x,y). If the treatment approach, by way of example, consists of adding material to the cornea **126**, then one choice for the location of reference plane **131** is tangential to the surface of cornea **126** (i.e. at z=O). This is illustrated schematically with reference to FIG. **1**D, where the curvature of the cornea **126** is greatly exaggerated for clarity of illustration.

The appropriate corneal addition at any (x,y) transverse coordinate is, to within a small error, given by:

$$\Delta z(x,y)/(n_c-1) \quad (2)$$

where n_c is the refractive index of corneal tissue or 1.3775. The method described in detail below calculates Δz(x,y) by first measuring the local slopes in wavefront **130**, i.e. ∂W(x, y)l∂x and ∂W(x,y)/∂y, at a number of points in the transverse x and y directions in reference plane **131** and then generating a mathematical description of W(x,y) having slopes in best possible agreement with the experimentally determined values. One such slope ∂W(x,y)/∂x is illustrated with reference again to FIG. **1**D. In doing this, a small error is introduced due to the fact that distorted wavefront **130** is measured at the reference plane **131** while wavefront **130** emerged from a curved corneal surface just posterior to reference plane **131**. By way of example, an error $E_x(x,y)$ is the lateral displacement in the x-direction at each (x,y) location at the measurement plane (i.e., reference plane **131**) to the curved corneal surface. A similar error will be manifest for any measurements involving curved optical surfaces. The error will generally increase with both (x,y) displacement from the point of tangency and local wavefront error.

The magnitude of error $E_x(x,y)$ can be found for each measurement location (x,y) measured at an arbitrary coordinate, e.g., (x_0,y_0) by projecting that location back to the point of origin on the cornea **126**. This is explained mathematically with reference again to FIG. **1**D, where by way of example, it is assumed that the error is in the plane of the figure, i.e., the plane defined by $y=y_0$, although it is quite straightforward mathematically to extend the analysis to include errors in the y-dimension. The quantification of a line L tracing the propagation of the wavefront **131** measured at (x_0,y_0) in the z_0 reference plane from the corneal surface to the reference plane is:

$$L(x) = z_0 - \frac{(x - x_0)}{\partial W(x_0, y_0)/\partial x} \quad (3)$$

If the corneal surface in the plane of the figure is described by the expression $S(x_0,y_0)$, then the point of origin for the wavefront **131** in question can be found by finding the point of intersection between L(x) and S (x,y_0). Mathematically, one finds the value x^1, that satisfies $L(x^1)=S(x_0,y_0)$. The error $E_x(x_0,y_0)$ is then given as $Ex(x_0,y_0)=x^1-x_0$. Extending the analysis to consider errors in the y-direction would yield a similar expression for E_y where $E_y(x_0, y_0)=y^1-y_0$. If significant, these transverse errors can be compensated for by laterally displacing the aberration calculated at each (x,y) coordinate by the amounts $E_x(x,y)$ and $E_y(x,y)$.

In the case of human corneas, the transverse error under most circumstances will be negligible. The error will be zero at the origin where the corneal tissue and reference plane **131** are tangent. For human corneas, the tissue is approximately spherical with a radius of curvature of approximately 7.5–8.0 mm. The treatment radius is typically no more than 3 mm, and local wavefront radius of curvature will almost never exceed 50 mm (a 20 diopter refractive error). The transverse error E at a 3 mm treatment radius for a local wavefront radius of curvature of 50 mm is less than 40 μm.

For certain ophthalmic procedures, wavefront analysis can also be used repetitively during the procedure to provide useful feedback information. One example of such use would be following placement of an intra-ocular lens implant (IOL). The analysis helps to identify whether the appropriate refractive power IOL has been inserted, or whether a different refractive power IOL should be used.

In order to perform wavefront analysis in a manner compatible with procedures such as those described above, the amount of spatial separation of component portions of wavefront **130** relative to the corresponding component portions of the planar or ideal wavefront **110** is measured. It is the system and method of the present invention that allows such separation to be objectively and accurately measured for even substantially aberrated eyes **120** including those exhibiting severe defects such as severe myopia or hyperopia.

For the evaluation or measurement portion of the present invention, the patient's pupil should ideally be dilated to approximately 6 mm or more, i.e., the typical size of a human pupil in low light. Smaller amounts of dilation or no dilation at all may also evaluated or measured. In this way, the eye is evaluated while it is using the greatest area of the cornea so that any measurement takes into account the largest usable corneal area of the patient's eye. A lesser amount of the cornea is used in daylight where the pupil is considerable smaller, e.g., on the order of 3 millimeters. Dilation can be brought about naturally by implementing the measurement portion of the present invention in a low light environment such as a dimly lit room. Dilation can also be induced through the use of pharmacologic agents.

Referring now to FIG. **2**, a simplified schematic of one exemplary embodiment of the apparatus **10** of the present invention is illustrated. The apparatus **10** includes a laser **12** for generating optical radiation used to produce a small-diameter laser beam **14**. The laser **12** generates a collimated laser light beam (represented by dashed lines for the beam **14**) of a wavelength and power that is eye-safe. For ophthalmic applications, appropriate wavelengths would include the entire visible spectrum and the near infrared

spectrum. By way of example, appropriate wavelengths may be in a range of from approximately 400 to 1000 nanometers, including 550, 650, 850 useful wavelengths. While operation in the visible spectrum is generally desired, since these are the conditions in which the eye operates, the near infrared spectrum may offer advantages in certain applications. For example, the patient's eye may be more relaxed if the patient does not know measurement is taking place. Regardless of the wavelength of the optical radiation, power should be restricted in ophthalmic applications to eye safe levels. For laser radiation, appropriate eye-safe exposure levels can be found in the U.S. Federal Performance Standard for Laser Products. If the analysis is to be performed on an optical system other than the eye, the examination wavelength range logically should incorporate the intended performance range of the system.

To select a small-diameter collimated core of laser light beam **14**, an iris diaphragm **16** is used to block all of laser light beam **14** except for the laser beam **18** of a size desired for use. In terms of the present invention, the laser beam **18** will have a diameter in the range of approximately 0.5–4.5 millimeters with 1–3 millimeters being typical, by way of example. A badly aberrated eye uses a smaller diameter beam while an eye with only slight aberrations can be evaluated with a larger diameter beam. Depending on the output divergence of the laser **12**, a lens, as will be later described, can be positioned in the beam path to optimize collimating of the beam.

Laser beam **18**, as herein described by way of example, is a polarized beam that is passed through a polarization sensitive beam splitter **20** for routing to a focusing optical train **22** which optical train operates to focus the laser beam **18** through the optics of the eye **120** (e.g., the cornea **126**, pupil **125** and the lens **124**) to the retina **122**. It is to be understood that the lens **124** may not be present for a patient that has undergone a cataract procedure. However, this does not affect the present invention.

In the illustrated example of FIG. **2**, the optical train **22** images the laser beam **18** as a small spot of light at or near the eye's fovea centralis **123** where the eye's vision is most acute. Note that the small spot of light could be reflected off another portion of retina **122** in order to determine aberrations related to another aspect of one's vision. For example, if the spot of light were reflected off the area of the retina **122** surrounding the fovea centralis **123**, aberrations specifically related to one's peripheral vision could then be evaluated. In all cases, the spot of light may be sized to form a near-diffraction limited image on the retina **122**. Thus, the spot of light produced by laser beam **18** at fovea centralis **123** does not exceed approximately 100 micrometers in diameter and, typically, is on the order of 10 micrometers.

The diffuse reflection of the laser beam **18** back from the retina **122** is represented in FIG. **2** by solid lines **24** indicative of radiation that passes back through the eye **120**. The wavefront **24**, earlier described with reference to FIG. **1B** as distorted wavefront **130** impinges on and is passed through the optical train **22** and on to the polarization sensitive beam splitter **20**. The wavefront **24** is depolarized relative to the laser beam **18** due to reflection and refraction as the wavefront **24** emanates from the retina **122**. Accordingly, the wavefront **24** is turned at the polarization sensitive beam splitter **20** and directed to a wavefront analyzer **26** such as a Hartmann-Shack (H-S) wavefront analyzer. In general, the wavefront analyzer **26** measures the slopes of wavefront **24**, i.e., the partial derivatives with respect to x and y, at a number of (x,y) transverse coordinates, as earlier described with reference to FIGS. **1C** and **1D**. This partial derivative information is then used to reconstruct or approximate the original wavefront with a mathematical expression such as a weighted series of Zernike polynomials.

The polarization states for the incident laser beam **18** and the beam splitter **20** minimizes the amount of stray laser radiation reaching the sensor portion of the wavefront analyzer **26**. In some situations, stray radiation may be sufficiently small when compared to the radiation returning from the desired target (e.g., the retina **122**) so that the polarization specifications are unnecessary.

The present invention is able to adapt to a wide range of vision defects and as such achieves a new level of dynamic range in terms of measuring ocular aberrations. Dynamic range enhancement is accomplished with the optical train **22** and/or a wavefront sensor portion of the wavefront analyzer **26**. With continued reference to FIG. **2**, the optical train **22** includes a first lens **220**, a flat mirror **221**, a Porro mirror **222** and a second lens **224** all of which lie along the path of laser beam **18** and the wavefront **24**. The first lens **220** and the second lens **224** are identical lenses maintained in fixed positions. The Porro mirror **222** is capable of linear movement as indicated by arrow **223** to change the optical path length between the lenses **220** and **224**. However, it is to be understood that the present invention is not limited to the particular arrangement of the flat mirror **221** and the Porro mirror **222** and that other optical arrangements, as will herein be described by way of example, will be used without departing from the teachings and benefits of the present invention.

A "zero position" of the Porro mirror **222** is identified by replacing the eye **120** illustrated with reference again to FIG. **2**, by a calibration source, as will be described later by way of further example, of collimated light to provide a reference wavefront such as the perfect plane wave **110**, earlier described with reference to FIG. **1A**. Such a source could be realized by a laser beam expanded by a beam telescope to the diameter that will cover the imaging plane of wavefront analyzer **26** and adjustment of the Porro mirror **222** until the wavefront analyzer **26** detects the light as being collimated. Note that the changes in optical path length brought about by the Porro mirror **222** can be calibrated in diopters to provide an approximate spherical dioptric measurement, as will be explained further below.

The dynamic range of the apparatus **10** is further improved by providing an improved wavefront sensor arrangement **28** as illustrated with reference to FIGS. **3** and **4**. The wavefront analyzer **26** includes an opaque imaging plate **32** having an array of holes **34** passing therethrough, a planar array **36** of light-sensitive cells such as charge coupled device (CCD) cells **38**, and a processor **40** operable with the planar array **36** of the CCD cells **38**. The combination of the plate **32** and the planar array **36** provides one embodiment of the present invention. The plate **32** is held parallel to and spaced from the planar array **36** by a separation distance F. As will be explained further below, the separation distance F can be varied to adjust for signal gain. To do this, the planar array **36** is coupled to a positioning apparatus **42**, e.g., a conventional motorized linear positioner having precise movement capability, that adjusts the position of planar array **36** relative to the plate **32** for changing the separation distance F as indicated by arrow **43**. With respect to the array of holes **34**, each of the holes **34** are of equal size and shape with a circle being typical owing to its ease of manufacture. As herein described by way of example, a square array geometry is used for the array of holes **34**, although other array geometries will be used without departing from the teachings of the present invention.

As illustrated with reference to FIG. **4**, when the wavefront **24** impinges on the plate **32**, a portion of the wavefront **24**, indicated by arrow **26**, passes through the hole **34** to illuminate planar array **36**. To a first order, the resulting image formed by each such wavefront portion **25** is a positive shadow of the respective hole **34**. However, diffraction occurs as determined by the diameter D of each hole **34**, the wavelength λ of the light source (e.g. the wavefront **24**) and the separation distance F between the plate **32** and the planar array **36**. The value of F is varied by the positioning apparatus **42** to adjust the gain based on the particular patient as will be explained further below.

Note that performance of the plate **32** with holes **34** may also be accomplished using a solid plate or film made from a light-sensitive material such as a photo-lithographic film. In such a case, the array of holes **34** would be replaced by an array of shaped light transmissive apertures through which light passes when impinging thereon. The remainder of such a plate or film would be impervious to light. Such an embodiment permits the light transmissive apertures to be easily made to conform to any desired shape.

Regardless of how each wavefront portion **25** is generated, the present invention measures the amount of angular deflection of each wavefront portion **25** relative to a wavefront portion **112** that results from a calibration wavefront such as the planar wavefront earlier described. The calibration or planar wavefront of light results in the wavefront portion **112** impinging at a normal or perpendicular to plate **32** and illuminates a geometric spot **114** on the planar array **36**. In contrast, continuing with the wavefront **24** representing a distorted wavefront as described above, the wavefront portion **25** will exhibit an amount of angular deflection relative to the calibration wavefront portion **112**. The angular deflection causes the wavefront portion **25** to illuminate a geometric spot **27** on the planar array **36** that is offset from the spot **114**. In terms of the present invention, the amount of offset is measured relative to centroids **116** and **29** of spots **114** and **27**, respectively. In the two dimensions of the planar array **36**, the centroid **29** is typically deflected in both the x and y directions of the array **36**. Thus, the angular deflection in each of the x and y directions is given by $\Delta x/F$ and $\Delta y/F$, respectively.

With reference again to FIG. **2**, the lenses **220** and **224** in one embodiment are identical as mentioned above. However, in certain applications it may be desirable to magnify or minify the wavefront at the wavefront sensor. This can be accomplished by using lenses **220** and **224** of different focal lengths and adjusting dimensions of the apparatus **10** accordingly. For ophthalmic evaluation, the object plane of the apparatus should ideally be tangent to the corneal surface which can be achieved by a variety of means. Thus, each point at the object plane of the optical train **22** very nearly corresponds to the same point on the cornea **126**. However, since the cornea **126** is curved, there will be a slight lateral displacement. The plate **32** described earlier with reference to FIG. **4** of the wavefront analyzer **26**, or an imaging plane of any wavefront sensor portion, is positioned at the focal plane of lens **220**. In this way, the object plane is always imaged on the plate **32** in direct correspondence with the wavefront image emerging from cornea **126**. This will be true regardless of the optical path length between the lenses **220** and **224**. There are several advantages to this structure, one of which is that there are very good planar arrays of light-sensitive cells that are commercially available to image an area corresponding to the 6 millimeter central circular region of the cornea.

The plate **32** (or the imaging plane of any wavefront sensor portion of a wavefront analyzer) breaks the wavefront **24** into wavefront pieces that can each be measured independently in terms of propagation direction at the planar array **36**. Since in an embodiment herein described by way of example, the optical train **22** does not magnify or reduce the image in the object plane, a point at the object plane corresponds to the same point at the image plane of the optical train. With the Porro mirror **222** set at its zero position, the direction each portion of the wavefront **24** is traveling toward the object plane is reproduced exactly at the image plane of wavefront analyzer **26**. By way of example, if one wavefront portion at a location in the object plane was traveling away from the optical axis at an angle of 20° with respect to the optical axis that is perpendicular to the object plane, the wavefront portion at the same location in the image plane will also be traveling away from the optical axis at an angle of 20°.

Note that a person who is myopic will produce a wavefront such that the wavefront portions/pieces isolated by the plate **32** will converge toward the center of planar array **36**. A hyperopic person will produce a wavefront such that the wavefront pieces isolated by the plate **32** diverge. Thus, a person with a significant vision error becomes difficult to evaluate because wavefront portions can either overlap (myopia) at the planar array **36** or spill off (hyperopia) the planar array.

In the present invention, five ways of compensating for such severe aberrations are herein described by way of example. The first way is to utilize a wavefront sensor with sufficiently small light sensitive cells **38** and sufficiently large holes **34** (or any other transmissive aperture). In this way, measurement of each wavefront piece can be performed to an acceptable accuracy using a small value for F. A second way is to move planar array **36** along the optical axis to change the separation distance F to the plate **32**. For a person with a severe aberration, the planar array **36** is positioned close to the plate **32** to keep the projected wavefront portions well separated and on the planar array. For a mild aberration, the planar array **36** is moved to increase the separation distance F to the plate **32** to make a more accurate measurement. The advantage of moving the planar array **36** to change the separation distance F to the plate **32** is that the wavefront analysis is easily achieved for any position. Yet another way of compensating for severe aberrations using the present invention is to change the optical path length between lenses **220** and **224**. Moving the Porro mirror **222** will not affect where the wavefront hits the plate **32**, but will change the angular deflections at which the projected wavefront portions pass through the plate **32**, i.e., $\Delta x/F$ and $\Delta y/F$. Decreasing the optical path length between lenses **220** and **224** will tend to pull the wavefront portions toward the center of planar array **36** thereby compensating for hyperopia. Increasing the optical path length between lenses **220** and **224** will tend to spread the wavefront portions toward the edges of the planar array **36** thereby compensating for myopia. The degree to which the angular deflection associated with each wavefront piece is altered is a linear function of its distance off the optical axis and the movement of the Porro mirror **222** from its zero position. A fourth way of compensating for severe aberrations is to insert one or more trial lenses of specified sphero-cylindrical power at the location of the intermediate focal plane, as will be discussed in detail later in this section. This serves to reduce or remove low order aberrations from the wavefront so that displacement of spots at the CCD cells **38** is minimized and accurate evaluation can proceed. The effect of the specified lens addition is then included in the final wavefront reconstruction. A fifth way is to increase the

magnification of the wavefront at the wavefront sensor relative to that at the eye. This is accomplished by an appropriate choice of lenses in the relay optic design. Magnification will reduce the slope of the wavefront uniformly, thereby reducing the displacement of each spot at the CCD.

By way of example, to accurately determine the centroid **29** of the spot **27** of light impinging on the planar array **36**, a fine structure of cells **38** relative to a spot size is provided. Each spot covers a plurality of cells **38**. One method used to determine the centroid **29** of each spot **27** unambiguously with respect to a spot caused by another one of the holes **34**, assigns a unique number of cells **38** to each hole **34**. The "assigned areas" are designated, as illustrated with reference to FIG. **5**, by way of example, with the heavy grid lines **39**. It is to be understood that the grid lines **39** are not actual physical boundaries between cells **38** but are shown simply to illustrate the unique designated areas containing a plurality of the cells **38**. It is anticipated that other centroid strategies will be utilized that do not necessitate such partitioning of the array **36** given the teachings of the present invention. An alternative method for identifying and correlating centroids is later described in this section.

By way of example, the present invention could also be practiced with a wavefront analyzer that replaces plate **32** described with reference to FIG. **3**, with a two dimensional array of identical spherical lenslets **33**, as illustrated with reference to FIG. **6**. In such an embodiment, the lenslet array **33** may be operable by the positioning apparatus **42** such that separation distance F is independent of the focal length f that defines the focal plane of the lenslet array **33** which is represented by dashed line **35**. Each wavefront portion **37** passed through a sub-aperture of the lenslet array **33** is reduced in size (e.g., diameter) but is not necessarily brought to a minimum focus at the planar array **36** as it would be if separation distance F were equal to focal length f. In the operation of this embodiment configuration, the lenslet array **33** is positioned to concentrate the light in each wavefront portion of an area for providing sufficient intensity onto the planar array **36**, yet still illuminating a substantial plurality of cells **38** for greatest accuracy in determining the deflection of the centroids **29**.

Regardless of the structure of the wavefront sensor, the processor **40** computes each two-dimensional centroid **29** of each spot **27** generated by the wavefront **24**. The amount of two dimensional centroid shift relative to the centroid of the calibrating spot for each designated area associated with a corresponding hole **34** (or sub-aperture of lenslet array **33**) is divided by the separation distance F to generate a matrix of local slopes of the wavefront, i.e., $\partial W(x,y)/\partial x$ and $\partial W(x,y)/\partial y$ at the (x,y) coordinates of the centers of holes **34**. For simplicity of discussion, these will be indicated by $P(x,y)=\partial W(x,y)/\partial x$ and $Q(x,y)=\partial W(x,y)/\partial y$, respectively.

Numerous methods exist for using the partial derivative data to calculate the distorted wavefront **130** and **24** as described above with reference to FIGS. **1**B and **2**. One acceptable approach is that described by Liang et al. in the aforementioned Journal of the Optical Society of America paper, where the wavefront is approximated using Zernike polynomials. This is a standard analytic technique described in numerous optics texts such as "Principles of Optics, 11 by M. Born and E. Wolf, Pergamon Press, Oxford, England, 1964. By way of example, the Zernike polynomial approach will be discussed herein. However, it is to be understood that other mathematical approaches can be used in approximating the distorted wavefront. By way of example, such approaches may include the use of Fourier series and Taylor series.

$$W(x,y)=\sum_{i=0}^{n} C_i Z_i(x,y) \tag{4}$$

Briefly, the wavefront W(x,y) is expressed as a weighted sum of the individual polynomials where Ci are the weighting coefficients, and $Z_i(x,y)$ are the Zernike polynomials up to some order. The upper limit n of the summation is a function of the number of Zernike polynomials, i.e., the highest order, used to approximate the true wavefront. If m is the highest order used, then

$$n=(m+1)(m+2)/2 \tag{5}$$

Derivation of the Zernike polynomials up to an arbitrary order n is described in numerous optical texts such as the aforementioned book by Born and Wolf. One possible method of determining the centroid **29**, **116** of a spot **27**, **114**, respectively, as earlier described with reference to FIGS. **4** and **5**, and calculation of the Zernike weighting coefficients will now be explained. The directions of the unit normals at the center of each hole **34** are based on the centroids of the spots on cells **38**. Since each spot will illuminate a plurality of cells varying intensity, a standard amplitude-weighted centroid calculation can be used to find the center of each spot. In order to clearly delineate each centroid from background noise, by way of example, resulting from spurious light reaching the CCD surface between valid spots, standard mathematical techniques such as a matched spatial filter can be applied to the CCD data prior to centroid identification.

An alternative method is herein described for identifying individual spots and correlating their geometry. The apparatus is configured such that the optical axis is aligned to the center of a particular aperture at the entrance face of the wavefront sensor. This aperture is located at or near the center of the entrance face. If the probe beam entering the eye is also aligned to the system optical axis, then due to the reversible nature of light rays, a light spot will always be seen directly behind the aligned aperture. That is, a spot will always be seen on the CCD sensor at this location, regardless of the wavefront aberrations, and will always correspond to the overlying aperture. Immediately adjacent spots will be minimally displaced from their zero slope" locations. As one moves further from the central reference spot, generally greater spot displacements will occur. Using this knowledge, it is a relatively straight forward process to identify all the spots in the CCD pattern and establish their geometric relationships.

The displacement of the centroid from that of a perfectly collimated light beam, corresponding to ideal and emmetropic vision, is then calculated and used to determine the wavefront slope at each sample location. The location of the centroids for a collimated light beam may either be directly measured in a calibration step prior to the patient exam, or taken from a calculated reference pattern based on the wavefront sensor construction.

Multiple exposures may be used to check for improper eye alignment or eye movement during individual exposures. If eye movement during exposures cannot be analyzed successfully by acquiring multiple exposures, then the apparatus **10** can be augmented by the addition of an eye tracker **25**, illustrated with reference again to FIG. **2**. One possible placement of the eye tracker **25** is herein illustrated. However, it is to be understood that the eye tracker **25** could

be placed elsewhere within the apparatus **10**. In this way, wavefront analysis is performed even during a limited amount of eye motion.

A one-time calibration exposure can also be used to determine the relative sensitivities of the individual cells. This is made in uniform collimated light with plate **32** removed. The responses of individual cells are then recorded. For each light transmissive aperture (e.g, hole **34**), the centroid in the collimated case serves as a dedicated origin for the particular hole. The shift from the "origin" for each hole to the centroid caused by the wavefront **24** (as observed in this coordinate system) is determined by the direction of the wave surface corresponding to that hole. If $\Delta x(m,n)$ is the x-component of the (m,n)th centroid and F is the plate separation, then the P-value for the (m,n)th centroid is:

$$P(m,n)=\partial x(m,n)/\partial z=\Delta x(m,n)/F \tag{6}$$

The corresponding expression for Q is:

$$Q(m,n)=\partial y(m,n)/\partial z=\Delta y(m,n)/F \tag{7}$$

Thus, each P(m,n) and Q(m,n) represents the partial derivatives of W(x,y) with respect to x and y for the (x,y) coordinates of each hole **34**. For an m-order Zernike approximation of the original wavefront, the experimentally determined P's and Q's are then used in the following equations to calculate the appropriate C_i weighting coefficients as follows:

$$P(m,n)=\frac{\partial W(x,y)}{\partial x}=\sum_{i=0}^{n} C_i \frac{\partial Z_i(x,y)}{\partial x} \tag{8}$$

$$Q(m,n)=\frac{\partial W(x,y)}{\partial x}=\sum_{i=0}^{n} C_i \frac{\partial Z_i(x,y)}{\partial x} \tag{9}$$

By using a least-squares approx(m,n)/∂zach to minimize the error between the actual wavefront slopes on the left hand side in the above equations and the Zernike approximations on the right hand side, optimal values for the weighting coefficients can be obtained.

In one possible approach to calculating a centroid (x_c,y_c) each hole **34** is assigned its dedicated area of the array **36** or $(i_{m,n}\pm\Delta i, j_{m,n}\pm\Delta j)$. This square of many light-sensitive cells is large enough that neighboring hole images never encroach, and all illumination from this hole is contained. The square contains $4\Delta i^*\Delta j$ cells.

If array **36** is designated $C_{k,1}=(x_c(i,j),y_c,(i,j)),k$, 1=0 . . . $2\Delta 1$, $2\Delta j$, and the spacing on centers is $\Delta x=\Delta y=d$, the measured cell responses are V (k,1) and the relative responsivities are R (k, I), then the x-component x_c, a function of i, j is represented by

$$x_c(i,j)=[\Sigma_{k,1}V(k,1)^*R(k,1)^*d^*k]/[\Sigma_{k,1}V(k,1)^*R(k,1)] \tag{10}$$

and the y-component y_c, as a function of i,j is represented by

$$y_c(i,j)=[\Sigma_{k,1}V(k,1)^*R(k,1)^*d^*1]/[\Sigma_{k,1}V(k,1)^*R(k,1)] \tag{11}$$

Then, if $(x_{c0}(i,j),y_{c0}(i,j))$ is the "origin centroid" for the (i,j) hole, i.e., made in perpendicular collimated light, and $(x_{cw}(i,j),y_{cw}(i,j))$ is the corresponding centroid found for the wavefront to be measured, then the relative centroid shift $(x_{cr}(i,j)), Y_{cr}(i,j))$ is found as

$$x_{cr}(i,j)=x_{cw}(i,j)-x_{c0}(i,j) \tag{12}$$

$$y_{cr}(i,j)=y_{cw}(i,j)-y_{c0}(i,j) \tag{13}$$

The values P(i,j) and Q(i,j) are determined from

$$P(i,j)=x_{cr}(i,j)/F \tag{14}$$

and

$$Q(i,j)=y_{cr}(i,j)/F \tag{15}$$

The surface partial derivatives P(i,j) and Q(i,j) for the array of hole centers of plate **32** are next used to calculate the appropriate Zernike polynomial weighting coefficients to describe the original wavefront W(x,y). This will now be explained by way of illustration for a 7×7 square array of holes **34**. However, it is to be understood that other sizes and shapes of hole arrays could be used.

First, a 1×98 matrix (i.e., column vector) PQ(k) is formed as

$$PQ(k)=P(7i+j),j=0 \ldots 6,i=0 \ldots 6,k=0 \ldots 48 \tag{16}$$

$$PQ(k)=Q(7i+j),j=0 \ldots 6,i=0 \ldots 6,k=49 \ldots 98 \tag{17}$$

with j cycling for each i, i.e., PQ (18)=P (2,5).

The matrix PQ is multiplied from the left with a transition matrix TM to get the matrix C as follows

$$C=TM^*PQ \tag{18}$$

where TM is a 98 wide by 14 high matrix and C is a 1 wide by 14 high matrix or column vector. C is the matrix C_k k=1, . . . , 14 such that, to a least square error,

$$W(x,y)=\Sigma_k C_k^* Z_k(x,y) \tag{19}$$

and TM is calculated for a given aperture, e.g., a 6 millimeter pupil aperture. The functions Z_k (x,y) in equation (19) are the Zernike polynomials. There is no standard convention as to their sequence. Thus, for consistency, it is important that the same sequence is used to produce the set C_k that was chosen for deriving the matrix TM. They occur in groups of the same order, which is the highest exponent in the group, with the total number of members in an order increasing with the order. For example, in a fourth order analysis, orders up to and including 4 are used (less Z_0—the single member of order 0 that is the constant 1 which describes the reference position of the group in the z direction). Since wavefront **24** is moving along z (at the velocity of light), this "piston term" describes only an arbitrary offset in Z, and this term may be ignored. The first 5 orders (0, 1, . . . , 4) contain 15 functions including the piston term.

Thus, in the illustrated example, 14 values of C_k are calculated as coefficients of 14 Zemike polynomials. By way of example, one such order used to calculate TM is herein illustrated, and includes both the Zernike functions and their partial derivatives. ZERNIKE (X,Y) POLYNOMIAL EXPANSION THROUGH ORDER 4

dZ(14)/dy	$+4y^3 - 12x^2y$

The choice of sequencing the Zernike polynomials dictates the interpretations of the C_k in equation (19) and therefore the order of terms in the TM matrix. Hence, the TM matrix is calculated after the choice is made. The development of the TM matrix for the illustrated example will be explained below.

Note that the fourth order analysis is only an example and is not the only possibility. A Zernike analysis can be done to any order. In general, the higher the order, the more accurate the result over the tested points. However, an exact polynomial fit over the tested points is not necessarily desirable. Such fits have the typical disturbing property that, unless the surface itself happens to be an exact polynomial of order no higher than that used for the surface fit, forcing an exact fit at separated points often causes wild swings between fitted points. That is, in polynomial surface fitting, an exact fit at a finite number of points can yield a poor average fit for a general function.

Calculation of the $\Delta z\ (x,y)$ optical path difference information from the Zernike reconstruction of the wavefront is accomplished simply by subtracting a constant from the Zernike approximation. The value of the constant will depend on the desired characteristics of $\Delta z\ (x,y)$. Depending on the method chosen to compensate for the aberrations (e.g., lens addition, etc.) it may, for example, be desirable to set either the maximum, mean or minimum value in $\Delta z\ (x,y)$ equal to zero.

The development of the transition matrix TM will now be explained for the illustrated example of a 7×7 array of holes in plate **32**. At each point (x_i,y_j), the tangents of the components of the normal are P (x_i,y_j) and Q (x_i,y_j) where

$$P(x_i,y_j)=\partial W(x_i,y_j)/\partial x \tag{20}$$

and

$$Q(x_i,y_j)=\partial W(x_i,y_j)/\partial y \tag{21}$$

Combining these with equation (11),

$$P(x_i,y_j)=\Sigma_k C_k \partial W(x_i,y_j)/\partial x \tag{22}$$

and

$$Q(x_i,y_j)=\Sigma_k C_k \partial W(x_i,y_j)/\partial y \tag{23}$$

each applicable to 49 (i,j) combinations. These are combined into a single column vector PQ that is 98 elements high, i.e., a 98×1 matrix. Defining two matrices C_k (14 high×1 wide) and $M_{k,(i,j)}$ (14 wide×98 high)

$$(M_{k,(i,j)})=\partial Z_k(x_i,y_j)/\partial x;\partial Z_k(x_i,y_j)/\partial y \tag{24}$$

where the x-derivatives are the first 49 rows and the y-derivatives are the last 49 rows. Then, equation (19) can be rewritten as the matrix equation

$$(PQ)=(M)(C) \tag{25}$$

where the top 49 rows of M are the $\partial W\ (x_i, y_j)/\partial y$.

The expression in equation (25) gives the normal components in terms of the Zernike coefficients for a surface described by the array of 14 C's. These are exact, but it is not guaranteed that the actual total surface can be described by such an array of coefficients. Accordingly, if it is assumed that the description is within an acceptable tolerance, i.e., tolerating the errors that remain after least square error determination, then equation (26) can be considered to define the column vector C implicitly in terms of the mathematical matrix M and the measured vector PQ, both of which are known. The method of effecting the solution under the minimization condition is as follows. First, equation (25) is multiplied on the left by MT, the transpose of M such that

$$(M^T)(PQ)=(M^T)(M)(C)=(S)(C) \tag{26}$$

where

$$S\equiv M^TM \tag{27}$$

is a square and symmetric matrix, e.g., of dimensions 14×14 (with each element the sum of 98 products). Such a matrix has an inverse unless the determinant of its coefficients is zero. Since this is based on the Zernike polynomials alone, and they are all independent of each other, the determinant is non-zero, so that an inverse S^{-1} is defined. Next, equation (25) is multiplied on the left by S^{-1} to yield

$$(S^{-1})(M^T(PQ)=(S^{-1})(S)(C)=(I)(C)=C \tag{28}$$

Then, the mathematical transition matrix (independent of measurement) is

$$(TM)=(S^{-1})(M^T) \tag{29}$$

and the "best fit" array of C's from the measured PQ's can be produced by the simple matrix multiplication

$$(C)=(TM)(PQ) \tag{30}$$

To evaluate the eye unambiguously, all spots illuminating the planar array **36** due to a wavefront **24** are incident on the planar array simultaneously. If it is desired to reduce effects of eye movement, a pulsing or shuttering laser source may be used, or an eye tracker.

With reference again to FIGS. **7** and **8**, a beam of linearly polarized light (S-component) is emitted from a diode laser (670 nm, 3 mW by way of example), which beam of light passes through an electromechanical shutter, which controls the duration of light exposure on the eye **14** of the patient, and in particular, the exposure of the retina **18** of the eye **14** illustrated with reference again to FIGS. **7** and **8**. It is expected that alternate sources of light, for example, non-coherent and non-polarized, as well as alternate light transmitting techniques will come to the mind of those skilled in the art. When the shutter is open, the projected beam, collimated light from the diode laser, is directed by a long focal length lens for focusing on the anterior surface **22** of the cornea **24** of the eye **14**, as illustrated with reference to FIG. **7**, passing through the pupil **72** and lens **28** of the eye **14**, and onto the retina **18** as the small measurable spot **16**. In an alternate embodiment, the lens comprises a zoom lens for varying the focus and moving the focus location as desired. By focusing on the cornea **24**, the measurement is minimally dependent on the curvature of the cornea. However, other locations proximate the corneal surface are acceptable.

It is typical in the art of eye measurements to form a collimated beam and attempt to focus the collimated beam onto the retina, using lenses and lens combinations with the optics of the eye to produce the smallest possible spot **36**, as earlier described with reference to FIG. **8**. Lenses and focusing techniques typically take valuable time and include multiple attempts to focus a spot on the retina using various lenses and lens combinations to accommodate each unique vision of each patient being measured. With this technique, and the understanding that most of the blurring results from the curvature of the cornea, the technique eliminates the need to find lenses or lens combinations to minimize the size of the spot on the retina that is used as the secondary source of radiation.

With reference now to FIGS. **9–11**, an exemplary embodiment of the apparatus **10** will be herein described beginning with series **300**, which improved apparatus **300** is constructed as a patient examination station which allows the patient **302** to be comfortably positioned for the measurement of the eye **120**, as earlier described. For convenience to the technician operating the apparatus **300**, a computer monitor, mouse, and keyboard are located on a separate cart for this embodiment of the present invention, herein described. The apparatus **300** includes a housing **304** having a platform **306** which is carried by a rigid frame **308**. The frame **308** includes wheels **310** to facilitate shipping and installation at the clinical site, as well as locking and leveling feet **312** for securing the apparatus to the supporting floor **314**. Once the apparatus is positioned, the integrated leveling feet **312** are deployed to provide a stable stationary frame **308**, and thus platform **306**.

As illustrated, by way of example with reference again to FIGS. **9–11**, the patient **302** sits at a patient end **316** of the apparatus **300**, with his or her head resting in a headrest **318**, which headrest is adjustable in directions left/right (X-direction), up/down (Y-direction), or toward/away (Z-direction) relative to the platform **306**, using adjustment assembly **320**. The headrest **318** is attached to the lower surface of the platform **306** which forms an optical table for mounting optical components thereon, as illustrated with reference to FIG. **12**, and as will herein be described in further detail. The housing **304** includes a removable optical table cover **322** which protects the optical components carried within the housing. The optical table cover **322** is secured to the platform **306** with keyed locks to prevent unauthorized access to the optical components. The platform **306** is bolted to the rigid frame at four locations **307**, as illustrated with reference again to FIGS. **9** and **10**. The frame **308** also carries electronics **324** and a computer **326** which includes the processor **40** earlier described with reference to FIG. **6**, as well as a connector plate for a computer keyboard, monitor and mouse. The frame **308** also includes an upper bay **328** housing electronics controlling optical components carried by the platform **306**, and a lower bay **330** housing an uninterruptible power supply (UPS) and an isolation transformer.

As illustrated with reference again to FIGS. **9–12**, three ports are positioned within the cover **322**, and include an examination port **332** to allow the wavefront measurement of the eye **120** to take place, and two eye illumination ports **334** which allow lamps **336** carried within the housing **304** to illuminate the eye for visualization by an internal video camera **338**. In addition, the adjustment assembly **320** includes a position sensor **321** which senses an x-direction displacement for detecting a position of the headrest **318** to the left or to the right of a reference center line location **3191**. A signal indicative of the sensed displacement is provided to the computer **326** for automatically recording the appropriate eye **120** (e.g. left or right) being measured.

As illustrated with reference again to FIG. **12**, the platform **306** provides an optical table with the patient positioning the eye **120** for measurement by the apparatus **300**. The platform surface measures approximately two feet by four feet, with the optical components fixed to the surface using a combination of commercial and customized precision hardware mounts. All transmissive optical elements have surface anti-reflection coating optimized for the selected probe beam wavelength. The optical layout includes five distinct optical pathways which share the optical elements as will herein be described, by way of example. With reference again to FIG. **12**, a first optical path **340**, a fixation target image optical path illustrated in isolation in FIG. **12**A for convenience to the reader, displays a fixation target image to the patient seated at the apparatus **300**. The patient aligns his/her visual axis to the optical axis **342** by looking at the center of a target reticle **344** having a grid pattern. With reference again to FIG. **12**, a second optical path **346**, a video image optical path illustrated in isolation in FIG. **12**B for convenience to the reader, captures a video image of the corneal plane. This allows the technician to assist in aligning the eye **120** for examination, and to record the exact location of the eye during each measurement using software reticles superimposed on a video image. With reference again to FIG. **12**, a third optical path **348**, a probe laser optical path illustrated in isolation in FIG. **12**C for convenience to the reader, sends a probe laser beam **350** into the eye **120** along the optical axis **342**. As earlier described with reference to FIGS. **2** and **7**, the probe laser beam **14**, herein referred to with numeral **350** is attenuated to an eye-safe intensity and linearly polarized before being focused onto the corneal surface. With reference again to FIG. **12**, a fourth optical path **352**, a re-emitted wavefront optical path illustrated in isolation in FIG. **12**D for convenience to the reader, conveys the reflected wavefront **24** of FIG. **2**, and herein described with numeral **354** re-emitted from the eye **120** and directed towards a wavefront sensor **356**. To accomplish this, first

and second afocal relay stages **358**, **360** transfer the reflected wavefront **354** from the corneal plane of the eye **120** to the entrance face of the wavefront sensor **356**. Finally, with reference again to FIG. **12**, a fifth optical path **362**, a calibration wavefront optical path illustrated in isolation in FIG. **12**E for convenience to the reader, injects collimated laser light into the wavefront transfer path leading to the sensor **356**. Software operable within the computer **326**, described earlier with reference to FIG. **9**, uses collimated light wavefront sensor output data to calibrate the apparatus **300** prior to patient measurement.

With continued reference to FIGS. **12**, and **12**A, the first optical path **340** is herein described as a fixation path which provides a reference image to the patient, such that the eye **120** is properly aligned when the patient is fixating on the reticle **344** of a reference target **366**. A target illumination lamp **368** back-lights the fixation target **366**, which fixation target image reaches the patient eye **120** by transmission through a 50/50 beam splitter **370**, lenses **372**, reflection in 50/50 beam splitters **374**, **376**, and transmission through lens combinations of afocal relay stage **358**, as well as through polarizing beam splitter **378**. In addition, a spectral filter is placed over the target illumination lamp **368** to remove radiation over the 620–790 nm wavelength range that might otherwise interfere with a wavefront measurement at **670** nm. The lens combinations in the first relay stage **358** contain identical lens elements mounted in reverse order. Each consists of two meniscus lens elements, with an interposed achromatic doublet. The lens combinations work in tandem as a unity magnification afocal relay stage.

The optical elements including the polarizing beam splitter **378**, the lenses of the first afocal stage **358**, the beam splitters **374**, **376**, and one lens **380** of the lenses **372** are mechanically fixed in place on the surface of the platform **306**. The optical elements including a lens pair **382** of the lenses **372**, the beam splitter **370**, the fixation target **366**, and the illumination lamp **368** are all mounted on one precision linear translation stage, capable of movement along the optical axis **342** of this pathway. Translation of these optical elements focuses the fixation target **366** for the patient's view, compensating for any myopia/hyperopia present in the eye **120**. During patient examination the focus translation stage is adjusted to place the target optically just beyond the eye's infinity focal plane. This allows the patient to see a relatively distinct reticle pattern without stimulating accommodation by the eye **120**. The beam splitters **378**, **376**, **374** serve as interfaces between other optical pathways within the optical axis **342**, as will herein be described in further detail. By way of example, the beam splitter **370** is included for alignment purposes. A photo-detector **384** attached to the center of the left edge of beam splitter **370** senses light transmitted toward the fixation target along the optical axis.

With reference again to FIGS. **12** and **12**B, the second optical path **346** captures video images of the eye **120** at an examination plane. This allows the clinical operator/technician to assist in patient alignment, and to measure actual eye displacement during the wavefront measurement. As earlier described, the illumination lamps **336** illuminate the eye **120**. The image of the eye is conveyed to the video camera **338** by transmission through the polarizing beam splitter **378** and the lens combinations **358**, reflection in the 50/50 beam splitter **376**, transmission through the 50/50 beam splitter **374**, reflection off mirror **386**, and transmission through lens **388**. All these optical elements are fixed in place on the surface of the platform **306**. By way of example, this second path **346** provides a video field of view approximately 22 mm in diameter at the eye plane, with a limiting resolution of ~64 mm. As earlier described, a number of filters are placed in front of each eye illumination lamp **336** to reduce the spectral bandwidth of the radiation reaching the eye **120**. By way of example, these will includes a blue filter to remove light at wavelengths below ~455 nm (for eye safety), an infrared filter to remove light at wavelengths above ~920 nm (for eye safety), and a rejection filter to remove light over the wavelength range 620 nm–790 nm (to prevent interference with the wavefront measurement at 670 nm).

With continued reference to FIGS. **12** and **12**C, the third optical path **348** irradiates a small spot on the patient's retina with eye safe laser radiation, as earlier described with reference to FIGS. **1**A–**1**D. The irradiated retinal spot on the fovea centralis **123** of the retina **122** is, as herein described, the origin of the re-emitted wavefront **130** measured by the sensor **356**. The output beam, probe laser beam **350** from diode laser **390** reaches the patient eye **120** by transmission through a linear polarizer and attenuator **392**, lens **394**, shutter **396**, and reflection off mirror **398** and in the polarizing beam splitter **378**. All these elements are fixed in position.

In one embodiment of the present invention, output of the diode laser **390** is essentially collimated and is focused onto a corneal surface of the eye **120** by lens **394**. The projected probe laser beam **350**, collimated light from the diode laser **390**, is directed by a long focal length lens **394** for focusing on the anterior surface of the cornea **126** of the eye **120**, as illustrated by way of example with reference again to FIG. **1**B, passing through the pupil and lens **124** of the eye **120**, and onto the retina **122** as a small measurable spot on the fovea centralis **123**. As earlier described with reference to FIG. **7**, in one embodiment, the lens **394** illustrated with reference again to FIG. **12**, comprises a zoom lens for varying the focus and moving the focus location as desired. By focusing on the cornea **126**, the measurement is minimally dependent on the curvature of the cornea. However, other locations proximate the corneal surface are acceptable.

While diffraction and various aberrations are present, the present invention **5** avoids the aberration effects from the cornea which typically dominate. The lens of the eye **120** contributes a relatively small aberration effect when compared to that of the cornea **126**. Further, and with regard to the selection of the lens **394**, selecting a lens with a short focal length would provide a relatively large incident angle of the beam **350**, a well focused point on the surface of the cornea **126**, and less aberration effects from the cornea. A small incident angle provides a larger focus point on the cornea **126**, but a more desirable smaller spot on the retina **122**, which spot size will depend on the wavelength and starting point size and focal length of the lens **394** selected. Embodiments of the present invention including lenses of approximate one half meter and 100 mm, by way of example, haves been effectively used.

The polarizer **392** linearly polarizes the probe beam **350** into an s-state (by way of example, out of the plane of the drawing of FIG. **12**). The angled interior interface of the polarizing beam splitter **378** reflects s-polarized light, so that light entering the eye **120** is s-polarized. A linear polarizer **400** is angled with respect to the polarizer **392** and works in conjunction with the attenuator to attenuate probe beam power delivered to the eye **120** to less than 10 μW, by way of example. The diode laser **390** is triggered by an external electrical trigger signal **402**. A nominal illumination duration for eye measurement is 700 ms. The shutter **396** is included as an additional safeguard against overexposure of the eye **120** to the probe laser beam **350**. The shutter **396** is normally

closed and is opened by an independent electrical trigger signal **404** synchronized to the laser trigger signal **402**.

By way of example, one retinal exposure for each illumination by the probe beam is 10 μW×0.7 s=7 μJ. Up to 10 repeat measurements may be obtained during a single patient examination session. Such exposures are well within the safety limits defined in the American National Standard for Safe Use of Lasers (ANSI Z136.1-1993, American National Standards Institute, New York, N.Y.). In that reference, the maximum permissible exposure (MPE) for "intrabeam" viewing a laser beam in the 400–700 nm wavelength range and the 18×10^{-6} to 10 second pulse duration range is $1.8*t^{3/4}$ mJ/cm^2. (t is the pulse duration in seconds). A limiting aperture for the eye is identified as approximately 7 mm in diameter. As a result, an allowable single-pulse energy is $0.6927*t^{3/4}$ mJ. For a single 0.7 second pulse the MPE is 530 μJ, almost two orders of magnitude larger than a delivered energy per pulse, for the apparatus herein described. An additional calculation is performed to assess the safety of the repetitive exposures. The relevant calculation in the Standard multiplies the single pulse MPE by $n^{-1/4}$, where n is the total number of pulses in the exposure duration T_{max}. For the apparatus of the present invention, the 10-pulse safety limit is 530 μJ/pulse$\times10^{-0.25}$= 298 μJ/pulse, still a factor of 40 larger than the actual pulse energy focused into the eye.

As illustrated with reference again to FIGS. **12** and **12**D, the fourth optical path **352** conveys the wavefront **354**, earlier identified by numeral **130** with reference to FIG. **1**B, emerging from the eye **120** to the wavefront sensor **356**, herein described using a Hartman-Shack sensor by way of example for the wavefront analysis. The wavefront **354** re-emitted by the eye **120** in response to the probe beam **350** irradiation is conveyed to a CCD camera **406** by transmission through the polarizing beam splitter **378**, the first afocal relay stage **358** lens combination, the 50/50 beam splitter **376**, a trial lens holder **408**, the second afocal relay stage **360** lens combination, reflection off mirror **410**, and transmission through microlens array **412**, as earlier described with numeral **33** with reference to FIG. **6**. With the exception of the changeable trial lens holder **408**, illustrated with reference to FIGS. **12**F and **12**G, all these optical elements are fixed in place on the surface of the platform **306**.

The polarizing beam splitter **378** transmits only linearly polarized light in a p-state. The radiation of the probe beam **350** reflected from the corneal surface of the eye **120** will retain the incident s-state polarization and will not be appreciably transmitted by the beam splitter **378**. In contrast, light that has been scattered off the retina of eye **120**, light forming the wavefront **354** of interest, will be largely depolarized. The p-polarized fraction of this light will be transmitted by the beam splitter **378**. Thus the beam splitter **378** selectively suppresses the corneal surface reflection that could otherwise complicate the wavefront measurement. A wavefront originating at the corneal plane of eye **120** is transferred to a plane of the trial lens holder **408** with unity magnification. This plane of the trial lens holder **408** provides an intermediate pupil plane and is included for placing an ideal N-diopter lens **409**, see FIGS. **12**F and **12**G, at the trial lens plane to change the spherical curvature of the wavefront **354** by N-diopters, without altering other aberration content. The capability to reduce/remove the general wavefront curvature in a preselected manner significantly extends the dynamic range in wavefront measurement, without degrading the measurement accuracy. Trial lenses **409***a*–**409***m*, by way of example and herein described of varying spherical powers, ranging from −16 diopters to +8 diopters in two-diopter increments, are mounted on a rotating wheel **407** of the holder **408**. The wheel's axis of rotation is parallel to but offset from the optical axis **342**. Turning the wheel places one of a plurality of preselected trial lenses at the trial lens plane. The wheel has precision mechanical detents that register the selected lens properly in the optical path.

A narrow band-pass optical filter is also placed at trial lens holder **408** location just anterior to the lens position. This filter has maximum transmission for 670 nm wavelength radiation (the probe beam wavelength), and a bandwidth of approximately 10 nm (full-width-half-maximum). This filter is used to reject spurious light (from the fixation target illumination, the eye illumination, and the like) from the wavefront path.

In one embodiment, as herein described by way of example, each of the lenses of the second afocal relay stage **360** consists of three lens elements, two meniscus lenses and an interposed achromatic doublet. However, they are not identical, and their combined action serves to magnify the passing wavefront **130**. The wavefront **354** at the trial lens holder **408** location is imaged onto the surface of the microlens array **412** with a magnification of 1.22. Magnification of the wavefront image by this defined factor of 1.22 reduces the wavefront slope at each point in the image plane by the same 1.22 factor. This extends the measurement dynamic range of the device, again without decreasing accuracy. In addition, this magnification distributes the wavefront **130** over more elements, CCD cells **38** as earlier described with reference to FIG. **6**, in the microlens array **412**, thus increasing the number of slope measurements provided by the wavefront sensor **356**. The mirror **410** is included to fit elements of the apparatus **300** within the dimensions of the platform **306**. In addition, the mirror **410** also allows optical alignment adjustment for the microlens array **412** and the CCD camera **406** combination. As earlier described, by way of example, with reference to FIGS. **3**–**6**, the microlens array contains a square array of microlenses which divide the incident wavefront into a transverse array of secondary "wavelets." These wavelets are focused onto a detector surface of the CCD camera, which is positioned parallel to the microlens array and one focal length posterior thereto. The pattern of focused wavelets in the CCD image is used to calculate the shape of the incident wavefront.

As illustrated with reference again to FIGS. **12** and **12**E, the calibration beam path **362** provides the collimated beam **364** to the Hartman Shack wavefront sensor **356**. Wavefront data for the collimated beam **364** is used as a reference in reconstructing the aberrated wavefront **354** from the real eye measurement. The source for the collimated reference beam **364** consists of a diode laser **414** coupled to beam expander **416**. In one embodiment of the invention herein described, the diode laser **414** used for reference is identical to the diode laser **390** used for the probe beam path **348**. The collimated reference beam **364** is conveyed to the CCD camera **406** by transmission through polarizer/attenuator **418**, negative lens and aperture **420**, aperture and positive lens **422**, reflection off mirror **424**, transmission through aperture **426**, reflection in the polarizing beam splitter **378**, transmission through the first afocal relay stage **358**, the 50/50 beam splitter **376**, the trial lens holder **408**, the second afocal relay stage **360**, reflection off the mirror **410**, and finally transmission through the microlens array **412**. Except for trial lens holder **408**, all these optical elements may be fixed in position on the surface of the platform **306**.

The optical element of the polarizer and attenuator **418** contains two linear polarizers and a neutral density filter.

The linear polarizer furthest from the diode laser **414** polarizes the laser radiation in the s-state for maximum reflection in the polarizing beam splitter **378**. The linear polarizer closest to the diode laser **414** is partially "crossed" with respect to the polarizer **378** to attenuate the laser power. The neutral density filter further attenuates the beam, such that the laser power reaching the CCD Camera **406** is optimal for calibration of the sensor **356**. The negative lens and positive lens of elements **418**, **420** expand the diode laser output and form the collimated reference beam **36**. Intervening apertures of elements **418**, **420** transmit only the central portion of the expanding beam with the most uniform intensity. The mirror **424** is included to reduce the overall dimensions of the apparatus **300**. The aperture **426** is conjugate to the corneal plane, and is included so that the collimated reference beam **364** illuminates approximately the same area on the microlens array **412** as would the wavefront **354** re-emitted by a maximally dilated eye.

By way of illustration, optical components suitable for use with embodiments of the present invention herein described by way of example, are provided with reference to Table 1. An electrical component layout of the apparatus **300** is illustrated with reference to FIG. **13**, wherein a dashed box **428** indicates the platform **306** with the heretofore described element carried thereon. Except for the computer monitor, keyboard, and mouse all other electrical components are located within the frame under the optical table. Switches in the diagram are all located on a front panel **430** of the electronics **324** for ease in operator/technician access, as described earlier with reference to FIG. **9**. Electrical power from the clinical facility is drawn by an isolation transformer, which in turn supplies power to an uninterruptible power supply (UPS). The UPS delivers power to three power strips carried in the frame **308**. The host computer **326** has a self contained On/Off switch, as do the three power strips. One power strip **432** supplies power to the shutter controller **434**, which commands the probe laser shutter **396** through the signal **404**, two dual power supplies **436**, each capable of providing both 5 VDC and 9–15 VDC output, the host computer **326**, a computer monitor **438**, and a third power strip **440**. One dual power supply supplies 5 VDC power to the two patient illumination lamps **336**, and 9 VDC power to the target illumination lamp **368**. A second dual power supply supplies 5 VDC power to both diode lasers **390**, **414**. A user-accessible 3-position switch **442** allows the system operator/technician to provide power to either the probe laser **390** or the calibration laser **414**, with a center switch position being the "off" state.

A third power strip **444** supplies power to the CCD electronics controller **446**. The power strip **440** also supplies power to cooling fans **448** located on the platform and within the frame.

By way of example and for illustration purposes, operation of the apparatus **300** may generally proceed with the operator/technician first activating each of the electrical elements, with the CCD electronics controller **434** being last to be enabled. The operator then activates the calibration laser **414** via the 3-position switch **442**. The operator then instructs the computer **326** to acquire a calibration wavefront measurement. The computer **326** relays this command to the CCD controller electronics **446**, which activates the CCD camera **406** to take a predefined exposure. The CCD controller electronics **446** also sends trigger signals **402**, **404** described earlier with reference to FIG. **12**, to the probe laser **390** and the probe laser shutter **396**. However, since the probe laser **390** is not powered at this point, no probe beam **350** is delivered. Calibration CCD data are transferred to the CPU of the computer **326**, and stored for later analysis. The calibration laser **414** is switched off at the end of the calibration procedure.

The technician/operator then proceeds to patient measurements. The output switch **442** at the dual voltage power supply **436** is positioned to a probe laser setting. The probe laser **390** is now in a "ready" state awaiting an additional trigger signal to operate. The operator then positions the patient appropriately in the apparatus **300** as earlier described with reference to FIGS. **9–11**, with the assistance of an image from the video camera **338** displayed on the computer monitor, by way of example. With the patient situated, the operator instructs the computer **326** to obtain wavefront data, as earlier described with reference to FIGS. **2–7**. The computer **326** relays appropriate commands to the CCD electronics controller **446**, which triggers the probe laser **396** to fire, triggers the shutter controller **434** to open the probe laser shutter **396**, and exposes the CCD camera **406**. CCD camera image data is transferred back to the computer **326**. The computer **326** includes software that analyzes the patient and calibration data to calculate the patient wavefront profile for use. At the end of the data collection, the operator shuts down the electronics, starting with the CCD electronics controller **446**.The software integrated into the apparatus **300** may be described, by way of example, as including: A graphical user interface (GUI) to allow the technician to perform all desired operations to enter and save patient information and perform the desired measurements; database and file system interfaces to allow for the saving and tracking of patient information, measurement, and hardware details; control of the electro-optical and electro-mechanical components as necessary in order to be able to accurately and safely perform the desired measurements; and processing of the measurement data to generate mathematical descriptions of the aberrations (the optical path difference) measured in the subject eye.

By way of further example, patient measurement and apparatus configuration information is stored in multiple tables in a Microsoft Access™ 7.0 database. The interface to this within the code is based upon the Microsoft Foundation Classes (MFC) wrapper to the Microsoft Jet Engine. The framework generates a Structured Query Language (SQL) to create, retrieve and update records in the database. Use of the Microsoft Access application to access the data is not needed. In one embodiment of the present invention, the following data may be stored in the database: patient information—name, address, medical record number, and the like; measurement Information—geometry, time of measurement, and the like; and system Information—hardware serial numbers and key hardware parameters.

Additionally, the software may be developed with two operating levels—password-protected and not-password-protected. From within the password-protected-mode, the technician/operator has access to system configuration information and features necessary for system setup and maintenance that are not accessible from the not-password-protected mode. All patient entry and measurement capabilities are available from the not-password-protected mode. All patient information desired in order to be able to uniquely identify and track the patient is entered via the graphical user interface (GUI) and stored in the Microsoft Access database. Selecting the "Patient Data" menu item brings up a patient information data information screen, from which the technician can enter new patient data as well as being able to review and edit existing information. The patient data that can be stored and retrieved, typically includes: name, address, medical record number, data of

birth, phone number, sex, manifest and cycloplegic refractions and vertex distance as well as centration information.

Centration information that is measured via a centration process and stored as part of the patient record describes the position of the center of the constricted pupil with respect to the center of the limbus. This information is used in aligning the patient for the measurement where the goal is to align the visual axis of the eye with the optical axis **342** of the apparatus **300**. When the centration procedure is invoked a list is displayed of all patients that have been entered into a database operable with the apparatus **300** but have not yet had the centration steps performed. The monitor displays all patient information including a review of centration information, or alternatively, for just those patients entered for a given time period. In order to perform centration for a given patient and eye, that patient is selected from this list by clicking on the desired patient/eye with the mouse. An example of the centration process is illustrated with reference to FIG. **14**. Once a patient has been selected, the patient is instructed to look into the apparatus **300** and at the fixation target **366**, as earlier described with reference to FIG. **12**.

By way of further disclosure, the fixation target **366** is, as earlier described, included so that the patient **302** can stare along the optical axis **342** of the apparatus **300**. For best fixation, the target should be clearly visible to the patient. However, care should be taken to see that the patient does not attempt to accommodate when fixating on the target. This would occur if the target were optically closer than the patient's infinity focal plane. If the patient did accommodate, i.e., if the lens in the eye changed shape to provide increased focusing, then the eye would appear excessively myopic during the wavefront measurement. To avoid this, the fixation target optics are adjusted so that the target appears to lie optically just beyond the patient's far-field focus. Thus for each patient the target will appear relatively clear, but not in sharp focus. The patient may initially try to accommodate to improve the sharpness of the image, but will eventually find that the clearest image is seen for the most relaxed (non-accommodative) state. This technique is known as "fogging," and is routinely performed by optometrists when doing clinical evaluations. The eye drops used to dilate the eye for the measurement also reduce the lens' ability to accommodate, thereby further ensuring valid wavefront measurement.

With reference again to FIG. **14**, an image of the patients eye **120** is frozen. Two reticles **450**, **452** are then used to locate the centers **454**, **456** of the constricted pupil and limbus, respectively. Each reticle **450**, **452** can be moved and sized—one reticle **450** is positioned over the perimeter of the constricted pupil **458** and the other reticle **452** over the limbus **460**. Once they have been located, the information is saved to the database. This can be performed for as many patients as is desired and the centration procedure is then exited.

For illustration, a sequence of events followed in measuring the refractive errors in an eye and computing the corresponding optical path difference (OPD) is illustrated with reference to FIG. **15**. By way of example, steps include performing a reference measurement **462**. To provide a reference with which to compare the measurement of the eye **120** and also to check the alignment of the apparatus **300**, a reference measurement is made using the collimated laser light **36**, as earlier described with reference to FIG. **12**. The software forces the operator to make at least one such measurement at the start of each day and an additional one at the end of each day. More reference measurements can be performed as desired by the operator. When patient measurements are performed, the measurement records in the database identify which reference measurements correspond to each measurement, i.e., which reference image was the latest one done prior to the measurement. A "Perform Reference Measurement" screen may be provided for viewing a sample reference image.

A next step includes selecting a patient and eye to measure **464**. The patient and eye to be measured may be selected from a "Patient Select" dialog screen. It is desired that all patients are displayed along with a check mark to show whether or not centration has been performed for that patient. If a patient is selected that has not yet had centration performed then the operator is informed of this and no measurement can be performed. Once a valid patient/eye has been selected to be measured then the perform measurement dialog is displayed which includes GUI buttons necessary in order for the operator to perform and check the measurement.

A next step includes aligning the eye using the video camera and reticles **466**. The apparatus **300** is operated with the visual axis of the eye aligned, as close as is practically possible, to the optical axis **342** before performing a measurement. The center of the constricted pupil **454** is used as the approximate anatomical landmark for the visual axis. Given that the eye **120** is dilated when the measurement is performed, it is not possible to directly determine this center. However, the centration procedure performed on each patient defines the center of the constricted pupil **454** with respect to the limbus **460** and thus it is possible to use the position of the limbus to place the eye **120** in a desired location.

As illustrated with reference to FIG. **16**, a reticle **468** is displayed on screen that is offset from the optical axis by the appropriate amount such that when the limbus **460** of the eye **120** is aligned to this reticle **468**, the eye **120** is positioned as desired. Prior to taking the measurement, it is the operator's responsibility to ensure that the patient is positioned appropriately such that the limbus **460** is aligned with the reticle **468** while the patient is looking at the fixation target **366**.

A measurement is then performed **470**. Once the eye **120** is aligned, the operator presses an "acquire" button to perform the wavefront measurement of the patients eye. The system response to the acquire command is as follows:

1. Video image is frozen
2. Probe beam laser is activated
3. External shutter is opened so that the probe beam can reach the eye
4. CCD shutter opens and the CCD is exposed to the re-emitted wavefront (1–4 generally performed simultaneously)
5. CCD shutter closes and the exposure is completed
6. CCD data is transmitted to the computer
7. External shutter closes and the probe beam turns off.

The software continually checks the status of the CCD electronics and the temperature of the camera and only allows measurements to be taken when everything is working nominally.

A review of eye and apparatus geometry is accepted or rejected **472**. Although it is not necessary for the eye **120** to be perfectly aligned with respect to the optical axis **342** (the software compensates for minor misalignments), it is desirable for it to be close. The eye **120** will have been aligned prior to the measurement but uncontrollable eye motion (e.g. saccades and loss-of-fixation) may make the alignment sub-optimal at the time of the exposure. To check that the

alignment is acceptable, the video image of the eye is frozen at the time the measurement is taken. The operator then aligns a reticle to the limbus ring and presses a "check geometry" button on the GUI. If the software determines that the alignment is not acceptable, the operator is informed of this and a new exposure is made as desired. By way of example, and with reference to FIG. **17**, optimal measurement as herein described, would have the limbus **460** aligned to circle B. In actuality, the eye **120** was offset during the exposure and the limbus **460** was aligned to circle A. The difference between these two states is shown by the line A'B'. The software determines whether or not the image is acceptable based on the length of A'B'.

It is also at this point that the operator records the rotational state of the eye. Prior to the wavefront measurement, a pattern of four line segments **474** arranged in an "X" pattern **476**, as illustrated with reference to FIG. **18**, around the periphery of the cornea are applied to the eye using a mechanical instrument. The pattern **476** consists of two pairs of collinear line segments **474** angled at 45° with respect to each other. Each line segment **474** is 4 mm long, and collinear segments are separated by 7 mm. At the same time the limbus ring reticle is aligned with the actual limbus in the frozen video image, an X reticle that matches this pattern is aligned to the applied eye marks in the frozen image. The orientation information is then saved by the software along with the limbus position data.

As a next step in the process, the CCD image is processed, accepted and saved, or rejected **478**, as illustrated with reference again to FIG. **15**. If the geometry of the measurement is acceptable, it is then probable that the quality of the CCD image will be high. It is desirable, however, to check that this is so. The software processes the image and then presents an auto-scaled image to the operator to review. If the software determines that the image is unacceptable then the operator will be informed of this and a new exposure made. If the user decides that the image is unacceptable for whatever reason then the image can be manually rejected at this stage. An example of an unacceptable image is illustrated with reference to FIG. **19**. In this example, a significant portion **479** of the image is obscured in some manner, resulting in wavefront data for only part of the pupil. By unacceptable, it is meant that such an image is not believed to result in the accuracy and precision of measurement that is desired for surgical procedures which are obtained by the present invention. It does not mean that such as illustrated may not be usable in any sense.

Once a valid measurement has been made the next step **480** is to measure the local slopes of the wavefront **130**, as earlier described with reference to equations herein presented. As described with reference to FIGS. **4–6**, it is necessary for the software to compute the centroids **116** of the clusters of light on the CCD array **38** and then determine the distances of each of these centroids **116** from the corresponding reference centroids **29**. The centroids are determined by first computing which pixels should be processed and grouping them together into clusters. The intensity-weighted centroid of each cluster is then computed. As illustrated with reference to FIG. **20**, an example of an image from a myopic eye with the computed centroids **482** of cluster **484** marked by "X"s is shown. FIG. **21** illustrates a close-up of one of the clusters **484** and displays not only the centroid **482** but also the pixels **486** used in the centroiding calculation for the cluster **484**. CCD pixels **488** processed in the centroiding algorithm are marked by dots. This algorithm, by way of example, isolates centroids by use of a spacial filter which removes stray light signals that create noise for the CCD image. Such filtering may be desirable before calculation of light cluster positions.

Without filtering, computation of the cluster centroids may be made difficult as a result of noise on the image such that individual pixels with no actual data content may be brighter than pixels containing relevant data, speckle in the image may result in valid data clusters having irregular profiles with significant variation in intensity of adjacent pixels, haze or background noise may be high relative to the actual data or may be non-uniform across the image, intensity of valid data may be non-uniform across the image, scatter from different parts of the eye may result in spurious signals on the image, and high aberrations in the eye may significantly distort the clusters of valid data, by way of examples. The spatial filter permits a re-computation of the brightness of each pixel in a bitmap using a weighted averaging technique that considers surrounding pixels. In a particular application herein described for illustration and by way of example, the spatial filter is designed to yield a maximum value when centered on valid data, reduce an effect of individual bright pixels or small groups thereof, normalize background levels, smooth valid data profiles, and simplify the task of extracting the valid data from background noise or haze. One filter employed in one embodiment of the present invention is square (n×n) and includes real values (positive and negative) assigned to each pixel. The filter is designed to be optimally matched to images obtained from eyes with high, yet measurable, levels of aberration. By wave example, a cross-section through the filter is illustrated with reference to FIG. **23**A. An effect of applying such a filter improves an image such as illustrated with reference to FIG. **23**B to the image illustrated with reference again to FIG. **20**, by way of example, a cleaner image and one that is easily processed for identification and computation of cluster centroids. By applying the filter, images that would otherwise be deemed to noisy or of insufficient quality to process, can now be processed and desired wavefront information computed.

The center of each centroid is calculated using a standard center of mass algorithm based on light intensity. The clusters and centroids illustrated with reference to FIG. **22** are illustrated with the locations of the corresponding reference centroids **490** also visible. The open circles in this figure indicate the locations of the reference centroids. Lines connect these with the associated sample centroids **482**. From the distances between the reference and measurement centroids **490**, **482** respectively, and the distance between the lens array **33** and the CCD plane **36**, described with reference to FIG. **6**, the local slopes are calculated. Given these local slopes and information about the apparatus setup, including any and all magnification factors, it is then possible to determine the local slopes at the pupil plane and, from these, and compute the optical path difference of the eye being measured.

A description of the wavefront is then made **492**. As earlier described, the reconstructed wavefront is described via a set of Zernike polynomials. The number of locations on the eye **120** at which the local slopes are determined (i.e. the number of sample points) greatly exceeds the number of terms in the polynomials that will describe the wavefront. A least-squares-fit calculation is done to find the coefficients that best describe the surface. The order of the polynomial used is sufficient to describe not only the spherical and cylindrical refractive powers (2^{nd} order) but also the levels of coma (3^{rd} order) and spherical aberration (4^{th} order) present.

An example of the computed Zernike coefficients for an eye and the corresponding wavefront reconstruction **493** is

illustrated with reference to FIG. **24**A. By way of example, for the wavefront illustrated with reference to FIG. **24**A, the spherical and cylindrical powers computed from the wavefront are −1.60/−1.13×150.4. The corresponding values obtained by an optometrist performing a phoropter examination (converted to the corneal plane) were −1.47/−1.19×150. The standard measurements of spherical and cylindrical powers agree well with the computation of spherical and cylindrical powers, but there are also higher order aberrations present. By way of further example, FIG. **24**B illustrates just these higher order aberrations **495** on the same scale as the plot of FIG. **24**A.

With regard to the optical path difference (OPD), scaling an optical path difference profile, OPD(x,y), by a refractive index difference (cornea to air) is not the only step. This wavefront measurement is made at a plane tangent to the cornea, as illustrated with reference to FIG. **25**, which is exaggerated to illustrate the effect. The image plane of the wavefront path is the lenslet array plate. The object plane of the wavefront path is the reference plane **494**. In this highly-exaggerated myopic case, herein described by way of example, one light ray **496** emerging from the eye **120** at transverse location a is detected at a transverse location b. The wavefront reconstructed from sensor data will have the slope of this ray at location b. Although this is true of the wavefront at the reference plane **494**, simple scaling of this wavefront would suggest a measurement at corneal location b that may not be entirely accurate. In actuality this effect is small. The radius of curvature of the cornea is typically on the order of 7.5 mm. (a range of 7–8 mm encompasses most eyes.) At a transverse location 3 mm from the corneal apex, the distance from the corneal surface to the reference plane is only ~0.63 μm. For a 10 diopter myope, a light ray exiting the cornea at a=3.0 mm will cross the reference plane at b=2.98 mm. The difference between a and b in this example is only 20 μm. Although small this geometric effect is systematic, having progressively greater impact on the measurement with increasing radial distance from the corneal apex. To increase accuracy, compensating for the curved geometry may be performed in the following manner:

1. Wavefront slopes are calculated at each measurement point in the reference plane.
2. The cornea is assumed to have a nominal radius of curvature (~7.5 mm).
3. The wavefront slopes measured at the reference plane is projected back onto the nominally curved cornea. The wavefront is measured to have a certain slope at b in the reference plane, described above. It is a straightforward mathematical process to calculate the point a where this ray exited the cornea.
4. The wavefront is reconstructed based on the measured slopes at the calculated corneal locations.

As above described, it is desirable to obtain the best information with a wavefront measurement having patient positioned at the apparatus **300**. The eye **120** being measured is at the desired location and looking in the appropriate direction. Based on analysis of the allowable eye-positioning tolerances, the apparatus **300** of this embodiment of the present invention provides the following patient position information:

The capability for ensuring that the subject eye is at the right location along the longitudinal (z) axis of the apparatus with an accuracy of +/−1 mm.

The capability for ensuring that the subject eye is properly positioned laterally with respect to the apparatus (i.e., in x-y) with an accuracy of +/−1 mm.

The capability for ensuring that the subject eye is desirably positioned in angle with respect to the apparatus (i.e., the difference between the visual axis and the optical axis of the system) with an accuracy of +/−0.5 degrees.

The capability for aligning an on-screen reticule to a set of marks applied to the eye outside the limbus to record the rotational orientation of the eye (i.e., about z) with respect to the apparatus with an accuracy of +/−one degree.

Once in position, the patient's eye can be successfully examined by the wavefront sensing technique. This embodiment of the apparatus includes a sufficient dynamic range to measure eyes over the expected scope of refractive errors.

The following list provides range and accuracy parameters, by way of example, for clinical wavefront measurements that can be obtained by this embodiment of the apparatus. This list is provided by way of illustration and does not limit the scope of the present invention.

1. capable of measuring wavefronts with spherical refractive powers in the range +6 to −15 diopters and cylindrical powers in the range 0 to −6 diopters.
2. capable of measuring coma and spherical aberration.
3. capable of measuring refractive errors over a pupil zone of up to 8 mm in diameter.
4. able to measure the refractive errors within the specified ranges to an accuracy of 0.042 μm RMS in air.

With reference again to FIG. **6**, and by way of further example, the output from wavefront analyzer **26**, e.g., the Zernike expansion of equation (19), can be used in a variety of ways. For example, the output may be used to continually or periodically monitor the progress or effects of an ophthalmic procedure, with such stored on disc or transmitted via e-mail, and the like. The output of the wavefront analyzer **26** is input to a processor **90** which converts the Zernike expansion of equation (19) into a form suitable for subsequent use as desired. Alternatively, the processor **90** may also be implemented at the processor **40** of the wavefront analyzer **26**, described earlier with reference to FIG. **6**.

By way of further example, the processor **90** can be used with preselected Zernike coefficients from the expansion of equation (19) to generate a standard sphero-cylindrical specification for a lens grinder **92** to produce a convectional optical lens, e.g., a lens for glasses, a contact lens, and the like.

As described earlier with reference to FIG. **12**, the apparatus **300** of the present venture includes first and second afocal relays stages **358**, **360**. To retain the benefit of wavefront magnification, as a means of increasing the dynamic range of the wavefront sensor **356** to accommodate patients with large refractive errors, while at the same time allowing for incorporation of a small format, inexpensive camera to record the wavefront slope data, a modification **500** to the apparatus **300** as illustrated with reference to FIG. **26**A is provided.

By way of example, a lens array may also be positioned and configured as illustrated with reference to FIG. **26**B, wherein a portion of the apparatus **300** of FIG. **12** includes the first and second afocal stages **358**, **360** within the optical axis **342**, and the wavefront sensor **356** consist of the microlens array and CCD camera separated by a fixed distant, as earlier described with reference to FIG. **6**. This optical path through the afocal relay stages results in an image of the corneal plane **502** at the lenslet array, i.e. at the entrance face of the actual wave front sensor **356**. This can be accomplished by a single afocal stage. As earlier described with reference to FIG. **12**, the apparatus **300** includes an intermediate image plane as insertion point, the holder **408**, for a trial lens. Placing a spherical lens into the optical axis **342** at the first image plane, in theory, could be used to remove the defocus wavefront error. This would

potentially expand the dynamic range of the apparatus **300**. However, the trial lens approach s a moving mechanism that can position lenses at the first image plane with tremendous accuracy in repeatability. It is highly desirable that alternative means be developed to address dynamic range.

One way to accomplish this is to magnify the corneal plane image at the lenslet array with the afocal stage **360**, earlier described. Magnification of the wavefront reduces the wavefront slope, so that the displacement of the focused lights spots on the CCD is decreased. The chosen magnification factor used with the apparatus **300** second afocal stage **360** is approximately 1.2 which is sufficient to cover the desired range in refractive errors. A magnification factor in excess of 1.5 is desirable for expanding the use of the apparatus **300**. However, simply magnifying the corneal plane has a drawback in that it necessitate a large aperture wavefront sensor. That is, both the lens array and the CCD camera preferably have large cross-sectional areas to encompass the magnified image of the point of plane. This is not a significant issue for the lens array. However, a large format CCD camera is quite expensive and such cameras are only available from a limited number of vendors.

To resolve such concerns, the modification **500** illustrated with reference again to FIG. **26**A is provided. The corneal plane **502** is imaged at a reference plane **504** by an afocal relay stage **506**, which magnifies the corneal plane by a preselected amount. The lenslet array **412** is placed at the reference plane **504**. Focused spots of light from the eye **120** are produced at the lenslet array focal plane **504**. Rather than place the CCD detector face at the reference plane **504**, an optical train **508** is inserted to image the array focal plane **413** at yet another plane, a final image plane **510**, at which plane the CCD detector face is positioned. The afocal relay stages **358**, **360** described earlier with reference to FIGS. **12** and **26**B, may or may not be included, as desired. However, the magnification of the array focal plane at the final image plane **510** is provided. This allows a small, relatively inexpensive, active area camera to be used as the light recording element in the wavefront sensor. Details of optical design including magnification specifics can be adjusted to maximize performance for a given camera and lens array plate specification.

The advantages of the present invention are numerous. A totally objective approach is presented for measuring ocular aberrations. The approach is effective for a wide range of vision defects. Accordingly, the present invention will be of great utility in a wide variety of clinical applications. For example, the calculated Zernike coefficients can be used to develop a completely objective lens prescription. In addition, each of the wavefront sensor embodiments provides for a greater degree of accuracy over the prior art with respect to measuring wavefront deflections. Further, the present wavefront sensor can be adjusted in terms of gain simply by adjusting the separation distance between the imaging plane of the sensor and the planar array of light-sensitive cells.

The objective measurement of the present invention will also find great utility for a large variety of applications where the "patient" is unable to provide feedback as d by conventional eye diagnosis. For example, the present invention could be used to evaluate the eyes of any patient not possessed of demonstrative communicative skills, e.g., babies, animals, dead specimens, as well as any constructed optical system, since the present invention is an objective analysis not requiring any assessment from the "subject". All that is necessary is for the subject's eye to be properly positioned so that proper optical access to the eye can be obtained.

The present invention will also be used in the area of identification should it be determined that each eye's Zernike coefficients are unique. Then, the present invention would find great utility in the fields of law enforcement, credit card/bank security, or any other field where positive identification would be beneficial.

Although the invention has been described relative to a specific embodiment thereof, there are numerous variations and modifications that will be readily apparent to those skilled in the art in light of the above teachings. It is therefore to be understood that, within the scope of the appended claims, the invention may be practiced other than as specifically described.

That which is claimed is:

1. A method for determining higher order aberrations of an eye requiring a correction of greater than −6 diopters, the method comprising:

directing an optical beam onto a retina of an eye;

reflecting the optical beam from the retina of the eye;

determining characteristics of a wavefront in the reflected optical beam; and

generating data based on the characteristics of the wavefront, which data quantifies at least one higher order aberration of the eye.

2. An apparatus for determining aberrations of an eye comprising:

a patient head rest comprising an adjustment, the patient head rest associated with an optical table having a base, the base comprising:

a) a probe beam generating apparatus for providing a probe beam;

b) probe beam directing optics operable with the probe beam generating apparatus, the probe beam directing optics comprising a beam splitter, a mirror, and a lens operable within a beam path of the probe beam, the probe beam directing optics being capable of directing the probe beam toward an eye of a patient positioned on the patient head rest;

c) video image components, the video image components comprising a light source for illuminating the eye of the patient, and a mirror and a video camera for viewing the eye, the video image components being capable of generating an image of the eye of a patient positioned on the patient head rest;

d) eye fixation components, the eye fixation components comprising a fixation target for viewing by the eye of a patient, a light source for illuminating the target, and a lens and a mirror operable within a path of the target, the fixation components being capable of generating a target that the eye of a patient positioned on the patient head rest can view; and

e) wavefront directing and analyzing components operable with the eye of a patient, the wavefront directing and analyzing components comprising a lens, a mirror, a microlens array, and a camera operable within an optical path of the eye, and a data processor operable with the camera, the wavefront directing and analyzing components being capable of measuring a wavefront emanating from the eye of a patient positioned on the patient head rest and determining aberrations of said eye that range from at least about + or −1 diopters to at least about + or −6 diopters.

3. A method for determining higher order aberrations of an eye requiring a correction of greater than −6 diopters of myopia, the method comprising the steps of:

directing an optical beam onto a retina of an eye;

reflecting the optical beam from the retina of the eye;

determining characteristics of a wavefront in the reflected optical beam; and

generating data based on the characteristics of the wavefront, which data quantifies at least one higher order aberration of the eye.

4. A method for determining higher order aberrations of an eye requiring a correction of greater than +6 diopters of hyperopia, the method comprising the steps of:

directing an optical beam onto a retina of an eye;

reflecting the optical beam from the retina of the eye;

determining characteristics of a wavefront in the reflected optical beam; and

generating data based on the characteristics of the wavefront, which data quantifies at least one higher order aberration of the eye.

5. An apparatus for determining aberrations of an eye, comprising:

a patient head rest associated with an optical table having a base, the base having:

i) a probe beam generating apparatus for providing a probe beam;

ii) probe beam directing optics operable with the probe beam generating apparatus, the probe beam directing optics comprising a beam splitter, a mirror, and a lens operable within a beam path of the probe beam, the probe beam directing optics being capable of directing the probe beam toward an eye of a patient positioned on the patient head rest;

iii) video image components, the video image components comprising a light source for illuminating the eye of the patient, and a mirror and a video camera for viewing the eye, the video image components being capable of generating an image of the eye of the patient positioned on the patient head rest;

iv) eye fixation components, the eye fixation components comprising a fixation target for viewing by the eye of a patient, a light source for illuminating the target, and a lens and a mirror operable within a path of the target, the fixation components being capable of generating a target that the eye of the patient positioned on the patient head rest can view; and

v) wavefront directing and analyzing components operable with the eye of a patient, the wavefront directing and analyzing components comprising a lens, a mirror, a microlens array, and a camera operable within an optical path of the eye, and a data processor operable with the camera, the wavefront directing and analyzing components being capable of measuring a wavefront emanating from the eye of the patient positioned on the patient head rest and determining higher order aberrations of the eye that range from at least about +1 diopter to at least about +6 diopters and from at least about −1 diopter to at least about −6 diopters.

6. A method for determining higher order aberrations of an eye requiring a correction of greater than +6 diopters, the method comprising:

directing an optical beam onto a retina of an eye;

reflecting the optical beam from the retina of the eye;

determining characteristics of a wavefront in the reflected optical beam; and

generating data based on the characteristics of the wavefront, which data quantifies at least one higher order aberration of the eye.

(57) **ABSTRACT**

This invention is an anti-glare device comprising a flexible, soft material that is rolled as a sleeve to be wrapped around, while projecting from an end of an objective lens housing such as is found on telescopic scopes, spotting scopes, binoculars, cameras and video cameras to prevent sun glare on the lens or lenses of such devices regardless of the angle of the sun rays otherwise engaging such lens or lenses.

BACKGROUND OF THE INVENTION

The field of the invention relates to geometrical instruments and specifically to an adjustable anti-glare device for use on devices having objective lenses, i.e., a variety of telescopes spotting scopes, binoculars, cameras, and video cameras.

DESCRIPTION OF THE PRIOR ART

Sunshade equipment for use in providing protection from glare on objective lenses is used in the prior art. Examples of such devices may be found in U.S. Pat. No. 5,181,140 to Brown et al, which is for a sun shading device for binoculars, and U.S. Pat. No. 4,089,117, which is for a sunshade for a rifle scope. U.S. Pat. No. 4,384,767 to Kawai is for a hood-like structure that is clamped onto a camera lens. U.S. Pat. No. 4,610,517 to Fukino et al is for a similar type of lens hood that clamps to a lens housing. These devices are designed to reduce glare on the lenses from above, but they do not fully address the problem of glare from either side.

U.S. Pat. No. 5,201,135 to Cowles does address the problem of additional glare sources, but discloses a rigid precise device that requires complicated manufacturing methods.

U.S. Pat. No. 5,101,298 to Lentz discloses a television lens shade including a soft mounting means to surround the lens and to support separate shading structures. It does not disclose the use of the mounting means as a sun shade.

All of the above listed shading devices are specific to only one field of objective lenses, i.e. rifle scopes, binoculars or cameras. The present invention is not specific to only one field as it is so completely adjustable that it fits a variety of types of objective lenses in housings, i.e. telescopic scopes, spotting scopes, binoculars, cameras,, or video cameras.

The present invention is effective, attached easily, and quickly removed. All of the prior inventions required more complicated methods of manufacture than those required by the present invention. There continues to be a need for a new and improved anti-glare device for objective lenses and the present invention substantially fills that need.

SUMMARY OF THE INVENTION

The primary use of this invention is as an attachment to a housing for an objective lens or lenses to reduce glare upon the lens or lenses. This anti-glare device is comprised of a sheet of thin, flexible foam rubber, or the like, having sufficient rigidity to maintain a rolled assigned shape around the housing of the lens or lenses while projecting beyond an end of the housing. Strips of hook and loop type members, sold under the trade name "Velcro", or other devices, are used for holding the sheet in the rolled configuration as a sleeve around the housing and projecting beyond an end of the housing. This construction permits the attachment of the anti-glare device quickly and firmly to the housings of many different types of objective lenses. The anti-glare device of the invention is easily and quickly removed and folds up compactly and is easily stored in pockets, camera cases, etc. This anti-glare device also costs less to manufacture and fits on a larger variety of lens housings than do devices heretofore known.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a side view of the invention attached to a rifle scope.

FIG. **2** is a perspective view of the invention showing proper attachment of "Velcro" fasteners.

FIG. **3** is an end elevation view showing the invention attached to a spotting scope.

FIG. **4** is a perspective view of two units of the invention attached to binoculars.

FIG. **5** is a perspective view of the invention attached to a video camera.

FIG. **6** is a perspective view of the invention attached to a camera.

DETAILED DESCRIPTION OF THE INVENTION

This anti-glare device of the invention comprises an adjustable, elongated, flexible wrap around sleeve **10** that is designed as an adjustable anti-glare device for use on housings containing objective lenses and that is particularly suitable for use on a variety of telescopic scopes, spotting scopes, binoculars,cameras, or video cameras. As illustrated in FIGS. **1**, **3**, **4**, **5**, and **6**, the sleeve **10** is designed to fit snugly around the outer surface of housings of a variety of telescopic scopes, spotting scopes, binoculars, cameras and video cameras and to extend beyond the lens or lenses within the housings to provide shade. As shown in FIGS. **1**, **3**, **4**, **5**, and **6**, sleeve **10** is wrapped fully around a lens housing and then is secured to itself with "Velcro" strips including loops **12** and hook like members **13**, as a fastening system. Sleeve **10** is designed to prevent: light from glaring on the lens or lenses of a wide variety of telescopic scopes, spotting scopes, binoculars, cameras, and video cameras, such as are illustrated in FIGS. **1**, **3**, **4**, **5**, and **6**. Sleeve **10** is constructed of any material **11** having size, flexibility, and shape holding properties to allow it to snugly grip the outer surface or surfaces of said variety of housings of telescopic scopes, spotting scopes, binoculars, cameras, or video cameras and to maintain its assigned shape, without collapsing as it projects beyond the end of the housing. Material such as foam rubber, plastic, nylon, or foam coated, light, flexible metal **11** are suitable, for example. A sufficient amount of "Velcro" loop materials **12** and hook materials **13** is used to enable the sleeve **10** to fit a variety of telescopic scopes, spotting scopes, binoculars, cameras, and video cameras.

The "Velcro" loop material strips **12** and **13** are attached by gluing or sewing to the inner and outer surfaces of the foam rubber, or the like, **11** in such a manner as to cause the foam rubber **11** to form an elongated sleeve **10** when the loop material **12** and hook material **13** surfaces of the "Velcro" material are interlocked. As best illustrated in FIG. **2**, the sleeve **10** is tightly wrapped around a lens housing and is secured by means of interlocking of the "Velcro" loop material **12** and hook material **13** around the housing surface of a variety of telescopic scopes, spotting scopes, binoculars, cameras, and video cameras. For use on binoculars two units of the sleeve are required, as illustrated in FIG. **4**, with one unit wrapped around the housing at the remote end of each lens assembly of the binocular,

It will be apparent that the sizes and shapes of the loop material **12** and hook material **13** can be varied, as desired. However, the fastening system formed by such loop material and hook material must secure the rolled sleeve **10** to the lens housing while allowing a side edge of the sleeve to project beyond the lens housing while allowing a side edge of the sleeve to project beyond the lens housing and with the edge being held in the rolled configuration without collapsing.

Although a preferred embodiment of my invention has been herein disclosed it is to be understood that such disclosure is by way of example and that variations are possible without departing from the subject matter coming within the scope of the following claim, which subject matter I regard as my invention.

I claim:

1. An anti-glare device for use with objective lenses mounted in a housing, said device comprising:

an elongated strip of flexible, soft material having a length between ends to wrap around a housing containing objective lenses and to overlap on itself, a width to project from said housing and sufficient rigidity to maintain an encircling formation projecting from said housing;

connector means fixed to one face of one of said ends of said elongate strip of flexible, soft material; and

co-operating connector means fixed to at least an opposite end of said elongate strip of flexible, soft material, said connector means interlocking when one of said ends overlaps the other of said ends when said elongate strip is wrapped around and projects from an end of said housing.

(57) **ABSTRACT**

An infrared refractive lens triplet having color correction properties for radiation within the 3 to 12 micrometer spectral band for use with a quantum well detector for simultaneous dual band imagery. In certain embodiments of the invention, two widely spaced triplets form a Petzval-type objective lens. Each lens triplet is made up of a negative zinc sulfide lens, a positive zinc selenide lens, and a negative gallium arsenide lens coaxially positioned along a chief ray of the lens system.

DUAL INFRARED BAND OBJECTIVE LENS

BACKGROUND

1) Field of the Invention

The present invention relates to an objective lens system and, in particular, a Petzval objective, capable of simultaneous dual band imagery in both the 3–5 and 8–12 micrometer spectral ranges, for use with a dual spectral band detector, such as a quantum well detector.

2) Discussion of Related Art

Recent advancements in quantum well detector technologies permit the simultaneous processing and display of dual infrared band imagery with a single detector at a single focal plane. There are advantages of imaging each spectral band and the possibility of focusing both bands simultaneously may yield greater information for surveillance and/or target discrimination by imaging devices.

Imaging devices, search and track sensors such as forward looking infrared systems, and other types of optical devices which operate in the 3–12 micrometer spectral region use either reflective or refractive objective lens systems. An advantage of reflective optics is that they operate within a wide spectral band. However, reflective optics systems have several undesirable features, such as, for example, a more limited field of view and a large physical size. In addition, central obstructions in reflective optics limit the modulation transfer function (MTF), or sine wave response.

Additionally, efficient cold shielding is important with any cooled detector array. Reflective optics are not appropriate for wide field of view applications, particularly when efficient cold shielding is necessary.

In the past, refractive lens systems have been designed for limited ranges, e.g., either the 3–5 or the 8–12 micrometer bands. This is because the refractive indices of the component lens materials vary significantly between the two spectral bands. For example, germanium behaves like a crown (a low dispersion material) in the 8–12 micrometer wavelengths and like a flint (a high dispersion material) in the 3–5 micrometer region. Systems designed to operate in one band exhibit intolerable chromatic aberrations in the other band. The design for either long wave (8–12 micrometers) or short wave (3–5 micrometers) lenses are commonplace, but the need for simultaneous dual band operation is a relatively new requirement.

The number of optical materials that can transmit wavelengths in the spectral range of interest for this application is limited, and many infrared lens materials are soft or water soluble, which make them unsuitable for tactical systems.

Several studies have been carried out to isolate optical material combinations that yield refractive lens designs that are color corrected over the entire 3–12 micron spectral region. The following publications describe such studies: Thomas H. Jamieson, "Ultrawide Waveband Optics", *Optical Engineering*, Vol. 23, No. 2, April 1984, pages 111–116; M. O. Lidwell, "Achromatism of Lenses for Thermal IR", *Proceedings SPIE*, Vol. 518, 1984, pages 73–80; and, M. Roberts and P. Rogers, "Wide Waveband Infrared Optics", *Proceedings SPIE*, Vol. 1013, 1988, pages 84–91.

These publications describe optical design studies that employ many different infrared lens material combinations. The solutions described in these studies yield excellent color correction over the spectral range of 3–12 microns, but the material combinations are poor choices from the standpoint of durability, manufacturability and reliability.

SUMMARY

The present invention overcomes the problems of the prior art by providing a combination of lens materials that yield excellent broad band color correction in the 3–12 micron spectral range; that are durable, easily produced and highly reliable; and therefore that are suitable for tactical infrared imaging systems.

Specifically, the present invention is an optical lens system made up of at least one lens triplet of a negative zinc sulfide lens, a positive zinc selenide lens, and a negative gallium arsenide lens, each of the lenses being positioned along a chief ray for simultaneous dual band imagery in both the 3–5 and 8–12 micrometer spectral bands. Alternatively, the lens system can include two widely spaced, net positive triplets, forming a Petzval-type lens. A quantum well detector may be placed at the focal plane for dual band image detection.

BRIEF DESCRIPTION OF THE DRAWINGS

The invention may be best understood by reference to the following detailed description when read in conjunction with the following drawings, wherein:

FIG. **1** illustrates a YZ profile of a wide band Petzval objective lens employing two widely spaced triplets in accordance with the present invention;

FIGS. **2***a*–**2***c* are spot diagrams illustrating the performance achieved in the spectral band of 3–5 micrometers; and

FIGS. **3***a*–**3***c* are spot diagrams illustrating the performance achieved in the spectral band of 8–12 micrometers.

DETAILED DESCRIPTION

The index of refraction of optical materials varies with wavelength. The refractive index is generally higher at shorter wavelengths so that light converges faster (the focal length is shorter) than at longer wavelengths. This spread in the focal position over a spectral range is the primary chromatic aberration called axial color. It is relatively easy to correct the axial color aberration in either the 3–5 or the 8–12 micrometer spectral range by simply combining low and high dispersion elements and dividing the magnification power of the lens system among positive and negative lens elements. Color correction of both bands is much more difficult.

The present inventor has discovered a unique combination of lens powers, including an aspheric surface, and materials that yield color correction for both spectral bands simultaneously. The type of lens and the materials are, in order of their appearance along a chief ray of a focal optical lens system, as follows:

Lens	Material
Negative	Zinc sulfide (ZnS)
Positive	Zinc selenide (ZnSe)
Negative	Gallium arsenide (GaAs)

Recent advances in the quantum well detectors, or any present or future detectors capable of dual spectral band imagery, give rise to a need for dual band optics such as disclosed herein so that such detectors can be utilized to their best efficiency.

An exemplary set of lens characteristics for a conventional quantum well detector is as follows:

Effective Focal Length (EFL)	7.5"
f/#	2.0
Field of View	4.0 × 4.0 degrees
Pixel Size	0.002"
Format Size	0.5 × 0.5
Spectral Range	3 to 5 μm and 8 to 12 μm
Cold Shield Efficiency	100%

To achieve the above characteristics, the simple lens triplet, while acceptable for some applications, does not provide optimum speed and field of view. Speed refers to the light gathering power of the lens. In commercial camera optics, this property of the lens system is indicated by the f/number. The exposure time required for a given photograph is proportional to the square of the f/number and will be shorter when a lens with a low f/number is used; thus, a lens having a higher speed reduces light gathering time.

Two widely spaced triplets in the form of a Petzval-type lens provide an optimum speed and field of view for the above-listed lens characteristics. A classic Petzval lens involves two spaced doublets, but the term is used here by analogy because each triplet is a net positive lens group.

The six element combination with two aspheric surfaces can be optimized on the ACCOSV optical design program. A resulting lens design shown in FIG. **1** and listed in Table 1 below.

Naturally, other lens characteristics can be used within the scope of the present invention. The above data is exemplary and reflects an optimum lens data for a particular quantum well detector chip.

In the preferred embodiments of the present invention, in each lens triplet, a first lens **10**, **13** is negative, a second lens **11**, **14** is positive, and a third lens **12**, **15** is negative as taken along the chief ray. Surfaces **10**B and **13**B of the ZNS lens are selected for receiving aspheric surfaces. ZnS is a diamond turnable lens material which greatly eases manufacturing requirements. Also, of the manufacturing methods available for making ZnS lenses, the Cleartran™ method provides a better, more homogenous material (C_ZnS) which is clearer in the 3–5 micrometer range than produced by some other methods.

As illustrated in FIG. **1**, parallel light impinging on the Petzval lens system is focused on an image plane **18**. A quantum well detector **19** can be placed at the image plane **18**. A cryogenic vessel or Dewar houses the quantum well detector **19** to maintain the detector **19** at a temperature of approximately 77° Kelvin in order to increase detector sensitivity. The cold shield **20** of the Dewar is shown.

In these types of systems, optimum performance is achieved by cold shielding the detector array. This is done by introducing a cold diaphragm, or cold shield **20**, with an aperture stop **17** in front of the detector array so that the viewing angle of the detector to the warm background is limited as nearly as possible to only that required for transmission of radiation from the scene. Since the amount of radiation reaching the detector from the cold shield **20** is negligible compared to the amount reaching the detector from the warm background of the field of view, induced noise in the detector is minimized. The cold shield **20** is typically placed within the Dewar. Also included in the optical system may be a Dewar window **16**.

The performance achieved in each spectral band is shown by the spot diagrams in FIGS. **2***a*–**2***c* and **3***a*–**3***c*. Rays representative of three wavelengths in each of the 3 to 5 and 8 to 12 spectral bands from an on-axis and two off-axis field points are distributed through the full aperture and are traced through the system, producing FIGS. **2***c*, **2***a* and **2***b*, respectively. In FIG. **2***a*, the FOB-Y is 1.0000 and the FOB-X is 0.0000; in FIG. **2***b*, the FOB-Y is 0.7000 and the FOB-X is 0.0000; in FIG. **2***c*, the FOB-Y is 0.0000 and the FOB-X is 0.0000; in FIG. **3***a*, the FOB-Y is 1.0000 and the FOB-X is 0.0000; in FIG. **3***b*, the FOB-Y is 0.7071 and the FOB-X is 0.0000; and in FIG. **3***c*, the FOB-Y is 0.0000 and the FOB-X is 0.0000, wherein FOB stands for fractional object height. FOB refers to the object point (or field angle when the object is at infinity) from which rays are traced.

As shown in FIGS. **2***a*–**2***c* and **3***a*–**3***c*, the square in phantom is the pixel size of a typical quantum well detector, e.g., 50.8×50.8 micrometers (0.002 inches). In FIGS. **2***a*–**2***c* and **3***a*–**3***c*, all spot diagram origins are on the chief ray. Since virtually all of the ray intercepts are contained within the pixel, the image resolution will be limited by such a detector.

By the above disclosed imaging system, the optimum capability of a quantum well detector can be utilized. A quantum well detector's capability could go under-utilized without an optical system such as disclosed herein that can simultaneously deliver the image quality required over both the 3 to 5 μm and 8 to 5 μm spectral bands. The lens system in accordance with the present invention yields excellent broadband color correction by a combination of infrared lens material suitable for tactical applications.

Certain preferred embodiments of the invention have been described by way of example. Various other embodiments and components thereof will be apparent, particularly in applying the lens triplets to perform various functions. Various parameters may be optimized for different purposes. For example, a beam splitter may be introduced into the lens system to split an image into the 3–5 μm range and the 8–12 μm range, whereupon the lens powers may vary and color correction requirements loosened because of the using more than one focal plane. The lens system can be useful with detectors capable of imaging either the 3 to 5 μm or 8 to 12 μm spectral bands, and an imaging system can be envisioned wherein high and low spectral band detectors can be selectively placed at the focal plane(s), by use of a beam splitter or employing a detector change-over mechanism. Naturally, optimum performance is achieved when employing a single detector capable of detecting both the 3 to 5 μm and 8 to spectral bands. The foregoing description is offered as illustrative and not limitative. Other variations and equivalents thereof are intended to be encompassed by the invention, which is defined by the claims appended hereto.

I claim:

1. An optical imaging system comprising:

a lens system simultaneously focusing light in both the 3–5 and 8–12 micrometer spectral bands onto a single focal plane, wherein said lens system includes:

a first, negative zinc sulfide lens,

a second, positive zinc selenide lens, and

a third, negative gallium arsenide lens,

each of said first through third lenses being positioned along a chief ray and capable of simultaneous dual band imagery in both the 3–5 and 8–12 micrometer spectral bands; and

a detector, located at said single focal plane, capable of simultaneous dual band imagery in both the 3–5 and 8–12 micrometer spectral bands.

2. An optical imaging system according to claim **1**, wherein said detector is a quantum well detector.

3. An optical imaging system according to claim **1**, wherein said lens system further includes:

a fourth, negative zinc sulfide lens,

a fifth, positive zinc selenide lens,

a sixth, negative gallium arsenide lens,

each of said first through sixth lenses being positioned along a chief ray, said first through third and said fourth through sixth lenses forming two widely spaced triplets.

4. An optical imaging system according to claim **3**, wherein said two widely spaced triplets form a Petzval-type lens.

5. An optical imaging system according to claim **3**, wherein said lens system further includes a field flattener lens, and a cold shield diaphragm.

6. An optical imaging system according to claim **1**, wherein at least one of said lenses has an aspheric surface.

7. An optical imaging system according to claim **6**, wherein said aspheric surface is on said second zinc selenide lens.

8. An optical imaging system according to claim **3**, wherein a surface on said fifth zinc selenide lens is aspheric.

9. An optical imaging system according to claim **3**, wherein said lens system has the following basic lens data:

(57) **ABSTRACT**

The present invention relates to image-formation on any selected kind of objective body. The characterizing features reside in such that, based upon fed image data, required images are formed on an image-transferable sheet acting for image carry-over service and in reliance on sublimation image transfer technique, and then, by the use of said sheet with said images thus formed thereon, the formed images thereon are transferringly applied on the objective body. By adopting the above measures, the objective body can be formed sharply and clearly with any desired images, irrespective of kind and configuration thereof, with such superior results of highly improved unity and solidability between the formed images and the objective body to be decorated with.

IMAGE FORMATION ON OBJECTIVE BODIES

This is a continuation of application Ser. No. 08/797,726 filed Feb. 11, 1997, now allowed, which in turn is a divisional of Ser. No. 08/395,850 filed Feb. 28, 1995 now U.S. Pat. No. 5,629,259 which in turn is a continuation of Ser. No. 08/034,186, filed Mar. 18, 1993, now U.S. Pat. No. 5,451,560 which in turn is a continuation of Ser. No. 07/467,415 filed Jan. 19, 1990, now abandoned, which in turn is a division of Ser. No. 07/138,384 filed Dec. 8, 1987 now U.S. Pat. No. 4,923,848, of which is a National Stage Application of PCT/JP87/00228 filed on Apr. 10, 1987.

TECHNICAL FIELD

This invention relates to methods and apparatus for the formation of images as prints on objective bodies through transfer of images preformed by the sublimation transfer technique, and more specifically it relates to such systems as adapted for the formation of images on any selected objective body, such as cards, clothes, papers, and transparent sheets, although these are not limitative to the present invention.

BACKGROUND ART

Reliance is made generally upon the normal printing technique for formation of images on objective bodies. For the execution of the printing technique, provision and use of printing plates (forms or blocks) are requisite. No matter how simple the image-printing is, the plate-making is a very time-consuming the laborious procedure. This is much more so in the printing of various and complexed image combinations, such as those of graphic or portrait images combined with characters, letters or barcodes, as an example, representing extremely complicated and troublesome work.

Further, in the normal printing operation, various operating conditions, including ink selection and the like, must be carefully considered, depending upon the kind and nature of the printing object, thus the best selection thereof is highly delicate and not as simple as expected.

The present invention is proposed upon careful consideration of the foregoing facts, and an object of the invention is to provide a unique process for the formation of sharp and clear images regardless of the kind and nature of the object to be printed upon, and usable and effective materials and apparatuses for carrying out this unique process.

The method of thermal image transfer (sublimation image transfer) on clothes or fabrics with the use of thermal transfer dyestuffs has been practiced for a long time. In this conventional process, a dyestuff picture layer carrying thermal transfer dyestuff is formed on a substrate sheet which is then subjected to heat in an overlapped state on a cloth or fabric, the dyestuff thereby being transferred thermally onto the latter for forming the desired images thereon. By utilizing this technique, and with recent development of the image forming technology concerning fine thermal printers and the like, various fine image forming processes have been proposed to provide fine images which are comparable to photographic images and are transferred onto plastic films from thermal transfer sheets carrying thermal transfer dyestuffs.

According to these recently proposed processes, various images of cameras, or TVs, graphic images of personal computers and the like can be reproduced-easily in the form of hard copies on the surface of a transferred material

such-as a paper or the like sheet carrying thereon a fixedly attached layer of polyester resin, as an example. These images thus reproduced represent an amply high level comparable to those obtained by photography or fine printing arts.

The thermal transfer process so far set forth has an advantage in that it can form any image in a convenient manner yet entails a problem in that it is limited to image-transferred products preferably of polyester and the like materials which must be dyed with thermal transfer dyes. On the other hand, the image-transferred products must be limited to specifically selected shapes, preferably film, sheet or the like configuration, and thus, such materials as wood, metal, glass or ceramics cannot be formed with images in this way. Further, even if the material is plastics such as polyester or the like, and when the image-forming surface is curved or undulated, or physical body other than sheet, even if it represents a plane surface, it is almost impossible to reproduce images precisely thereon, which naturally constitutes a grave problem in the art.

With recent development and enlargement of utilizing fields of various card-style products, such as cash-cards, telephone-cards, prepayment cards; and ID-cards, there are increasing demands for providing these cards with images, symbols and codes, so as to give various other functional and/or decorative effects. Moot of these cards are of planar form, but they are frequently not pliable and/or have uneven rough portions due to provision of characters and symbols, resulting in great difficulty in the scheduled image formation relying upon the thermal image transfer process.

There is therefore an urgent demand among those skilled in the art for the provision of a unique technique capable of forming sharp and clear images of desired patterns on the surface of an objective body of any preferred kind of material and having any shape and configuration and surface condition of any kind, and indeed, for combining and unifying image- and decoration effects.

DISCLOSURE OF THE INVENTION

The present invention is basically based on such a principle that a first image transfer pattern is formed on an image transfer material, preferably an image-transferable sheet, and in the form of dyestuff images through the sublimation image transfer process executed by first image transfer means, depending upon given image data, preferably including those of letters, characters, symbols, line images, graduated graphic representations, and then the first transfer pattern is transferred to second transfer means for retransferring the images onto an objective body so as to provide a final product.

Based upon the image data fed from various image data input means and at the first image-transfer means, a thermal head is actuated to execute printing operation through a dyestuff film (thermal image-transfer sheet) on an image-transfer material (or more specifically on an image-transferable material which means an image-transferable sheet. This image-printing is carried out according to the sublimation or sublimative image transfer technique. Thus, in this case, the dyestuff on the dyestuff film is transferred or shifted under the influence of heat energy from the thermal head onto the image-transferable material through sublimation, thus providing the first image-transferred means. Since this first image-transferred means has been thus formed with the images by the sublimated dyestuff, they are, then, transferred onto the second image-transferable means which will be brought into tight contact with the

object to be decorated and subjected to heat and pressure for execution of further image-transfer operation to provide the final desired product.

In the present invention, the image-transfer material (image-transferable sheet) is, as above referred to, formed with images by the sublimative image transfer technique for providing first image-transfer means which has highly sharp and clear images as the operation and results of the characterizing feature of the sublimation image-transfer technique. Therefore, because of the transfer of such sharp and clear images onto the object, it becomes possible to form the images thereon, and indeed, practically irrespective of the kind and nature of the object. In this way, thus, fine image-formation is assured onto practically any objective substance.

And further, by execution of control of the thermal energy applied during the sublimative image-transfer step, the resulting color effect is superior and the image quality is good.

The images sublimatingly applied and formed in the foregoing way are subjected to a further transfer, and onto a substrate product, for providing a final decorative product as desired. In this final product, it should be noted that the underlying layer underneath the images during the sublimative image-transfer stage appears now at the top, acting thus as a kind of protecting layer upon up-and-down positional conversion during execution of the second and final image-transfer stage, resulting in realization of various and numerous effects. As an example, attainment of substantial reduction of contamination, improvement of light resistance, weather resistance and chemical resistance; substantial reduction of color fading; provision of glazing effect; easier and simpler introduction of granular and/or undulated image appearance.

The inventive process is carried into effect basically in such a manner that an image-reception layer provided on one surface of an image-transferable sheet is subjected to an image-forming step with the use of dyestuff capable of depositing therein depending upon the fed image data, so as to form the required images, and then, the image-reception layer of the image-transferable sheet, having been image-fixed and thus now image-carrying, is stuck onto the surface of the object to be decorated upon.

As for the image-transferable sheet adapted for use in the image-transfer during execution of the inventive process, it consists basically of a sheet-like substrate and a reception layer attached, however, in a separable manner, onto one surface thereof. As a modification of the inventive process from the basic mode set forth above, the sheet-like substrate is caused to remain, even after completion of the image-transfer step, as may be occasionally required. In this modified case, it is unnecessary to make the image-reception layer of the image-transfer sheet separable.

Under occasion, the inventive process may be brought into effect in such a way that the image-reception layer of the image-transfer sheet is transferred upon execution of the image-forming step, and indeed, once onto an intermediate image-transfer substrate which is then retransferred, together with the once transferred image-reception layer, onto the surface of an object to be decorated on, and thus, in a retransferring manner.

BRIEF DESCRIPTION OF THE DRAWING

In the accompanying drawings:

FIG. **1A** is a block diagram, showing a preferred embodiment of the apparatus according to the present invention;

FIG. **1B** is a schematic view illustrating at B-**1**, B-**2** and B-**3**, several image-transfer steps for the execution of a process according to the invention;.

FIG. **1C** is a schematic view of an image-transfer step, using a platen roll;

FIG. **1D** is a plan view of part of a multi-color dyestuff film adapted for use in an image-forming step;

FIG. **1E** is a schematic view for the illustration of several image-transfer steps;

FIG. **2** is a flow chart of successive operation steps with use of a data-processor, shown in FIG. **1**, functioning as an operating center;

FIG. **3A** is a schematic block diagram, showing a data-processor for the printer;

FIG. **3B** is a block diagram of a sublimative image-transferring printer adopted in the present invention, as a preferred embodiment thereof;

FIG. **4** is a schematic block diagram, showing a color correction unit shown in FIG. **3A**, and several related parts cooperating therewith;

FIG. **5** is a schematic block diagram of a comparator and several related parts cooperating therewith;

FIG. **6** is a circuit block diagram of an image-transfer head shown in FIG. **1B**;

FIG. **7** is a graph showing operational characteristics of a color tone or -gradation corrector unit shown in FIG. **3A**;

FIG. **8** is a table for the illustration, as an example, of picture- or image-elements, as expressed in binary signals;

FIG. **9** is a table showing a conversion operation, as an example, of a parallel/series converter shown in FIG. **3A**;

FIG. **10** is a flow chart, illustrating the operation of the sublimative image transfer printer;

FIG. **11** is a plan view of a final decorative product prepared according to the inventive technique;

FIG. **12** is a sectional view of the product card shown in FIG. **11**, and taken along a section line A—A shown therein;

FIGS. **13** through **31** are a series of sectional views, respectively illustrating several structural examples of image-transferable sheets, suitable for use in the invention; and

FIGS. **32**(*a*), (*b*), and (*c*) are sectional views, indicating final transfer steps.

BEST MODES FOR CARRYING OUT THE INVENTION

Referring now to FIG. **1A** and FIGS. **1B-1**, **1B-2** and **1B-3**, a basic schema of the inventive image data processing and image formation will be illustrated. First, in FIG. **1A**, numeral **101** represents an image input means which is adapted for forming image data based upon optical and the like inputs delivered from a TV-camera, line sensor or the like. Other than those above enlisted only by way of example, video; CD; TV; scanner; personal computer, captain system, capable of providing R.G.B.—and picture image and the like signals may also be utilized in a similar way. The image signal data delivered from the image input means are fed through a data processor **104** to a memory **105** for being stored therein. These stored data can be taken out from the memory and fed through data processor **104** to display means **102** for being displayed thereat.

To the data processer **104**, a mouth/tablet digitizer and/or the like position data processer **103** is electrically connected for introducing position data concerning displayed images

appearing at the display **102**. In addition, key board and the like character data input means **106** and font generator **109** are provided for introducing character data. Still further, a barcode generator **110** is provided for introducing barcode when necessary. By the use of these means and units, various additional processing modes can be executed.

The thus processed data are subjected to conversion at a data converter **107** into proper data adapted for operating a sublimation transfer printer and fed forward through a driver **108** to the thermal head.

In this case, by controlling the current duration period to the thermal element of the thermal head, the transfer quantity from the dyestuff film (thermal transfer sheet) is controlled depending upon the thermal energy of the element for realization of the desired gradation degree of concentration on the transfer sheet. There are two different modes of such control of current duration period as follows:

(a) A method for controlling the pulse length corresponding to the picture element in the impressed data to the thermal element of the thermal head or, more specifically, a series data introduced as input to the shift register shown in FIG. **6** and to be described more specifically hereinafter.

(b) A method for controlling the number of pulses of the pulse series corresponding to the picture elements of the data impressed upon the thermal element in the thermal head (in this case, the pulse length being constant).

The degree of gradation of the transfer image can be controlled in the above mentioned way by the regulation of the current-conducting period depending upon the desired gradation degree. On the other hand, the image concentration can be controlled by adjusting the pulse length or the number of pulses contained in the pulse series in correspondence to the picture elements contained in the data as introduced in the shift register and depending upon the driving mode of the thermal head. Further in this case, if the number of gradation of introduced image data is larger than that which can be expressed by the printer unit, a proper conversion operation can be performed by the known strobe control method. As an example, in such case, the conversion of gradation number 256 to 64 may be executed by a ROM, and the thus reduced gradation number can be used as output.

Next, referring to FIGS. **1**B at **1**B-**1** and **1**B-**2**, reference numeral **121** represents a thermal head which receives signals from the driver **108** shown in FIG. **1**A. This thermal head **121** is arranged in opposition to platen roll **122**, forming the printing position therebetween. The dyestuff film (thermal transfer sheet) is fed from a delivery roll **123** to a winding roll **124** through this printing position, these structural and functional features being commonly employed in both the arrangements shown in FIGS. **1**B at **1**B-**1** and **1**B-**2**.

In the case of FIG. **1**B, **1**B-**1**, the mechanism is so arranged that card or sheet style transfer sheets are printed with dyestuff images.

On the other hand, in the case of FIGS. **1**B, **1**B-**2**, the mechanism is so arranged that cards are continuously produced with the use of a film style transfer sheet and a dyestuff film in combination.

Now turning back to FIGS. **1**B, **1**B-**1**, a number of transfer sheets (cards, sheets or the like) have been stacked and stored within a storage casing **125** and are being thrust upward from below by a spring so that the uppermost sheet is kept in pressure contact with a take-out roll **126**. With the rotation of the roll **126**, the sheets are successively delivered from the casing **125** by conveyer belts **127**, **128** onto a platen roll **122**. Each one of the sheets is fixed on the peripheral surface of the platen roll, now positionally indexed, by means of a gripper or the like mechanical attaching and separating means, static attracting means, or electromagnetic attaching means. Then, the roll **122** is so rotated that the transfer sheet is positioned at the ready-for-printing-position.

Next, the thermal head **121** is brought into pressure contact with the transfer sheet through the intermediary of the dyestuff film, and then the thermal head **121** is energized with electric current while the dyestuff film and platen roll **122** are moved in synchronism for the execution of image transfer (first image transfer).

Upon execution of the image transfer, the platen roll **122** is rotated, the gripper is released and the take-out roll **129** is rotated and brought into pressure contact for taking out the image transfer sheet onto a tray **130**.

The thus taken-out sheet is brought into overlapped state with a new image transfer sheet, not shown, and then, both the sheets are fusingly united together by pressure application of a heated roll, not shown, for execution of a second transfer step job. The whole operation has thus been completed. Before the fusion process, the sheets may be subjected to punching, trimming and/or the like processing, if necessary.

By execution of the foregoing operational steps, a monocolor printing operation has been completed. However, in the case of multicolor printing, use is made of tricolored or quadruple colored dyestuff film and the corresponding printing operations must be repeated. In this case, upon completion of a single monocolor printing procedure, the platen roll is rotated without contact of the take-out roll **129**, until it arrives again at the gag printing-initiation position, and so on.

In the following, a tricolor printing job will be illustrated with reference to FIGS. **1**B, **1**B-**2**, and with use of three different series color zones, of cyan, magenta and yellow.

First, a platen roll **122** is positionally indexed, and an image transfer sheet taken out from the roll **131** and a dyestuff film taken out from the roll **123** are brought into pressure contact in an overlapped state. Then a thermal head **121** is pressed against the platen roll **122** through the intermediary of the overlapped sheets. At this stage, the platen roll **122** is rotated counterclockwise while synchronism is kept between the platen roll **122** and the dyestuff film, and the thermal head **121** is kept electrically energized. In this way, the first color printing is executed.

Further, the dyestuff film is fed to the second color zone position, and then, the platen roll **122**, the dyestuff film and the image transfer sheet are fed forward clockwise around the center roll **122**. Thus a second color printing step is executed.

Further, the print-serviced two color sections of the film is fed back counter clockwise around the center of the platen roll **122** for the execution of a third color printing step. Then, each card sheet is taken out from the stack **200** under the action of take-out rolls or the like, not shown, towards and between a pair of thermal transfer rolls **132**, **133**, brought into overlapping state with the image transfer sheet positionally indexed and already subjected to image transfer steps as was described above, and finally subjected to a picture printing operation by pressurizing application of the thermal image transfer rolls **132**, **133** from both sides of each taken-out card, and so on.

The color-printing step with the use of the thermal head is carried into effect in the following manner, as an example.

(First Color Printing)

Platen roll, image transfer sheet and dyestuff film perform the printing while they are moved in the counterclockwise direction.

(Second Color Printing)

Platen roll and image transfer sheet are moved in the clockwise direction while the dyestuff film is moved at the same speed and in the counterclockwise direction for performing the color printing under consideration.

(Third Color Printing)

Platen roll, image transfer sheet and dyestuff film are moved in the counterclockwise direction for execution of the color printing under consideration.

In the modified arrangement shown in FIG. **1**B, **1**B-**3**, thermal image transfer rolls **132**, **133** have been replaced by a flat press type image transfer head having up-and-down movable flat printer elements **132'**, **133'**.

It should be noted that in the course of the foregoing first and second image transfer steps, image reversal phenomenon is necessarily brought about upon execution of each image transfer step. In other words and more specifically, when two successive image transfer steps in the foregoing sense are executed, reverse images which have once appeared will return to the original normal images. Therefore, when the printed-out products are to be provided upon execution of the first image transfer step, it is necessary to provide reversed image data in the signal porocessing system. For this purpose, it is only necessary to reverse the addressing order at the data introduction or readout stage into or from the memory.

In the modified arrangement shown in FIG. **1**C, the foregoing platen roll means has been replaced by a metal block **141** lined with a rubber plate **142** in an overlapped manner. The image transfer sheet and dyestuff film are fed out from respective rolls **131** and **123**. With the use of this modified arrangement, the dyestuff surface layer of the dyestuff film can be brought into tight contact with the image-receiving surface layer of the image transfer sheet, and thermal energy will be transferred evenly form the thermal head **121** to the dyestuff film.

In this case, the image transfer sheet is delivered from the roll **131**, and the desired zone or region of the sheet is set underneath the rubber plate **142** (step **1**).

At the same time, the dyestuff film shown in FIG. **1**D on an enlarged scale is delivered from the roll **123** and a selected one of the different color regions is set underneath the rubber plate **142** (step **2**).

Next, the thermal head **121** is brought into the rear surface of the dyestuff film which is the opposite surface to the dyestuff-coated front layer, and the head **121** is driven while it is being translated in the direction shown by an arrow A, images thereby being formed at the specifically allocated zone(s) or region(s) of the image transfer sheet (step **3**).

Further, the thermal-head **121** and rolls **416** and **418** are shifted downwards as shown by arrows Br so as to form an idle gap between the image transfer sheet and the dyestuff film for allowing the latter to shift towards the next following color region (step **4**).

Further, the thermal head **121** and rolls **416** and **418** are returned to their original positions, whereupon the third and further succeeding steps are repeatedly executed until a certain predesired number of color printings are completed.

As shown in FIG. **1**D, the dyestuff film is colored to have several different color regions denoted by Y (yellow), M (magenta), C (cyan) and Bk (black). However, the arrangement order is not limited to that shown: Y; M; C and Bk. In addition, as occasionally required, the Bk-region may be dispensed with. Further, as the color elements to be adopted in the Y, M, C-system may not be limited to the three primary colors provided by the subtractive color mixture. On occasion, a characterizing color which means such a color as preadjusted to provide an objective specifically selected one may be used to form the images concerned. As a further modification, the arrangement shown in FIG. **1**C may be so modified that the traveling direction of the image transfer sheet is selected to be perpendicular to that of the dyestuff film.

FIG. **2** is an operation flow chart for showing schematically operational modes taking the data processor **104** adopted in the embodiment shown in FIG. **1** as the centrum of description. The operational contents of several working parts downstream of the data converter **107** will be set forth separately hereinbelow. Now referring to FIG. **2**, in combination with FIG. **1** and at the step of **S101**, image pickup operation is carried out by means of the image pickup means **101**. For execution of this step, it may be better to pick up the face of a person per se which is to be represented on the card, or alternatively, a photograph, portrait or imagery product thereof will do. Depending upon the nature of the object, a TV camera, line sensor or the like instrument may naturally be selectively utilized.

The data taken by the image pickup means **101** are stored through the data processor **104** at a memory **105** (**S102**). By the use of these stored data, image or images is/are displayed at the display **102** (**S103**). Since this display image is not yet subjected to any processing, it is generally unsuitable for representing on the card. However, under certain circumstances, it may be represented thereon as it is.

Then, the operator observed the displayed image or images on the display unit **102** and adjudges whether additional processing is necessary or not (**S104**). If it is not necessary, he will manipulate the key board **106** to make a certain operation, resulting in the termination of processing at the data processing unit **104**, data being fed out therefrom to the succeeding data converter **107**.

On the contrary, when additional processing is necessary, the operator observes carefully the displayed image or images on the unit **102** and adjudges whether the picture image data, or character data or barcode data should be processed. If the picture image data should be processed, such an operation is made for selecting the proper mass of trimming or layout within the menu range of position-data input means **103**. By the execution of this operation, functions and operations at steps **S105** and **S106** can be executed at one stroke. If trimming is taken as an example, the next step is executed in such a way that position data are fed from the position input means **103** to the data-processer **104** with the use of a carsor. When a tablet digitizer is used as the position data input means, the carsor image displayed in an overlapped manner on the displayed picture image appearing at the display unit **102** by carsor manipulation is positionally specified beforehand in registration with the specified position on the card, for determining the trimming range. Then the operation is carried out in such a way that the picture image data outside the specified trimming range are canceled. By completing these operations, data processing operations relating to step **107** are executed, and, then, the mass for completion of the menu range is selected out. By these measures, steps progress through **S109** to **S102**, and data storing is executed, and further, display representation is brought about through step **S103**. If there is no need for additional processing, an operation termination manipulation is carried out as before at key board **106**, and further operations will be made through data converter **107**.

As for the layout, the operation is carried out with the position data input means **103**, similarly as in the foregoing trimming operation. More specifically, layout is selected out in the menu range of position data input means **103**, and the overall configuration of the card and the display position of picture image are shown at display unit **102**. Then, image inclination correcting operation and the like are carried out so as to realize correspondence thereof with the displayed positional information, the processing operations relating to step **S108** thereby being brought about. After completion of these operations, the mass for the ending in the menu range is selected.

In this way, when selection is made from the menu range by reliance on the position data input means **103**, trimming or layout operation can be brought about. At this stage, when manual operation is carried out at the key board **106**, introduction of character data is executed (**S110**). As the character data in this sense, in the case of ID card, as an example, the name and/or birthday, month and year of the owner may be used. The data introduced from the key board **106** in accordance with the output character style from the font generator **109** are shown at the display unit **102** in the specified positions on the displaying surface and respectively arranged in accordance with display items. The operator acknowledges these items and detailed displays of the represented images. When he acknowledges them as being true, he will operate the key board **106** for showing the operation ending (**S111**).

Upon ending the operations as described above, the data are stored in memory **105** (**S102**) and represented at the display **102**. The operator will acknowledge again this fact, and upon the execution of this, the operations are terminated.

As for the barcode introduction, the data are subjected to inputing at steps **S112** and **S113**, as in a manner similar to the character data introduction as set forth above. The barcodes and the like data may be introduced separately through printing or other mechanical method.

In FIG. **3**A, a data processing circuitry usable in the sublimation image transfer printing method is shown only schematically. As shown, the circuitry **107** comprises a picture element density converter **3**; a color corrector **4**; a gradation corrector **10**; a memory **11**; a switch **12**; a buffer **13** and parallel/series converter **14**. The picture element density converter **3** is connected to a picture image input unit **100**.

The unit **100** serves for generation of three primary color data of R.G.B.- or Y.M.C.-mode from original picture images and is connected through the picture element density converter **3** to the color corrector **4**. The converter **3** converts the picture element density of the image data fed from the unit **100** to the desired one, by subtracting or supplementing, as the case may be, image data for each color element. It should be mentioned that for attaining high quality hard copies, conversion of the picture element density to at least 10 lines/ma or so is preferable.

Color corrector **4** consists preferably of a color decoder, level adjuster or color converter, and serves to correct three primary color data converted to those of a predetermined density of picture elements in consideration of characteristics of the image transfer ink in the image transfer sheet and in addition to provide black color data.

The data processing circuitry **107** is connected through a driver **108** to the sublimation image transfer printer.

In FIG. **4**, an example of the color corrector **4** is shown schematically in structure. As shown, it comprises adders **6**Y; **6**M and **6**C, a black color data calculator **7**, and primary and secondary color correction circuits **8** and **9**. Primary color correction circuit **8** serves for making correction of turbidity of the image transfer ink, while secondary color correction circuit **9** provides a capability of arbitrary and selective correction control relative to specifically selected color hue.

The gradation corrector **10** is so arranged as to make correction of the gradation of the data for each color Y, M, C or K (representing black color) fed from the foregoing color corrector **4** when necessary. For this purpose, the corrector **10** includes a gradation circuit (not shown) and the like, whereby a certain mode of highlight stressing or shadow stressing is introduced and realized.

The memory **11** functions to preserve temporarily the data of each color delivered from the gradation corrector **10**, a selection switch **12** being provided at the output side of the memory for selective writing-in of the data of each color to the buffer **13**. The buffer **13** is capable of writing-in the data of one line of the image transfer head **16** and kept in connection with the parallel/series converter **14** adapted for converting parallel data into series data. Additionally, in the simplified machine, black color data series is dispensed with in some instances.

In FIG. **5**, a schematic construction of the parallel/series converter **14** is shown. As shown, parallel data delivered from the buffer **13** are fed to an input side of a comparator **22**, while outputs from a counter **23** are fed to another input side of the comparator **22** which delivers the converted series data to the driver **15** for driving a thermal head **121**.

If necessary, however, the comparator **22** may be replaced by a converter table, not shown, utilizing a parallel/series converting ROM.

In FIG. **6**, a detailed circuit schema of the thermal head **121** is shown. As shown, series data delivered from the comparator **22** are fed into a shift register SR and thence, after being subjected to latching at a latch circuit LT, fed to thermal elements HE through NAND gates NA which are fed at respective one side inlets with strobe signals.

Next, referring to FIG. **3**A, the operation of the data processing circuitry **107** will be described more specifically.

First, when three primary color image data are fed from the picture image inlet circuit **100** to the picture element density converter **3**, the latter converts these three primary color data to those which represent a predetermined picture element density and then are fed to the color correction unit **4**. In this case, it is assumed that the unit **4** is fed with three primary color data expressed in respective concentration signals, which are of yellow: **Y0**; of magenta: **M0** and of cyan: **C0**, respectively, in the present example.

These data: **Y0**; **M0** and **C0** are, as shown in FIG. **4**, fed through respective adders **6**Y; **6**M and **6**C to the black color data calculator **7**, to provide a K-output as expressed mathematically by the following formula:

$$K=\min(Y, M, C)$$

wherein, "min" represents a function which provides a possible minimum value.

These data: **Y0**, **M0** and **C0** are fed from the converter **3** to the primary color correction circuit **8** to provide primarily corrected data **Y1**, **M1** and **C1** which are thence fed to the secondary color correction circuit **9** to provide, through calculation, secondarily corrected data: **Y2**, **M2** and **C2**, respectively. These are then fed to respective adders **6**Y, **6**M and **6**C, which add them to respective data **Y0**, **M0** and **C0**, to provide respectively added output data Y, M, and C to be fed to the gradation correcter circuit **10**, respectively, after being utilized for calculation of the K-output signal value.

The primary color correction circuit **8** serves to calculate primarily corrected data: **Y1**, **M1** and **C1** which are necessarily utilized for correct-out of transfer ink turbit. In this case, the original data: **Y0**, **M0** and **C0** are subjected to matrix calculation to provide the primarily corrected data **Y1**, **M1** and **C1**, as folows:

$$Y1=k_{11}\cdot C0-k_{12}\cdot M0+ti\ k_{13}\cdot Y0$$

$$M1=k_{21}\cdot C0+k_{22}\cdot M0-k_{23}\cdot Y0$$

$$C1=k_{31}\cdot C0+k_{32}\cdot M0-k_{33}\cdot Y0$$

where, k_{ij} represents weight coefficients;

i=1–3;

and

j=1–3.

The secondary color correction circuit **9** serves to calculate secondary color correction data **Y2**, **M2** and **C2** from primary color correction data **Y1**, **M1** and **C1** by modifying the latter to make certain thereto by performing matrix calculations so as to provide a capability for making an arbitral and selective color control at a certain specifically selected-out color hue, in the following manner:

$$Y2=Y1+l_{11}\cdot\Delta B+l_{12}\cdot\Delta C+l_{13}\cdot\ \cdot\Delta G+l_{14}\cdot\Delta Y+l_{15}\cdot\Delta R+l_{16}\cdot\Delta M$$

$$M2=M1+l_{21}\cdot\Delta B+l_{22}\cdot\Delta C+l_{23}\cdot\Delta G+l_{24}\cdot\Delta Y+l_{25}\cdot\Delta R+l_{26}\cdot\Delta M,$$

and

$$C2=C1+l_{31}\cdot\Delta B+l_{32}\cdot\Delta C+l_{33}\cdot$$

$$\Delta G+l_{34}\cdot\Delta Y+l_{35}\cdot\Delta R+l_{36}\cdot\Delta M$$

wherein, l_{ij} represents weight coefficients:

i=1–3;

j=1–6;

ΔB, ΔC, ΔG, ΔY, ΔR, ΔM:
characterizing color data.

Thus, when these-secondary correction data **Y2**, **M2** and **C2** are added to the corresponding original data **Y0**, **M0** and **C0** by means of respective adders **6Y**, **6M** and **6C** and under proper selection of weight coefficients k_{ij} for primary color correction circuit **8**, any color discrepancy of the ideal color of the ink appearing on the printed picture images under the action of the sublimation transfer printer can be arbitrarily ammended. In this case, when the weight coefficients l_{ij} for the secondary correction circuit **9** are selected out properly, the color tone of the printing picture images can be modified to an arbitrary degree.

Further, as for the black color data K, correction data **K2** can be calculated by the following formula. With use of these correction data **K2**, which are added to the original black color data K, the desired correction can be executed in a similar manner.

$$K2=K+m1\cdot\Delta B+m2\cdot\Delta C+m3\cdot\Delta G+m4\cdot$$

$$\Delta Y+m5\cdot\Delta R30\ m6\cdot\Delta M$$

wherein, Mi represents weight coefficients:

i=1–6.

In this way, output data: Y, M, C and K delivered from the color correction circuit **4** are introduced into the gradation corrector **10** as inputs thereof, and each constituent of these data can be subjected to correction as desired.

FIG. **7** shows several characteristic curves illustrating corrections by means of the gradation corrector **10**. More specifically, f**0** represents a standard characteristic curve; f**1** a highlight-stressing operation curve; f**2** a shadow-stressing operation curve; f**3** a highlight-and-shadow stressing operation curve; and f**4** a medium tone stressing operation curve.

As indicated in FIG. **7**, by presetting, as necessary, the tone-reproducing characteristics, which determine the relationship between that concentration of color data and that of the prints printed by means of a sublimation image transferring printer, a color tone similar to that possessed by the original image can be reproduced. More specifically, when no correction is adopted, the curve f**0** is used, while in the case of correction, any selected one of these curves f**1** to f**4** may be utilized depending upon the part of gradation to be stressed. Further, it should be noted that the tone reproducing characteristic curves are not exclusively limited to those which have been specifically shown and described above. As an example, the control of gradation correction by color tone reproducing characteristic mentioned above is executed by a gradation circuit, not shown, and the setting of the color tone reproducing characteristic is brought about by manipulation of any selected one of the control knobs, not shown, which are provided separately for "highlight"; "medium tone" and "shadow".

Y.M.C.K.-data subjected to correction by the gradation corrector **10** are once stored in the memory unit **11**. The thus stored data may be read out from the memory for each color by manipulation of the selection switch **12** and, after provisional storing, per one line of transfer head **16**, at the buffer **13**, introduced into the parallel/series converter **14** for conversion thereby into corresponding series data.

Another example of the data processing circuit for the sublimation transfer printer is shown only schematically in FIG. **3**B. As shown, the processing circuit in **107'** comprises a level regulator **503**; a color converter **504**; an A/D converter **505** and a parallel/series converter **14**.

As the image data introduced into the processing circuit **107'**, those which have been subjected to conversion into R.G.B.-signals in the color decoder **502** from composite video signals delivered from a T.V. camera, VTR or the like are used. On the other hand, R.G.B.-signals delivered from a personal computer, captain system or the like means are introduced as input into the level adjuster **503**.

As the color correction method with the use of the foregoing arrangements, it is possible, more specifically, to adjust the hue saturation and/or brightness in the color decoder **502**, or to adjust the signal level of each color light of R.G.B.-system in the level regulator **503**.

As an example, the color conversion from R.G.B.- to Y.M.C.-system can be executed in the color converter **504**. The simplest possible method in this color conversion is to procure the opposite color to each of the normal colors.

The thus produced color signals of Y.M.C.-system issubjected to A/D conversion and then fed successively through the parallel/series converter **14** and the driver **108** to the thermal head, not shown, to carry out printing in the sublimation transfer principle.

Additionally, in normal cases, with the use of the foregoing system composition, input image data must be of static mode. However, by provision of memory means in front of the color decoder or at an intermediate position between the A/D converter and parallel/series converter, animating images can be processed.

The series data converted in the foregoing manner in the data converter **107** or **107'** are fed to the shift register SR

shown in FIG. **6** by n-image elements and then, upon being subjected to latching in the latch circuit LT are further delivered to NAND gate NA as its inputs. When a strobe signal ST is fed as input to the NAND gate NA, the foregoing n-image element data is fed to the thermal element HE.

FIG. **8** is a schematic diagram, showing signals for respective image elements. The gradation has been so selected that the first image element is at the highest gradation level, while the n-th image element corresponds to the lowest gradation level, and that the second to (n−1)th image elements vary linearly in gradation levels, so as to provide representatively a better understandable example of the invention.

Next, the operation of the parallel/series converter **14** will be described.

First, as shown in FIG. **5**, image elements data A, consisting of parallel data, more specifically, comprising parallel eight bit data A**0**–A**7**, are fed to one-side inputs of comparator **22**, while another side inputs thereof are fed with outputs B, comprising eight bit increment outputs B**0**–B**7**, of counter **23**. The counter **23** counts clock signals in increments, the outputs B**0**–B**7** being successively varied.

The comparator **22** performs comparison between the two inputs A and B, so as to deliver successively outputs of binary "1" until the increment output B is brought into coincidence with image elements data A, or more specifically, under the condition of A>B and A=B, while, thereafter, binary "0"-outputs are delivered therefrom. More specifically, comparator **22** will continue to deliver binary "1" until an increment value which corresponds to the weight of concentration of image element data A is given thereto. As an example, if the image element data A has a concentration of gradation **128** of a total **256**, output "1" will be repeated to deliver 128 times first and then, output "0" will follow after again 128 times, so as to provide in total a specific series data peculiarly in this case.

These series data are taken out from the comparator **22** in the form of A>B- and A≧B-outputs and of A=B- outputs through an attributed OR-gate **24**, and in the present example, the gradation consists of 256 steps or increments. However, in practice, the gradation may represent a smaller number of steps. As an example, if the incrementing bit is B**1** instead of hitherto employed B**0**, the gradation will have 128 steps; and if B**2** is employed, it will have only 64 steps. In this way, the gradation setting may be varied in a simple manner.

When in the foregoing way, the output B from the counter **23** is stepwise incremented, such series data consisting of a first series of "1" will be delivered until the relationship between the image elements data A and the output B from counter **23** becomes A=B, and of a second series of "0" issued thereafter, as shown in FIG. **8**.

In FIG. **9**, a conversion mode at the parallel/series converter **14**, which, however, is different from that shown in FIG. **8**, as an example, is shown again in the form of a matrix. As shown, when the image data are of 8-bit parallel kind, as an example, the gradation data are ranged from 0 to 255, providing, therefore, binary series data from "00 . . . 00" to "11 . . . 11".

In this way, the data, per line in the transfer head **16**, kept preserved in the buffer **13** are fed to the parallel/series converter **14** for providing as outputs therefrom into corresponding series data which are then delivered through the driver **15** to the transfer head **16** and thus recorded on a print paper P supported on the transfer drum **17**.

FIG. **10** represents a flow chart illustrating the operation of the sublimate printer as employed in the present invention.

At the first step **S1**, print papers are set in position and the printing ribbon is also set in position ready for performing the required procedure.

At the second step **S2**, printing operation is initiated, and line printings are executed, line by line, accompanying necessary intermittent line shifts, with relation to any selected one of four colors: C (cyan); M (magenta); Y (yellow) and K (black) being carried out. Refer to **S3** and **S4**. When line printings with the selected-out single color have been completed (**S5**), the image transfer sheet is replaced by another color sheet (**S6**) and so on. In this way, line printings are completed in all four colors. In this case, it is naturally most preferable to use a long extended single transfer sheet on which four color ink regions are repeatedly printed in a certain predetermined pattern. The image reception paper is initiated to make print from a certain prescribed position for each of these colors (**S8**). When all of the printing steps have been completed with the four colors, the paper is discharged from position (**S9**) and the printing operation is terminated to be repeated.

In FIG. **11**, a card style sample of the final products according to this invention is shown in front view at **200**. FIG. **12** is a sectional view thereof. Numeral **201** represents the substrate material of the card; **202** a display layer; **203** a surface protecting layer; and **204** a display image as an example. Depending upon the kind of usage and when necessary, the protecting layer **203** may be dispensed with. It should be noted that the display image **204** on the display layer **202** is represented by a sublimative dyestuff, as a characterizing feature of the present invention.

As the main and substantial material of the image transfer sheet, various plain papers, converted papers, plastic resin sheets or the like may be used per se or in combination. When a plastic resin sheet which can be colored directly with a sublimative dye or dyes is used, these image transfer substrates (articles or objects) as at **201** can be united each with the display layer **202**. Each of these substrate materials, when it is of the card style, may have generally such dimensions; thickness of 0.68 to 0.80 mm and size; 11 to 8×8 to 5 cm.

As the material of the display layer **202**, various known materials which may be colored with sublimative dyestuffs, such as polyethylene, polypropylene, polyester, ABS, AS, polyvinylchloride, polyvinyl/vinyl acetate copolymer, polystyrene, polyacrylate, polyester, polyamide, polyurethane and the like plastic material, may be advantageously utilized. As will be more specifically described hereinafter, this material layer can be united with the substrate material layer **201**. In the case of such unified structure with substrate layer **201**, the thickness and size dimensions may be substantially as the same as before. However, when normal and/or converted papers or metals, which are practically impossible to color with sublimative dyestuffs, are used as the substrate layer **201**, various methods can be utilized for desired coloring. As an example, a solution including at least any selected one of plastic resin materials capable of coloring with sublimative dyestuffs may be coated on the substrate surface, or alternatively used in the form of a film which is laminated thereon. This kind of film preferably has a thickness of about 3 to 50 μm or so. One of main characterizing features represented in and by the final products **200** is that the appearing display image or images as at **204** is/are formed at least partially or wholly with a sublimative dyestuff or dyestuffs. Additionally, the process for formation of such images can be executed in the conventional art.

As an example, the processing method may be executed conventionally as follows.

As an example, a sublimative image transferable sheet, such as a paper sheet, plastic resin film or sheet capable of acting as the carrier is coated on its surface with any suitable binder resin carrier carrying sublimative a dyestuff or dyestuffs under heat, is overlapped on the display layer **202** and then subjected to heat from behind the heat-transferable sheet, preferably in the pattern mode, so as to transfer the dyestuff or dyestuffs into the display layer **202**. It is proper to select the molecular weight of 250 or larger of the dyestuff, for improving the fastness thereof. However, a molecular weight higher than 370 is more favorable. In the case of provision of the surface protecting layer, there is practically no limitation to the selectability of the dyestuff molecular weight.

The sublimative image transfer may be executed directly on the surface of substrate **201** provided with the display layer **202**. Or alternatively, a carrying, image transferable sheet is prepared separately and, after formation of the image **204** thereon, may be stuck onto or laminated on the substrate **201**.

Image-Carrying and Image-Transferable Sheet

In the following, structure, material, usage and application purpose of the image-transferable sheet to be employed in the present invention will be described in detail:

FIG. **13** illustrates only basically and in schematic sectional view the image-transferable sheet adopted in the present invention, while FIGS. **14** through **19** and **22** through **24** illustrate preferable embodiments thereof.

The basic structure of the image transferable sheet **310** is characterized in that, as shown in FIG. **13**, a sheet-like substrate **301** is provided at its one surface with an image-reception layer **302** capable of peel-off from the substrate. By adopting such a structural configuration of the image-transferable sheet, the image-reception layer **302** can be formed with the required image or images with the use of an image transferable sheet having thermally shiftable dyestuff, and then, the image-formed, image-reception layer **302** is peeled off from substrate **301** and attached firmly, preferably as by sticking, on the surface of any selected object or article with use of any suitable means. In this way, various conventional drawbacks inherent in the comparative conventional technique can be basically overcome.

More specifically, as the material of the aforementioned image-reception layer **302**, limitation must be imposed to those which can be colored with thermally shiftable or transferable dyestuff. However, upon formation of necessary images and upon peel-off from the sheet-like substrate **301**, the image-reception layer **302** may be attached fixedly onto the surface of glass-made, metal-made or wooden-made products or plastic-resin made ones which are very difficult to color with thermally shiftable and transferable dyestuffs, indeed, by reliance on conventional sticking techniques as properly adopted in consideration of the specific nature and kind of the material of decorative products to be ornamented. Further, the image-formed and peeled-off, image-reception layer **302** from the sheet substrate **301**, is highly thin and thus sufficiently pliable so that it may be applied even onto any uneven and complicated surface of a product to be decorated or ornamented, having undulations, convexities, concavities, recesses and projections. Therefore, a maximum possible better fitness of the image-reception layer to be ornamented is attained and guaranteed by the present invention. Thus, practically no limitation in the attaching use thereof may be encountered. Further, in sharp contrast to conventional sealing seals and the like, the very thin image-reception layer bearing necessary images can be applied easily to the product per se in a very uniform manner, thus providing no raised and thickened feeling, and giving rise to no foreign feeling upon attachment.

FIG. **14** shows a further example of the image transferable sheet **310**. In this case, there is provided a parting agent layer **303** on the surface of image-reception layer **302**. Between the latter and the sheet substrate **301**, there is provided a parting agent layer **303'**. If necessary, however, any one of the two layers **303**; **303'** may be dispensed with.

The first parting agent layer **303** is provided for prevention of thermal fusion between the image-reception layer **302** and an image transferable sheet, not shown, as may occur during image transfer and formation on the first layer **302** through transfer of thermally transferable dyestuff from the said transferable sheet to the first layer. If there is no risk of such thermal fusion of the above nature, or when the image-transferable sheet has been already provided with such a parting agent layer, the present provision thereof may be unnecessary. As for another parting agent layer **303'**, it is for the purpose of making the latter peel-off operation, to be executed after image-forming step, easier. When the sheet-like substrate **301** is made of polyester or the like material which has, as it is, sufficient separability from image-reception layer **302**, provision of parting agent layer may naturally bedispensed with.

FIG. **15** illustrates a still further example of image transferable sheet **310**. In this case, between the image-reception **302** and the sheet-like substrate **301**, an intermediate layer **304** and/or parting agent layer **303'** is/are provided. The laminating order is optional and thus not binding. The intermediate layer **304** will serve to assist the image formation to be rather firm and beautiful, the image formation being carried out by transferring the thermally shifting and transferring dyestuff from the image transferable sheet to the image-reception layer **302**. For this purpose, the intermediate layer **304** may take, for example, the form of a cushioning layer or heat insulating layer. When a cushioning layer is provided as the intermediate layer **304**, the cohesion between the image transferable sheet and the image reception layer **302** is greatly improved and the thermal shift and transfer of the dyestuff during image formation with the use of a thermal head is evenly executed, the image formation thereby being carried out amply in correspondence with the supplied image signals. Further, when a heat insulating layer consisting of a highly heat-insulative material is used as the intermediate layer **304**, ineffective release of the heat applied during'shift and transfer of the dyestuff from the image transferable sheet to the image-reception layer **302** can be reduced to a minimum possible, the effective thermal efficiency thereby being correspondingly improved and ample image formation being accelerated. If necessary, however, these cushioning layer-and heat-oinsulating layer can be prepared independently and arranged concurrently in any arranging order.

Additionally, when the intermediate layer **304** is arranged at a higher level than the parting agent layer **303'**, the intermediate layer **304** will be conjointedly peeled off in the case of peel-off of the image-reception layer **302**. On the contrary, when the intermediate layer **304** is arranged at a-lower level than the parting agent layer **303'**, the intermediate layer will remain on the sheet-like substrate **301** after execution of the separation of image-reception layer **302**. In this case, therefore, the intermediate layer **304** may be made preferably and at least substantially transparent, when the peeled-off image-reception layer **302** is stuck on a decorative product, while directing the surface of parting agent layer **303** towards the latter.

In the modifications shown in FIGS. **16**, **17**, and **18**, modified from the foregoing embodiment shown in FIG. **15**,

a further protecting layer **305** is provided between the image-reception layer **302** and the sheet-like substrate **301**. This protecting layer **305** serves to prevent deterioration of the formed images in the image-reception layer **302** when the latter is stuck on the decorating product while directing the surface (more specifically the image-formed surface) towards the product. For example, this protecting layer **305** is prepared from a superior material which exhibits at least one of desirous properties such as antiwearing, light-fast, weather proofing and anti-chemical qualities. With the use of the protecting layer **305** having these superior qualities, the images can represent improved fastness in the above various aspects, even after execution of the foregoing sticking procedure.

In the modification shown in FIG. **16**, the protecting layer **305** is arranged between the intermediate layer **304** and the parting agent layer **303'**.

In the further modification shown in FIG. **17**, the protecting layer **305** is arranged between the image-reception layer **302** and the parting agent layer **303'**.

In still another modification shown in FIG. **18**, the intermediate layer **304** takes the role of the protecting layer **305**.

In each of these modifications, the protecting layer **305** is arranged in neighboring relationship with the partition agent layer **303'**, whereby the image-formed and remotely arranged, image-reception layer **302**, kept in its up-and-down reversed state, is capable of adhering securely to the decorative product, so as to be positioned as an uppermost layer, as may be required. In a still further modification shown in FIG. **19**, derived from that shown in FIG. **14**, a sticking layer **306** is further provided between the image-reception layer **302** and the partition agent layer **303**. It should be noted, however, that such a sticking layer as at **306** may beprovided in any one of other foregoing examples and modifications, if necessary, in neighboring relationship with the parting agent layer **303'**.

The provision of such a sticking layer as at **306** is highly valuable when the image-formed and peeled-off, image-reception layer is adhering without position reversal onto the decorative product. With this arrangement mode, the protecting layer **305** shown in FIGS. **16**, **17**, and **18** may be dispensed with. If, however, the protecting layer **305** is composed of a material in the form of a sheet-like substrate, the part to be peeled off is thereby strengthed, the peel-off procedure thus being greatly facilitated.

By previous provision of the sticking layer **306**, the image-formed and peeled-off, image-reception sheet **302** can be caused to adhere as it is onto the decorative product without use of a separate sticking agent. As the sticking layer **306**, an ordinary sticking agent which is active at room temperature can be used. Or alternatively, a heat-sensible or light-sensitive sticking agent may be used, if necessary.

In the foregoing, the main structure of the image transferable sheet employed in the present invention has been described in detail. However, other structural modes than those set forth hereinbefore which occur easily to those skilled in the art may be employable in the invention, and thus they may be included within the scope of the invention without departing from the appended claims.

It should be further noted that, in the present invention, the sheet-like substrate may be provided on its one surface with an image-transferable layer capable of peeling off through the intermediary of only one weakly sticking layer.

FIG. **22** shows only schematically in a sectional view a preferred embodiment of such an image-transferable go sheet, denoted with same reference numeral **310**.

As shown in FIG. **22**, the image-transferable sheet **310** represents a basic structural characteristic such that any suitable sheet-like substrate **301** is provided on one of the surfaces with an image-reception layer **302** through an only weakly sticking intermediate layer **402**, the layer **302** thus being easily peeled-off when desired. By providing the image-transferable sheet with such a structural characteristic as set forth above, desired positive or negative images are formed by transferring thermally shiftable and transferable dyestuff from the image heat transferable sheet to the image-reception layer **302**, and the thus image-formed layer is peeled off from the sheet-like substrate **301** and then attached onto any suitably selected product with the use of proper means or attached per se thereon without the peeling-off operation, the substrate then being peeled off, whereby an image-formed final product can be obtained.

In the foregoing example, it should be noted that the image reception sheet **302** per se has only a thin thickness and thus represents only poor feedability during the sheet-feeding period within the printer at the time of image formation, insufficient cushioning effect and only insufficient thermal efficiency during the printing operation, and further, it is very difficult to treat in advance of as well as after execution of the image formation. Therefore, the coexistence of the image-reception layer **302** and the sheet-like substrate **301** is absolutely necessary. In addition, it is a requisite requirement that the image reception layer **302** be easily peeled off from the sheet-like substrate **301** upon execution of the image-forming operation, and thus, the layer **302** and the sheet **301** should not be stuck too strongly together. In order to satisfy this requirement, provision is made of weakly stuck layer **402** therebetween. Thus, it should be noted that the term "weakly stuck" employed in this specification and appended claims may be defined as "to be separable by finger's end and the like means from each other without entailing destruction or breakage of the parts originally stuck together". It is worthwhile to say, in considering the relative relationship between the image-reception layer **302** and the sheet-like substrate **301**, there is no necessity to provide the weakly-stuck layer **402** if the aforementioned peeling-off is very easy to bring about.

FIG. **23** illustrates still another modification of the image-transferable sheet **310** denoted by the same reference numeral **310** only for simplicity and convenience, wherein a further parting agent layer **303** is provided on the surface of image-reception layer **302**.

This layer **302** is provided for occasional thermal sticking between the thermal image transferable sheet, not shown, and the image reception layer **302** in the progress of thermal shift and transfer of the dyestuff from the sheet to the layer **302**. This provision of the parting agent layer **303** may be dispensed with if there is no risk of occurrence of such disadvantageous sticking attachment or the sheet under consideration has already been fitted with such a parting agent layer.

A modification shown in FIG. **24** from that shown in FIG. **23** has such a modified structure that a protecting layer **305** is provided between the image-reception layer **302** and the weakly stuck layer **305**. This layer **305** serves to prevent otherwise occurring deterioration of the images at the image-reception layer **302** which has been formed with preferably reversed images and subjected to peeling-off, together with protecting layer **305**, preferably a plastic sheet layer, from the sheet-like substrate **301** and finally stuck onto the decorative product, while directing the image-formed surface of the image-reception layer towards the product. The protecting layer **305** is made of a material having various excellent physical properties, such as anti-wearing-, light-fastness and antichemical characteristics. Provision of

such a protecting layer improves various fastness performances of the formed images after sticking attachment of the image-reception layer **302**.

When necessary, a separate parting agent layer, not shown, may be provided between the protecting layer **305** and the weakly stuck layer **402** for providing easy peel-off capability between these two layers **305** and **402**, as being applicable to the example shown in FIG. **24**. If the surface of the protecting layer **305** should have sufficient peel-off capability, it is natural to provide such an intermediate parting agent layer as above.

Further, in the case of the image-transferable sheet **310**, it is naturally easy to separate from each other through a peel-off operation, upon the formation of necessary images thereon and before practical use thereof as the image-transfer sheet, and a cut-out slit as at **407** in the sheet-like substrate **301** may be provided forattaining such an easy separation as stated above at a portion of the sheet **310** in proximity to one end thereof. Upon the provision of such a cut-out slit as at **407**, the thus formed flap-like portion can be easily folded out by the operator's finger-tip, thereby affording convenience in a peel-off operation.

The usable materials and composing methods of the foregoing image transferable sheets will now be described.

As a material usable for the sheet-like substrate may be any one or any combination of the following categories;

(1) synthetic paper (polyolefin-series; polystyrene series and the like);

(2) fine quality paper; art paper; coated paper; cast-coated paper, wall paper, back-up paper; backing paper; resin-, emulsion- or synthetic rubber-imprignated paper; resin-admixed paper; paper board; cellulose fiber paper;

(3) polyolefin-, polyvinyl chloride-, polyethylene terephthalate; polystyrene; polymethacrylate; polycarbonate and the like plastic film or sheet.

Use of the synthetic paper belonging to the foregoing category (1) is highly suitable for the purpose of the present invention since the surface thereof generally represents a microvoid layer which provides a low heat conductivity and thus a high heat-insulating peformance. A laminated material representing any combination of the foregoing categories (1), (2) and (3) can be used in the present invention. A representative and recommendable example of such a laminate is that of cellulose fiber paper and synthetic paper or that of cellulose fiber paper and plastic resin film or sheet. Among others, use of the first mentioned kind of laminate will provide an advantage in that the thermal instability such as thermal elongation or shrinkage possessed by the synthetic paper component is compensated for by the cellulose fiber paper, whereby a high thermal sensibility is demonstrated during the printing step due to low thermal conductivity of the synthetic paper component. Further, in the case of the present paper combination, however, a further modified combination of a three-layer laminate: synthetic paper-cellulose fiber paper-synthetic paper may be more advantageously employed for making the frequently appearing lesser by providing a well-balanced structure between both the surfaces of the final laminate.

As the synthetic paper mentioned above, any suitable one usable as a synthetic paper substrate used as a component of the image-transferable sheet layer may be used. As a recommendable example thereof, having a fine porous fine paper structure layer, the synthetic paper called "YUPO", manufactured and sold by Oji Yuka Goseishi Kabushiki Kaishal Tokyo, may be mentioned. This paper layer having a fine pore structure may be prepared in such a way that a suitable plastic resin material containing a filler of finely divided state is subjected to a mechanical elongation step. When the image-transferable sheet composed of the synthetic paper sheet containing finely divided air as above mentioned is formed with images through a thermal image transfer setp, the concentration of the thus formed images is surprisingly high and no fluctuation of image configuration and concentration is encountered, thanks to the heat insulation effect provided by the very existence of fine air pores, in addition to the improved thermal energy efficiency. Especially, due to the advantageous cushioning effect provided by the air-filled fine pores, the image-receiving layer is supposed to be rather advantageously affected during the image formation step. As an alternative measure, the paper-like layer containing the above-mentioned fine air pores may be, if desired, provided directly with the core material consisting of the cellulose fiber paper or the like.

It is further possible to use plastic film in addition to the cellulose fiber paper in the laminate described above. Still further, a laminate of said cellulose fiber paper and plastic film composed together can be used.

As the method for co-sticking of synthetic paper and cellulose fiber paper, use of a known adhesive agent is naturally adopted, as an example. Or alternatively, the extrusion-laminating, heat-adhesion, or the like process may be relied upon, as the case may be. On the other hand, as the sticking-process between the synthetic paper and the plastic film, the lamination process to be carried out simultaneously with the formation of the film may be adopted. Calendering or the like method may be utilized for the same purpose. Selection of any suitable one of the several foregoing sticking processes depends upon the kind of material or the like condition of the partner member to be stuck together with the synthetic paper. As for the adhesive agent mentioned above, emulsion adhesive such as ethylene-vinyl acetate copolymer, polyvinyl acetate or the like, aqueous solution type adhesive polyester containing carboxyl radicals; or the like may be mentioned. On the other hand, as the laminating use adhesive, organic solvent solution type one such as polyurethane-, acrylic- or the like, may be mentioned.

The material for the image-reception layer must be suitable for reception of heat-transfer dyestuff, such as sublimative disperse dye from the image transfer sheet and holding and maintaining the thus formed images thereon. From the view point of image-holding and blocking prevention, use of such synthetic resin as having glass transition temperature higher than 40° C. may be advantageous. For example, the synthetic resins set forth in the following items (a) through (e) may be used separately or in combination.

(a) Ester bond-bearing resins: Polyester resin; polyacrylic ester resin; polycarbonate resin; polyvinyl acetate resin; styrene acrylate resin; vinyltoluene acrylate resin and the like.

(b) Urethane bond-bearing resins; Polyurethane resin and the like.

(c) Amide-bond carrying resins: Polyamide resins (nylons).

(d) Urea-bond carrying resins: Urea resins and the like.

(e) Other high polar-bond carrying substances:

Polycaprolacton resin; polystyrene resin; polyvinylchloride resin; polyacrylonitrile resin and the like.

The image-reception layer may be prepared from a resin mixture of saturated polyester and vinylchloridevinyl acetate copolymer. As the saturated polyester, such commercialized products: "Vylon 200"; "Vylon 290"; "Vylon 600";

"Vylon 103" and the like, manufactured and sold by Toyoboseki K.K., Osaka, Japan; "KA-1038C" (manufactured and sold by Arakawa Kagaku K.K., Osaka, Japan; "TP 220"; "TP 235", manufactured and sold by Nippon Gosei K.K., Osaka, Japan; may be advantageously used. The vinyl chloride-vinyl acetate copolymer may have preferably 85–97 wt. % of vinyl chloride component, the polymerization degree being between about 200 and 800. The vinyl chloride-vinyl acetate copolymer may further contain a vinyl alcohol component, maleic acid component within the purpose of the invention in addition to the main components. According to our experiments, it has been found that these modified copolymers should have rather superior compatibility with polyester resin. The image-reception layer may be, if necessary, composed of polystyrene resin, for example, in this case, styrene monomer, preferably styrene, α-methyl styrene, and vinyl toluene may be used separately or in the form of copolymer or saying in general sense polystyrene resin. Further, such styrene copolymer resin may be used as specifically recommendable material in the above sense, comprising said styrene monomer(s) with other monomer, preferably for example, acrylic acid ester, methacrylic acid ester, acrylonitrile, methacrylonitrile and the acrylic or methacrylic monomer, or further styrene copolymer resin comprising maleic acid anhydride.

It should be noted, however, that among others, polyester series resin is especially superior for the purpose of the present invention.

In any of the foregoing embodiments, however, white pigment is preferably admixed with the material of the image-reception layer for improving the whiteness thereof and further accentuating the sharpness and fineness of the images when transferred thereto and to provide a manually writing-on performance. As the white pigment for this purpose, the following materials may be used separately or in any combination: titanium oxide; zinc oxide; china clay calcium carbonate; finely divided silica and the like.

For further improving the whiteness fluorescent whiteness-increasing agent or -bleaching agent may be added to. Further, for improving the light fastness of transferred images, ultraviolet absorption agent and/or photostabilizing agent may be added to, preferably in a quantity of 0.05 to 10 and 0.5 to 3 weight parts per 100 weight parts of the material resin composing the image-reception layer.

The image-transferable sheet used in the present invention is preferably constituted for improving the separability from the image-transfer sheet in such a way that the surface of the image-reception layer is formed with a partition agent layer, or instead, such agent is admixed to the image-reception layer. As for the partition agent to be used for this purpose, polyethylene wax; Amido Wax, Teflon Powder or the like solid wax; surface active agents such as fluorine-contained agent or phosphoric acid ester series surfactant; silicone oil or the like may be selectively used. Among others, silicone oil may be advantageously utilized.

The silicone oil may be used in oily state, but a hardenable type thereof may be rather advantageous. As the hardenable silicone oil, reaction-hardening one, photo-hardening one, catalytically hardening or the like one may be used selectively according to necessity. However, use of the reaction-hardenable one is most highly recommendable. Silicone oil of this type may be obtained, as example, by reacting amino-modified silicone oil with epoxy-modified silicone oil to obtain a reaction-hardened product. As for the amino-modified silicone oil, "KF-394", "KP-857", "KF-858"; and "X-22-3680"; "X-22-3801C" (manufactured and sold by Shinetsu Kagaku Kogyo K.K., (Tokyo, Japan)) and equivalents thereof may be used. As for the epoxy-modified silicone oil, "KF-100"; "KF-101"; "KF-60-164"; and "KF-103" (manufactured by Shinetsu, above mentioned) and equivalents thereof may be used. Further, as the catalytically hardenable and photohardenable silicone oils in the above sense, "KS-705F"; "KS-770" of the catalytic hardenable or hardened silicone oils, manufactured by Shinetsu; and "KS-720" and "KS-774" of the photo-hardenable or hardened silicone oils (manufactured equally by Shinetsu) and equivalents thereof may be used. The adding quantity of each of these hardenable or hardened silicone oils may advantageously range from 0.5 to 30 wt. % depending on the material of the resin composing the image-reception layer.

At least a part of the image-reception layer is coated with a solution or dispersion of any of the foregoing partition agents in a suitable solvent and dried and further treated, a suitable parting layer being provided thereon. A particularly suitable partition agent for the formation of this kind of partition layer is the aforementioned reaction type hardenable one obtainable by reacton of an amine-modified silicone oil with an epoxy-modified one. The thickness of the partition layer is 0.01–5 μ, preferably 0.05–2μ.

It should be noted that when silicone oil is admixed during formation of the image-reception layer, the silicone oil will bleed out after coating and the parting agent layer can be formed by the hardening even after such bleeding. In order to improve the parting ability between the image transferable layer and sheet-like substrate, it is possible to provide a parting layer consisting of a heat-hardenable resin, preferably of the melamine series, and having better affinity for the image transferable layer compositions. For the same purpose as above, however, without special provision of the parting layer, a protecting layer consisting of polymethyl methacrylate resin or cellulose acetate propionate can be provided.

For the formation of the image transferable layer, a solution or dispersion of a material composition suitable for the purpose is applied on the sheet-like substrate through conventional coating or printing. As an alternative way, a separate film or sheet for the image transferable layer **302** is formed preparatorily on a provisional carrier sheet or film and then, as a succeeding step, subjected to an image-transfer onto the substrate.

The intermediate layer is made of either a cushioning or a porous material. In some cases, the intermediate layer may additionally function as the adhesive layer.

The cushioning layer is mainly composed of such a resin which has a value of 100%-modulus as defined at JIS-K-6031 (Japanese Industrial Standard) of less than 100 kg/cm^2. If this value should exceed the above prescribed value, the rigidity will become much higher than that recommended for the intermediate layer. When the layer is formed with such disadvantageous material resin, sufficient adhesion between the heat image-transfer sheet and the image-reception layer cannot be maintained during the printing step. The lower limit of the prescribed 100%-modulus is of the order of 0.5 kg/cm^2 in actual practice.

Preferable kinds of resin to be used for the above purpose, may be enlisted as follows:

polyurethane resin; polyester resin; polybutadine resin; polyacrylic acid ester resin; epoxy resin; polyamide resin; rosin-modified phenol resin; terpene phenol resin; ethylene/vinylacetate copolymer resin; and the like.

These resins can be used independently or in combination of two or more kinds. Since these resins are rather viscous and tend to give rise to manufacturing troubles inorganic

additives may be admixed, such as, for example, silica; alumina; clay; calcium carbonate; amide series substance such as amide stearate; and/or the like.

The cushioning layer is preferably formed with the use of one or more of the above specified resins, occasionally with the addition of suitable additive(s); solvent or diluent, prepared into a coating agent or printing ink which is then applied on, according to a known coating or printing process and then subjected to drying to provide a coating. The thickness of the coating should be between 0.5–50 μm, preferably 2–20 μm or so. With a thickness less than 0.5 μm, the coating will not be able to compensate for the surface irregularities on the substrate, thus being ineffective for the desired purpose. On the other hand, when the thickness exceeds the above specified maximum value or more specifically 50 μm, the overall thickness of the image-transferable layer becomes much too large, so that handling troubles may be encountered during wind-up and overlapping procedures, without attaining further effect as desired. In addition, in this case, a loss of production economy will be inevitably introduced.

The thus obtainable improvement of intimate adhesion between the heat-image transfer sheet and the thermally image-transferable sheet by the provision of the above intermediate layer may be conceivably attributed to the lower rigidity of the intermediate layer per se, whereby it is liably to be deformed under the influence of the printing pressure, and further to the generally relatively low glass transition temperature and softening temperature of the aforementioned kinds of resin resulting in further lowering of rigidity and tendency to deform than at room temperatures upon reception of heat energy during the image printing step.

The porous layer may be formed generally in the following four ways: 1) through 4).

1) Emulsion of polyurethane or the like resin, methylmethacrylate-butadiene series synthetic rubber latex is foamed by mechanical agitation, coated, and dried on the sheet substrate into a layer.
2) The synthetic resin emulsion or synthetic rubber latex is admixed with a foaming agent and the liquid mixture is coated and dried on the substrate into a layer.
3) Vinyl chloride-plastisol, polyurethane or the like synthetic resin or styrene-butadiene series or the like synthetic rubber is added with a foaming agent and the liquid mixture is coated on the substrate and subjected to heating to provide a foamed layer formed thereon.
4) A thermoplastic resin or synthetic rubber is dissolved in an organic solvent to provide a solution, and a non-solvent (including that containing aqueous main component), and the latter solution are mixed together to provide a liquid mixture, said nonsolvent being less volatile than the organic solvent and having a considerable mutual solubility with the solvent, and showing, however, non-solubility with the thermoplastic resin or synthetic rubber. The thus prepared liquid mixture is then coated on the sheet-like substrate and dried, to provide a porous membrane upon micro-coagulation of the constituents. The resulting microporous layer can be utilized for the above purpose.

It should be noted that the layers produced by any of the foregoing three processes 1) to 3) have rather large foams contained therein, and thus when the foaming solution for the image-transferable layer is applied thereon and dried, the latter may exhibit excessively coarse surface conditions. Therefore, in order to obtain an optimumly image-transferable smooth surface capable of providing transferred images of high uniformity, provision of the micro-porous layer prepared by the process as set forth in the foregoing item 4) is highly recommendable.

As the thermoplastic resin suitable for the formation of the above porous layer, saturated polyester; polyurethane; vinylchloride-vinylacetate copolymer; cellulose acetopropionate and the like can be used. Further, as the synthetic rubber usable for the same purpose, those of styrene-butadiene series, isoprene series, urethane and the like series may be used. Still further, as the organic solvent and non-solvent liquid used for the formation of the microporous layer, various known substances may be used. Generally speaking, however, methyl ethyl ketone; alcohol and the like are representatively used. On the other hand, as the non-solvent, water is mostly used.

The thickness of the porous layer usable in the present invention is preferably greater than 3 μm, especially preferably in the range of 5 to 20 μm. With the use of a porous layer having a thickness of less than 3 μm, the desired cushioning and heat-insulating effects cannot be attained.

As was referred to hereinbefore in the description stage for the formation of the image-transferable layer, the intermediate layer may act simultaneously as the sticking layer in some cases.

This kind of intermediate layer(s) may be provided on one or both of the surfaces of the thermally image-transferable sheet.

In practice, however, an electrostatic charge may accumulate in the material of the thermally image-transferable sheet during its processing step or during running through the printer. As a countermeasure, a proper antistatic agent may be applied on one surface of the image-transferable layer or on the bottom surface of the thermally image-transferable sheet or it can be included in the material of the image-transferable layer. As the antistatic agent in this sense, a surfactant such as a cation-exchange agent (for example, a quaternary ammonium salt, polyamide derivatives and the like) may be advantageously used. Further, an anion exchange type surfactant, such as alkyl sulfonate may be used. Otherwise, amphoteric ion type surfactants or even, non-ionic surfactants may be used for the same purpose.

On the other hand, the antistatic agents may be coated on the surface of image-reception layer by gravure-coating, bar-coating or the like process or alternatively, these agents may be kneaded with the material resin and then subjected to transfer towards the surface during the coating formation and drying step for preparing and providing the image-transferable layer. As the antistatic agents to be admixed with the image-transferable layer material resin, cation-type acrylic polymers may be employed.

The protecting layer is peeled off together with the image-transferred layer, from the sheet-like substrate, and then stuck, in inverted reversed state, onto any desired decorative object, the protecting layer thereby being positioned at the uppermost position, for improving the anti-wearing-light-proofing and anti-chemical performances of the image-bearing layer. As the material adapted for the formation of the protecting layer, for example, alkyd resin; phenol-modified alkyd resin; aminoalkyd resin; phenol resin; urea resin, melamine resin; silicone resin, thermosetting acryl resin, thermosetting polyurethane resin and the like thermosetting resin or normal temperature setting resin; further, ultraviolet hardenable resin; electron ray hardenable and the like activating energy flux hardenable resins or thermoplastic resins such as polyester-; polyurethane-; polyvinyl acetate resin; vinyl chloride-vinyl acetate copolymer resin; polyolefin resin, acryl resin and the like, can be used.

Preparation and use of a protecting layer comprising one or more of the above-mentioned resins are made in such a way that the material resin is dissolved in a properly selected solvent according to the necessity, so as to provide a coating liquid or ink, as the case may be, which is provided between the parting layer and the image transferable layer. The thickness thereof is generally 0.5 to 20 μm. It is also possible to form the protecting layer with the use of a resin film which consists of polyester-; acryl-; acrylpolyol-; polyvinyl chloride-; olefin resin or the like resin. It is further possible advantageously to admix an ultraviolet ray absorbing agent and/or photostabilizer to the material of the protecting layer.

The protecting layers prepared and formed in the foregoing way are thus not made integral with the sheet-like substrate or parting layer and, therefore, the peel-off operation of the sheet-like substrate upon execution of the image transfer is very simple and easy.

It is further recommendable, if necessary, to provide a slip-promoting layer on the bottom surface of the sheet-like substrate, which surface is naturally the one opposite to the image-transferable layer side, so as to properly adjust the friction between the image-transferable sheet and feed roll paper or carrier belt acting during passage through the printer and to improve the running performance of the thermally image-transferable sheet in the printer.

The slip-promoting layer can be formed by adding an organic powder such as polyethylene wax fluorine resin powder or an inorganic powder such as talc, according to necessity, to a resin such as polymethyl methacrylate resin; vinyl chloride-vinylacetate copolymer; vinyl chloride copolymer; cellulose acetate butylate; cellulose acetate propionate; styrene-acryl series or the like resin and kneading the resulting mixture to prepare a composition, applying this composition as a coating on the sheet substrate either directly or after application of a suitable primer treatment, and drying the coating thus applied. A suitable quantity of the slip-promoting layer is 0.5 to 5 g/m^2 after drying.

In the embodiments shown in FIGS. **22**, **23**, and **24**, as the adhesive agent to be used in the slightly weak or weak adhesive layer, it should be noted that those conventionally used adhesives for adhesive tapes and seals can all be used. Preferred examples are polyisoprene rubber; polyisobutyl rubber; styrene butadiene rubber; butadiene acrylonitrile rubber and the like rubber-series resins; (meth)acrylic acid ester-series resins; polyvinyl ether-series resins; polyvinyl acetate-series resins; vinylchloride-acetate copolymer series resins; polystyrene-series resins; polyester-series resins; polyamide-series resins; polychlorinated olefin-series resins; and polyvinyl butyrol-series resins. To the suitably selected adherent may be added a proper quantity of a stickness improver, such as rosin; dammar; polymerized rosin; partially hydrogenated rosin; ester rosin; polyterpene-series resins, terpene-modified substances; petroleum-originated resins; cycropentadiene-series resins; phenol resins; styrene resins; xylene resins; and coumarone-indene resin. Further, when necessary, to the mixture may be added a softening agent, filler; antiaging substance or the like conventional agent(s). As the material for the formation of slightly or weak-adherent layer said above, emulsion type adhesive, preferably of acryl acid ester series can be used. As for the parting function after a long time of preservation, emulsion type adhesives are highly recommendable. These adhesive agents are easily procurable from market.

When necessary, these adhesives are added with proper organic solvent(s) for the adjustment of the viscosity, and then applied by roll coating, die-coating, knife coating, gravure coating or the like conventional technique on the surface of the sheet-like substrate, image-reception layer or protecting layer, so as to provide an adhesive agent layer. The thus formed adhesive layer is preferably of a thickness of 1–50 μm, although this is not limitative.

Formation of Images

In the following, the decorating process according to this invention will be set forth in detail. Utilization of the image-transferable sheet according to this invention constitutes an important main feature thereof.

In FIGS. **20** and **21**, basic practising processes will be described first.

The embodiment shown in FIG. **20** is a result of the use of the transferable sheet shown in FIG. **13**. First, a known transfer sheet 320 is applied onto the image-transferable sheet **310** in an overlapped manner such that the dye-carrying layer **321** is kept in opposition to the image-reception layer **302** of image-transfer sheet **320**, and heat energy is applied, as schematically shown by a plurality of arrows, in accordance with image signals fed at a thermal head, not shown, from the side of image-transferable sheet **310**, or preferably, from the side of the image-transfer sheet **320**, thereby forming the desired images as at **307** in the image-reception layer **302**. Next, the image-reception layer **302** formed therein with the desired images **307** is peeled off from sheet-like substrate **301** and stuck onto the decorative product **306**. Or alternatively, both the sheets **302**; **301** are stuck onto the product **306** without preparatory peeling-off. In the latter case, the peel-off step may be executed after execution of the stickingly attaching step. In the above former case, and in such a case where an adhesive agent layer **306** has preparatorily provided between image-reception layer **302** and sheet-like substrate **301** as was set forth hereinbefore, the sticking attachment is carried into effect in such a way that the adhesive layer **306** is kept in opposing contact with the product **330**, and then the sticking operation is brought about by application of heat and pressure or light and pressure, depending upon the nature and structure of the layer **306**. In this way, the decoration according to the present invention is completed as a preferred one mode thereof.

On the other hand, if there is no preparatory provision of the adhesive layer, either the surface of product **330** or of the peeled-off image reception layer **302**, may be coated with the adhesive agent, and the latter layer **302** per se or otherwise in the up-and-down reversed state may be stickingly attached onto the product **330** (refer to FIG. **21**).

Since the image-reception layer **302** is composed generally of such thermoplastic resin material as is liable to be colored with thermally transferable dyestuff, it can be thermally and fusingly attached to plastic resin-made formlings, clothes or metals even with provision of an adhesive layer, if necessary.

In this case, the image-bearing layer **302**, the image thereof having been formed in the aforementioned way, is stuck on, through the intermediary of the adhesive agent layer **306** as shown in FIG. **25**, while retaining the sheet-like substrate **301** on the surface of the image-reception layer **302**.

A modification of the last-mentioned mode is shown in FIG. **26**. In this case, sheet-like substrate **301** is formed on the surface of the product **330** and the image-reception layer **302** is formed as the outermost layer. Further, in this case, sheet-like substrate **301** and product **330** may be stuck together, and, through the intermediary of a suitable adhesive layer, sticking layer or heat-sealable sheet or the like.

As for the transparent film usable as the said sheet-like substrate, it must be transparent to such a degree as not to

conceal the images formed in the image-reception layer, and, in addition, it must have superior surface properties such as, for instance, antiwearing characteristics. As an example, polyolefine; polyvinyl chloride; polyethylene terephthalate; polystyrene; polymethacrylate; polycarbonate and the like plastic resin-made films may be used upon variously surface conditioning. If these transparent films should be too thick, the images will be raised, and the unitary feelings may be lost when these are stuck on respective products to be decorated. Therefore, the film thickness is preferably of the order of 0.5 to 50 μm.

In the case of a further embodiment of the present invention, the image reception layer of image transferable sheet which has been, however, formed with necessary images is subjected to image transfer treatment onto an intermediate image transferable substrate, the latter is then subjected to an image-retransfer with the images, and the thus retransferred images are again transferred onto the surface of the product to be decorated. In the following, this image transfer mode will be set forth in detail.

Embodiments shown in FIGS. **27**, **28** and **29** represent such a process for execution of image transfer operation as by the intermediary of intermediate image transfer sheet **510**. First, as shown in FIG. **27**, a thermally image-transfer sheet **320** having a thermal transferable dyestuff layer **321** is overlapped to image-transfer sheet **510** which is, at this stage, not formed with images **307** and thus consists of a thermal image-transferable sheet, in such a way that the dyestuff layer **321** or more specifically the parting layer **322** is in opposition to the image-reception layer **302** of the foregoing sheet **510**. In such a case, however, that heat energy is supplied in accordance with image-forming signals delivered from the thermal head, not shown, and, indeed, preferably from the side of the sheet **320** as hinted by a plurality of double-line arrows for thermal formation of desired images (positive images) as at **307** in the image-reception layer **302**, it is highly recommendable to provide an adhesive layer **402** between the layer **302** and sheet-like substrate **301**.

Then, with the use of the image transfer sheet **510** formed with positive images **307**, the images of layer **302** are transferred, as shown in FIG. **28**, to a separate intermediate substrate **501**, which is, however, fitted with a protecting film layer **305**, thus, the transfer being carried out, in fact, onto the latter, and indeed, with the correspondingly inverted images, attached with same reference numeral only for convenience, from the foregoing layer **302**. In this case, it is preferable to subject the adhesive layer **402** of the image-transfer sheet **510** to the image-transfer operation, together with the image-reception layer **302**. Further, as for the intermediate image-transfer substrate **501**, it is recommendable to provide the protecting film layer **305** through the intermediary of a weak-adhesive layer **402'** as shown. The thus provided intermediate image-transfer sheet **610** represents generally the image-transferable sheet.

FIG. **29** illustrates the step for transfer of theimage-reception layer **302** now carrying positive images **307** onto the object **330** to be decorated and under utilization of the previously described intermediate image-transfer sheet **610**.

More specifically, the intermediate image-transfer sheet **610** is overlapped onto the said object **330** in such a way that the adhesive layer **402** of the former in opposition to the surface of the object **330** and pressurized together. Then, the intermediate transfer substrate **501** together with the weak-adhesive layer **402'** is peeled off from the remainder of the thus-pressurized assembly, the now image-carrying layer **302** formed with positive images **307** covered with protecting the film layer **305** thereby remaining in the transferred state on the product **330**. In the case of no provision of the protecting film layer **305** on the intermediate image-transferable sheet **610**, the layer **302** remains in an exposed state. Therefore, an overcoat layer, if necessary, can be provided on the now image-carrying layer **302**.

The previously set forth process carried out by the use of said intermediate image-transferable sheet can be executed by means of the apparatus which is shown schematically in FIG. **1**E.

In this apparatus, more specifically, there is provided a carrier system comprising a series of rolls **411**, **412**, **413** and **414** for conveying the intermediate transfer substrate (sheet), arranged in addition to the apparatus shown in FIG. **1**B. More specifically, the substrate is drawn out from feed roll **414**, conveyed through successive rolls **413**; **412** and retransferred onto one of the products **200**. Other operations are same as set forth hereinbefore with reference to FIG. **1**B. Further, in the case of FIG. **1**E, the final product may take the form of a roll-like substrate which is subjected to an image transfer operation through the intermediate substrate, by transferring its image-carrying, image-transferable layer, for later being punched out properly. Alternatively, under occasion, it may be subjected to half-cut operations downstream of roll **122**.

As was set forth herein above, the preferable method for the formation of desired images on the image-transferable sheet is carried out by use of a heat image-transfer sheet comprising a sheet-like substrate having a layer including a thermally transferable dye (evaporative dye). The heat image-transfer sheet which can be utilized in this method is known per se. And almost every kind of these known sheets can be useful in the practice of the present invention. It should be noted that by employing the foregoing image-transfer method, mono-color or full-color images can be easily formed as occasion may desire.

It should be further noted that details of such heat image-transferable sheet can be easily understood with reference to our U.S. patent application Ser. No. 833,039. As for the heat image-transferable sheet usable in the present invention, the coating layer of the sheet (coating film) may include a parting agent. By adopting this measure, the image-reception layer of the image-transferable sheet or the surface thereof, to be subjected to sublimative image-transfer, must not have a separate parting agent layer, the adhesive ability between the image-reception and the surface of object to be decorated can be still further improved upon execution of the sublimative image-transfer and image-formation at the image-reception layer and adherent attachment thereof to the object. As the parting agent to be included in the coating layer of the thermally image-transferable sheet (coating film), silicone oil; silicone resin; phosphoric ester or the like surfactant; and/or chelate—and the like agents, may be selectively utilized. These agents, upon mixed, will ooze out from inside to the outer surface of the coating layer, resulting in providing a better parting quality. However, it is preferable to properly select the kind and nature of the parting agent to be used for this purpose, being such that the agent cannot transfer to the image-reception layer of the image transferable sheet during the sublimating image-transfer stage. The adding quantity of the parting agent may preferably be 3-25 wt. parts based upon the total amount of resin and coating composing the coating layer taken as 100 wt. %.

In practice, any kind of conventionally known heat transfer sheets is overlapped on the thermally image-transfer sheet employed in the present invention, and then necessary heat energy of 5–100 mj/mm^2 is applied by use of a

conventionally known heat transfer unit, for instance, "Video-printer: VY-100" manufactured and sold by Hitachi Seisakusho, Tokyo, or its equivalent machine, for the formation of necessary images on the image-reception layer of the image-transfer sheet as set forth hereinbefore.

Peel-off operation for removal of the image-reception layer formed with necessary images in the above manner may be carried into effect in a very easy manner, so as to provide it in a thin film carrying the images thereon. In case where the thus-peeled off film carrying the images is provided beforehand with an adhesive layer, composed of a suitable adhesive agent as was referred to, at the opposite surface to the image-carrying one, the peeled-off film can be, as it is, stuck on the object to be decorated. It is natural that this adhesive attachment procedure can be performed only partially and locally on selected part of the whole surface of the object, or totally thereon, as the case may be. On the contrary, if the peel-off film is provided beforehand with no adhesive layer, the film can be subjected occasionally to a heat fusion onto the surface of the object, if the physical properties or material kind thereof is suitable for such kind of thermal fusion. Or alternatively, a properly selected adhesive agent can be preparatorily applied onto the surface of the film or object, and then, the stick-on job can be executed.

If the image-reception layer is provided preparatorily with a parting layer thereon, as was referred to, the latter layer can be removed off partially or wholly, by grinding or rubbing operation after execution of the sublimating image-transfer job, for avoiding otherwise occurrence of ill effect by the very presence of parting layer in the adhesive attachment of the image-carrying layer film onto the decorative object.

In case of that where the image-transferable sheet is provided with a protecting layer and the latter is composed of a plastic resin film, this film may preferably be cut into pieces or subjected to punch-cuttings.

FIG. **32** illustrates successive die-cutting steps in sectional views, serving for the above purpose. In this case, as shown in FIG. **32** at (a), only image-reception layer **305** of the image-transferable sheet **310**, which has been image-formed through the way of the foregoing image-transfer step, are die-cut by operation of a cutter **801**. Next, as shown in FIG. **32** at (b), a pair of hot stamps **132**'; **133**' are used to execute a pressurizing job under heat from opposite sides, thereby the decorative product **330** being processed into a final product provided tightly with an image-reception layer and a protecting layer, as shown in FIG. **32** at (c).

Further, when occasion desires, the image-carrying film is reversed up-and-down in position after execution of the peel-off job, and, the film is stuck onto the product to be decorated in such a state that the image-carrying surface of the film is kept in direct opposition to the product's decorating surface. In this case, however, it would be rather preferable that in advance of preparatory peel-off of the image-reception layer, the image-carrying transferable sheet is stuck onto the surface of the product to be decorated, and indeed, preferably with use of an adhesive agent, in such a way that the image-carrying layer is kept in direct opposition to the product surface and finally, the sheet-like substrate is peeled off, so as to leave the image-carrying surface on the product's surface.

As in the foregoing, when the images are once reversed and then stuck onto the object to be decorated, the forming images are preferable to reverse in mode (mirror-like relationship) the original to those of reversed mode.

It is further possible that the transfer or sticking-on of the image-carrying layer is carried out through the intermediary of a separate fusing sheet.

In FIG. **30**, use of such fusing sheet **701** for reimage-transfer operation of image-carrying layer **2** already formed with necessary images **307**, however, of reversed mode, and onto the surface of a product.

More specifically, the image-transferable sheet **310** is overlapped onto the product **330** to be decorated in such a way that the image-reception layer **302** carrying the necessary images **307** is kept in opposition to the surface of the product, and indeed, through the intermediary of a fusing seat **701** and then these three components are pressurized together. Further, sheet-like substrate **301**, together with parting layer **303**', is peeled off, thereby the image-reception layer **302**, now having positive images **307** formed thereon, and protecting the latter, being transferred onto the product **330**. Itwill be seen in this case, that there is no need for this transfer job, to provide in advance on adhesive layer on the surface of image-reception layer **302** and/or on the surface of the product **330**, and further that a direct heat fusion onto the surface of the product **330** which may be composed of plastic resin, textile fabric, metal or the like common material, however, through the intermediary of a heat-fusible or heat-sealable sheet.

In case where the protecting layer **305** is of plastic resin, similar composing technique as mentioned above may be employed by substituting a weak-sticking layer **402**' for parting layer **303**'.

As the heat-fusible or heat-sealable sheet as at **701** employable in the present invention, it may be composed of one or other material capable of adhering under heat, pressure or both, especially suitable one of those which become soft to be adhesive upon heating. These heat adhering materials in the form of sheets will be, upon softening, charge the pores, meshes or stitches of the product material composed preferably of textiles, woven or non-woven; knits, rough-surface papers or meshed materials, thereby the surface of the product becoming highly smooth for well receiving the image-reception layer **302** for desired image-retransfer with trouble, which effect is superior in the art.

On the contrary, when such heat-fusible or heat adhesive sheet materials which may be called "heat bond sheets" as at **701** are not utilized, it is highly difficult to realize the image-retransfer operation onto certain kind of objects such as rough-surfaced or rough-meshed fabric or the like. Even if the retransfer job could be executed, the obtained images may be blurred and the adhesive may be insufficient, on account of the very thin thickness of the image-reception layer **302**, thus giving rise to technical and commercial troubles.

As for the heat fusible sheet **701** to be used in the foregoing manner, ethylene/vinyl acetate copolymer, nylon copolymer; epoxy/phenol copolymer; epoxy/vinyl copolymer; acrylic resin; polyester resin; or polyolefin resin and the like thermoplastic resins (heat sensible adhesive agents) which are formed into sheets or films may be used. These materials must be softened at 100-250° C. or so to represent viscous adhesive characteristics. These materials are, when used, capable of being stuck to both the image-transferred product **330** and the image-carrying layer **302**.

These heat bond sheets **701** have generally thickness of 1–200 μm. When the surface of the product **330** to be decorated is relatively smooth, the sheet selected out may be of relatively thin thickness, while, on the contrary, when the surface of the decorative product **330** is relatively rough, as in the case of textile fabrics, unwoven fabrics, meshed fabrics or the like, use of thicker heat bond sheets is rather recommendable.

As set forth above, the use of heat bond sheets is highly recommendable in the decorative image-transfer onto rough

surface products, such as those of rough fabrics, woven or non-woven, knitted clothes, meshed one or the like, thereby a better quality image-transfer being executed, in spite of the meshed or highly undulating surface conditions of the objects to be decorated.

Further in the present invention, during the adhering attachment of the image-reception layer already formed with necessary images onto the object or product, an additional processing step is preferably introduced for prevention of occasional interference in the foregoing adhering attachment step, by rubbing-off or grinding-off part or whole of the parting layer, provided on the surface of the now image-carrying layer, upon completion of the sublimating image-transfer step.

Still further, in such a case that the image-transferable sheet is fitted with a protecting layer which is composed of a plastic resin film, the latter must in advance be subjected to punching or the like cutting step for cutting the film into desirously sized pieces.

FIG. **32** represents such a die-cut (half-cut) process in sectional schema. In this case, at first, as shown at (a) of FIG. **32**, the image-reception layer **302** of an image-transferable sheet **310**, now formed with necessary images through a sublimative image-transfer step, and the protecting layer **305**, are subjected to a die-cutting process by means of a cutter **801** to shape a desired shape. And then, as shown at (b) in FIG. **32**, the cut-out piece is subjected to a pressurizing step under heat by means of a pair of hot stamps **132'**; **133'** to provide a final decorative object, as shown at (c) in FIG. **32**, which is composed of a product **330** to be decorated, however, now attached integrally and jointly with image-carrying layer **302** and protecting layer **305**.

Applied Products

The products applicable with the inventive process for decorating purposes are not limited to occasionally employed kind, shape and nature of the materials. Preferred examples of the usable product may be: cartons; vessels or packages; bags; cassette cases; cassette halves; floppy cases; paper packages and envelopes; stock certificates; personal and bank cheques; bills; bonds; certificates; notifications; car tickets; travel tickets; betting tickets; tax stamps; postage stamps; entrance tickets, money-exchangeable papers and documents; cash-cards, credit cards, orange cards, telephone cards; member's cards; greeting cards; postcards, name cards; driver's certificates; IC-cards; optical cards and the like various cards; accounting cards and documents-envelopes; tags; OHP-sheets; slide films; bookmark slips; calendars; posters; pamphlets; menus; passports; POP-goods and articles; coasters; displays; nameplates; keyboards; cosmetics; personal ornaments (watches; cigarette lighters); stationaries; construction materials; radio-receiving sets; T.V.-sets; speakers; table calculators; automotive gauge boards; emblems; keys; clothes; wearing commodities; footwears; appliances; OA-instruments; sample books; tickets in general, albums; computer graphic and/or medicare graphic image printouts; and the like, where the material kinds, sizes and configurations are regardless for purposes of the invention.

The aforementioned goods and instruments may have printed or the like other images in advance of execution of the process of the invention. Or conversely, the goods and instruments can be formed with necessary images in accordance with the present process, and then, additional images may be formed in conventional printing or the like process.

As an example, when the invention is applied to a card style intermediate product, it is possible to combine image-forming means of the present invention with conventional recording means. As the latter, magnetic recording by use of a magnetic material layer; optical recording by use of an optical recording layer; preferably composed of a membrane having low melting point metal; application of hologram; embossing formation of characters and numerals; application of personal face photograph; engraved formation of personal face or the like; human signatures; recorded information with use of IC-memory; mechanical printing; formation of bar codes; formation of characters and patterns by use of printer, typewriter or pen plotter may be used independently or in any combination.

In the following, the present invention will be more fully described by way of preferred embodiments. In these embodiments, parts or % will be given by weight, not otherwise specifically referred to.

As the image transfer film (dye film) used for sublimating transfer onto the image-transferable sheets, a polyester film, 6 μm thick, subjected to a heat-resisting treatment on one surface thereof only, and bearing color ink composition areas of yellow, magenta and cyan, respectively, was used. The coating rate of the color ink composition was 1.0 g/m^2 when measuring at the dry state.

These color ink compositions were as follows.

Yellow ink composition	
polyvinyl butyral resin ("Eslek-BX-1", manufactured and sold by Sekisui Kagaku K.K., Tokyo)	4.80 parts
dispersion dye ("PTY-52, Disperse Yellow-141", manufactured and sold by Mitsubishi Kasei Kogyo Co., Ltd., Tokyo)	5.50 parts;
methyl ethyl ketone	55.00 parts;
toluene	34.70 parts;
(parting agent	1.03 parts)

Magenta ink composition	
polyvinyl butyral resin (same as above in the case of yellow color, ink)	3.92 parts;
dispersion dye ("MS Red G, disperse red 60", manufactured and sold by Mitsui Toatsu K.K.)	2.60 parts;
dispersion dye ("Macrolex Red Violet R, Disperse Violet 26", manufactured and sold by Beyer A.G., West Germany)	1.40 parts;
methyl ethyl ketone	43.34 parts;
toluene	43.34 parts;
(parting agent	0.40 part)

Cyan color ink composition	
polyvinyl butyral resin (same as in said yellow color ink composition)	3.92 parts;
dispersion dye ("Kayaset Blue-714, solvent blue-63", manufactured and sold by Nippon Kayaku K.K., Tokyo)	5.50 parts;
methyl ethyl ketone	68.18 parts;
(parting agent	0.94 parts)

Each of the foregoing color ink compositions was prepared with and without addition of parting agent.

As the parting agent occasionally used in each of the foregoing color ink compositions, any of the following specific agents may be employed:

(a) silicone alkyd parting agent, "KR-5206", manufactured and sold by Shinetsu Kagaku Kogyo K.K., Tokyo;

(b) graft polymer of silicone and acryl, "GS-30", manufactured and sold by Toa Gosei Kagaku K.K.;

(c) silicone graft polymer, "US 3000", manufactured and sold by the above company;

(d) phosphoric acid ester, natrium salt, "RE-410", manufactured and sold by Toho Kagaku Kogyo K.K.;

(e) natural phosphoric acid ester, "Lecytin" , manufactured and sold by Ajinomoto Co., Ltd., Tokyo;

(f) silicone oil, "KF 412", manufactured and sold by Shinetsu Kagaku Kogyo K.K., Tokyo;

(g) aluminum chelate agent, "ALM", manufactured and sold by Ajinomoto; and

(h) titanium chelate agent, "TTS", manufactured and sold by Nippon Soda K.K., Tokyo.

EXAMPLE A-1

As the substrate, a laminate of a synthetic paper, "Yupo FPG 150 μm thick" manufactured and sold by Oji Yuka Co., Ltd., Tokyo, and a polyester film, 6 μm thick, was prepared and coated on the polyester film side surface by a wire bar with a mixture of pull-separating varnish, "Bakurinisu 45" manufactured and sold by Showa Ink Co., Ltd., Tokyo, with an ultra-violet absorbing agent, or more specifically, 2.5-bis (5'-tert-butylbenzoxazolyl (2))-thiofin, 0.5% based on the resin content of the varnish, and dried up to provide a protecting layer of 1 g/m^2, when weighed upon drying.

Then, on the surface of the foregoing protecting layer, an ink composition adapted for the formation of an image-reception layer was coatingly applied and dried up. The applied quantity amounted to 7 g/m^2 when measured upon drying.

Ink composition for the formation of image-reception layer	
polyester resin (manufactured and sold by Toyobo K.K.)	100 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu Kagaku Kogyo K.K., Tokyo)	5 parts;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu Kagaku Kogyo)	5 parts;
solvent (methyl ethyl ketone/toluene/ cyclohexanon 4/2/2)	900 parts.

The ink composition was coated, dried up and cured one day under normal temperature. Then, the layer was kept at 100° C. for 30 minutes under beat, for letting the silicone to bleed up to the surface, to provide an image-transferable layer formed on its surface with a hardened silicone layer.

On the thus-provided image-reception layer, a sublimating image-transfer film was overlapped which is composed of cyan color sublimative dye (molecular weight being higher than 250) carried by a proper binder resin and thermal energy is fed thereon from a thermal head adapted for receiving electric signals representing cyan color components obtained by a color analysis of a portrait photograph, as an example, for providing portrait images corresponding thereto. Then, two successive sublimative image-transfer jobs were executed with use of respective sublimating image-transfer films carrying sublimative magenta and yellow color dyes, each molecular weight being higher than 250, and substantially in the manner set forth above. In this way, after all, an overall combined display image composed of a full color portrait, in combination with several characters and graphics, was provided.

The image-reception layer of the sheet, now carrying these display images, was overlapped on the card substrate composed of a polyester resin sheet, 100 μm thick, which had been primed to white-opaque state, and pressurized together at 160° C. by means of heated pressure rolls. Then, the polyester film was peeled off at the interface with the protecting layer, thereby providing a final product card transferrd with image-reception layer now carrying the desired image display.

It was found that the overall surface of the product card was generally smooth and showing no raised feeling of the thus-formed and displaying images. Even upon an accelerated testing of the product card for three months held in an atmosphere of 40° C., the images showed no blurrings as well as no interlayer separation. Further, according to an accelerated light-proof test carried out as prescribed in JIS-Standard with use of a carbon arc lamp, the results showed to be classified to JIS-4 or -5 corresponding to an acceptable superior performance. Additionally, a surface scratch test and the like showed also superior durability.

EXAMPLE A-2

The foregoing image-transferable sheet, now image-carrying, as processed in Example A-1, is then subjected to a peel-off operation for separating the image-carrying layer from the sheet. Then, an adhesive agent of polyester series was coated on the exposed surface of the peeled-off film, and stuck under pressure on a curved surface part of a telephone set. The images could follow up to the stuck curvature into a unitary solid mass, and indeed, without inviting any stuck-on feeling, contrary to the case when a sticky loose-leaf stamp should have been stuck on. In this way, miracle viewing feelings as obtainable with direct-printing operation only, were created and maintained.

EXAMPLE A-3

A white polyester film, baked on one surface thereof with melamine coating, "E 20", 100 μm thick, manufactured and sold by Toray Co., Ltd. Tokyo, is formed on the opposite surface with a slipping layer, same as in the following Example C-2, through application of polyurethane primer. And an identification mark was provided thereon through the way of regular printing technique. On the melamine resin-baked surface of the white polyester resin film, a layer of peeling varnish (of polymethyl methacrylate-series), manufactured and sold by Showa Inku. Co., Ltd., Tokyo) was applied in dry quantity of 2 g/m^2 and dried up to provide a definite layer.

On the thus-formed protecting layer, the following image-reception layer-forming composition was coated and dried up, so as to form an image-heat transferable sheet. The coated composition was in quantity of 6 g/m^2 by dry weight.

Image-reception layer-forming composition	
polyester resin ("Vylon 600", Tg: 47° C., manufactured and sold by Toyobo, Osaka)	80 parts;
polyester resin	20 parts;

-continued

Image-reception layer-forming composition	
("Vylon 290", Tg: 77° C., manufactured and sold by Toyobo)	
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu Kagaku Kogyo)	7 parts;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu Kagaku Kogyo)	7 parts;
solvent (methyl ethyl ketone/toluene = 1/1)	800 parts.

On the image-reception layer of the foregoing heat image-transferable sheet, reversed images composed of full color portrait images together with characters and graphics by use of a thermal head, as in the same way with Example A-1, were formed.

Next, the image-reception layer, however, now carrying the reversed images formed in the foregoing manner was brought into contacting and overlapping state with the image displayable surface on a card style substrate made of white color polyester resin, 125 μm thick, preparatorily primer treated as before, and pressurized together under the action of thermal rolls, and the white polyester film, 100 μm, was peeled off between the protecting layer and the melamine-baked layer, thus providing a final card-style product transferred with the image-reception layer now carrying the necessary images.

The surface of the final card style product represented a smooth and slippery, without fear of interlayer separation and with superior light resistant power.

EXAMPLE A-4

A white foam polyester resin film, "Merinex", 125 μm thick, manufactured and sold by ICI, was provided with an identification mark on one surface thereof, with regular printing technique.

Then, on the opposite surface of the white foam polyester resin film to the foregoing surface formed with the identification mark, a coating of a polyurethane-series primer was applied and dried up. Further, the following protecting layer-forming composition was applied in dry quantity of 3 g/m^2 and dried up to form a protecting layer.

Protecting layer-forming composition	
acrylic polyole ("Acrit 6416MA", manufactured and sold by Taisei Kako K.K.)	41 parts;
toluene	36 parts;
methyl ethyl ketone	27 parts;
diisocyanate ("Colonate", manufactured and sold by Nippon Polyurethane K.K.)	6 parts.

On the above protecting layer, the following composition was applied in dry quantity of 3 g/m^2 and dried up, to provide an intermediate layer.

Intermediate layer-forming composition	
polyester resin ("Vylon 290", manufactured and sold by Toyo Boseki (Toyobo) K.K., Osaka)	15 parts;
toluene/methyl ethyl ketone = 1/1	85 parts.

On the thus-formed intermediate layer, an image-reception layer which is substantially same with that in the foregoing Example A-3 was provided, so as to form an image-transferable sheet. Then, as same in the foregoing Example A-3, correspondingly inverted images were formed on the image-reception layer and further then, subjected to transfer onto the card substrate by use of thermal rollers. In this way, a final product card, having an image transferable, yet now image-formed layer, was provided.

This card showed favorable results of light-resisting test. Further, it showed a better scratch test result than the foregoing card obtained in Example A-3.

EXAMPLE A-5

Substrate

A white polyester film, "E-20", 100 μm thick, manufactured and sold by Toray Co., Ltd., Tokyo, was used.

Intermediate layer-forming composition	
Polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki K.K., Osaka)	15 parts;
toluene/methyl ethyl ketone = 1/1 (dry weight: 5 g/m^2)	85 parts.

Protecting layer-forming composition	
"Hakuri-Nisu" (acrylic resin varnish, manufactured and sold by Showa Ink K.K.) (dry weight)	2 g/m^2

Image-reception layer-forming composition	
polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki K.K., Osaka)	10 parts;
polyester resin ("Vylon 200", supplied by Toyo Boseki K.K.)	5 parts;
toluene/methyl ethyl ketone = 1/1	85 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu Kagaku Kogyo)	1 part;
epoxy-modified silicone ("X-22-343", supplied by Shinetsu Kagaku Kogyo)	1 part.
(coated quantity (dry)	5 g/m^2)

With use of the foregoing composition and processed in similar way as in Example A-3, to provide a final card product, having an image-reception layer transferred with necessary images.

EXAMPLE A-6

Substrate

White polyester resin film, "E-20", 100 μm thick, manufactured and sold by Toray was coated with polyurethane-series primer and dried up.

Parting layer-forming composition	
melamine resin ("Meran 45", manufactured and sold by Hitachi Kasei)	100 parts;
hardener (para-toluenesulfonic acid)	20 parts;
(coating quantity (dry), 2 g/m^2)	

Protecting layer-forming composition	
vinylchloride-vinylacetate ("Vinylite VYHH", manufactured and sold by Union Carbide Corp.)	15 parts;
methyl ethyl ketone = 2/1	85 parts;
(coating quantity (dry): 2 g/m^2)	

Intermediate layer-forming composition	
polyurethane resin ("Takelac T-3350", manufactured and sold by Takeda Pharmaceutical Company, Osaka, of 23%-concentration)	50 parts;
isopropyl alcohol	15 parts;
toluene	25 parts;
methyl ethyl ketone	10 parts.
(coating quantity (dry) 5 g/m^2)	

Image-reception layer composition	
polystyrene resin ("Picolastic D125" (Tg = 53° C.), manufactured and sold by Hercules	15 parts;
toluene/methyl ethyl ketone = 1/1	85 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu Kagaku)	1 part;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu Kagaku)	1 part.
(coating quantity (dry): 6 g/m^2)	

The foregoing composition was prepared and used as in the same manner with Example A-3, to provide a card with the image-reception layer subjected to image-transfer as desired.

EXAMPLE B-1

As the substrate, a polyester resin film, 6 μm thick, was used and a polyester resin-series primer was coated on one surface thereof and dried up. Further, the following ink composition was applied and dried up. The coating quantity of the composition was set to about 7 g/m^2.

Image-reception layer-forming composition	
polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki K.K.)	100 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu Kagaku)	5 parts;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu Kagaku)	5 parts;
solvent (methyl ethyl ketone/toluene/cyclohexanone = 4/2/2)	900 parts.

The ink composition was coated, dried up and left standing for a full day, and then subjected to heat treatment at 100° C. for 30 minutes, so as to bleed the silicone towards the film surface for providing thereon an acceptable image-reception layer composing the active surface.

Then, a sublimative image-transferable film, composed of a resin binder evenly mixed with a proper amount of sublimative cyanic dye, the molecular weight being higher than 250, was overlapped on the above image-reception layer and applied with heat energy by means of a thermal head supplied with electric signals corresponding to cyanic color components of a portrait full color photograph as determined by regular color analysis, thus providing cyanic color component images.

Next, as for magenta and yellow color components, similar respective processings were executed and finally, full color display portrait images could be formed.

Then, the exposed surface of image-reception layer of the thus-display image-formed film was overlapped on a card substrate composed of a white opaque, hard vinyl chloride resin sheet, 100 μm thick and pretreated with a conventional primer, and then this assembly was subjected to heat and pressure by means of a pair of heated rolls. In this way, a card product stuck with an image-transferable and now carrying layer was provided.

The surface of this card was generally smooth and slippy, the thus-formed images thereon providing no raised feelings. In an accelerated test of these formed images in hot atmosphere of 40° C. for a continuous period of three months, there were no appreciable image blurring and interlayer separation. Upon execution of a light exposure test in accordance with prescribed conditions in JIS with use of an arc lamp, the results were classified to JIS-4 to 5 Classes which means as acceptable and better image quality. Scratch test results were also superior.

EXAMPLE B-3

A sticking layer, 1 μm thick, was formed with a polyamide resin sticking agent on the image-carrying surface of the image-transferable sheet, image-formed in the manner as described in foregoing Example B-1, and the thus provided sheet was stuck on the curved surface of a glass tumbler. These images express practically no stuck-on feelings, rather providing such a touch and viewing feeling as if they had been formed by the regular and direct printing technique.

EXAMPLE C-1

With use of the image-transferable sheet prepared in the foregoing Example A-1, images were formed substantially

in accordance with procedures mentioned therein, however, with exception of the formation ofreversed images, and then, the image-carrying layer was, without execution of the foregoing peel-off operation, stuck on a portion of curved outer surface of a glass tumbler, whereupon the sheet-like substrate was peeled off, together with the weak-sticking layer. The thus-applied images represent almost no sticking-on grip and viewing feeling, as if they should have been applied through regular and direct-printing technique.

EXAMPLE C-2

On the surface of a transparent polyester film, 12 μm thick, employed as a protecting film, the following image-reception layer forming composition was applied to form a coated layer (in quantity of 6 g/m^2 when measuring upon drying), dried up and left as it was for full one day. Then, it was held at 100° C. for 30 minutes, to form an image-reception layer. On the surface thereof, a parting surface layer was found to exist, which was composed of a combined hardened product of amino-modified silicone resin and epoxy-modified silicone resin.

Image-reception layer-forming composition	
polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki)	100 parts;
amino-modified silicone resin ("KF-393", manufactured and sold by Shinetsu)	7 parts;
epoxy-modified silicone resin ("X-22-343", manufactured and sold by Shinetsu)	5 parts;
solvent (methyl ethyl ketone/toluene = 1/1)	800 parts.

As the substrate, on the other hand, white polyester resin film, "E-20", 75 μm, manufactured and sold by Toray, was used and coated on one surface thereof with a polyurethane-series primer and dried up. Then, the following composition (in the dried quantity of 1 g/m^2) and dried up, so as to provide a smooth and stick layer.

Smooth layer-forming composition	
polymethyl methacrylate resin ("Dianal BR-85", manufactured and sold by Mitsubishi Rayon Co., Ltd., Tokyo)	12 parts;
polyethylene wax ("MF8F", manufactured and sold by Dulacon Co.)	0.5 part;
toluene/methyl ethyl ketone = 1/1	85 parts.

On the opposite surface of the-white-polyester resin sheet to the smoothed surface there, a primer coating of polyurethane-series is applied and dried up, and further coated thereon with the following composition, in quantity of 3 g/m^2, so as to provide a weak-sticky layer.

Weak-sticky layer-forming composition	
weak-sticky adhering agent ("Esdyme AE-206", manufactured and sold by Sekisui Kagaku Kogyo K.K., Tokyo)	50 parts;
water	50 parts.

The weak-sticky adhering layer is brought into contact with the protecting film consisting of a polyester film, 12 μm thick, at the opposite surface to the image-reception layer, and then subjected to heat and pressure, to provide an image-transferable sheet. Upon bringing the image-reception layer of the image-transferable sheet and the dyestuff layer of the heat-image transfer sheet into contact with each other, heat energy was applied from a thermal head, as in the similar manner mentioned in the foregoing Example A-1, and thus heat image-transfer job was executed, so as to provide reversed mode images for expressing a full color portrait as well as characters and graphics.

Next, the image-reception layer formed with the reversed images thereon was overlapped onto the image-displayable surface of a card style substrate, 100 μm thick, made of a white color polyester resin material preparatorily applied with a primer layer by coating a composition, consisting of "Vylon 200", 100 μm thick, manufactured and sold by Toyo Boseki K.K., and then subjected together to heat and pressure by means of at least a heated roll at 160° C. Then, the white polyester film, 75 μm thick, and the weak-sticky adhesive layer were peeled off in unison, for providing a final decorative product card having the image-reception layer transferred with images and carrying dislay images.

This card had a highly smooth surface and was not liable to invite any interlayer separation and showed superior light fastness.

In place of white color polyester-made card substrate preparatorily formed with a primer layer, such a modification was prepared and experimented that the white polyester sheet was formed on its rear surface with a magnetic layer, while, on its front surface there is formed with a write-on layer which consists of proper filler and resin as conventionally, so as to provide a telephone card. This processed telephone card had the write-on layer provided with display images formed by image-transfer.

EXAMPLE C-3

On the surface of a transparent polyester film, 9 μm thick, used as the protecting layer, an intermediate layer was provided by coating. The coated amount was 5 g/m^2 as measured upon being dried up.

Intermediate layer-forming composition	
polyurethane resin ("Takelack T-3350", solid content 23%, manufactured and sold by Takeda Pharmaceutical Co., Ltd., Osaka)	50 parts;
isopropyl alcohol	15 parts;
toluene	25 parts;
methyl ethyl ketone	10 parts.

Onto the intermediate layer, the following composition was applied for the formation of an image-reception layer. The coated quantity was 5 g/m^2 as measured upon being dried up.

Image-reception layer-forming composition	
polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki)	10 parts;
polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki)	5 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	1 part;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	1 part;
solvent (methyl ethyl ketone/toluene = 1/1)	85 parts.

On the other hand, a white color polyester film, which was similar to that employed in the foregoing Example C-2 was formed with a slidingly smooth layer, as well as a weak-sticking adhesive layer, the latter being brought into intimate contact with a transparent polyester film, 9 μm thick, at the opposite surface to the image-reception layer and then, subjected to heat and pressure, for providing a heat image-transferable sheet. As further processed in the similar manner in the foregoing Example C-2, full-color photographic images (reversed images) were thus formed on the image-reception surface. In this way, a final product card, having its image-reception layer transferringly formed with display images.

EXAMPLE C-4

Substrate

White color polyester sheet, "E-20", 100 μm thick, manufactured and sold by Toray was formed thereon with a polyurethane-series primer coating. Then, a weak-sticking layer was applied thereon with use of the following composition.

Weak-sticking layer-forming composition	
weak-sticking agent ("Esdyne AE-206", manufactured and sold by Sekisui Kagaku Kogyo K.K., Tokyo)	50 parts;
water	50 parts.

Protecting layer-forming composition	
polyester resin ("Vylon-200", manufactured and sold by Toyo Boseki)	15 parts;
diisocyanate ("Colonate L", manufactured and sold by Nippon Polyurethane Co., Ltd.)	1 part;
toluene/methyl ethyl ketone = 1/1	84 parts.

Image-reception layer-forming composition	
polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki K.K.)	10 parts;
vinyl chloride-vinyl acetate copolymer resin ("Vinylite VAGH" (Tg = 79° C.), manufactured and sold by Union Carbide Corp)	5 parts;
toluene/methyl ethyl ketone = 1/1	85 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	1 part;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	1 part.

With use of the above composition and processed substantially same as in the foregoing Example C-2, a final card product was obtained.

EXAMPLE D-1

An image-transferable sheet was prepared as in the foregoing Example A-1 and thermally image-transferred with reversed mode images of a full color portrait photograph, to provide an intermediate image-transfer medium. The latter is overlapped by its image-reception layer onto the surface of a sheet of rough-textured cotton cloth, however, through the intermediary of an acrylic acid ester-vinyl acetate copolymer sheet, 100 μm thick. Then, the assembly was subjected to heat and pressure. Then, the substrate sheet and weak-sticky adhesive layer, together, were peeled off. The thus transfered images have sufficient surface smoothness, showing superior surface conditions.

Without use of the bond-attaching sheet in the above process and when similar image-transfer job as above was performed, the resulted images followed the surface undulations appearing disadvantageously on the material product of the rough fabrics and thus were highly uneven, and further, on account of insufficient adhering performance acting between the image-receiving layer and the woven fabrics serving as product material, easy and frequent separations took place therebetween.

EXAMPLE D-2

In the similar way as was disclosed in the foregoing Example D-1, an intermediate image-transfer medium carrying reversed images was prepared and overlapped on a polymethacrylate board preparatorily subjected to surface-roughening operation through a conventional sand-blasting step, and through the intermediary of a bond-adhering sheet pressurized together under heat, as was employed in Example D-1. Then, the sheet-like substrate was peeled off, together with the weak adhesive layer. The thus-provided images were highly smooth and even in spite of the highly rough and undulating conditions at the surface to be image-transferred. In addition, the image-carrying surface showed superior results in various resisting tests.

Without use of the foregoing bond-sticking layer, the similarly transferred images showed considerable undulations and distortions. Further, on account of insufficient adhering performance, easy and frequent peel-offs of applied images were feared.

EXAMPLE D-3

On the surface of a polyester resin film, 25 μm thick, the following composition adapted for the formation of bond-

sticking layer was coated and dried up, in dried quantity of 5 g/m^2, to provide a film formed thereon a bond sticking sheet.

Bond-sticking sheet-forming composition	
polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki)	15 parts;
methyl ethyl ketone/toluene = 1/1	84 parts.

The bond-sticking sheet surface, together the polyester resin film proper, was brought into contact with the image-representing surface of a white color polyester made-card substrate, 25 μm thick, and then, subjected to heat and pressure by means of at least a heat roll kept at 200° C., arranged to supply heat energy from the side of the polyester resin surface, thereby heat bonding the bond-sticking sheet onto the card surface, whereupon the polyester resin film being forcedly peeled off.

Further then, as in the similar way as adopted in foregoing Examples C-2; A-3; A-4 and C-3, use is made of the image-reception layers representing reversed images thereon, the respective image-reception layers were whereupon brought into contact with the card's bond-sticking surface of the card and subjected to heat and pressure by use of at least a heat roll kept at 200° C. Then, the white color polyester resin substrate was peeled off, together with the weak-sticky adhering layer. In this way, a final product card displaying the portrait photograph was obtained.

EXAMPLE D-4

Substrate

A white color polyester resin sheet, "E-20", 100 μm thick, manufactured and sold by Toray Co. Ltd., was coated with a polyurethane-series primer. On the surface of the thus precoated sheet, the following composition was coated to form a weak-sticking adhesive layer.

Weak-sticking adhesive component	
weak-sticking adhesive agent, ("Esdyne AE-206", manufactured and sold by Sekisui Kagaku)	50 parts.

Image-reception layer-forming composition	
polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki)	7.5 parts;
polyester resin ("Vylon 290", manufactured and sold by Toyo Boseki)	7.5 parts;
toluene/methyl ketone = 1/1	85 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	1 part;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	1 part.

The foregoing compositions were prepared. On the other hand, a polyester resin film, 25 μm thick, was coated on one surface thereof with a 15%-solution of polyester resin, "Vylon 200", manufactured and sold by Toyo Boseki, in toluene/methyl ethyl ketone=1/1 and dried up. The coating quantity was adjusted to 5 g/m^2 when measuring in dried state. In this way, a bond-sticking sheet was provided.

Then, the coated surface of the thus prepared bond-sticking sheet was brought into contact with the image display surface of a card style substrate of white color-hard vinyl chloride or the like resin material preparatorily subjected to a primer coating treatment in overlapping state and then, the whole assembly was subjected to heat and pressure with use of at least a heated roll to 130° C., thus the bond-sticking layer being stuck on the card surface. Under this condition, the polyester resin film, 25 μm thick, was peeled off.

Then, the image-reception layer, now carrying thereon reversed images, was brought into contact with the bond-sticking sheet and the resulted whole was subjected to heat and pressure by use of at least a heated roll and the white color polyester resin substrate, together with the weak-sticking adhesive layer, was peeled off. In this way, the card, now displaying the portrait images, was provided.

EXAMPLE D-5

Substrate

Same as in the foregoing Example D-4.

Weak-sticking adhesive layer

Same as in the foregoing Example D-4.

Protecting layer-forming composition	
polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki)	15 parts;
diisocyanate ("Colonate L", manufactured and sold by Nippon Polyurethane)	1 part;
toluene/methyl ethyl ketone = 1/1	84 parts.

Image-reception layer-forming composition	
polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki)	10 parts;
toluene/methyl ethyl ketone = 1/1	85 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	1 part;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	1 part.

With use of the foregoing materials and compositions, the processings were carried out as in the foregoing Example D-4, to provide a final product card displaying portrait images as was desired.

EXAMPLE D-6

Substrate

Same as in the foregoing Example D-4.

Weak-sticking adhesive layer

Same as in the foregoing Example D-4.

Image-reception layer-forming composition	
polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki)	10 parts;
vinyl chloride-vinyl acetate copolymer resin ("Vinylite VAGH", manufactured and sold by Union Carbide Corp.)	5 parts;
toluene/methyl ethyl ketone = 1/1	85 parts.

The foregoing materials and compositions were prepared and processed in the similar way as in the foregoing Example D-4, to provide a final product card, displaying the desired portrait images as were desired.

EXAMPLE E-1

On a polyethylene terephthalate film, 9 μm thick, a solution of saturated polyester resin, "Vylon 600", manufactured and sold by Toyo Boseki, in toluene/methyl ethyl ketone=1/1, was coated by reliance of the known reverse roll-coating process, and dried up. The coated quantity was 7 g/m^2 when measuring in dry condition. In this way, a weak-sticking adhesive layer could be formed.

On the weak-sticking adhesive layer, the following composition, 3 g/m^2 (dry), was coated by means of an oblique-lined gravure roll for solid and full printing use and in the reverse roll-coating process, and then dried up, to provide an image-reception layer.

Image-reception layer-forming composition	
polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki)	70 parts;
polyester resin, ("Vylon 290", manufactured and sold by Toyo Boseki)	30 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	5 parts;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	5 parts;
methyl ethyl ketone (wt. ratio 1/1)	700 parts.

On the opposite surface to the image-reception layer of the thus-prepared image-transferable sheet, a synthetic paper substrate, "Yupo FPG 110", 110 μm thick, manufactured and sold by Oji Yuka K.K., coated with "Vylon 600" as the adhesive agent in quantity of 10 g/m^2 (dry) was stuck intimately together.

On the other hand, a polyethylene terephthalate film substrate, 6 μm thick, preparatorily provided on one surface thereof with a heat-resisting layer was used and the following composition was applied on the opposite surface of the substrate with use of a wire bar and dried up, in the quantity of 1 g/m^2 (dry), so as to provide a dyestuff layer. In this way, a heat image-transferable sheet was prepared and provided.

Dyestuff layer-forming composition	
dispersion dye ("Kayaseo Blue-136", manufactured and sold by Nippon Kayaku K.K.)	4 parts;
ethylhydroxyethyl cellulose	6 parts;
methylethylketone/toluene (wt. ratio: 1/1)	90 parts.

The dyestuff layer of the foregoing heat image-transfer sheet was brought into contact with the image-reception layer of the image-transferable sheet in overlapping manner, then, heat energy was applied from a thermal head from the side of heat-resisting layer of the heat image-transfer sheet, thereby dyestuff being transferred to the image-reception layer of image-transferable sheet, and indeed, for the formation of positive images.

Then, the image-transferable sheet, now carrying the required positive images was stuck together under heat and pressure at 140° C. for 5 seconds on the intermediate image-transfer substrate prepared in the following manner, in mutually opposed manner. Then, the synthetic paper "Yupo" was peeled off at the intersurface between the polyester resin film and the "Vylon 600" layer. In thus way, the inventive image-transfer sheet (intermediate image-transfer medium) carrying the corresponding reverse images was provided.

Method for the preparation of intermediate image-transfer substrate

A sheet-of fine quality or stick paper, unit weight: 82 g/m^2 was applied with a coating, about 20 μm thick, of polyethylene resin through conventional extrusion coating process. Thereon, further, a catalyst-added toluene solution of a parting agent silicone, "KS-707", manufactured and sold by Shinetsu was applied and dried up in quantity of about 2 g/m^2 (dry), for the purpose of curing. Thereon, still further, the following coating liquid composition was applied by means of a conventional coating bar and dried up, to provide an intermediate image transfer substrate. The thus coated and dried resin quantity was measured to 7 g/m^2.

Coating liquid composition	
polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki)	100 parts;
methyl ethyl ketone/toluene (mixing ratio by weight: 1/1)	700 parts.

A sheet of coated paper, pretreated for pore-filling, was coated, in the similar manner as above, with the foregoing liquid composition, to provide an image-transferable medium. On and with the presently coated surface, the image carrying surface of the foregoing intermediate image-transfer medium is brought into opposing contact and stuck together under heat and pressure at 140° C. for 7 seconds. Finally, the laminate of fine-quality paper and polyethylene was peeled off, to provide a final decorative product now displaying the positive images as required.

It will thus be seen that by adopting the above processing steps, the positive images formed under the action of the thermal head are transferred, through the intermediary of intermediate image transfer medium, onto the final object to be decorated, and indeed, in the form of positive mode. It will be further seen that, since the dyestuff is well distributed

within the image-reception layer, the transferred positive images are highly sharp and fresh, in addition to much profundities.

Since a resin layer was overlappingly applied on the thus-formed images, weather fastness, frictional durability and light-fastness of the finally formed images could be highly and amazingly improved. When suitable ultraviolet absorbing agent, antioxydant, quenching agent and/or radical scavenger is added to, further improvement of the light-fastness can be attained.

EXAMPLE E-2

The substrate of image-transferable medium adopted in the foregoing Example E-1 was replaced by a hard polyvinyl chloride card, 100 μm thick, and other processing modes were same as in Example E-1. In this way, a high quality, positive-image transferred, decorative final product was successfully provided. When the image include human portrait photograph, the final product was highly useful for ID-card.

EXAMPLE E-3

The substrate of image-transferable medium adopted in the foregoing Example E-1 was replaced by a transparent polyester film, and other processing modes were same as employed therein. In this way, a transparent film formed with the wanted positive images of better quality as before was obtained. This film was highly useful in OHP-services.

EXAMPLE E-4

A sheet of high quality paper, unit weight: 104 g/m^2, was coated with a layer of polypropylene resin, thickness: about 20 μm, through the way of conventional extrusion coating technique, then the coating was further coated with a silicone solution for use in parting service and hardenable under electron rays and dried up. The quantity of the coating silicone was about 1 g/m^2 upon drying. In this way, an electron-hardened, provisional substrate was provided. On this substrate, the following, image-reception layer-forming composition was applied as a layer by use of a coating bar, and then dried up, for providing an image-reception layer. The coated resin quantity in the above last step amounted about 5 g/m^2.

Image-reception layer-forming composition	
polystyrene ("Picolastic D 150" (Tg = 69° C.), manufactured and sold by Rika-Hercules Co., Ltd.	100 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	7 parts;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	7 parts.

Further processing was carried out as was set forth in the foregoing Example E-2, for providing a final product card, carrying thereon the wanted positive images of same superior quality, as was in Example E-2.

EXAMPLE E-5

On the image transferable medium used in the foregoing Example E-4, however, in the present Example, a thermoplastic resin, adhesive, polyolefine-series film, "Adwin 500", manufactured and sold by Showa Denko K.K., Tokyo, was applied as a layer. Other materials were used and processed as set forth therein. In this way, a decorative final product formed with necessary positive was obtained with superior results.

Industrial Availabilities

As will be well understood from the foregoing detailed description of the invention, it is possible according to the present inventive system, to form highly easily and evenly the desired images sharply and attractingly on any product and object to be decorated or graphically ornamented, substantially irrespective of material kind and configuration thereof, and indeed, with a surprising unitary touch and feeling with the substrate. Therefore, the invention can be utilized broadly and conveniently in such various industrial fields, where unitary formation of various images, characters, symbols, numerals and graphics, on and to the articles, objects and substrate products to a sufficiently miracle and attracting degree.

What is claimed is:

1. A method for producing a sublimatingly image-transferred product comprising an article and an image reception layer provided on said article, said image reception layer having a sublimatingly transferred image, said method comprising the steps of:

providing an article to be image-transferred;

providing image data;

forming an image, on the basis of the image data, on an image reception layer by means of a thermal printer having thermal heads; and

transferring the image reception layer onto a surface of the article to produce a sublimatingly image-transferred product.

2. The method according to claim **1**, wherein said image formed on said image-reception layer is formed at a bottom portion thereof and is positioned to face towards the article or on the outer surface of said image-reception layer.

(57) **ABSTRACT**

Vision in an eye is corrected using an energy source for generating a beam of optical radiation and focusing optics disposed in the path of the beam for directing the beam through the eye, where the beam is reflected back from the retina of the eye as a wavefront of radiation to be measured. An optical correction based on an optical path difference between the measured wavefront and a desired plane wave, and refractive indices of the media through which the wavefront passes is provided to a laser delivery system with a laser beam sufficient for ablating corneal material from the cornea of the eye. The laser beam is directed at selected locations on the cornea for ablating the corneal material in response to the optical correction to cause the measured wavefront to approximate the desired plane wave, and thus provide an optical correction.

OBJECTIVE MEASUREMENT AND CORRECTION OF OPTICAL SYSTEMS USING WAVEFRONT ANALYSIS

CROSS-REFERENCE TO RELATED APPLICATIONS

This application is a continuation of and incorporates by reference application Ser. No. 09/496,368 now abandoned, filed Feb. 2, 2000, which itself is a continuation of abandoned application Ser. No. 08/756,272, filed Nov. 25,1996, all commonly owned with the present application.

FIELD OF THE INVENTION

The invention relates generally to optical aberration measurement and correction, and more particularly to the objective measurement and correction of optical systems having a real image focus such as human and animal eyes.

BACKGROUND OF THE INVENTION

Optical systems having a real image focus can receive collimated light and focus it at a point. Such optical systems can be found in nature, e.g., human and animal eyes, or can be man-made, e.g., laboratory systems, guidance systems, etc. In either case, aberrations in the optical system can affect the system's performance. By way of example, the human eye will be used to explain this problem.

Referring to FIG. **1**A, a perfect or ideal eye **100** is shown diffusely reflecting an impinging light beam (not shown for sake of clarity) from the back of its retina **102** (i.e., the fovea centralis **103**) through the eye's optics to include lens **104** and cornea **106**. For such an ideal eye in a relaxed state, i.e., not accommodating to provide near-field focus, the reflected light (represented by arrows **108**) exits eye **100** as a sequence as of plane waves, one of which is represented by straight line **110**. However, an eye normally has aberrations that cause deformation or distortion of the wave exiting the eye. This is shown by way of example in FIG. **1**B where aberrated eye **120** diffusely reflects an impinging light beam (again not shown for sake of clarity) from the back of its retina **122** of the fovea centralis **123** through lens **124** and cornea **126**. For aberrated eye **120**, reflected light **128** exits eye **120** as a sequence of distorted wavefronts, one of which is represented by wavy line **130**.

Currently, there are a number of technologies that attempt to provide the patient with improved visual acuity. Examples of such technologies include remodeling of cornea **126** using refractive laser surgery or intra-corneal implants, and adding synthetic lenses to the optical system using intraocular lens implants or precision-ground spectacles. In each case, the amount of corrective treatment is typically determined by placing spherical and/or cylindrical lenses of known refractive power at the spectacle plane (approximately 1.0–1.5 centimeters anterior to cornea **126**) and asking the patient which lens or lens combination provides the clearest vision. This is obviously a very imprecise measurement of the true distortions in wavefront **130** because 1) a single spherocylindrical compensation is applied across the entire wavefront, 2) vision is tested at discrete intervals (i.e., diopter units) of refractive correction, and 3) subjective determination by the patient is required in order to determine the optical correction. Thus, the conventional methodology for determining refractive errors in the eye is substantially less accurate than the techniques now available for correcting the ocular aberrations.

One method of measuring ocular refractive errors is disclosed by Penney et al. in "Spatially Resolved Objective Autorefractometer," U.S. Pat. No. 5,258,791, issued Nov. 2, 1993. Penney et al. teach the use of an autorefractometer to measure the refraction of the eye at numerous discrete locations across the corneal surface. The autorefractometer is designed to deliver a narrow beam of optical radiation to the surface of the eye, and to determine where that beam strikes the retina using a retinal imaging system. Both the angle of the beam's propagation direction with respect to the optical axis of the system and the approximate location at which the beam strikes the corneal surface of the eye are independently adjustable. A small uncertainty or error in the location of the beam's point of incidence on the cornea exists due to the curved corneal surface. For each point of incidence across the corneal surface, the refraction of the eye corresponding to that surface point can be determined by adjusting the angle at which the beam strikes the cornea until the beam refracted on to the iris strikes the fovea centralis. Adjustment of the beam angle of propagation can be accomplished either manually by the patient or automatically by the autorefractometer if a feedback loop involving a retinal imaging component is incorporated.

Penney et al. further teach the use of the autorefractometer measurements in determining the appropriate corneal surface reshaping to provide emmetropia. This is accomplished by first obtaining accurate measurement of corneal surface topography (using a separate commercially available device). A mathematical analysis is then performed using the initial corneal topography at each surface reference point, the measured refraction at each surface point, and Snell's law of refraction, to determine the required change in surface contour at each reference point. The contour changes at the various reference points are then combined to arrive at a single reshaping profile to be applied across the full corneal surface.

The major limitation to the approach described by Penney et al. is that a separate measurement of corneal topography is required to perform the Snell's Law analysis of needed refraction change. This requirement adds significantly to the time and cost of the complete diagnostic evaluation. Furthermore, the accuracy of the refraction change analysis will be dependent on the accuracy of the topographic measurement and the accuracy of the autorefractometer measurement. In addition, any error in the spatial orientation of the topography "map" with respect to the refraction map will degrade the accuracy of the needed correction profile.

A second limitation to the approach described by Penney et al. is that test points on the corneal surface are examined sequentially. Eye motion during the examination, either voluntary or involuntary, could introduce substantial errors in the refraction measurement. Penney et al. attempt to provide detection of such eye movement by deliberately including measurement points outside the pupil, i.e., in the corneal region overlying the iris, where the return from the retina will obviously be zero at specific intervals in the examination sequence. However, this approach may still allow substantial undetected eye movement error between such iris reference points.

At present, no corrective method is based on the concurrent examination of the complete distortions in wavefront **130**. Measurement of wave aberrations of the human eye, i.e., ocular aberrations, has been studied for a number of years. One prior art method and system are disclosed by Liang et al. in "Objective Measurement of Wave Aberrations of the Human Eye With the Use of a Hartmann-Shack Wave-front Sensor," Journal of the Optical Society of America, Volume 11, No. 7, July 1994, p.p. 1949–1957. Liang et al. teach the use of a Hartmann-Shack wavefront

sensor to measure ocular aberrations by measuring the wavefront emerging from the eye by the retinal reflection of a focused laser light spot on the retina's fovea. The actual wavefront is reconstructed using wavefront estimation with Zernike polynomials.

The Hartmann-Shack wavefront sensor disclosed by Liang et al. includes two identical layers of cylindrical lenses with the layers arranged so that the lenses in each layer are perpendicular to one another. In this way, the two layers act like a two-dimensional array of spherical lenslets that divide the incoming light wave into subapertures. The light through each subaperture is brought to focus in the focal plane of the lens array where a charge coupled device (CCD) image module resides.

The system of Liang et al. is calibrated by impinging an ideal plane wave of light on the lenslet array so that a reference or calibrating pattern of focus spots is imaged on the CCD. Since the ideal wavefront is planar, each spot related to the ideal wavefront is located on the optical axis of the corresponding lenslet. When a distorted wavefront passes through the lenslet array, the image spots on the CCD are shifted with respect to the reference pattern generated by the ideal wavefront. Each shift is proportional to the local slopes, i.e., partial derivatives, of the distorted wavefront which can be used to reconstruct the distorted wavefront, by means of modal wavefront estimation with Zernike polynomials.

However, the system disclosed by Liang et al. is effective only for eyes having fairly good vision. Eyes that exhibit considerable myopia (near-sightedness) would cause the focus spots to overlap on the CCD thereby making local slope determination impossible for eyes having this condition. Similarly, eyes that exhibit considerable hyperopia (farsightedness) deflect the focus spots such that they do not impinge on the CCD thereby again making local slope determination impossible for eyes having this condition.

Another limitation of the system of Liang et al. is the configuration of the Hartmann-Shack sensor in that the lenses must be uniform in order to define a uniform lenslet array so that the entire array shares a common focal plane and does not itself induce distortions in the wavefront. However, the manufacturing costs associated with such constraints are considerable.

Thus, owing to all of the above-noted limitations, Liang et al. can only achieve wavefront measurement for a relatively small class of patients. Such patients can have, at most, mildly distorted vision.

SUMMARY OF THE INVENTION

It is an object of the present invention to provide a method and system for objectively measuring aberrations of optical systems by wavefront analysis and for using such measurement to generate an optical correction.

Another object of the present invention is to provide for the objective measurement of ocular aberrations having a dynamic range that can cope with large amounts of such aberrations so as to be useful in practical applications.

Still another object of the present invention to provide a method and system for objectively measuring ocular aberrations using a wavefront analyzer of simple and inexpensive design.

It is further an object to correct vision by ablating corneal material using a laser beam directed to locations on the surface of the cornea of the eye in response to the objective measurements, thereby providing a measured wavefront that approximates a desired wavefront such as a plane wave.

Other objects and advantages of the present invention will become more obvious hereinafter in the specification and drawings.

To meet such objects, an optical correction system for correcting visual defects of an eye is provided which includes a wavefront analyzer disposed in the path of a wavefront emanating from the eye for determining an optical path difference between a plane wave and the wavefront, a converter for providing an optical correction based on the path difference and refractive indices of media through which the wavefront passes, and a laser beam having power sufficient for ablating corneal material of the cornea of the eye, wherein the optical correction is achieved by the removal of a selected amount of the corneal material.

A method aspect of the invention includes enhancing vision of an eye by optically correcting the eye based on an optical path difference between a plane wave and a wavefront emanating from the retina of the eye and refractive indices of media through which the wavefront passes, to thereby cause the wavefront to approximate the shape of the plane wave. Further, corneal surface altering is based on a Zernike reconstruction of the wavefront, and the optically correcting includes dividing the optical path difference by a difference between an index of refraction of corneal material and an index of refraction of air. The cornea is then ablated using a laser beam directed at selected locations on the surface of the cornea for altering the corneal surface of the eye without regard to a resulting topography of the surface of the cornea.

In accordance with the present invention, an energy source generates a beam of radiation. Optics, disposed in the path of the beam, direct the beam through a focusing optical system, e.g., an eye, that has a rear portion thereof functioning as a diffuse reflector. The beam is diffusely reflected back from the rear portion as a wavefront of radiation that passes through the focusing optical system to impinge on the optics. The optics project the wavefront to a wavefront analyzer in direct correspondence with the wavefront as it emerges from the focusing optical system. A wavefront analyzer is disposed in the path of the wavefront projected from the optics and calculates distortions of the wavefront as an estimate of ocular aberrations of the focusing optical system. The wavefront analyzer includes a wavefront sensor coupled to a processor that analyzes the sensor data to reconstruct the wavefront to include the distortions thereof.

In one embodiment, the radiation is optical radiation and the wavefront sensor is implemented using a plate and a planar array of light-sensitive cells. The plate is generally opaque but that has an array of light transmissive apertures that selectively let impinging light therethrough. The plate is disposed in the path of the wavefront so that portions of the wavefront pass through the light transmissive apertures. The planar array of cells is arranged parallel to and spaced apart from the plate by a selected distance. Each portion of the wavefront passing through one of the light transmissive apertures illuminates a geometric shape covering a unique plurality of cells. In another embodiment, the wavefront sensor comprises a two-dimensional array of spherical lenslets and a planar array of cells. The array of lenslets defines a focal plane that is a focal length away therefrom. The array of lenslets is disposed in the path of the wavefront where portions of the wavefront pass therethrough. The planar array of cells is arranged parallel to and spaced apart from the array of lenslets by a selected distance independent of the focal length. Similar to the first embodiment wavefront sensor, each portion of the wavefront illuminates a geometric shape covering a unique plurality of cells. Regardless of

which wavefront sensor is used, the distance between the planar array of cells and the opaque plate, or the array of lenslets, can be varied to adjust the slope measurement gain of the wavefront sensor and thereby improve the dynamic range of the system.

Another measure of dynamic range enhancement is provided by the focusing optics. The focusing optics includes first and second lenses maintained in fixed positions in the path of the beam and wavefront. An arrangement of optical elements is disposed between the lenses in the path of the beam and the wavefront. The optical elements are adjustable to change the optical path length between the lenses.

If an optical correction is desired, the distortions are converted to an optical correction which, if placed in the path of the wavefront, causes the wavefront to appear approximately as a plane wave. The optical correction can be in the form of a lens or an amount of corneal material ablated from the eye.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1A** is a schematic view of the ideal eye reflecting light from its retina as a planar wavefront;

FIG. **1B** is a schematic view of an aberrated eye reflecting light from its retina as a deformed wavefront;

FIG. **1C** is a schematic view of the distorted wavefront relative to a reference plane to show the wavefront error or optical path difference as a function of transverse distance in the propagation direction;

FIG. **1D** is a schematic view of the distorted wavefront relative to a reference plane that is tangent to the surface of the cornea;

FIG. **2** is a simplified schematic of the system for determining ocular aberrations in accordance with the essential features of the present invention;

FIG. **3** is a schematic of one embodiment of a Hartmann Shack wavefront analyzer used in the present invention;

FIG. **4** is a perspective view of a portion of the pinhole imaging plate and planar array of light-sensitive cells comprising the wavefront sensor from the embodiment of FIG. **3** where the deflection of a wavefront piece associated with an aberrated eye is shown in comparison with a wavefront piece associated with a calibration or planar wavefront;

FIG. **5** is a plan view of a designated area on the planar array of light-sensitive cells associated with a corresponding hole;

FIG. **6** is a schematic of another embodiment of a wavefront analyzer used in the present invention;

FIG. **7** is a schematic view of an embodiment of the present invention suitable for ophthalmic use; and

FIG. **8** is a side view of a cornea showing a thickness of corneal material to be ablated as an optical correction generated by the present invention.

DETAILED DESCRIPTION OF THE INVENTION

By way of illustrative example, the present invention will be described with respect to diagnosing and correcting a human eye. However, it is to be understood that the teachings of the present invention are applicable to any optical system having a real image focus that can (or can be adapted to) diffusely reflect a focused spot of radiation from a rear portion of the optical system back through the optical system as a wavefront of radiation. Thus, the present invention can be used with human or animal eyes of patients that may be alive or dead, or any man-made optical system satisfying the criteria regarding the real image focus.

The method of using wavefront analysis to determine an appropriate optical correction will be introduced with reference to the eye example and the aid of the schematic shown in FIG. **1C**. For convenience, a coordinate system is defined where positive x is upward in the plane of the figure, positive y is outward from the plane of the figure, and positive z is to the right along the propagation direction. Distorted wavefront **130** can be described mathematically as W(x,y).

One method of measuring the distortions in wavefront **130** is to determine the spatial separation Δz between a reference plane **131** (analogous to ideal wavefront **110**) at a known distance z_O from the eye at each (x,y) point of distorted wavefront **130** as the leading edge of wavefront **130** traverses distance z_O. This is illustrated in FIG. **1C** and is described mathematically as

$$\Delta z(x,y)=z_0-W(w,y) \quad (1)$$

These Δz measurements define the inappropriate optical path differences due to the aberrations in the test eye. The appropriate correction consists of removing these optical path differences. Ideally, such correction is performed at reference plane **131**.

Depending on the corrective therapy (i.e., corneal tissue ablation, synthetic lens addition, etc.), the amount of material removed or added at each (x,y) coordinate can be calculated directly if the refractive index of the material in question is known. For many procedures, such as intraocular lens implantation or radial keratotomy, such wavefront analysis can be performed repetitively during the procedure to provide feedback information as to the appropriate endpoint of the procedure.

In terms of the illustrative example, the differences Δz(x, y) between the distorted and ideal wavefronts are the consequence of the aberrations in the eye. Ideal correction of those aberrations consists of introducing an optical path difference at reference plane **131** of negative Δz(x,y). If the treatment approach consists of removing tissue from the surface of the cornea by laser ablation, then a logical choice for the location of reference plane **131** is tangential to the surface of cornea **126** (i.e., z_O=0). This is shown schematically in FIG. **1D** where the curvature of cornea **126** is greatly exaggerated for clarity of illustration. Ablation could then be carried out discretely at each (x,y) coordinate along the cornea by a laser beam delivery and eye tracking system such as disclosed in U.S. patent application Ser. No. 08/232,615, filed Apr. 25, 1994, owned by the same assignee as the present invention, and which is incorporated herein by reference.

The appropriate corneal ablation depth at any (x,y) transverse coordinate is, to within a small error, given by

$$\Delta z(x,y)/(n_c-1) \quad (2)$$

where n_c is the refractive index of corneal tissue or 1.3775. The method described in detail below calculates Δz(x,y) by first measuring the local slopes in wavefront **130**, i.e., δW(x,y)/δx and δW(x,y)/δy, at a number of points in the transverse x and y directions in reference plane **131** and then generating a mathematical description of W(x,y) having slopes in best possible agreement with the experimentally determined values. One such slope $\delta W(x_O,y_O)/\delta x$ is referenced in FIG. **1D**. In doing this, a small error is introduced due to the fact that distorted wavefront **130** is measured at reference plane **131** while wavefront **130** emerged from a

curved (corneal) surface just posterior to reference plane **131**. This error is similar to that encountered with the prior art method of Penney et al. discussed above. The error $E_x(x,y)$ is the lateral displacement in the x-direction at each (x,y) location at the measurement plane (i.e., reference plane **131**) to the curved corneal surface. A similar error will be manifest for any corrections involving curved optical surfaces. The error will generally increase with both (x,y) displacement from the point of tangency and local wavefront error.

The magnitude of error $E_x(x,y)$ can be found for each measurement location (x,y) measured at an arbitrary coordinate, e.g., (x_O,y_O) by projecting that location back to the point of origin on cornea **126**. This can be explained mathematically using FIG. **1**D. For simplicity, the explanation will assume that the error is only in the plane of the figure, i.e., the plane defined by $y=y_O$, although it is quite straightforward mathematically to extend the analysis to include errors the y-dimension. The quantation of the line L tracing the propagation of the wavefront element measured at (x_O,y_O) in the z_O reference plane from the corneal surface to the reference plane is:

$$L(x) = z_0 - \frac{(x - x_0)}{\delta W(x_0, y_0)/\delta x} \tag{3}$$

If the corneal surface in the plane of the figure is described by the expression $S(x_O,y_O)$, then the point of origin for the wavefront element in question can be found by finding the point of intersection between L(x) and $S(x,y_O)$. Mathematically, this requires finding the value x' that satisfies $L(x')=S(x_O,y_O)$. The error $E_x(x_O,y_O)$ then is given as $E_x(x_O,y_O)=x'-x_O$. Extending the analysis to consider errors in the y-direction would yield a similar expression for E_Y where $E_Y(x_O,y_O)=y'-y_O$. If significant, these transverse errors can be compensated for by laterally displacing the aberration correction calculated at each (x,y) coordinate by the amounts $E_X(x,y)$ and $E_Y(x,y)$

In the case of human corneas, the transverse error under most circumstances will be negligible. The error will be zero at the origin where the corneal tissue and reference plane **131** are tangent. For human corneas, the tissue is approximately spherical with a radius of curvature of approximately 7.5–8.0 mm. The corrective treatment radius is typically no more than 3 mm, and local wavefront radius of curvature will almost always exceed 50 mm (a 20 diopter refractive error). The transverse error E at a 3 mm treatment radius for a local wavefront radius of curvature of 50 mm is less than 40 mm.

For certain ophthalmic procedures, wavefront analysis can also be used repetitively during the corrective procedure to provide useful feedback information. One example of such use would be in cataract surgery where wavefront analysis could be performed on the eye following placement of an intra-ocular lens implant (IOL). The analysis could help identify whether the appropriate refractive power IOL has been inserted, or whether a different refractive power IOL should be used. Another example of repetitive wavefront analysis would be during keratoplastic procedures where the cornea of the eye is deliberately distorted by altering the mechanical tension around the periphery thereof. Here, repetitive wavefront analysis could be used to refine the degree of induced tension change at each point around the cornea thereby providing the tool to obtain, optimum surface curvature for best visual acuity.

In order to perform wavefront analysis in a manner compatible with corrective procedures such as those described above, the amount of spatial separation of component portions of wavefront **130** relative to the corresponding component portions of a planar or ideal wavefront must be measured. It is the system and method of the present invention that allows such separation to be objectively and accurately measured for even substantially aberrated eyes including those exhibiting severe defects such as severe myopia or hyperopia.

For the evaluation or measurement portion of the present invention, the patient's pupil should ideally be dilated to approximately 6 millimeters or more, i.e., the typical size of a human pupil in low light. In this way, the eye is evaluated while it is using the greatest area of the cornea so that any correction developed from such measurement takes into account the largest usable corneal area of the patient's eye. (A lesser amount of the cornea is used in daylight where the pupil is considerable smaller, e.g., on the order of 3 millimeters.) Dilation can be brought about naturally by implementing the measurement portion of the present invention in a low light environment such as a dimly lit room. Dilation can also be induced through the use of pharmacologic agents.

Referring now to FIG. **2**, a simplified schematic of the system of the present invention depicting its essential elements is shown and referenced generally by numeral **10**. System **10** includes laser **12** for generating the optical radiation used to produce a small-diameter laser beam. Laser **12** is typically a laser generating collimated laser light (represented by dashed lines **14**) of a wavelength and power that is eye-safe. For ophthalmic applications, appropriate wavelengths would include the entire visible spectrum from approximately 400–710 nanometers and the near infrared spectrum from approximately 710–1000 nanometers. While operation in the visible spectrum is generally preferable (since these are the conditions in which the eye operates), the near infrared spectrum may offer advantages in certain applications. For example, the patient's eye may be more relaxed if the patient does not know measurement is taking place. Regardless of the wavelength of the optical radiation, power should be restricted in ophthalmic applications to eyesafe levels. For laser radiation, appropriate eye-safe exposure levels can be found in the U.S. Federal Performance Standard for Laser Products. If the analysis is to be performed on an optical system other than the eye, the examination wavelength range logically should incorporate the intended performance range of the system.

To select a small-diameter collimated core of laser light **14**, an iris diaphragm **16** can be used to block all of laser light **14** except for laser beam **18** of a size desired for use by the present invention. In terms of the present invention, laser beam **18** can have a diameter in the range of approximately 0.5–4.5 millimeters with 1–3 millimeters being typical. A badly aberrated eye requires a smaller diameter beam while an eye with only slight aberrations can be evaluated with a larger diameter beam. Depending on the output divergence of laser **12**, a lens (not shown) can be positioned in the beam path to optimize collimation.

Laser beam **18** is a polarized beam that is passed through a polarization sensitive beam splitter **20** enroute to being directed to a focusing optical train **22**. Optical train **22** operates to focus laser beam **18** through the optics of eye **120** (e.g., cornea **126**, pupil **125** and lens **124**) to the back of the eye's retina **122**. (It is to be understood that lens **124** may not be present for a patient that has undergone a cataract procedure, however, this does not affect the present invention.) In the illustrated example, optical train **22** images laser beam **18** as a small spot of light at or near the

eye's fovea centralis **123** where the eye's vision is most acute. Note that the small spot of light could be reflected off another portion of retina **122** in order to determine aberrations related to another aspect of one's vision. For example, if the spot of light were reflected off the area of retina **122** surrounding the fovea centralis **123**, aberrations specifically related to one's peripheral vision could be evaluated. In all cases, the spot of light is sized to form a near-diffraction limited image on retina **122**. Thus, the spot of light produced by laser beam **18** at fovea centralis **123** does not exceed approximately 100 micrometers in diameter and, typically, is on the order of 10 micrometers.

The diffuse reflection of laser beam **18** back from retina **122** is represented in FIG. **2** by solid lines **24** indicative of the wavefront of radiation that passes back through eye **120**. Wavefront **24** impinges on and is passed through optical train **22** enroute to polarization sensitive beam splitter **20**. Wavefront **24** is depolarized relative to laser beam **18** due to reflection and refraction as wavefront **24** comes off retina **122**. Accordingly, wavefront **24** is turned at polarization sensitive beam splitter **20** and directed to a wavefront analyzer **26** such as a Hartmann-Shack (H-S) wavefront analyzer. In general, wavefront analyzer **26** measures the slopes of wavefront **24**, i.e., the partial derivatives with respect to x and y, at a number of (x,y) transverse coordinates. This partial derivative information is then used to reconstruct or approximate the original wavefront with a mathematical expression such as a weighted series of Zernike polynomials.

The purpose of the above-specified polarizations states for incident laser beam **18** and beamsplitter **20** is to minimize the amount of stray laser radiation reaching the sensor portion of wavefront analyzer **26**. In some situations, stray radiation may be sufficiently small when compared to the radiation returning from the desired target (e.g., retina **122**) so that the above polarization specifications are unnecessary.

The present invention is able to adapt to a wide range of vision defects and as such achieves a new level of dynamic range in terms of measuring ocular aberrations. Dynamic range enhancement is accomplished with optical train **22** and/or the wavefront sensor portion of wavefront analyzer **26** as will now be explained.

In the illustrated embodiment, optical train **22** includes a first lens **220**, a flat mirror **221**, a Porro mirror **222** and a second lens **224** all of which lie along the path of laser beam **18** and wavefront **24**. First lens **220** and second lens **224** are identical lenses maintained in fixed positions. Porro mirror **222** is capable of linear movement as indicated by arrow **223** to change the optical path length between lenses **220** and **224**. However, it is to be understood that the present invention is not limited to the particular arrangement of flat mirror **221** and Porro mirror **222** and that other optical arrangements could be used between lenses **220** and **224** to change the optical path length therebetween.

The "zero position" of Porro mirror **222** can be identified by replacing eye **120** in FIG. **2** by a broad beam source (not shown) of collimated light to simulate a perfect plane wave. Such a source could be realized by a laser beam expanded by a beam telescope to the diameter that will cover the imaging plane of wavefront analyzer **26** and adjusting Porro mirror **222** until wavefront analyzer **26** detects the light as being collimated. Note that the changes in optical path length brought about by Porro mirror **222** can be calibrated in diopters to provide an approximate spherical dioptric correction as will be explained further below.

The dynamic range of system **10** can be further improved by utilizing a preferred embodiment wavefront analyzer to include an improved wavefront sensor arrangement. One such wavefront sensor arrangement will now be explained with the aid of FIGS. **3** and **4**. In FIG. **3**, the wavefront analyzer includes an opaque imaging plate **32** having an array of holes **34** passing therethrough, a planar array **36** of light-sensitive cells such as charge coupled device cells **38**, and a processor **40** coupled to planar array **36** of cells **38**. The combination of plate **32** and planar array **36** comprises the unique wavefront sensor of this embodiment. Plate **32** is maintained parallel to and spaced apart a separation distance F from planar array **36**. As will be explained further below, separation distance F can be varied to adjust the gain of the sensor. To do this, planar array **36** is coupled to a positioning apparatus **42**, e.g., a conventional motorized linear positioner having precise movement capability, that can adjust the position of planar array **36** relative to plate **32** to change separation distance F as indicated by arrow **43**. With respect to the array of holes **34**, each of holes **34** is of equal size and shape with a circle being typical owing to its ease of manufacture. In the illustrated example, a square array geometry is used for array of holes **34** although other array geometries can be used.

As shown in FIG. **4**, when wavefront **24** impinges on plate **32**, a piece or portion of wavefront **24**, indicated by arrow **25**, passes through hole **34** to illuminate planar array **36**. To a first order, the resulting image formed by each such wavefront piece **25** is a positive shadow of the respective hole **34**. However, diffraction does occur in a way determined by the diameter D of each hole **34**, the wavelength A of the light source (i.e., wavefront **24**) and the separation distance F between plate **32** and planar array **36**. The value F is varied by positioning apparatus **42** to adjust the gain based on the particular patient as will be explained further below.

Note that the function provided by plate **32** with holes **34** could also be accomplished using a solid plate or film made from a light-sensitive material such as a photolithographic film. In such a case, the array of holes **34** would be replaced by an array of shaped light transmissive apertures through which light passes when impinging thereon. The remainder of such a plate or film would be impervious to light. The advantage achieved by such an embodiment is that the light transmissive apertures could easily be made to conform to any desired shape.

Regardless, of how each wavefront piece **25** is generated, the present invention measures the amount of angular deflection of each wavefront piece **25** relative to a wavefront piece that would result from a planar wavefront. This is best seen in FIG. **4** where the calibration or planar wavefront of light results in a wavefront piece represented by arrow **112** (normal to plate **32**) that illuminates a geometric spot **114** on planar array **36**. In contrast, assuming wavefront **24** represents a distorted wavefront as described above, wavefront piece **25** will exhibit an amount of angular deflection relative to (calibrating) wavefront piece **112**. The angular deflection causes wavefront piece **25** to illuminate a geometric spot **27** on planar array **36** that is offset from (calibrating) spot **114**. In terms of the present invention, the amount of offset is measured relative to the centroids **116** and **29** of spots **114** and **27**, respectively. In the two dimensions of planar array **36**, centroid **29** is (typically) deflected in both the x and y directions of array **36**. Thus, the angular deflection in each of the x and y directions is given by $\Delta x/F$ and $\Delta y/F$, respectively.

In the preferred embodiment, lenses **220** and **224** are identical as mentioned above. However, in certain applications it may be desirable to magnify or minify the wavefront

at the wavefront sensor. This can be accomplished by using lenses **220** and **224** of different focal lengths and adjusting the apparatus dimensions accordingly. For ophthalmic evaluation, the object plane of the apparatus should ideally be tangent to the corneal surface which can be achieved by a variety of means. Thus, each point at the object plane of optical train **22** very nearly corresponds to the same point on the cornea (although since the cornea is curved, there will be a slight lateral displacement). Plate **32** (or the imaging plane of any wavefront sensor portion) of wavefront analyzer **26** is positioned at the focal plane of lens **220**. In this way, the object plane is always imaged on plate **32** in direct correspondence with the wavefront image emerging from cornea **126**. This will be true regardless of the optical path length between lenses **220** and **224**. There are several advantages to this structure, one of which is that there are very good planar arrays of light-sensitive cells that are commercially available to image an area corresponding to the 6 millimeter central circular region of the cornea. Additional advantages will now be explained.

The purpose of plate **32** (or the imaging plane of any wavefront sensor portion of wavefront analyzer **26**) is to break wavefront **24** into wavefront pieces that can each be measured independently (in terms of propagation direction) at planar array **36**. Since in the preferred embodiment optical train **22** does not magnify or reduce the image in the object plane, a point at the object plane corresponds to the same point at the image plane of optical train **22**. With Porro mirror **222** set at its "zero position," the direction each piece of wavefront **24** is traveling at the object plane is reproduced exactly at the image plane of wavefront analyzer **26**. For example, if a wavefront piece at a location in the object plane was traveling away from the optical axis at an angle of 20° with respect to the optical axis that is perpendicular to the object plane, the wavefront piece at the same location in the image plane will also be traveling away from the optical axis at an angle of 20°.

Note that a person who is myopic will produce a wavefront such that the wavefront pieces isolated by plate **32** will converge toward the center of planar array **36**. A hyperopic person will produce a wavefront such that the wavefront pieces isolated by plate **32** diverge. Thus, a person with a significant vision error becomes difficult to evaluate because wavefront pieces can either overlap (myopia) at planar array **36** or spill off (hyperopia) planar array **36**.

In the present invention, there are three ways of compensating for such severe aberrations. The first way is to utilize a wavefront sensor with sufficiently small light-sensitive cells **38** and sufficiently large holes **34** (or any other transmissive aperture). In this way, measurement of each wavefront piece can be performed to an acceptable accuracy using a small value for F. The second way is to move planar array **36** along the optical axis to change the separation distance F to plate **32**. For a person with a severe aberration, planar array **36** is positioned close to plate **32** to keep the projected wavefront pieces well separated and on planar array **36**. For a mild aberration, planar array **36** can be moved to increase the separation distance F to plate **32** to make a more accurate measurement. The advantage of moving planar array **36** to change the separation distance F to plate **32** is that the wavefront analysis is easily achieved for any position. The third way of compensating for severe aberrations in the present invention is to change the optical path length between lenses **220** and **224**. Moving Porro mirror **222** will not affect where the wavefront hits plate **32**, but will change the angular deflections at which the projected wavefront pieces pass through plate **32**, i.e., $\Delta x/F$ and $\Delta y/F$. Decreasing the optical path length between lenses **220** and **224** will tend to pull the wavefront pieces toward the center of planar array **36** thereby compensating for hyperopia. Increasing the optical path length between lenses **220** and **224** will tend to spread the wavefront pieces toward the edges of planar array **36** thereby compensating for myopia. The degree to which the angular deflection associated with each wavefront piece is altered is a linear function of its distance off the optical axis and the movement of Porro mirror **222** from its zero position.

In order to accurately determine the centroids of a spot of light impinging on array **36**, it is necessary to provide a fine structure of cells **38** relative to a spot size. In other words, each spot must cover a plurality of cells **38**. In the preferred embodiment, to determine the centroid of each spot unambiguously with respect to a spot caused by another one of holes **34**, a unique number of cells **38** is assigned to each hole **34**. The "assigned areas" are designated in FIG. **5** by the heavy grid lines **39**. It is to be understood that grid lines **39** are not actual physical boundaries between cells **38** but are shown simply to illustrate the unique designated areas containing a plurality of cells **38**. Other centroid strategies can be utilized that do not necessitate such partitioning of array **36**.

Since the wavefront sensor of the present invention does not focus each wavefront piece to a minimum at the surface of array **36**, a larger plurality of cells **38** are illuminated by each geometric spot so that the centroid of each spot can be determined to a greater precision than was previously possible.

The present invention could also be practiced with a wavefront analyzer that replaced plate **32** (FIG. **3**) with a two-dimensional array of identical spherical lenslets **33** as shown in FIG. **6**. To achieve the advantages of the present invention, array **33** is positioned by positioning apparatus **42** such that separation distance F is independent of the focal length f that defines the focal plane of array **33** which is represented by dashed line **35**. In other words, each wavefront piece (e.g., wavefront piece **37**) passed through a subaperture of array **33** is reduced in size (e.g., diameter) but is not necessarily brought to a minimum focus at array **36** as it would be if separation distance F were equal to focal length f. Thus, in practice, array **33** is positioned to concentrate the light in each wavefront piece over an area for sufficient intensity on planar array **36**, yet still illuminate a substantial plurality of cells **38** (as described above) for greatest accuracy in determining the deflection of the spot's centroid.

Regardless of the structure of the wavefront sensor, processor **40** computes each two-dimensional centroid of each spot generated by a wavefront **24**. The amount of two-dimensional centroid shift (relative to the centroid of the calibrating spot) for each designated area associated with a corresponding hole **34** (or subaperture of array **33**) is divided by the separation distance F to generate a matrix of local slopes of the wavefront, i.e., $\delta W(x,y)/\delta x$ and $\delta W(x,y)/\delta y$ at the (x,y), coordinates of the centers of holes **34**. For simplicity, these will be indicated by $P(x,y)=\delta W(x,y)/\delta x$ and $Q(x,y)=\delta W(x,y)/\delta y$, respectively.

Numerous methods exist for using the partial derivative data to calculate the original (distorted) wavefront. One acceptable approach is that used by Liang et al. in the aforementioned paper where the wavefront is approximated using Zernike polynomials. This is a standard analytic technique described in numerous optics texts such as "Principles of Optics," by M. Born and E. Wolf, Pergamon Press, Oxford, England, 1964. By way of example, the Zernike

polynomial approach will be discussed herein. However, it is to be understood that other mathematical approaches can be used in approximating the distorted wavefront.

Briefly, the wavefront W(x,y) is expressed as a weighted sum of the individual polynomials

$$W(x, y) = \sum_{i=0}^{n} C_i Z_i(x, y) \tag{4}$$

where C_i are the weighting coefficients, and $Z_i(x,y)$ are the Zernike polynomials up to some order. The upper limit n on the summation is a function of the number of Zernike polynomials, i.e., the highest order, used to approximate the true wavefront. If m is the highest order used, then

$$n=(m+1)(m+2)/2 \tag{5}$$

Derivation of the Zernike polynomials up to an arbitrary order n is described in numerous optical texts such as the aforementioned book by Born and Wolf.

One possible method of determining a centroid of a spot and calculation of the Zernike weighting coefficients will now be explained. The directions of the unit normals at the center of each hole **34** are based on the centroids of the spots on cells **38**. Since each spot will illuminate a plurality of cells with varying intensity, a standard amplitude-weighted centroid calculation can be used to find the center of each spot. Each centroid must be measured twice, once for perpendicular collimated light, and again for the wavefront to be analyzed. Of course, all spots are imaged simultaneously during each exposure.

Multiple exposures may be used to check for improper eye alignment or eye movement during individual exposures. If eye movement during exposures cannot be analyzed successfully by acquiring multiple exposures, then system **10** can be augmented by the addition of an eye tracker **25**. One possible placement of eye tracker **25** is shown in FIG. **2**. However, it is to be understood that eye tracker **25** could be placed elsewhere in system **10**. One such eye tracker is disclosed in the aforementioned U.S. patent application Ser. No. 08/232,615. In this way, wavefront analysis could be performed even during a limited amount of eye motion.

A one-time calibration exposure can also be used to determine the relative sensitivities of the individual cells. This is made in uniform collimated light with plate **32** removed. The responses of individual cells are then recorded.

For each light transmissive aperture (e.g., hole **34**), the centroid in the collimated case serves as a dedicated origin for the particular hole. The shift from the "origin" for each hole to the centroid caused by wavefront **24** (as observed in this coordinate system) is determined by the direction of the wave surface corresponding to that hole. If Δx(m,n) is the x-component of the (m,n)th centroid and F is the plate separation, then the P-value for the (m,n)th centroid is

$$P(m,n)=\delta x(m,n)/\delta z=\Delta x(m,n)/F \tag{6}$$

The corresponding expression for Q is:

$$Q(m,n)=\delta y(m,n)/\delta z=\Delta y(m,n)/F \tag{7}$$

Thus, each P(m,n) and Q(m,n) represents the partial derivatives of W(x,y) with respect to x and y for the (x,y) coordinates of each hole **34**. For an m-order Zernike approximation of the original wavefront, the experimentally determined P's and Q's are then used in the following equations to calculate the appropriate C_i weighting coefficients as follows:

$$P(m, n) = \frac{\delta W(x, y)}{\delta x} = \sum_{i=0}^{n} C_i \frac{\delta Z_i(x, y)}{\delta x} \tag{8}$$

$$Q(m, n) = \frac{\delta W(x, y)}{\delta x} = \sum_{i=0}^{n} C_i \frac{\delta Z_i(x, y)}{\delta x} \tag{9}$$

By using a least-squares approx(m,n)/δzach to minimize the error between the actual wavefront slopes on the left hand side in the above equations and the Zernike approximations on the right hand side, optimal values for the weighting coefficients can be obtained.

In one possible approach to calculating a centroid (x_c,y_c,) each hole **34** is assigned its dedicated area of the array **36** or ($i_{m,n}$±Δi, $j_{m,n}$±Δj). This square of many light-sensitive cells is large enough that neighboring hole images never encroach, and all illumination from this hole is contained. The square contains 4Δi*Δj cells.

If array **36** is designated $c_{k,1}$=(x_c(i,j),y_c(i,j)), k, 1=0 . . . 2Δ1, 2Δj, and the spacing on centers is Δx=Δy=d, the measured cell responses are V(k,1) and the relative responsivities are R(k,I), then the x-component x_c, a function of i,j is represented by

$$x_c(i,j)=[\Sigma_{k,1}V(k,1)*R(k,1)*d*k]/[\Sigma_{k,1}V(k,1)*R(k,1)] \tag{10}$$

and the y-component y_c, as a function of i,j is represented by

$$y_c(i,j)=[\Sigma_{k,1}V(k,1)*R(k,1)*d*1]/[\Sigma_{k,1}V(k,1)*R(k,1)] \tag{11}$$

Then, if (x_{c0}(i,j), y_{c0}(i,j)) is the "origin centroid" for the (i,j) hole, i.e., made in perpendicular collimated light, and (x_{cw}(i,j), y_{cw}(i,j)) is the corresponding centroid found for the wavefront to be measured, then the relative centroid shift (x_{cr}(i,j), Y_{cr}(i,j)) is found as

$$x_{cr}(i,j)=x_{cw}(i,j)-x_{c0}(i,j) \tag{12}$$

$$y_{cr}(i,j)=y_{cw}(i,j)-y_{c0}(i,j) \tag{13}$$

The values P(i,j) and Q(i,j) are determined from

$$P(i,j)=x_{cr}(i,j)/F \tag{14}$$

and

$$Q(i,j)=y_{cr}(i,j)/F \tag{15}$$

The surface partial derivatives P(i,j) and Q(i,j) for the array of hole centers of plate **32** are next used to calculate the appropriate Zernike polynomial weighting coefficients to describe the original wavefront W(x,y). This will now be explained by way of illustration for a 7×7 square array of holes **34**. However, it is to be understood that other sizes and shapes of hole arrays could be used.

First, a 1×98 matrix (i.e., column vector) PQ(k) is formed as

$$PQ(k)=P(7i+j),\ j=0 \ldots 6,\ i=0 \ldots 6,\ k=0 \ldots 48 \tag{16}$$

$$PQ(k)=Q(7i+j),\ j=0 \ldots 6,\ i=0 \ldots 6,\ k=49 \ldots 98 \tag{17}$$

with j cycling for each i, i.e., PQ (18)=P(2,5).

The matrix PQ is multiplied from the left with a transition matrix TM to get the matrix C as follows

$$C=TM*PQ \tag{18}$$

where TM is a 98 wide by 14 high matrix and C is a 1 wide by 14 high matrix or column vector. C is the matrix C_k k=1, . . . , 14 such that, to a least square error,

$$W(x,y)=\Sigma_k C_k * Z_k(x,y) \quad (19)$$

and TM is calculated for a given aperture, e.g., a 6 millimeter pupil aperture.

The functions Z_k (x,y) in equation (19) are the Zernike polynomials. There is no standard convention as to their sequence. Thus, for consistency, it is important that the same sequence is used to produce the set C_k that was chosen for deriving the matrix TM. They occur in groups of the same order, which is the highest exponent in the group, with the total number of members in an order increasing with the order. For example, in a fourth order analysis, orders up to and including 4 are used (less Z_0—the single member of order 0 that is the constant 1 which describes the reference position of the group in the z direction). Since wavefront **24** is moving along z (at the velocity of light), this "piston term" describes only an arbitrary offset in Z, and this term may be ignored. The first 5 orders (0, 1, . . . ,4) contain 15 functions including the piston term.

Thus, in the illustrated example, 14 values of C_k are calculated as coefficients of 14 Zernike polynomials. By way of example, one such order used to calculate TM is given in Table 1, which includes both the Zernike functions and their partial derivatives.

TABLE 1

ZERNIKE (X,Y) POLYNOMIAL EXPANSION THROUGH ORDER 4

	Polynomial Order 0
Z(0)	+1
dZ(0)/dx	0.0
DZ(0)/dy	0.0
	Polynomial Order 1
Z(1)	+y
dZ(1)/dx	0.0
dZ(1)/dy	+1
Z(2)	+x
dZ(2)/dx	+1
dZ(2)/dy	0.0
	Polynomial Order 2
Z(3)	$+1 + 2y^2 + 2x^2$
dZ(3)/dx	+4x
dZ(3)/dy	+4y
Z(4)	+2xy
dZ(4)/dx	+2y
dZ(4)/dy	+2x
Z(5)	$-y^2 + x^2$
dZ(5)/dx	+2x
dZ(5)/dy	−2y
	Polynomial Order 3
Z(6)	$-2y + 3y^3 + 3x^2y$
dZ(6)/dx	+6xy
dZ(6)/dy	$-2 + 9y^2 + 3x^2$
Z(7)	$-2x + 3xy^2 + 3x^3$
dZ(7)/dx	$-2 + 3y^2 + 9x^2$
dZ(7)/dy	+6xy
Z(8)	$-y^3 + 3x^2y$
dZ(8)/dx	+6xy
dZ(8)/dy	$-3y^2 + 3x^2$
Z(9)	$-3xy^2 + x^3$
dZ(9)/dx	$-3y^2 + 3x^2$
dZ(9)/dy	−6xy
	Polynomial Order 4
Z(10)	$+1 - 6y^2 + 6y^4 - 6x^2 + 12x^2y^2 + 6x^4$
dZ(10)/dx	$-12x + 24xy^2 + 24x^3$
dZ(10)/dy	$-12y + 24y^3 + 24x^2y$
Z(11)	$-6xy + 8xy^3 + 8x^3y$
dZ(11)/dx	$-6y + 8y^3 + 24x^2y$
dZ(11)/dy	$-6x + 24xy^2 + 8x^3$
Z(12)	$+3y^2 - 4y^4 - 3x^2 + 4x^4$
dZ(12)/dx	$-6x + 16x^3$
dZ(12)/dy	$+6y - 16y^3$
Z(13)	$-4xy^3 + 4x^3y$
dZ(13)/dx	$-4y^3 + 12x^2y$
dZ(13)/dy	$-12xy^2 + 4x^3$
Z(14)	$+y^4\ 6x^2y^2 + x^4$
dZ(14)/dx	$-12xy^2 + 4x^3$
dZ(14)/dy	$+4y^3 - 12x^2y$

The choice of sequencing the Zernike polynomials dictates the interpretations of the C_k in equation (19) and therefore the order of terms in the TM matrix. Hence, the TM matrix must be calculated after the choice is made. The development of the TM matrix for the illustrated example will be explained below.

Note that the fourth order analysis is only an example and is not the only possibility. A Zernike analysis can be done to any order. In general, the higher the order, the more accurate the result over the tested points. However, an exact polynomial fit over the tested points is not necessarily desirable. Such fits have the typical disturbing property that, unless the surface itself happens to be an exact polynomial of order no higher than that used for the surface fit, forcing an exact fit at separated points often causes wild swings between fitted points. That is, in polynomial surface fitting, an exact fit at a finite number of points can yield a poor average fit for a general function. For ophthalmic application of the system as described above, computer simulations suggest that a sixth order Zernike analysis may yield the best results.

Calculation of the $\Delta z(x,y)$ optical path difference information from the Zernike reconstruction of the wavefront is accomplished simply by subtracting a constant from the Zernike approximation. The value of the constant will depend on the desired characteristics of $\Delta z(x,y)$. Depending on the method chosen to correct the aberrations (e.g., laser ablation, lens addition, etc.) it may, for example, be desirable to set either the maximum, mean or minimum value in $\Delta z(x,y)$ equal to zero.

The development of the transition matrix TM will now be explained for the illustrated example of a 7×7 array of holes in plate **32**. At each point (x_i,y_j), the tangents of the components of the normal are $P(x_i,y_j)$ and $Q(x_i,y_j)$ where

$$P(x_i,y_j)=\delta W(x_i, y_j)/\delta x \quad (20)$$

and

$$Q(x_i,y_j)=\delta W(x_i,y_j)/\delta y \quad (21)$$

Combining these with equation (11),

$$P(x_i,y_j)=\Sigma_k C_k \delta W(x_i,y_j)/\delta x \quad (22)$$

and

$$Q(x_i,y_j)=\Sigma_k C_k \delta W(x_i,y_j)/\delta y \quad (23)$$

each applicable to 49 (i,j) combinations. These are combined into a single column vector PQ that is 98 elements high, i.e., a 98×1 matrix. Defining two matrices C_k (14 high×1 wide) and $M_{k(i,j)}$ (14 wide×98 high)

$$(M_{k,(i,j)})=\delta Z_k(x_i,y_j)/\delta x;\ \delta Z_k(x_i,y_j)/\delta y \quad (24)$$

where the x-derivatives are the first 49 rows and the y-derivatives are the last 49 rows. Then, equation (19) can be rewritten as the matrix equation

$$(PQ)=(M)(C) \tag{25}$$

where the top 49 rows of M are the $\delta W(x_i, y_j)/\delta y$.

The expression in equation (25) gives the normal components in terms of the Zernike coefficients for a surface described by the array of 14 C's. These are exact, but it is not guaranteed that the actual total surface can be described by such an array of coefficients. Accordingly, if it is assumed that the description is within an acceptable tolerance, i.e., tolerating the errors that remain after least square error determination, then equation (26) can be considered to define the column vector C implicitly in terms of the mathematical matrix M and the measured vector PQ, both of which are known. The method of effecting the solution under the minimization condition is as follows.

First, equation (25) is multiplied on the left by M^T, the transpose of M such that

$$(M^T)(PQ)=(M^T)(M)(C)=(S)(C) \tag{26}$$

where

$$S\equiv M^T M \tag{27}$$

is a square and symmetric matrix, e.g., of dimensions 14×14 (with each element the sum of 98 products). Such a matrix has an inverse unless the determinant of its coefficients is zero. Since this is based on the Zernike polynomials alone, and they are all independent of each other, the determinant is non-zero, so that an inverse S^{-1} is defined. Next, equation (25) is multiplied on the left by S^{-1} to yield

$$(S^{-1})(M^T)(PQ)=(S^{-1})(S)(C)=(I)(C)=C \tag{28}$$

Then, the mathematical transition matrix (independent of measurement) is

$$(TM)=(S^{-1})(M^T) \tag{29}$$

and the "best fit" array of C's from the measured PQ's can be produced by the simple matrix multiplication

$$(C)=(TM)(PQ) \tag{30}$$

To evaluate the eye unambiguously, all spots illuminating planar array **36** due to a wavefront **24** must be incident on planar array **36** simultaneously. This is achieved by pulsing or shuttering the laser source (i.e., laser **12**) such that pulse duration is less than the saccadic motion interval of the eye, i.e., a few milliseconds. Alternatively, the laser source could be left on continuously and wavefront **24** could be shuttered to appear as a wavefront pulse of a duration that is less than saccadic motion of the eye. Accordingly, as shown in FIG. **2**, shutter **50** could be positioned in the path of laser beam **18** before eye **120** or in the path of wavefront **24** before wavefront analyzer **26**.

An implementation of the present invention suitable for clinical use is shown schematically in FIG. **7** and is referenced generally by numeral **11**. Like reference numerals are used to describe elements that are the same as those described above with respect to system **10**. Accordingly, the like elements and their functions will not be described further.

A dichroic beam splitter **52** is interposed between beam splitter **20** and optical train **22** to introduce fixation target optics **60** and observation optics **70** into system **11** which are optically separated from one another by 50/50 beam splitter **54**. Functionally, fixation target optics provide eye **120** with visible light in the shape of a target. The visible light generated by fixation target optics **60** is reflected by dichroic beam splitter **50** and directed through optical train **22**.

It is to be understood that fixation target optics **60** can be implemented in a variety of fashions. By way of example, one such embodiment is shown and includes visible light source **61**, light diffuser **62**, target **63**, field stop **64**, lens **65** and iris **66**. Light source **61** and light diffuser **62** are used to provide uniform illumination of fixation target **63**. Field stop **64**, lens **65**, and iris **66** are used in conjunction with optical train **22** to present a clear image of the fixation target to (patient) eye **120**.

Functionally, observation optics **70** allows a technician to view and document the eye evaluation procedure. While a variety of implementations of observation optics **70** are possible, one such implementation is shown by way of example. In FIG. **7**, observation optics **70** includes field lens **71**, lens **72**, iris **73**, lens **74**, and camera **75**. A ring illuminator **80** is placed in front of eye **120** to illuminate same for observation and/or filming purposes.

The output from wavefront analyzer **26**, e.g., the Zernike expansion of equation (19), can be used in a variety of ways. For example, the output could be used to continually or periodically monitor the progress or effects of an ophthalmic procedure. The output could also be used to develop an optical correction for eye **120**. The optical correction will make wavefront **24** appear approximately as a plane wave. As described above, the optical correction can be implemented in a variety of ways. In each case, the output of wavefront analyzer **26** is input to a processor **90** which converts the Zernike expansion of equation (19) into a form suitable for being implemented as one of the possible optical corrections. (The functions of processor **90** could also be implemented at processor **40** of wavefront analyzer **26**.)

Processor **90** could use some of the Zernike coefficients from the expansion of equation (19) to generate a standard sphero-cylindrical correction for lens grinder **92** to produce a conventional optical lens, e.g., a lens for glasses, a contact lens, etc. Processor **90** could also divide the Zernike reconstruction of the aberrated wavefront by the index of refraction of cornea **126** minus 1, to calculate the amount of corneal material to be ablated at each corresponding (x,y) location on the cornea. The amount of corneal material at each location is input to a laser beam delivery system that typically has eye tracking capability **94** such as described in the afore-mentioned U.S. patent application Ser. No. 08/232,615. Laser beam delivery and eye tracker **94** is placed in line with the optical axis of system **11**. The eye tracker portion of this element allows system **11** to respond unwanted eye motion. Laser beam delivery and eye tracker **94** would typically focus short pulses or "shots" of ablating laser light at cornea **126** or eye **120** to remove the specified thickness t of material at each location. This is shown diagrammatically in FIG. **8** where the uncorrected surface of cornea **126** is referenced by numeral **126**A and the corrected surface of cornea **126** after ablation is referenced by numeral **126**B.

In accordance with the present invention, ablation thickness t is specified across the aperture of the cornea measured, e.g., the 6 millimeter circle to which the eye's pupil was dilated during the measurement of the eye. Outside the prescribed treatment circle, a tapering blend zone of partial ablation may be added to minimize severe changes in corneal curvature and hence lessen regression. Laser beam delivery system **94** removes thickness t to achieve the optical correction, i.e., corrected cornea surface **126**B. Note that the optical correction is not concerned with the ultimate corneal topography, but instead removes corneal material to achieve an optical correction that takes into account all ocular aberrations of the eye. This is important because the shape of the corneal surface can be independent of the

correction required because the eye's vision depends on numerous factors besides corneal curvature. Hence, the best corneal surface topography for optimal vision may be far from regular in that it must compensate for the errors in the eye's other surfaces. Thus, it is apparent that the present invention can be used to provide corneal surface corrections other than the conventional spherical and/or cylindrical corrections.

The advantages of the present invention are numerous. A totally objective approach is presented for measuring ocular aberrations. The approach is effective for a wide range of vision defects. Accordingly, the present invention will be of great utility in a wide variety of clinical applications. For example, the calculated Zernike coefficients can be used to develop a completely objective lens prescription or a corneal correction that could be accomplished with laser ablation. In addition, each of the wavefront sensor embodiments provides for a greater degree of accuracy over the prior art with respect to measuring wavefront deflections. Further, the present wavefront sensor can be adjusted in terms of gain simply by adjusting the separation distance between the imaging plane of the sensor and the planar array of light-sensitive cells.

The objective measurement of the present invention will also find great utility for a large variety of applications in which the "patient" is unable to provide feedback as required by conventional eye diagnosis. For example, the present invention could be used to evaluate the eyes of any patient not possessed of demonstrative communicative skills, e.g., babies, animals, dead specimens, as well as any constructed optical system, since the present invention is an objective analysis not requiring any assessment from the "subject." All that is necessary is for the subject's eye to be properly positioned so that proper optical access to the eye can be obtained.

The present invention could also be used in the area of identification should it be determined that each eye's Zernike coefficients are unique. Then, the present invention would find great utility in the fields of law enforcement, credit card/bank security, or any other field where positive identification would be beneficial.

Although the invention has been described relative to a specific embodiment thereof, there are numerous variations and modifications that will be readily apparent to those skilled in the art in light of the above teachings. It is therefore to be understood that, within the scope of the appended claims, the invention may be practiced other than as specifically described.

That which is claimed is:

1. A system comprising:

an energy source for generating a beam of optical radiation;

focusing optics disposed in the path of said beam for directing said beam through a focusing optical system having a rear portion thereof functioning as a diffuse reflector, wherein said beam is diffusely reflected back from said rear portion as a wavefront of radiation that passes through said focusing optical system to impinge on said optics, said optics projecting said wavefront in direct correspondence with said wavefront impinging on said optics, said focusing optics comprising

a first lens maintained in a first fixed position in the path of said beam and said wavefront;

a second lens maintained in a second fixed position in the path of said beam and said wavefront; and

an arrangement of optical elements disposed between said first lens and said second lens in the path of said beam and said wavefront, said arrangement of optical elements being adjustable for changing the optical path length between said first lens and said second lens; and

a wavefront analyzer disposed in the path of said wavefront projecting from said optics for calculating distortions of the wavefront as an estimate of aberrations of said focusing optical system.

2. A system as in claim **1** wherein said energy source comprises:

a collimated laser for generating collimated laser light; and

an iris diaphragm disposed in the path of said collimated laser light to project a collimated core of said collimated laser light, wherein said collimated core is said beam of radiation having a diameter in the range of approximately 0.5 millimeters to approximately 4.5 millimeters.

3. A system as in claim **1** wherein said wavefront analyzer includes a wavefront sensor for dividing said wavefront into a plurality of optical radiation beams, wherein a focal plane of said first lens is at said wavefront sensor, and wherein a focal plane of said second lens is at an object plane of said focusing optical system.

4. A system as in claim **1** wherein said focusing optical system is an eye and wherein said wavefront analyzer includes a wavefront sensor for dividing said wavefront into a plurality of optical radiation beams, wherein a focal plane of said first lens is at said wavefront sensor, and wherein a focal plane of said second lens is at the pupil of said eye.

5. A system as in claim **1** wherein said wavefront analyzer is a Hartmann-shack wavefront analyzer.

6. A system as in claim **1** wherein said focusing optical system is any eye and further comprising means for causing said beam to occur as a pulse of duration that is less than the saccadic motion interval of said eye.

7. A system as in claim **1** wherein said focusing optical system is any eye and further comprising means for causing said wavefront to appear to said wavefront analyzer as a pulse of duration that is less than the saccadic motion interval of said eye.

8. A system as in claim **1** wherein said focusing optical system is any eye and further comprising a fixation target generator for generating visible light in the shape of a target, said fixation target generator arranged so that said visible light is directed through said optics wherein said visible light can be viewed by said eye.

9. A system as in claim **1** further comprising a converter for converting said distortions to an optical correction which, if placed in the path of said wavefront, causes said wavefront to appear approximately as a plane wave.

10. A system as in claim **9** wherein said converter converts said distortions to a lens prescription, and wherein said optical correction is achieved by a lens based on said lens prescription.

11. A system as in claim **9** wherein said optical system is an eye and wherein said converter converts said distortions to an amount of corneal material of complex geometric shape to be ablated from said eye, said system further comprising a laser beam delivery system for bombarding said eye with a plurality of small-diameter laser beam pulses of a wavelength and power that ablates said corneal material, wherein said optical correction is achieved by the removal of said amount of corneal material.

12. A system as in claim **11** wherein said laser beam delivery system further includes an eye tracker for monitoring motion of said eye and for adjusting the positions of said

plurality of small-diameter laser beam pulses in correspondence with said motion.

13. A system as in claim **9** wherein said optical system is an eye and wherein said converter converts said distortions to a prescribed alteration of corneal surface curvature of said eye, and wherein said optical correction is achieved by the reshaping of said corneal surface curvature of said eye based on said prescribed alteration.

14. A system as in claim **1** wherein said optical system is an eye and further comprising an eye tracker for monitoring motion of said eye.

15. A system comprising:

an energy source for generating a beam of radiation;

optics disposed in the path of said beam for directing said beam through a focusing optical system having a rear portion thereof functioning as a diffuse reflector, wherein said beam is diffusely reflected back from said rear portion as a wavefront of radiation that passes through said focusing optical system to impinge on said optics, said optics projecting said wavefront in direct correspondence with said wavefront impinging on said optics; and

a wavefront analyzer disposed in the path of said wavefront projecting from said optics for calculating distortions of the wavefront as an estimate of aberrations of said focusing optical system, said wavefront analyzer comprising

a plate that is light impervious except for an array of light transmissive apertures that allow impinging light to pass therethrough, said plate disposed in the path of said wavefront wherein portions of said wavefront pass through said array of light transmissive apertures;

a planar array of light-sensitive cells arranged parallel to and spaced apart from said plate by a selected distance, wherein each of said portions of said wavefront passing through one of said array of light transmissive apertures illuminates a geometric shape covering a unique plurality of cells from said planar array of cells;

a processor coupled to said planar array of cells for calculating said distortions based on a centroid of each said geometric shape; and

means for adjusting said selected distance between said plate and said planar array of cells.

16. A system as in claim **15** wherein each light transmissive aperture in said array of light transmissive apertures is of equal size.

17. A system as in claim **15** wherein each light transmissive aperture insaid array of light transmissive apertures is circular.

18. A system as in claim **15** wherein said array of light transmissive apertures is a square array.

19. A system as in claim **15** wherein said radiation is optical radiation and wherein said focusing optics comprises:

a first lens maintained in a first fixed position in the path of said beam and said wavefront;

a second lens maintained in a second fixed position in the path of said beam and said wavefront; and

an arrangement of optical elements disposed between said first lens and said second lens in the path of said beam and said wavefront, said arrangement of optical elements being adjustable for changing the optical path length between said first lens and said second lens.

20. A system comprising:

an energy source for generating a beam of optical radiation;

focusing optics disposed in the path of said beam for directing said beam through a focusing optical system having a rear portion thereof functioning as a diffuse reflector, wherein said beam is diffusely reflected back from said rear portion as a wavefront of radiation that passes through said focusing optical system to impinge on said optics, said optics projecting said wavefront in direct correspondence with said wavefront impinging on said optics, said focusing optics comprising

a first lens maintained in a first fixed position in the path of said beam and said wavefront;

a second lens maintained in a second fixed position in the path of said beam and said wavefront; and

an arrangement of optical elements disposed between said first lens and said second lens in the path of said beam and said wavefront, said arrangement of optical elements being adjustable for changing the optical path length between said first lens and said second lens; and

a wavefront analyzer disposed in the path of said wavefront projecting from said optics for calculating distortions of the wavefront as an estimate of aberrations of said focusing optical system, said wavefront analyzer comprising

a two-dimensional array of spherical lenslets that defines a focal plane that is a focal length away from said two-dimensional array of spherical lenslets, said two-dimensional array of spherical lenslets disposed in the path of said wavefront wherein portions of said wavefront pass through said two-dimensional array of spherical lenslets;

a planar array of light-sensitive cells arranged parallel to and spaced apart from said two-dimensional array of spherical lenslets by a selected distance independent of said focal length, wherein each of said portions of said wavefront passing through said two-dimensional array of spherical lenslets illuminates a geometric shape covering a unique plurality of cells from said planar array of cells;

a processor coupled to said planar array of CCD cells for calculating said distortions based on a centroid of each said geometric shape; and

means for adjusting said selected distance between said two dimensional array of spherical lenslets and said planar array of cells.

21. A system as in claim **20** wherein said optics comprises:

a first lens maintained in a first fixed position in the path of said beam and said wavefront;

a second lens maintained in a second fixed position in the path of said beam and said wavefront; and

an arrangement of optical elements disposed between said first lens and said second lens in the path of said beam and said wavefront, said arrangement of optical elements being adjustable for changing the optical path length between said first lens and said second lens.

22. An optical wavefront sensor, comprising:

a plate that is light impervious except for an array of light transmissive apertures that allow impinging light to pass therethrough, said plate disposed in the path of an optical wavefront wherein portions of said optical wavefront pass through said array of light transmissive apertures;

a planar array of lightsensitive cells arranged parallel to and spaced apart from said plate by a selected distance,

wherein each of said portions of said optical wavefront passing through one of said array of light transmissive apertures illuminates a geometric shape covering a unique plurality of cells from said planar array of cells; and

means for adjusting said selected distance between said plate and said planar array of cells.

23. An optical wavefront sensor as in claim **22** wherein each light transmissive aperture in said array of light transmissive apertures is of equal size.

24. An optical wavefront sensor as in claim **22** wherein each light transmissive aperture in said array of light transmissive apertures is circular.

25. An optical wavefront sensor as in claim **22** wherein said array of light transmissive apertures is a square array.

26. An optical wavefront sensor as in claim **22** further comprising a processor coupled to said planar array of cells for determining a centroid of each said geometric shape.

27. A method comprising the steps of:

generating a beam of optical radiation;

focusing said beam with focusing optics into an eye to image said beam as a focused spot forming a near-diffraction limited image at a back portion of the retina of said eye, wherein said beam is diffusely reflected back from the retina as a wavefront of radiation that passes through said eye;

allowing said wavefront to impinge on said focusing optics;

projecting, with said focusing optics, said wavefront in direct correspondence with said wavefront impinging on said focusing optics;

calculating distortions associated with said wavefront projecting from said focusing optics using a wavefront analyzer disposed in the path of said wavefront projecting from said focusing optics, wherein said wavefront analyzer includes a plate that is light impervious except for an array of light transmissive apertures that allow impinging light to pass therethrough, said plate disposed in the path of said wavefront wherein portions of said wavefront pass through said array of light transmissive apertures, and a planar array of light-sensitive cells arranged parallel to and spaced apart from said plate by a selected distance, wherein each of said portions of said wavefront passing through one of said array of light transmissive apertures illuminates a geometric shape covering a unique plurality of cells from said planar array of cells; and

adjusting said selected distance to adjust the gain of said wavefront analyzer.

28. A method according to claim **27** wherein said step of generating comprises the steps of: producing collimated laser light; and selecting a collimated core of said collimated laser light as said beam of optical radiation having a diameter in the range of approximately 0.5 millimeters to approximately 4.5 millimeters.

29. A method according to claim **27** wherein said step of focusing comprises the steps of:

fixing a first lens in a first position in the path of said beam and said wavefront;

fixing a second lens in a second position in the path of said beam and said wavefront; and

positioning an arrangement of optical elements between said first lens and said second lens in the path of said beam and said wavefront; and

adjusting positions of said arrangement of optical elements to change the optical path length between said first lens and said second lens.

30. A method according to claim **29** wherein said wavefront analyzer includes a wavefront sensor for dividing said wavefront into a plurality of optical radiation beamed wherein said step of fixing said first lens includes the Step of locating a focal plane of said first lens at said wavefront sensor, and wherein said step of fixing said second lens includes the step of locating a focal plane of said second lens at the pupil of said eye.

31. A method according to claim **27** wherein said step of focusing comprises the steps of:

fixing a first lens in a first position in the path of said beam and said wavefront;

fixing a second lens in a second position in the path of said beam and said wavefront; and

positioning an arrangement of optical elements between said first lens and said second lens in the path of said laser beam and said wavefront; and

adjusting positions of said arrangement of optical elements to change the optical path length between said first lens and said second lens.

32. A method according to claim **27** further comprising the step of Shattering said beam such that a pulse is directed through said focusing optics said pulse having a duration that is less than the saccadic motion interval of said eye.

33. A method according to claim **27** further comprising the step of puttering said wavefront such that said wavefront appears to said wavefront analyzer as a pulse of duration that is less than the saccadic motion interval of said eye.

34. A method according to claim **27** further comprising the steps of: generating visible light in the shape of a target; and directing said visible light through said focusing optics wherein said visible light can be viewed by said eye.

35. A method according to claim **27** further comprising the step of converting said distortions to an optical correction which, if placed in the path of said wavefront, causes said wavefront to appear approximately as a plane wave.

36. A method according to claim **35** wherein said optical correction is in the form of a lens.

37. A method according to claim **35** wherein said optical correction is in the form of an amount of corneal material to be ablated from said eye.

38. A method according to claim **35** wherein said optical correction is in the form of prescribed alteration of corneal surface curvature of said eye.

39. A method according to claim **27** further comprising the step of dilating the pupil of said eye to a size achieved in a low-light environment, said step of dilating being accomplished prior to said steps of focusing, allowing and projecting.

40. A method according to claim **27** further comprising the Steps of: performing an ophthalmic procedure on said eye; and performing said steps of generating, focusing, allowing, projecting and calculating at least once after said ophthalmic procedure has commenced to monitor the effects of said ophthalmic procedure on said eye.

41. A method according to claim **27** wherein said step of calculating comprises the step of calculating Zernike coefficients associated with said distortions.

42. A method comprising the steps of:

generating a beam of optical radiation;

focusing said beam with focusing optics into an eye to image said beam as a focused spot forming a near-diffraction limited image at a back portion of the retina of said eye, wherein said beam is diffusely reflected back from the retina as a wavefront of radiation that passes through said eye;

allowing said wavefront to impinge on said focusing optics;

projecting, with said focusing optics, said wavefront in direct correspondence with said wavefront impinging on said focusing optics;

calculating distortions associated with said wavefront projecting from said focusing optics using a wavefront analyzer disposed in the path of said wavefront projecting from said focusing optics, wherein said wavefront analyzer includes a two-dimensional array of spherical lenslets that defines a focal plane that is a focal length away from said two-dimensional array of spherical lenslets, said two-dimensional array of spherical lenslets disposed in the path of said wavefront wherein portions of said wavefront pass through said two-dimensional array of spherical lenslets, and a planar array of lightsensitive cells arranged parallel to and spaced apart from said two-dimensional array of spherical lenslets by a selected distance not equal to said focal length, wherein each of said portions of said wavefront passing through said two-dimensional array of spherical lenslets illuminates a geometric shape covering a unique plurality of cells from said planar array of cells having an array of holes passing therethrough; and

adjusting said selected distance to adjust the gain of said wavefront analyzer.

43. A method according to claim **42** wherein said step of focusing comprises the steps of: fixing a first lens in a first position in the path of said beam and said wavefront; fixing a second lens in a second position in the path of said beam and said wavefront; and positioning an arrangement of optical elements between said first lens and said second lens in the path of said beam and said wavefront; and adjusting positions of said arrangement of optical elements to change the optical path length between said first lens and said second lens.

(57) **ABSTRACT**

Vision in an eye is corrected using an energy source for generating a beam of optical radiation and focusing optics disposed in the path of the beam for directing the beam through the eye, where the beam is reflected back from the retina of the eye as a wavefront of radiation to be measured. An optical correction based on an optical path difference between the measured wavefront and a desired plane wave, and refractive indices of the media through which the wavefront passes is provided to a laser delivery system with a laser beam sufficient for ablating corneal material from the cornea of the eye. The laser beam is directed at selected locations on the cornea for ablating the corneal material in response to the optical correction to cause the measured wavefront to approximate the desired plane wave, and thus provide an optical correction.

OBJECTIVE MEASUREMENT AND CORRECTION OF OPTICAL SYSTEMS USING WAVEFRONT ANALYSIS

CROSS-REFERENCE TO RELATED APPLICATIONS

This application is a continuation of and incorporates by reference application Ser. No. 09/324,179, filed May 20, 1998, now abandoned, which itself is a continuation of abandoned application Ser. No. 08/756,272, filed Nov. 25, 1996, all commonly owned with the present application.

FIELD OF THE INVENTION

The invention relates generally to optical aberration measurement and correction, and more particularly to the objective measurement and correction of optical systems having a real image focus such as human and animal eyes.

BACKGROUND OF THE INVENTION

Optical systems having a real image focus can receive collimated light and focus it at a point. Such optical systems can be found in nature, e.g., human and animal eyes, or can be man-made, e.g., laboratory systems, guidance systems, etc. In either case, aberrations in the optical system can affect the system's performance. By way of example, the human eye will be used to explain this problem.

Referring to FIG. **1A**, a perfect or ideal eye **100** is shown diffusely reflecting an impinging light beam (not shown for sake of clarity) from the back of its retina **102** (i.e., the fovea centralis **103**) through the eye's optics to include lens **104** and cornea **106**. For such an ideal eye in a relaxed state, i.e., not accommodating to provide near-field focus, the reflected light (represented by arrows **108**) exits eye **100** as a sequence as of plane waves, one of which is represented by straight line **110**. However, an eye normally has aberrations that cause deformation or distortion of the wave exiting the eye. This is shown by way of example in FIG. **1B** where aberrated eye **120** diffusely reflects an impinging light beam (again not shown for sake of clarity) from the back of its retina **122** of the fovea centralis **123** through lens **124** and cornea **126**. For

Currently, there are a number of technologies that attempt to provide the patient with improved visual acuity. Examples of such technologies include remodeling of cornea **126** using refractive laser surgery or intra-corneal implants, and adding synthetic lenses to the optical system using intraocular lens implants or precision-ground spectacles. In each case, the amount of corrective treatment is typically determined by placing spherical and/or cylindrical lenses of known refractive power at the spectacle plane (approximately 1.0–1.5 centimeters anterior to cornea **126**) and asking the patient which lens or lens combination provides the clearest vision. This is obviously a very imprecise measurement of the true distortions in wavefront **130** because 1) a single spherocylindrical compensation is applied across the entire wavefront, 2) vision is tested at discrete intervals (i.e., diopter units) of refractive correction, and 3) subjective determination by the patient is required in order to determine the optical correction. Thus, the conventional methodology for determining refractive errors in the eye is substantially less accurate than the techniques now available for correcting the ocular aberrations.

One method of measuring ocular refractive errors is disclosed by Penney et al. in "Spatially Resolved Objective Autorefractometer," U.S. Pat. No. 5,258,791, issued Nov. 2,

1993. Penney et al. teach the use of an autorefractometer to measure the refraction of the eye at numerous discrete locations across the corneal surface. The autorefractometer is designed to deliver a narrow beam of optical radiation to the surface of the eye, and to determine where that beam strikes the retina using a retinal imaging system. Both the angle of the beam's propagation direction with respect to the optical axis of the system and the approximate location at which the beam strikes the corneal surface of the eye are independently adjustable. A small uncertainty or error in the location of the beam's point of incidence on the cornea exists due to the curved corneal surface. For each point of incidence across the corneal surface, the refraction of the eye corresponding to that surface point can be determined by adjusting the angle at which the beam strikes the cornea until the beam refracted on to the iris strikes the fovea centralis. Adjustment of the beam angle of propagation can be accomplished either manually by the patient or automatically by the autorefractometer if a feedback loop involving a retinal imaging component is incorporated.

Penney et al. further teach the use of the autorefractometer measurements in determining the appropriate corneal surface reshaping to provide emmetropia. This is accomplished by first obtaining accurate measurement of corneal surface topography (using a separate commercially available device). A mathematical analysis is then performed using the initial corneal topography at each surface reference point, the measured refraction at each surface point, and Snell's law of refraction, to determine the required change in surface contour at each reference point. The contour changes at the various reference points are then combined to arrive at a single reshaping profile to be applied across the full corneal surface.

The major limitation to the approach described by Penney et al. is that a separate measurement of corneal topography is required to perform the Snell's Law analysis of needed refraction change. This requirement adds significantly to the time and cost of the complete diagnostic evaluation. Furthermore, the accuracy of the refraction change analysis will be dependent on the accuracy of the topographic measurement and the accuracy of the autorefractometer measurement. In addition, any error in the spatial orientation of the topography "map" with respect to the refraction map will degrade the accuracy of the needed correction profile.

A second limitation to the approach described by Penney et al. is that test points on the corneal surface are examined sequentially. Eye motion during the examination, either voluntary or involuntary, could introduce substantial errors in the refraction measurement. Penney et al. attempt to provide detection of such eye movement by deliberately including measurement points outside the pupil, i.e., in the corneal region overlying the iris, where the return from the retina will obviously be zero at specific intervals in the examination sequence. However, this approach may still allow substantial undetected eye movement error between such iris reference points.

At present, no corrective method is based on the concurrent examination of the complete distortions in wavefront **130**. Measurement of wave aberrations of the human eye, i.e., ocular aberrations, has been studied for a number of years. One prior art method and system are disclosed by Liang et al. in "Objective Measurement of Wave Aberrations of the Human Eye With the Use of a Hartmann-Shack Wave-front Sensor," Journal of the Optical Society of America, Volume 11, No. 7, July 1994, p.p. 1949–1957. Liang et al. teach the use of a Hartmann-Shack wavefront sensor to measure ocular aberrations by measuring the

wavefront emerging from the eye by the retinal reflection of a focused laser light spot on the retina's fovea. The actual wavefront is reconstructed using wavefront estimation with Zernike polynomials.

The Hartmann-Shack wavefront sensor disclosed by Liang et al. includes two identical layers of cylindrical lenses with the layers arranged so that the lenses in each layer are perpendicular to one another. In this way, the two layers act like a two-dimensional array of spherical lenslets that divide the incoming light wave into subapertures. The light through each subaperture is brought to focus in the focal plane of the lens array where a charge coupled device (CCD) image module resides.

The system of Liang et al. is calibrated by impinging an ideal plane wave of light on the lenslet array so that a reference or calibrating pattern of focus spots is imaged on the CCD. Since the ideal wavefront is planar, each spot related to the ideal wavefront is located on the optical axis of the corresponding lenslet. When a distorted wavefront passes through the lenslet array, the image spots on the CCD are shifted with respect to the reference pattern generated by the ideal wavefront. Each shift is proportional to the local slopes, i.e., partial derivatives, of the distorted wavefront which can be used to reconstruct the distorted wavefront, by means of modal wavefront estimation with Zernike polynomials.

However, the system disclosed by Liang et al. is effective only for eyes having fairly good vision. Eyes that exhibit considerable myopia (nearsightedness) would cause the focus spots to overlap on the CCD thereby making local slope determination impossible for eyes having this condition. Similarly, eyes that exhibit considerable hyperopia (farsightedness) deflect the focus spots such that they do not impinge on the CCD thereby again making local slope determination impossible for eyes having this condition.

Another limitation of the system of Liang et al. is the configuration of the Hartmann-Shack sensor in that the lenses must be uniform in order to define a uniform lenslet array so that the entire array shares a common focal plane and does not itself induce distortions in the wavefront. However, the manufacturing costs associated with such constraints are considerable.

Thus, owing to all of the above-noted limitations, Liang et al. can only achieve wavefront measurement for a relatively small class of patients. Such patients can have, at most, mildly distorted vision.

SUMMARY OF THE INVENTION

It is an object of the present invention to provide a method and system for objectively measuring aberrations of optical systems by wavefront analysis and for using such measurement to generate an optical correction.

Another object of the present invention is to provide for the objective measurement of ocular aberrations having a dynamic range that can cope with large amounts of such aberrations so as to be useful in practical applications.

Still another object of the present invention to provide a method and system for objectively measuring ocular aberrations using a wavefront analyzer of simple and inexpensive design.

It is further an object to correct vision by ablating corneal material using a laser beam directed to locations on the surface of the cornea of the eye in response to the objective measurements, thereby providing a measured wavefront that approximates a desired wavefront such as a plane wave.

Other objects and advantages of the present invention will become more obvious hereinafter in the specification and drawings.

To meet such objects, an optical correction system for correcting visual defects of an eye is provided which includes a wavefront analyzer disposed in the path of a wavefront emanating from the eye for determining an optical path difference between a plane wave and the wavefront, a converter for providing an optical correction based on the path difference and refractive indices of media through which the wavefront passes, and a laser beam having power sufficient for ablating corneal material of the cornea of the eye, wherein the optical correction is achieved by the removal of a selected amount of the corneal material.

A method aspect of the invention includes enhancing vision of an eye by optically correcting the eye based on an optical path difference between a plane wave and a wavefront emanating from the retina of the eye and refractive indices of media through which the wavefront passes, to thereby cause the wavefront to approximate the shape of the plane wave. Further, corneal surface altering is based on a Zernike reconstruction of the wavefront, and the optically correcting includes dividing the optical path difference by a difference between an index of refraction of corneal material and an index of refraction of air. The cornea is then ablated using a laser beam directed at selected locations on the surface of the cornea for altering the corneal surface of the eye without regard to a resulting topography of the surface of the cornea.

In accordance with the present invention, an energy source generates a beam of radiation. Optics, disposed in the path of the beam, direct the beam through a focusing optical system, e.g., an eye, that has a rear portion thereof functioning as a diffuse reflector. The beam is diffusely reflected back from the rear portion as a wavefront of radiation that passes through the focusing optical system to impinge on the optics. The optics project the wavefront to a wavefront analyzer in direct correspondence with the wavefront as it emerges from the focusing optical system. A wavefront analyzer is disposed in the path of the wavefront projected from the optics and calculates distortions of the wavefront as an estimate of ocular aberrations of the focusing optical system. The wavefront analyzer includes a wavefront sensor coupled to a processor that analyzes the sensor data to reconstruct the wavefront to include the distortions thereof.

In one embodiment, the radiation is optical radiation and the wavefront sensor is implemented using a plate and a planar array of light-sensitive cells. The plate is generally opaque but that has an array of light transmissive apertures that selectively let impinging light therethrough. The plate is disposed in the path of the wavefront so that portions of the wavefront pass through the light transmissive apertures. The planar array of cells is arranged parallel to and spaced apart from the plate by a selected distance. Each portion of the wavefront passing through one of the light transmissive apertures illuminates a geometric shape covering a unique plurality of cells. In another embodiment, the wavefront sensor comprises a two-dimensional array of spherical lenslets and a planar array of cells. The array of lenslets defines a focal plane that is a focal length away therefrom. The array of lenslets is disposed in the path of the wavefront where portions of the wavefront pass therethrough. The planar array of cells is arranged parallel to and spaced apart from the array of lenslets by a selected distance independent of the focal length. Similar to the first embodiment wavefront sensor, each portion of the wavefront illuminates a geometric shape covering a unique plurality of cells. Regardless of

which wavefront sensor is used, the distance between the planar array of cells and the opaque plate, or the array of lenslets, can be varied to adjust the slope measurement gain of the wavefront sensor and thereby improve the dynamic range of the system.

Another measure of dynamic range enhancement is provided by the focusing optics. The focusing optics includes first and second lenses maintained in fixed positions in the path of the beam and wavefront. An arrangement of optical elements is disposed between the lenses in the path of the beam and the wavefront. The optical elements are adjustable to change the optical path length between the lenses.

If an optical correction is desired, the distortions are converted to an optical correction which, if placed in the path of the wavefront, causes the wavefront to appear approximately as a plane wave. The optical correction can be in the form of a lens or an amount of corneal material ablated from the eye.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1A** is a schematic view of the ideal eye reflecting light from its retina as a planar wavefront;

FIG. **1B** is a schematic view of an aberrated eye reflecting light from its retina as a deformed wavefront;

FIG. **1C** is a schematic view of the distorted wavefront relative to a reference plane to show the wavefront error or optical path difference as a function of transverse distance in the propagation direction;

FIG. **1D** is a schematic view of the distorted wavefront relative to a reference plane that is tangent to the surface of the cornea;

FIG. **2** is a simplified schematic of the system for determining ocular aberrations in accordance with the essential features of the present invention;

FIG. **3** is a schematic of one embodiment of a Hartmann Shack wavefront analyzer used in the present invention;

FIG. **4** is a perspective view of a portion of the pinhole imaging plate and planar array of light-sensitive cells comprising the wavefront sensor from the embodiment of FIG. **3** where the deflection of a wavefront piece associated with an aberrated eye is shown in comparison with a wavefront piece associated with a calibration or planar wavefront;

FIG. **5** is a plan view of a designated area on the planar array of light-sensitive cells associated with a corresponding hole;

FIG. **6** is a schematic of another embodiment of a wavefront analyzer used in the present invention;

FIG. **7** is a schematic view of an embodiment of the present invention suitable for ophthalmic use; and

FIG. **8** is a side view of a cornea showing a thickness of corneal material to be ablated as an optical correction generated by the present invention.

DETAILED DESCRIPTION OF THE INVENTION

By way of illustrative example, the present invention will be described with respect to diagnosing and correcting a human eye. However, it is to be understood that the teachings of the present invention are applicable to any optical system having a real image focus that can (or can be adapted to) diffusely reflect a focused spot of radiation from a rear portion of the optical system back through the optical system as a wavefront of radiation. Thus, the present invention can be used with human or animal eyes of patients that may be alive or dead, or any man-made optical system satisfying the criteria regarding the real image focus.

The method of using wavefront analysis to determine an appropriate optical correction will be introduced with reference to the eye example and the aid of the schematic shown in FIG. **1C**. For convenience, a coordinate system is defined where positive x is upward in the plane of the figure, positive y is outward from the plane of the figure, and positive z is to the right along the propagation direction. Distorted wavefront **130** can be described mathematically as W(x,y).

One method of measuring the distortions in wavefront **130** is to determine the spatial separation Δz between a reference plane **131** (analogous to ideal wavefront **110**) at a known distance z_O from the eye at each (x,y) point of distorted wavefront **130** as the leading edge of wavefront **130** traverses distance z_O This is illustrated in FIG. **1C** and is described mathematically as

$$\Delta z(x,y)=z_0-W(w,y) \quad (1)$$

These Δz measurements define the inappropriate optical path differences due to the aberrations in the test eye. The appropriate correction consists of removing these optical path differences. Ideally, such correction is performed at reference plane **131**.

Depending on the corrective therapy (i.e., corneal tissue ablation, synthetic lens addition, etc.), the amount of material removed or added at each (x,y) coordinate can be calculated directly if the refractive index of the material in question is known. For many procedures, such as intraocular lens implantation or radial keratotomy, such wavefront analysis can be performed repetitively during the procedure to provide feedback information as to the appropriate endpoint of the procedure.

In terms of the illustrative example, the differences Δz(x, y) between the distorted and ideal wavefronts are the consequence of the aberrations in the eye. Ideal correction of those aberrations consists of introducing an optical path difference at reference plane **131** of negative Δz(x,y). If the treatment approach consists of removing tissue from the surface of the cornea by laser ablation, then a logical choice for the location of reference plane **131** is tangential to the surface of cornea **126** (i.e., z_O=0). This is shown schematically in FIG. **1D** where the curvature of cornea **126** is greatly exaggerated for clarity of illustration. Ablation could then be carried out discretely at each (x,y) coordinate along the cornea by a laser beam delivery and eye tracking system such as disclosed in U.S. patent application Ser. No. 08/232,615, filed Apr. 25, 1994, owned by the same assignee as the present invention, and which is incorporated herein by reference.

The appropriate corneal ablation depth at any (x,y) transverse coordinate is, to within a small error, given by

$$\Delta z(x,y)/(n_c-1) \quad (2)$$

where n_c is the refractive index of corneal tissue or 1.3775. The method described in detail below calculates Δz(x,y) by first measuring the local slopes in wavefront **130**, i.e., δW(x,y)/δx and δW(x,y)/δy, at a number of points in the transverse x and y directions in reference plane **131** and then generating a mathematical description of W(x,y) having slopes in best possible agreement with the experimentally determined values. One such slope $\delta W(x_O,y_O)/\delta x$ is referenced in FIG. **1D**. In doing this, a small error is introduced due to the fact that distorted wavefront **130** is measured at reference plane **131** while wavefront **130** emerged from a

curved (corneal) surface just posterior to reference plane **131**. This error is similar to that encountered with the prior art method of Penney et al. discussed above. The error $E_X(x,y)$ is the lateral displacement in the x-direction at each (x,y) location at the measurement plane (i.e., reference plane **131**) to the curved corneal surface. A similar error will be manifest for any corrections involving curved optical surfaces. The error will generally increase with both (x,y) displacement from the point of tangency and local wavefront error.

The magnitude of error $E_X(x,y)$ can be found for each measurement location (x,y) measured at an arbitrary coordinate, e.g., (x_O,y_O) by projecting that location back to the point of origin on cornea **126**. This can be explained mathematically using FIG. **1**D. For simplicity, the explanation will assume that the error is only in the plane of the figure, i.e., the plane defined by $y=y_O$, although it is quite straightforward mathematically to extend the analysis to include errors the y-dimension. The quantation of the line L tracing the propagation of the wavefront element measured at (x_O,y_O) in the z_O reference from the corneal surface to the reference plane is:

$$L(x) = z_0 - \frac{(x - x_0)}{\delta W(x_0, y_0)/\delta x} \tag{3}$$

If the corneal surface in the plane of the figure is described by the expression $S(x_O,y_O)$, then the point of origin for the wavefront element in question can be found by finding the point of intersection between L(x) and $S(x,y_O)$. Mathematically, this requires finding the value x' that satisfies $L(x')=S(x_O,y_O)$. The error $E_X(x_O,y_O)$ then is given as $E_X(x_O,y_O)=x'-x_O$. Extending the analysis to consider errors in the y-direction would yield a similar expression for E_Y where $E_Y(x_O,y_O)=y'-y_O$. If significant, these transverse errors can be compensated for by laterally displacing the aberration correction calculated at each (x,y) coordinate by the amounts $E_X(x,y)$ and $E_Y(x,y)$

In the case of human corneas, the transverse error under most circumstances will be negligible. The error will be zero at the origin where the corneal tissue and reference plane **131** are tangent. For human corneas, the tissue is approximately spherical with a radius of curvature of approximately 7.5–8.0 mm. The corrective treatment radius is typically no more than 3 mm, and local wavefront radius of curvature will almost always exceed 50 mm (a 20 diopter refractive error). The transverse error E at a 3 mm treatment radius for a local wavefront radius of curvature of 50 mm is less than 40 mm.

For certain ophthalmic procedures, wavefront analysis can also be used repetitively during the corrective procedure to provide useful feedback information. One example of such use would be in cataract surgery where wavefront analysis could be performed on the eye following placement of an intra-ocular lens implant (IOL). The analysis could help identify whether the appropriate refractive power IOL has been inserted, or whether a different refractive power IOL should be used. Another example of repetitive wavefront analysis would be during keratoplastic procedures where the cornea of the eye is deliberately distorted by altering the mechanical tension around the periphery thereof. Here, repetitive wavefront analysis could be used to refine the degree of induced tension change at each point around the cornea thereby providing the tool to obtain, optimum surface curvature for best visual acuity.

In order to perform wavefront analysis in a manner compatible with corrective procedures such as those described above, the amount of spatial separation of component portions of wavefront **130** relative to the corresponding component portions of a planar or ideal wavefront must be measured. It is the system and method of the present invention that allows such separation to be objectively and accurately measured for even substantially aberrated eyes including those exhibiting severe defects such as severe myopia or hyperopia.

For the evaluation or measurement portion of the present invention, the patient's pupil should ideally be dilated to approximately 6 millimeters or more, i.e., the typical size of a human pupil in low light. In this way, the eye is evaluated while it is using the greatest area of the cornea so that any correction developed from such measurement takes into account the largest usable corneal area of the patient's eye. (A lesser amount of the cornea is used in daylight where the pupil is considerable smaller, e.g., on the order of 3 millimeters.) Dilation can be brought about naturally by implementing the measurement portion of the present invention in a low light environment such as a dimly lit room. Dilation can also be induced through the use of pharmacologic agents.

Referring now to FIG. **2**, a simplified schematic of the system of the present invention depicting its essential elements is shown and referenced generally by numeral **10**. System **10** includes laser **12** for generating the optical radiation used to produce a small-diameter laser beam. Laser **12** is typically a laser generating collimated laser light (represented by dashed lines **14**) of a wavelength and power that is eye-safe. For ophthalmic applications, appropriate wavelengths would include the entire visible spectrum from approximately 400–710 nanometers and the near infrared spectrum from approximately 710–1000 nanometers. While operation in the visible spectrum is generally preferable (since these are the conditions in which the eye operates), the near infrared spectrum may offer advantages in certain applications. For example, the patient's eye may be more relaxed if the patient does not know measurement is taking place. Regardless of the wavelength of the optical radiation, power should be restricted in ophthalmic applications to eyesafe levels. For laser radiation, appropriate eye-safe exposure levels can be found in the U.S. Federal Performance Standard for Laser Products. If the analysis is to be performed on an optical system other than the eye, the examination wavelength range logically should incorporate the intended performance range of the system.

To select a small-diameter collimated core of laser light **14**, an iris diaphragm **16** can be used to block all of laser light **14** except for laser beam **18** of a size desired for use by the present invention. In terms of the present invention, laser beam **18** can have a diameter in the range of approximately 0.5–4.5 millimeters with 1–3 millimeters being typical. A badly aberrated eye requires a smaller diameter beam while an eye with only slight aberrations can be evaluated with a larger diameter beam. Depending on the output divergence of laser **12**, a lens (not shown) can be positioned in the beam path to optimize collimation.

Laser beam **18** is a polarized beam that is passed through a polarization sensitive beam splitter **20** enroute to being directed to a focusing optical train **22**. Optical train **22** operates to focus laser beam **18** through the optics of eye **120** (e.g., cornea **126**, pupil **125** and lens **124**) to the back of the eye's retina **122**. (It is to be understood that lens **124** may not be present for a patient that has undergone a cataract procedure, however, this does not affect the present invention.) In the illustrated example, optical train **22** images laser beam **18** as a small spot of light at or near the

eye's fovea centralis **123** where the eye's vision is most acute. Note that the small spot of light could be reflected off another portion of retina **122** in order to determine aberrations related to another aspect of one's vision. For example, if the spot of light were reflected off the area of retina **122** surrounding the fovea centralis **123**, aberrations specifically related to one's peripheral vision could be evaluated. In all cases, the spot of light is sized to form a near-diffraction limited image on retina **122**. Thus, the spot of light produced by laser beam **18** at fovea centralis **123** does not exceed approximately 100 micrometers in diameter and, typically, is on the order of 10 micrometers.

The diffuse reflection of laser beam **18** back from retina **122** is represented in FIG. **2** by solid lines **24** indicative of the wavefront of radiation that passes back through eye **120**. Wavefront **24** impinges on and is passed through optical train **22** enroute to polarization sensitive beam splitter **20**. Wavefront **24** is depolarized relative to laser beam **18** due to reflection and refraction as wavefront **24** comes off retina **122**. Accordingly, wavefront **24** is turned at polarization sensitive beam splitter **20** and directed to a wavefront analyzer **26** such as a Hartmann-Shack (H-S) wavefront analyzer. In general, wavefront analyzer **26** measures the slopes of wavefront **24**, i.e., the partial derivatives with respect to x and y, at a number of (x,y) transverse coordinates. This partial derivative information is then used to reconstruct or approximate the original wavefront with a mathematical expression such as a weighted series of Zernike polynomials.

The purpose of the above-specified polarizations states for incident laser beam **18** and beamsplitter **20** is to minimize the amount of stray laser radiation reaching the sensor portion of wavefront analyzer **26**. In some situations, stray radiation may be sufficiently small when compared to the radiation returning from the desired target (e.g., retina **122**) so that the above polarization specifications are unnecessary.

The present invention is able to adapt to a wide range of vision defects and as such achieves a new level of dynamic range in terms of measuring ocular aberrations. Dynamic range enhancement is accomplished with optical train **22** and/or the wavefront sensor portion of wavefront analyzer **26** as will now be explained.

In the illustrated embodiment, optical train **22** includes a first lens **220**, a flat mirror **221**, a Porro mirror **222** and a second lens **224** all of which lie along the path of laser beam **18** and wavefront **24**. First lens **220** and second lens **224** are identical lenses maintained in fixed positions. Porro mirror **222** is capable of linear movement as indicated by arrow **223** to change the optical path length between lenses **220** and **224**. However, it is to be understood that the present invention is not limited to the particular arrangement of flat mirror **221** and Porro mirror **222** and that other optical arrangements could be used between lenses **220** and **224** to change the optical path length therebetween.

The "zero position" of Porro mirror **222** can be identified by replacing eye **120** in FIG. **2** by a broad beam source (not shown) of collimated light to simulate a perfect plane wave. Such a source could be realized by a laser beam expanded by a beam telescope to the diameter that will cover the imaging plane of wavefront analyzer **26** and adjusting Porro mirror **222** until wavefront analyzer **26** detects the light as being collimated. Note that the changes in optical path length brought about by Porro mirror **222** can be calibrated in diopters to provide an approximate spherical dioptric correction as will be explained further below.

The dynamic range of system **10** can be further improved by utilizing a preferred embodiment wavefront analyzer to include an improved wavefront sensor arrangement. One such wavefront sensor arrangement will now be explained with the aid of FIGS. **3** and **4**. In FIG. **3**, the wavefront analyzer includes an opaque imaging plate **32** having an array of holes **34** passing therethrough, a planar array **36** of light-sensitive cells such as charge coupled device cells **38**, and a processor **40** coupled to planar array **36** of cells **38**. The combination of plate **32** and planar array **36** comprises the unique wavefront sensor of this embodiment. Plate **32** is maintained parallel to and spaced apart a separation distance F from planar array **36**. As will be explained further below, separation distance F can be varied to adjust the gain of the sensor. To do this, planar array **36** is coupled to a positioning apparatus **42**, e.g., a conventional motorized linear positioner having precise movement capability, that can adjust the position of planar array **36** relative to plate **32** to change separation distance F as indicated by arrow **43**. With respect to the array of holes **34**, each of holes **34** is of equal size and shape with a circle being typical owing to its ease of manufacture. In the illustrated example, a square array geometry is used for array of holes **34** although other array geometries can be used.

As shown in FIG. **4**, when wavefront **24** impinges on plate **32**, a piece or portion of wavefront **24**, indicated by arrow **25**, passes through hole **34** to illuminate planar array **36**. To a first order, the resulting image formed by each such wavefront piece **25** is a positive shadow of the respective hole **34**. However, diffraction does occur in a way determined by the diameter D of each hole **34**, the wavelength λ of the light source (i.e., wavefront **24**) and the separation distance F between plate **32** and planar array **36**. The value F is varied by positioning apparatus **42** to adjust the gain based on the particular patient as will be explained further below.

Note that the function provided by plate **32** with holes **34** could also be accomplished using a solid plate or film made from a light-sensitive material such as a photolithographic film. In such a case, the array of holes **34** would be replaced by an array of shaped light transmissive apertures through which light passes when impinging thereon. The remainder of such a plate or film would be impervious to light. The advantage achieved by such an embodiment is that the light transmissive apertures could easily be made to conform to any desired shape.

Regardless, of how each wavefront piece **25** is generated, the present invention measures the amount of angular deflection of each wavefront piece **25** relative to a wavefront piece that would result from a planar wavefront. This is best seen in FIG. **4** where the calibration or planar wavefront of light results in a wavefront piece represented by arrow **112** (normal to plate **32**) that illuminates a geometric spot **114** on planar array **36**. In contrast, assuming wavefront **24** represents a distorted wavefront as described above, wavefront piece **25** will exhibit an amount of angular deflection relative to (calibrating) wavefront piece **112**. The angular deflection causes wavefront piece **25** to illuminate a geometric spot **27** on planar array **36** that is offset from (calibrating) spot **114**. In terms of the present invention, the amount of offset is measured relative to the centroids **116** and **29** of spots **114** and **27**, respectively. In the two dimensions of planar array **36**, centroid **29** is (typically) deflected in both the x and y directions of array **36**. Thus, the angular deflection in each of the x and y directions is given by $\Delta x/F$ and $\Delta y/F$, respectively.

In the preferred embodiment, lenses **220** and **224** are identical as mentioned above. However, in certain applications it may be desirable to magnify or minify the wavefront

at the wavefront sensor. This can be accomplished by using lenses **220** and **224** of different focal lengths and adjusting the apparatus dimensions accordingly. For ophthalmic evaluation, the object plane of the apparatus should ideally be tangent to the corneal surface which can be achieved by a variety of means. Thus, each point at the object plane of optical train **22** very nearly corresponds to the same point on the cornea (although since the cornea is curved, there will be a slight lateral displacement). Plate **32** (or the imaging plane of any wavefront sensor portion) of wavefront analyzer **26** is positioned at the focal plane of lens **220**. In this way, the object plane is always imaged on plate **32** in direct correspondence with the wavefront image emerging from cornea **126**. This will be true regardless of the optical path length between lenses **220** and **224**. There are several advantages to this structure, one of which is that there are very good planar arrays of light-sensitive cells that are commercially available to image an area corresponding to the 6 millimeter central circular region of the cornea. Additional advantages will now be explained.

The purpose of plate **32** (or the imaging plane of any wavefront sensor portion of wavefront analyzer **26**) is to break wavefront **24** into wavefront pieces that can each be measured independently (in terms of propagation direction) at planar array **36**. Since in the preferred embodiment optical train **22** does not magnify or reduce the image in the object plane, a point at the object plane corresponds to the same point at the image plane of optical train **22**. With Porro mirror **222** set at its "zero position," the direction each piece of wavefront **24** is traveling at the object plane is reproduced exactly at the image plane of wavefront analyzer **26**. For example, if a wavefront piece at a location in the object plane was traveling away from the optical axis at an angle of 20° with respect to the optical axis that is perpendicular to the object plane, the wavefront piece at the same location in the image plane will also be traveling away from the optical axis at an angle of 20°.

Note that a person who is myopic will produce a wavefront such that the wavefront pieces isolated by plate **32** will converge toward the center of planar array **36**. A hyperopic person will produce a wavefront such that the wavefront pieces isolated by plate **32** diverge. Thus, a person with a significant vision error becomes difficult to evaluate because wavefront pieces can either overlap (myopia) at planar array **36** or spill off (hyperopia) planar array **36**.

In the present invention, there are three ways of compensating for such severe aberrations. The first way is to utilize a wavefront sensor with sufficiently small light-sensitive cells **38** and sufficiently large holes **34** (or any other transmissive aperture). In this way, measurement of each wavefront piece can be performed to an acceptable accuracy using a small value for F. The second way is to move planar array **36** along the optical axis to change the separation distance F to plate **32**. For a person with a severe aberration, planar array **36** is positioned close to plate **32** to keep the projected wavefront pieces well separated and on planar array **36**. For a mild aberration, planar array **36** can be moved to increase the separation distance F to plate **32** to make a more accurate measurement. The advantage of moving planar array **36** to change the separation distance F to plate **32** is that the wavefront analysis is easily achieved for any position. The third way of compensating for severe aberrations in the present invention is to change the optical path length between lenses **220** and **224**. Moving Porro mirror **222** will not affect where the wavefront hits plate **32**, but will change the angular deflections at which the projected wavefront pieces pass through plate **32**, i.e., $\Delta x/F$ and $\Delta y/F$. Decreasing the optical path length between lenses **220** and **224** will tend to pull the wavefront pieces toward the center of planar array **36** thereby compensating for hyperopia. Increasing the optical path length between lenses **220** and **224** will tend to spread the wavefront pieces toward the edges of planar array **36** thereby compensating for myopia. The degree to which the angular deflection associated with each wavefront piece is altered is a linear function of its distance off the optical axis and the movement of Porro mirror **222** from its zero position.

In order to accurately determine the centroids of a spot of light impinging on array **36**, it is necessary to provide a fine structure of cells **38** relative to a spot size. In other words, each spot must cover a plurality of cells **38**. In the preferred embodiment, to determine the centroid of each spot unambiguously with respect to a spot caused by another one of holes **34**, a unique number of cells **38** is assigned to each hole **34**. The "assigned areas" are designated in FIG. **5** by the heavy grid lines **39**. It is to be understood that grid lines **39** are not actual physical boundaries between cells **38** but are shown simply to illustrate the unique designated areas containing a plurality of cells **38**. Other centroid strategies can be utilized that do not necessitate such partitioning of array **36**.

Since the wavefront sensor of the present invention does not focus each wavefront piece to a minimum at the surface of array **36**, a larger plurality of cells **38** are illuminated by each geometric spot so that the centroid of each spot can be determined to a greater precision than was previously possible.

The present invention could also be practiced with a wavefront analyzer that replaced plate **32** (FIG. **3**) with a two-dimensional array of identical spherical lenslets **33** as shown in FIG. **6**. To achieve the advantages of the present invention, array **33** is positioned by positioning apparatus **42** such that separation distance F is independent of the focal length f that defines the focal plane of array **33** which is represented by dashed line **35**. In other words, each wavefront piece (e.g., wavefront piece **37**) passed through a subaperture of array **33** is reduced in size (e.g., diameter) but is not necessarily brought to a minimum focus at array **36** as it would be if separation distance F were equal to focal length f. Thus, in practice, array **33** is positioned to concentrate the light in each wavefront piece over an area for sufficient intensity on planar array **36**, yet still illuminate a substantial plurality of cells **38** (as described above) for greatest accuracy in determining the deflection of the spot's centroid.

Regardless of the structure of the wavefront sensor, processor **40** computes each two-dimensional centroid of each spot generated by a wavefront **24**. The amount of two-dimensional centroid shift (relative to the centroid of the calibrating spot) for each designated area associated with a corresponding hole **34** (or subaperture of array **33**) is divided by the separation distance F to generate a matrix of local slopes of the wavefront, i.e., $\delta W(x,y)/\delta x$ and $\delta W(x,y)/\delta y$ at the (x,y), coordinates of the centers of holes **34**. For simplicity, these will be indicated by $P(x,y)=\delta W(x,y)/\delta x$ and $Q(x,y)=\delta W(x,y)/\delta y$, respectively.

Numerous methods exist for using the partial derivative data to calculate the original (distorted) wavefront. One acceptable approach is that used by Liang et al. in the aforementioned paper where the wavefront is approximated using Zernike polynomials. This is a standard analytic technique described in numerous optics texts such as "Principles of Optics," by M. Born and E. Wolf, Pergamon Press, Oxford, England, 1964. By way of example, the Zernike

polynomial approach will be discussed herein. However, it is to be understood that other mathematical approaches can be used in approximating the distorted wavefront.

Briefly, the wavefront W(x,y) is expressed as a weighted sum of the individual polynomials

$$W(x, y) = \sum_{i=0}^{n} C_i Z_i(x, y) \tag{4}$$

where C_i are the weighting coefficients, and $Z_i(x,y)$ are the Zernike polynomials up to some order. The upper limit n on the summation is a function of the number of Zernike polynomials, i.e., the highest order, used to approximate the true wavefront. If m is the highest order used, then

$$n=(m+1)(m+2)/2 \tag{5}$$

Derivation of the Zernike polynomials up to an arbitrary order n is described in numerous optical texts such as the aforementioned book by Born and Wolf.

One possible method of determining a centroid of a spot and calculation of the Zernike weighting coefficients will now be explained. The directions of the unit normals at the center of each hole **34** are based on the centroids of the spots on cells **38**. Since each spot will illuminate a plurality of cells with varying intensity, a standard amplitude-weighted centroid calculation can be used to find the center of each spot. Each centroid must be measured twice, once for perpendicular collimated light, and again for the wavefront to be analyzed. Of course, all spots are imaged simultaneously during each exposure.

Multiple exposures may be used to check for improper eye alignment or eye movement during individual exposures. If eye movement during exposures cannot be analyzed successfully by acquiring multiple exposures, then system **10** can be augmented by the addition of an eye tracker **25**. One possible placement of eye tracker **25** is shown in FIG. **2**. However, it is to be understood that eye tracker **25** could be placed elsewhere in system **10**. One such eye tracker is disclosed in the aforementioned U.S. patent application Ser. No. 08/232,615. In this way, wavefront analysis could be performed even during a limited amount of eye motion.

A one-time calibration exposure can also be used to determine the relative sensitivities of the individual cells. This is made in uniform collimated light with plate **32** removed. The responses of individual cells are then recorded.

For each light transmissive aperture (e.g., hole **34**), the centroid in the collimated case serves as a dedicated origin for the particular hole. The shift from the "origin" for each hole to the centroid caused by wavefront **24** (as observed in this coordinate system) is determined by the direction of the wave surface corresponding to that hole. If $\Delta x(m,n)$ is the x-component of the (m,n)th centroid and F is the plate separation, then the P-value for the (m,n)th centroid is

$$P(m,n)=\delta x(m,n)/\delta z=\Delta x(m,n)/F \tag{6}$$

The corresponding expression for Q is:

$$Q(m,n)=\delta y(m,n)/\delta z=\Delta y(m,n)/F \tag{7}$$

Thus, each P(m,n) and Q(m,n) represents the partial derivatives of W(x,y) with respect to x and y for the (x,y) coordinates of each hole **34**. For an m-order Zernike approximation of the original wavefront, the experimentally determined P's and Q's are then used in the following equations to calculate the appropriate C_i weighting coefficients as follows:

$$P(m, n) = \frac{\delta W(x, y)}{\delta x} = \sum_{i=0}^{n} C_i \frac{\delta Z_i(x, y)}{\delta x} \tag{8}$$

$$Q(m, n) = \frac{\delta W(x, y)}{\delta x} = \sum_{i=0}^{n} C_i \frac{\delta Z_i(x, y)}{\delta x} \tag{9}$$

By using a least-squares approx(m,n)/δzach to minimize the error between the actual wavefront slopes on the left hand side in the above equations and the Zernike approximations on the right hand side, optimal values for the weighting coefficients can be obtained.

In one possible approach to calculating a centroid $(x_c,y_c,)$ each hole **34** is assigned its dedicated area of the array **36** or $(i_{m,n}\pm\Delta i, j_{m,n}\pm\Delta j)$. This square of many light-sensitive cells is large enough that neighboring hole images never encroach, and all illumination from this hole is contained. The square contains $4\Delta i*\Delta j$ cells.

If array **36** is designated $C_{k,1}=(x_c(i,j),y_c(i,j))$, k, 1=0 . . . $2\Delta 1$, $2\Delta j$, and the spacing on centers is $\Delta x=\Delta y=d$, the measured cell responses are V(k, 1) and the relative responsivities are R(k,l), then the x-component x_c, a function of i,j is represented by

$$x_c(i,j)=[\Sigma_{k,l}V(k,l)*R(k,l)*d*k]/[\Sigma_{k,l}V(k,l)*R(k,l)] \tag{10}$$

and the y-component y_c, as a function of i,j is represented by

$$y_c(i,j)=[\Sigma_{k,l}V(k,l)*R(k,l)*d*l]/[\Sigma_{k,l}V(k,l)*R(k,l)] \tag{11}$$

Then, if $(x_{c0}(i,j), y_{c0}(i,j))$ is the "origin centroid" for the (i,j) hole, i.e., made in perpendicular collimated light, and $(x_{cw}(i,j), y_{cw}(i,j))$ is the corresponding centroid found for the wavefront to be measured, then the relative centroid shift $(x_{cr}(i,j), Y_{cr}(i,j))$ is found as

$$X_{cr}(i,j)=x_{cw}(i,j)-x_{c0}(i,j) \tag{12}$$

$$y_{cr}(i,j)=y_{cw}(i,j)-y_{c0}(i,j) \tag{13}$$

The values P(i,j) and Q(i,j) are determined from

$$P(i,j)=x_{cr}(i,j)/F \tag{14}$$

and

$$Q(i,j)=y_{cr}(i,j)/F \tag{15}$$

The surface partial derivatives P(i,j) and Q(i,j) for the array of hole centers of plate **32** are next used to calculate the appropriate Zernike polynomial weighting coefficients to describe the original wavefront W(x,y). This will now be explained by way of illustration for a 7×7 square array of holes **34**. However, it is to be understood that other sizes and shapes of hole arrays could be used.

First, a 1×98 matrix (i.e., column vector) PQ(k) is formed as

$$PQ(k)=P(7i+j),\ j=0 \ldots 6,\ i=0 \ldots 6,\ k=0 \ldots 48 \tag{16}$$

$$PQ(k)=Q(7i+j),\ j=0 \ldots 6,\ i=0 \ldots 6,\ k=49 \ldots 98 \tag{17}$$

with j cycling for each i, i.e., PQ (18)=P(2,5).

The matrix PQ is multiplied from the left with a transition matrix TM to get the matrix C as follows

$$C=TM*PQ \tag{18}$$

where TM is a 98 wide by 14 high matrix and C is a 1 wide by 14 high matrix or column vector. C is the matrix C_k k=1, . . . , 14 such that, to a least square error,

$$W(x,y)=\Sigma_k C_k * Z_k(x,y) \quad (19)$$

and TM is calculated for a given aperture, e.g., a 6 millimeter pupil aperture.

The functions Z_k (X,y) in equation (19) are the Zernike polynomials. There is no standard convention as to their sequence. Thus, for consistency, it is important that the same sequence is used to produce the set C_k that was chosen for deriving the matrix TM. They occur in groups of the same order, which is the highest exponent in the group, with the total number of members in an order increasing with the order. For example, in a fourth order analysis, orders up to and including 4 are used (less Z_0—the single member of order 0 that is the constant 1 which describes the reference position of the group in the z direction). Since wavefront **24** is moving along z (at the velocity of light), this "piston term" describes only an arbitrary offset in Z, and this term may be ignored. The first 5 orders (0, 1, . . . , 4) contain 15 functions including the piston term.

Thus, in the illustrated example, 14 values of C_k are calculated as coefficients of 14 Zernike polynomials. By way of example, one such order used to calculate TM is given in Table 1, which includes both the Zernike functions and their partial derivatives.

dZ(14)/dy	$+4y^3 - 12x^2y$

The choice of sequencing the Zernike polynomials dictates the interpretations of the C_k in equation (19) and therefore the order of terms in the TM matrix. Hence, the TM matrix must be calculated after the choice is made. The development of the TM matrix for the illustrated example will be explained below.

Note that the fourth order analysis is only an example and is not the only possibility. A Zernike analysis can be done to any order. In general, the higher the order, the more accurate the result over the tested points. However, an exact polynomial fit over the tested points is not necessarily desirable. Such fits have the typical disturbing property that, unless the surface itself happens to be an exact polynomial of order no higher than that used for the surface fit, forcing an exact fit at separated points often causes wild swings between fitted points. That is, in polynomial surface fitting, an exact fit at a finite number of points can yield a poor average fit for a general function. For ophthalmic application of the system as described above, computer simulations suggest that a sixth order Zernike analysis may yield the best results.

Calculation of the $\Delta z(x,y)$ optical path difference information from the Zernike reconstruction of the wavefront is accomplished simply by subtracting a constant from the Zernike approximation. The value of the constant will depend on the desired characteristics of $\Delta z(x,y)$. Depending on the method chosen to correct the aberrations (e.g., laser ablation, lens addition, etc.) it may, for example, be desirable to set either the maximum, mean or minimum value in $\Delta z(x,y)$ equal to zero.

The development of the transition matrix TM will now be explained for the illustrated example of a 7×7 array of holes in plate **32**. At each point (x_i,y_j), the tangents of the components of the normal are $P(x_i,y_j)$ and $Q(x_i,y_j)$ where

$$P(x_i,y_j)=\delta W(x_i,y_j)/\delta x \quad (20)$$

and

$$Q(x_i,y_j)=\delta W(x_i,y_j)/\delta y \quad (21)$$

Combining these with equation (11),

$$P(x_i,y_j)=\Sigma_k C_k \delta W(x_i,y_j)/\delta x \quad (22)$$

and

$$Q(x_i,y_j)=\Sigma_k C_k \delta W(x_i,y_j)/\delta y \quad (23)$$

each applicable to 49 (i,j) combinations. These are combined into a single column vector PQ that is 98 elements high, i.e., a 98×1 matrix. Defining two matrices C_k (14 high×1 wide) and $M_{k,(i,j)}$ (14 wide×98 high)

$$(M_{k,(i,j)})=\delta Z_k(x_i,y_j)/\delta x;\ \delta Z_k(x_i,y_j)/\delta y \quad (24)$$

where the x-derivatives are the first 49 rows and the y-derivatives are the last 49 rows. Then, equation (19) can be rewritten as the matrix equation

$$(PQ)=(M)(C) \tag{25}$$

where the top 49 rows of M are the $\delta W(x_i, y_j)/\delta y$.

The expression in equation (25) gives the normal components in terms of the Zernike coefficients for a surface described by the array of 14 C's. These are exact, but it is not guaranteed that the actual total surface can be described by such an array of coefficients. Accordingly, if it is assumed that the description is within an acceptable tolerance, i.e., tolerating the errors that remain after least square error determination, then equation (26) can be considered to define the column vector C implicitly in terms of the mathematical matrix M and the measured vector PQ, both of which are known. The method of effecting the solution under the minimization condition is as follows.

First, equation (25) is multiplied on the left by M^T, the transpose of M such that

$$(M^T)(PQ)=(M^T)(M)(C)=(S)(C) \tag{26}$$

where

$$S=M^TM \tag{27}$$

is a square and symmetric matrix, e.g., of dimensions 14×14 (with each element the sum of 98 products). Such a matrix has an inverse unless the determinant of its coefficients is zero. Since this is based on the Zernike polynomials alone, and they are all independent of each other, the determinant is non-zero, so that an inverse S^{-1} is defined. Next, equation (25) is multiplied on the left by S^{-1} to yield

$$(S^{-1})(M^T)(PQ)=(S^{-1})(S)(C)=(I)(C)=C \tag{28}$$

Then, the mathematical transition matrix (independent of measurement) is

$$(TM)=(S^{-1})(M^T) \tag{29}$$

and the "best fit" array of C's from the measured PQ's can be produced by the simple matrix multiplication

$$(C)=(TM)(PQ) \tag{30}$$

To evaluate the eye unambiguously, all spots illuminating planar array **36** due to a wavefront **24** must be incident on planar array **36** simultaneously. This is achieved by pulsing or shuttering the laser source (i.e., laser **12**) such that pulse duration is less than the saccadic motion interval of the eye, i.e., a few milliseconds. Alternatively, the laser source could be left on continuously and wavefront **24** could be shuttered to appear as a wavefront pulse of a duration that is less than saccadic motion of the eye. Accordingly, as shown in FIG. **2**, shutter **50** could be positioned in the path of laser beam **18** before eye **120** or in the path of wavefront **24** before wavefront analyzer **26**.

An implementation of the present invention suitable for clinical use is shown schematically in FIG. **7** and is referenced generally by numeral **11**. Like reference numerals are used to describe elements that are the same as those described above with respect to system **10**. Accordingly, the like elements and their functions will not be described further.

A dichroic beam splitter **52** is interposed between beam splitter **20** and optical train **22** to introduce fixation target optics **60** and observation optics **70** into system **11** which are optically separated from one another by 50/50 beam splitter **54**. Functionally, fixation target optics provide eye **120** with visible light in the shape of a target. The visible light generated by fixation target optics **60** is reflected by dichroic beam splitter **50** and directed through optical train **22**.

It is to be understood that fixation target optics **60** can be implemented in a variety of fashions. By way of example, one such embodiment is shown and includes visible light source **61**, light diffuser **62**, target **63**, field stop **64**, lens **65** and iris **66**. Light source **61** and light diffuser **62** are used to provide uniform illumination of fixation target **63**. Field stop **64**, lens **65**, and iris **66** are used in conjunction with optical train **22** to present a clear image of the fixation target to (patient) eye **120**.

Functionally, observation optics **70** allows a technician to view and document the eye evaluation procedure. While a variety of implementations of observation optics **70** are possible, one such implementation is shown by way of example. In FIG. **7**, observation optics **70** includes field lens **71**, lens **72**, iris **73**, lens **74**, and camera **75**. A ring illuminator **80** is placed in front of eye **120** to illuminate same for observation and/or filming purposes.

The output from wavefront analyzer **26**, e.g., the Zernike expansion of equation (19), can be used in a variety of ways. For example, the output could be used to continually or periodically monitor the progress or effects of an ophthalmic procedure. The output could also be used to develop an optical correction for eye **120**. The optical correction will make wavefront **24** appear approximately as a plane wave. As described above, the optical correction can be implemented in a variety of ways. In each case, the output of wavefront analyzer **26** is input to a processor **90** which converts the Zernike expansion of equation (19) into a form suitable for being implemented as one of the possible optical corrections. (The functions of processor **90** could also be implemented at processor **40** of wavefront analyzer **26**.) Processor **90** could use some of the Zernike coefficients from the expansion of equation (19) to generate a standard sphero-cylindrical correction for lens grinder **92** to produce a conventional optical lens, e.g., a lens for glasses, a contact lens, etc.

Processor **90** could also divide the Zernike reconstruction of the aberrated wavefront by the index of refraction of cornea **126** minus 1, to calculate the amount of corneal material to be ablated at each corresponding (x,y) location on the cornea. The amount of corneal material at each location is input to a laser beam delivery system that typically has eye tracking capability **94** such as described in the afore-mentioned U.S. patent application Ser. No. 08/232,615. Laser beam delivery and eye tracker **94** is placed in line with the optical axis of system **11**. The eye tracker portion of this element allows system **11** to respond unwanted eye motion. Laser beam delivery and eye tracker **94** would typically focus short pulses or "shots" of ablating laser light at cornea **126** or eye **120** to remove the specified thickness t of material at each location. This is shown diagrammatically in FIG. **8** where the uncorrected surface of cornea **126** is referenced by numeral **126**A and the corrected surface of cornea **126** after ablation is referenced by numeral **126**B.

In accordance with the present invention, ablation thickness t is specified across the aperture of the cornea measured, e.g., the 6 millimeter circle to which the eye's pupil was dilated during the measurement of the eye. Outside the prescribed treatment circle, a tapering blend zone of partial ablation may be added to minimize severe changes in corneal curvature and hence lessen regression. Laser beam delivery system **94** removes thickness t to achieve the optical correction, i.e., corrected cornea surface **126**B. Note that the optical correction is not concerned with the ultimate corneal topography, but instead removes corneal material to achieve an optical correction that takes into account all ocular aberrations of the eye. This is important because the

shape of the corneal surface can be independent of the correction required because the eye's vision depends on numerous factors besides corneal curvature. Hence, the best corneal surface topography for optimal vision may be far from regular in that it must compensate for the errors in the eye's other surfaces. Thus, it is apparent that the present invention can be used to provide corneal surface corrections other than the conventional spherical and/or cylindrical corrections.

The advantages of the present invention are numerous. A totally objective approach is presented for measuring ocular aberrations. The approach is effective for a wide range of vision defects. Accordingly, the present invention will be of great utility in a wide variety of clinical applications. For example, the calculated Zernike coefficients can be used to develop a completely objective lens prescription or a corneal correction that could be accomplished with laser ablation. In addition, each of the wavefront sensor embodiments provides for a greater degree of accuracy over the prior art with respect to measuring wavefront deflections. Further, the present wavefront sensor can be adjusted in terms of gain simply by adjusting the separation distance between the imaging plane of the sensor and the planar array of light-sensitive cells.

The objective measurement of the present invention will also find great utility for a large variety of applications in which the "patient" is unable to provide feedback as required by conventional eye diagnosis. For example, the present invention could be used to evaluate the eyes of any patient not possessed of demonstrative communicative skills, e.g., babies, animals, dead specimens, as well as any constructed optical system, since the present invention is an objective analysis not requiring any assessment from the "subject." All that is necessary is for the subject's eye to be properly positioned so that proper optical access to the eye can be obtained.

The present invention could also be used in the area of identification should it be determined that each eye's Zernike coefficients are unique. Then, the present invention would find great utility in the fields of law enforcement, credit card/bank security, or any other field where positive identification would be beneficial.

Although the invention has been described relative to a specific embodiment thereof, there are numerous variations and modifications that will be readily apparent to those skilled in the art in light of the above teachings. It is therefore to be understood that, within the scope of the appended claims, the invention may be practiced other than as specifically described.

That which is claimed is:

1. A method for enhancing vision in an eye, the method comprising:

determining an optical path difference between a plane wave and a wavefront emanating from a region of the retina of the eye; and

optically correcting for visual defects of the eye based on the optical path difference and refractive indices of media through which the wavefront passes, to thereby cause the wavefront to approximate the shape of the plane wave.

2. A method according to claim **1**, wherein the correcting includes forming a lens.

3. A method according to claim **1**, wherein the correcting includes ablating corneal material from the cornea of the eye.

4. A method according to claim **1**, wherein the correcting includes ablating corneal material from the cornea of the eye at selected discrete locations on the surface of the cornea using a laser beam delivery system for ablating the corneal material and thus altering the corneal surface.

5. A method according to claim **1**, wherein the optical path difference results from a Zernike reconstruction of the wavefront, and wherein the optically correcting includes dividing the optical path difference by a difference between an index of refraction of corneal material and an index of refraction of air.

6. A method for enhancing vision of an eye, the method comprising optically correcting the eye based on an optical path difference between a plane wave and a wavefront emanating from the retina of the eye and refractive indices of media through which the wavefront passes, to thereby cause the wavefront to approximate the shape of the plane wave.

7. A method according to claim **6**, wherein the correcting includes forming a lens.

8. A method according to claim **6**, wherein the correcting includes ablating corneal material from the eye.

9. A method according to claim **6**, wherein the correcting includes selectively altering the corneal surface of the eye.

10. A method according to claim **9**, wherein the corneal surface altering is based on a Zernike reconstruction of the wavefront, and wherein the optically correcting includes dividing the optical path difference by a difference between an index of refraction of corneal material and an index of refraction of air.

11. A method for enhancing vision of an eye, the method comprising:

providing a laser delivery system having a laser beam sufficient for ablating corneal material from the cornea of the eye;

measuring an optical path difference for a location at the surface of the cornea of the eye between a plane wave and a wavefront emanating from the retina of the eye;

directing the laser beam to the location on the surface of the cornea;

communicating an optical correction to the laser delivery system for the location based on the optical path difference and refractive indices of media through which the wavefront passes;

ablating corneal material at the location using the laser beam in response to the optical correction, to thereby cause the wavefront to approximate the shape of the plane wave at the location;

repeat the measuring, communicating and ablating for alternate locations at the surface of the cornea of the eye to thereby cause the wavefront to approximate the plane wave, thereby optically correcting visual defects for enhancing vision of the eye.

12. A method according to claim **11**, wherein the ablating results in selectively altering the corneal surface of the eye without regard to a resulting topography of the surface of the cornea.

13. A method according to claim **11**, wherein the optical path difference measuring results from a Zernike reconstruction of the wavefront, and wherein the optically correcting includes dividing the optical path difference by a difference between an index of refraction of corneal material and an index of refraction of air.

14. A method for correcting visual defects of an eye, the method comprising:

measuring a wavefront emanating from a region of the retina of the eye;

calculating distortions associated with the wavefront; and

converting the distortions to an optical correction based on a deviation of the wavefront from a plane wave and refractive indices of media through which the wavefront passes, to thereby cause the wavefront to approximate the shape of the plane wave.

15. A method according to claim **14**, wherein the converting comprises forming a lens, thereby providing the optical correction.

16. A method according to claim **14**, wherein the converting comprises providing a laser beam and the laser beam ablating corneal material from the eye, thereby providing the optical correction.

17. A method according to claim **16**, wherein the converting further comprises directing the laser beam to discrete locations on the surface of the cornea and selectively altering the surface at the discrete location without regard to a resulting topography of the surface, thereby providing the optical correction.

18. A method for correcting human eye vision by removing a preselected shape of material from the cornea of the eye using a laser beam, the preselected shape of material based on a difference between a measured wavefront emanating from the retina of the eye and a desired wavefront and refractive indices of media through which the wavefront passes.

19. A method according to claim **18**, wherein the desired wavefront is a planar wavefront.

20. A method of optically correcting for visual defects of a human eye by approximating the shape of a plane wave responsive to an optical path difference between the plane wave and a wavefront emanating from the retina of the eye and further modifying the shape based on refractive indices of media through which the wavefront passes.

21. A method according to claim **20**, wherein the optical path difference results from a Zernike reconstruction of the wavefront, and wherein the shape modifying includes dividing the optical path difference by a difference between an index of refraction of corneal material and an index of refraction of air.

22. A method according to claim **20**, wherein the approximating the shape includes forming a lens.

23. A method according to claim **20**, further comprising:

providing a laser delivery system having a laser beam sufficient for ablating corneal material from the cornea of the eye;

communicating an optical correction based on the optical path difference and refractive indices to the laser delivery system for providing a laser beam sufficient for ablating corneal material from the cornea of the eye;

ablating corneal material using the laser beam in response to the optical correction, to thereby cause the wavefront to approximate the shape of the plane wave.

24. An optical correction system for correcting visual defects of an eye, the optical correction system comprising:

an energy source for generating a beam of optical radiation;

focusing optics disposed in the path of the beam for directing the beam through the eye, wherein the beam is reflected back from the retina of the eye as a wavefront of radiation emanating from the eye;

a wavefront analyzer disposed in the path of the wavefront for determining an optical path difference between a plane wave and the wavefront; and

a converter for providing an optical correction based on the path difference and refractive indices of media through which the wavefront passes.

25. A system according to claim **24**, wherein the optical correction is a lens prescription.

26. A system according to claim **24**, wherein the optical correction provides an amount of corneal material to be ablated from the eye.

27. A system according to claim **26**, further comprising a laser beam delivery system for bombarding the eye with a plurality of small-diameter laser beam pulses of a wavelength and having power sufficient for ablating the corneal material, wherein the optical correction is achieved by the removal of the amount of corneal material.

28. The system as in claim **27**, wherein the laser beam delivery system includes an eye tracker for monitoring motion of the eye and for adjusting the positions of the plurality of small-diameter laser beam pulses in correspondence with the motion.

29. The system as in claim **24**, wherein the optical correction is a prescribed alteration of corneal surface curvature of the eye, and wherein the optical correction achieved by the reshaping of the corneal surface curvature of the eye is based on the prescribed alteration without regard to a resulting topography of the surface of the cornea.

30. An optical correction system for correcting visual defects of an eye, the optical correction system comprising:

a wavefront analyzer disposed in the path of a wavefront emanating from the eye for determining an optical path difference between a plane wave and the wavefront; and

a converter for providing an optical correction based on the path difference and refractive indices of media through which the wavefront passes.

31. A system according to claim **30**, further comprising:

an energy source for generating a beam of optical radiation; and

focusing optics disposed in the path of the beam for directing the beam through the eye, wherein the beam is reflected back from the retina of the eye as the wavefront of radiation emanating from the eye.

32. A system according to claim **30**, wherein the optical correction is a lens prescription.

33. A system according to claim **30**, further comprising a laser beam delivery system for bombarding the eye with a laser beam having power sufficient for ablating corneal material of the cornea of the eye, and wherein the optical correction is achieved by the removal of an amount of corneal material.

34. A system as in claim **33**, wherein the laser beam delivery system includes an eye tracker for monitoring motion of the eye and for adjusting the positions of the laser beam responsive to the motion.

35. A system as in claim **33**, wherein the optical correction is a prescribed alteration of corneal surface curvature of the eye, and wherein the optical correction achieved by the reshaping of the corneal surface curvature of the eye is based on the prescribed alteration without regard to a resulting topography of the overall surface of the cornea.

36. An optical correction system for correcting visual defects of an eye, the optical correction system comprising:

a wavefront analyzer disposed in the path of a wavefront emanating from the eye for determining an optical path difference between a plane wave and the wavefront;

a converter for providing an optical correction based on the path difference and refractive indices of media through which the wavefront passes; and

a laser beam having power sufficient for ablating corneal material of the cornea of the eye, wherein the optical

correction is achieved by the removal of a selected amount of the corneal material.

37. A system according to claim **36**, further comprising:

an energy source for generating a beam of optical radiation; and

focusing optics disposed in the path of the beam for directing the beam through the eye, wherein the beam is reflected back from the retina of the eye as the wavefront of radiation emanating from the eye.

38. A system as in claim **36**, further comprising an eye tracker for monitoring motion of the eye and for adjusting the positions of the laser beam responsive to the motion.

39. A system as in claim **36**, wherein the optical correction is a prescribed alteration of corneal surface curvature of the eye, and wherein the optical correction achieved by the reshaping of the corneal surface curvature of the eye is based on the prescribed alteration without regard to a resulting topography of the overall surface of the cornea.

40. A system according to claim **36**, wherein the converter provides the path difference from a Zernike reconstruction of the wavefront, and wherein the path difference is divided by a difference between an index of refraction of corneal material and an index of refraction of air.

(57) **ABSTRACT**

An objective optical system is disclosed having, in a first construction, in relative order from the object side, a first lens element of negative refractive power, a visual field conversion optical element which folds light rays incident thereon, a stop, and either one or two additional lens elements of positive refractive power which form an objective optical system. Certain prescribed conditions are satisfied in order that the objective optical system be compact and have acceptably small aberrations to thereby enable a high quality image to be formed. In a second alternative construction, the stop is positioned after the second lens element and the third lens element includes a convex surface on the image side and satisfies a prescribed condition. In a third alternative construction, an objective optical system is disclosed having, in relative order from the object side, a visual field conversion optical element which folds light rays incident thereon, a first lens element of positive or negative refractive power, a stop, and a second lens element of positive refractive power with a convex surface on the image side, wherein the second lens element satisfies a certain prescribed condition. In the second and third constructions, the system may be formed in two parts, an adaptor unit and a master unit, which are detachable from one another. The invention is particularly well-suited for forming images for an image pick-up element having pixels as small as 5 micrometers or less.

OBJECTIVE OPTICAL SYSTEM

BACKGROUND OF THE INVENTION

In recent years, image pick-up elements such as CCD devices have achieved high resolution and become compact as a result of advances in fine pattern technology which have enabled the pick-up element pixel size to be reduced. As a result of these advances, highly efficient and much smaller-sized objective optical systems have been in demand in optical systems which employ such image pick-up elements as, for example, endoscope systems. Especially in the case where an optical system employs, for example, a beam-folding prism or mirror which serves as a visual beam conversion element to provide a side or perspective view, there is the tendency for the entire optical system to become large as compared with an optical system that provides only a direct view. Thus, a size-reduction in such an optical system is desired. Moreover, while small size and high performance of an optical system are desired, nevertheless, an inexpensive objective optical system with three or fewer lens elements is also desired.

As a prior art example of an objective optical system that uses a visual field conversion optical element, the optical system described in Japanese Laid Open Patent Application No. H2-69710 is known. This prior art optical system combines a negative lens element, a visual field conversion optical element, a positive lens element and a positive lens element. However, since the refractive power of the negative lens element is weak, the correction of field curvature is insufficient. Moreover, since the Abbe number of a positive lens element is small, the amount of chromatic aberration is large.

Another prior art example of an objective optical system that uses a visual field conversion optical element is disclosed in Japanese Laid Open Patent Application No. H5-307139. This optical system consists of a negative lens element, a visual field conversion optical element, a positive lens element, and a positive lens element. However, the refractive index of the negative lens element is small and the generation of lateral color is large.

Another prior art example of a visual field conversion optical element is disclosed in Japanese Laid Open Patent Application No. 37-9530.

BRIEF SUMMARY OF THE INVENTION

This invention is an objective optical system for use with, for example, an endoscope. A first object of the invention is to provide an objective optical system that includes a visual field conversion optical element which folds the rays at least once. Such an optical element enables a side or perspective view in an optical system which is reduced in size as compared with prior art systems employing a visual field conversion optical element. A second object of the invention is to provide a visual field conversion optical element within an objective optical system that yields a high-quality image at low cost by employing in the objective optical system, at most, three lens elements that can be made of inexpensive materials.

BRIEF DESCRIPTION OF THE DRAWINGS

The present invention will become more fully understood from the detailed description given below and the accompanying drawings, which are given by way of illustration only and thus are not limitative of the present invention, wherein:

DETAILED DESCRIPTION

This invention is an objective optical system which includes a visual field-of-view conversion optical element (hereinafter termed a visual field conversion optical element) which may be formed, for example, by a beam-folding prism or mirror and which serves to provide a side or perspective view. Such an optical system can be used for various image pick-up systems, such as an endoscope, a video camera, a digital camera, and a conventional camera using silver-salt film. A visual field conversion optical element folds the light one or more times prior to the light being incident onto an image pick-up system, thereby enabling side or perspective viewing. Of course, the system of the present invention can be combined with a direct-view optical element, as well as with one or more additional visual field conversion optical elements in order to provide a view field that is nearly unlimited in extent. The present invention provides an objective optical system which includes a small-sized, highly efficient visual field conversion optical element, an aperture which serves as a stop, and additionally, either two or three lens elements (i.e., individual masses of optical material having optical power).

In the case where there are three lens elements, the relative arrangement of these components is, in order from the object side: a first lens element of negative refractive power, a visual field conversion optical element, a stop, a second lens element of positive refractive power, and a third lens element of positive refractive power. The surface at the image-side of the third lens element is convex, and the following Condition (1) is satisfied.

$$0.1<|R_{(3R)}/f|<20 \qquad \text{Condition (1)}$$

where

$R_{(3R)}$ is the radius of curvature of the image-side surface of the third lens element, and

f is the focal distance of the objective optical system.

For example, an objective optical system for an endoscope that provides a view field that includes a side or a perspective view requires that the image angle (i.e., picture angle) should be about 80 degrees or more. Thus, when an objective optical system having a visual field conversion optical element and a stop is composed of three lens elements, it is desirable that the relative order of the lens elements be as stated above, so that the optical system is of the retro-focus type.

In the case where there are only two lens elements, it is also desirable that the optical system be of the retro-focus type. This is accomplished by having the relative arrangement of the above components be, in order from the object side: a negative lens element, a visual field conversion optical element, a stop, and a positive lens element. However, this arrangement provides an asymmetrical refractive power relative to the stop. For this reason, the generation of aberrations such as astigmatism, coma, and lateral color tends to be large. In order to make the objective optical system more compact, the refractive power of each lens element needs to be strengthened. Therefore, the aberrations generated by each lens element become larger, and it becomes difficult to maintain high image-formation quality. In order to better correct aberrations, the surface at the image-side of the third lens element is made convex in a manner which satisfies the above-mentioned Condition (1).

When Condition (1) is satisfied, aberrations will be well-corrected, and this is especially the case with coma. If the absolute value of the ratio $R_{(3R)}/f$ is 0.1 or less, the refractive power of image-side surface of the third lens element will be too strong, resulting in the generation of excessive aberrations. Moreover, if the absolute value of the ratio $R_{(3R)}/f$ is 20 or more, the refractive power of the image-side surface of the third lens element will be too weak, and it will be difficult to make the objective optical system compact.

In addition, it is preferred that the following Conditions (2) and (3) be satisfied.

$$\nu(p)>42 \qquad \text{Condition (2)}$$

$$N_1>1.6 \qquad \text{Condition (3)}$$

where

$\nu(p)$ is the Abbe number of a lens element of positive refractive power, and

N_1 is the refractive index of the first lens element, in order from the object side.

In the optical system using an image pick-up element such as a CCD device, vignetting (i.e., limb-darkening) and color effects resulting from light rays which are incident at oblique angles to the surface of an image pick-up element need to be prevented. Therefore, it is desirable that the incident light rays strike the image pick-up surface perpendicularly. Where there are three lens elements, it is desirable that the image-side surface of the third lens element be convex. This assists in making the incident light rays strike the image pick-up surface perpendicularly. However, when the surface at the image-side of the third lens element is made convex, correction of aberrations, especially lateral color, generated by this surface becomes difficult.

In order to correct these aberrations, at least one of the positive lens elements must satisfy Condition (2). If Condition (2) is not satisfied, i.e., if the Abbe number $\nu(p)$ of a lens element with positive refractive power does not exceed 42, correction of lateral color will be difficult.

Condition (3) controls the generation of aberrations. By satisfying Condition (3), the refractive index of the first lens element, in order from the object side, is made sufficient to ensure that the aberrations generated by this lens element are small. In other words, if the refractive index of the first lens element exceeds 1.6, the aberrations generated by the first lens element can be sufficiently corrected. The stop is

desirable positioned between the visual field conversion optical element and the second lens element.

It is also desirable if the following Condition (4) is satisfied.

$$0.1<R_{(1R)}/f<3 \quad \text{Condition (4)}$$

where

$R_{(1R)}$ is the radius of curvature of the image-side surface of the first lens element, and

f is as defined above.

Condition (4) limits the aberrations generated by the image-side surface of the first lens element, in order from the object side. If the value of $R_{(1R)}/f$ is 0.1 or less, the aberrations generated by the first lens element will be too large. If the value of $R_{(1R)}/f$ is 3 or more, the refractive power of the first lens element will be too weak, resulting in it being difficult to make the objective lens system compact.

It is also desirable if the following Condition (5) is satisfied.

$$0.05<|f/f_1|<5 \quad \text{Condition (5)}$$

where

f is as defined above, and

f_1 is the focal distance of the first lens element.

Condition (5) also controls aberrations that are generated by the objective optical system of the invention. If the absolute value of the ratio f/f_1 is 0.05 or less, the refractive power of the first lens element will be too large and it will be difficult to satisfactorily correct the aberration outside an axis in the whole system. Moreover, if the absolute value of the ratio f/f_1 is 5 or more, it will be difficult to make the objective optical system compact.

An infrared cut-off filter may be used between the stop and the image surface. When the objective optical system of this invention is used with an image pick-up element which has a sensitivity to some extent to infrared wavelengths, such as CCD, an infrared cut-off filter is needed. However, when an infrared cut-off filter is used, the resulting difference of optical path length in the infrared cut-off filter between the light rays on-axis and off-axis will be large. This results in a disadvantage in that the coloring will be different at the center if the screen verses the peripheral areas of the screen. In the objective optical system of this invention, it is desirable to use an infrared cut-off filter between the image surface and a stop at an axial position where the difference in angle between on-axis and off-axis light rays is small.

It is also desirable if the following Condition (6) is satisfied.

$$1<Dp/f<10 \quad \text{Condition (6)}$$

where

Dp is the air conversion length from the image-side surface of the first lens element to the stop, and

f is as defined previously.

If the lower-limit value of Condition (6) is not satisfied, the construction configuration of a visual field conversion optical element will be difficult. Moreover, if the upper limit of Condition (6) is not satisfied, it will be difficult to make the whole system compact.

In order to correct the aberrations satisfactorily, when the image-side surface of the lens element nearest the image side is made into a convex shape, it is especially important that Condition (1) be satisfied when the pixel size of the image pick-up element of a CCD device is 5 micrometers or less. Moreover, it is desirable if the outer diameter of the lens element nearest the image side is 3 mm or less. Moreover, in order to make a much more favorable image-formation capability, it is desirable to satisfy the following Condition (1-1) instead of Condition (1).

$$0.5<|R_{(3R)}/f|<15 \quad \text{Condition (1-1)}$$

In order to satisfactorily correct the lateral chromatic aberration, at least one lens element surface among the lens elements on the image-side of the stop should desirable satisfy Condition (2). It is important that Condition (2) be satisfied when the pixel size of the image pick-up element of a CCD device is 5 micrometers or less. Moreover, satisfaction of Condition (2) is especially important when the outer diameter of the lens element nearest the image side is 3 mm or less. However, in order to obtain an objective optical system with a much more favorable image-formation capability, it is desirable to satisfy the following Condition (2-1) in lieu of merely satisfying Condition (2).

$$\nu(p)>45 \quad \text{Condition (2-1)}$$

In order to correct aberrations satisfactorily, it is desirable that the image-side surface of the first lens element (i.e., the negative lens element) satisfies Condition (3). Satisfaction of Condition (3) is important when the pixel size of the image pick-up element (such as a CCD device) is 5 micrometers or less. Moreover, satisfaction of Condition (3) is especially important when the outer diameter of the lens element nearest the image is 3 mm or less. However, in order to obtain an objective optical system with a more favorable image-formation capability, it is desirable to satisfy the following Condition (3-1) in lieu of merely satisfying Condition (3).

$$N_1>1.7 \quad \text{Condition (3-1)}$$

In order to satisfactorily correct aberrations, it is desirable that the negative lens element satisfies Condition (4). The satisfaction of Condition (4) is important when the pixel size of the image pick-up element (such as a CCD device) is 5 micrometers or less. Moreover, satisfaction of this condition is especially important when the outer diameter of the lens element nearest the image is 3 mm or less. However, in order to obtain an objective optical system which has a much more favorable image-formation capability, it is desirable to satisfy the following Condition (4-1) in lieu of merely satisfying Condition (4).

$$0.5<R_{(1R)}/f<3 \quad \text{Condition (4-1)}$$

It is desirable that the first lens element (i.e., the negative lens element) satisfies Condition (5). Satisfaction of Condition (5) is important when the pixel size of the image pick-up element is 5 micrometers or less. Moreover, satisfaction of Condition (5) is especially important when the outer diameter of the lens element nearest the image is 3 mm or less. However, in order to obtain an optical system which has a more favorable image-formation capability, it is desirable to satisfy the following Condition (5-1) in lieu of merely satisfying Condition (5).

$$0.1<|f/f_1|<3 \quad \text{Condition (5-1)}$$

In order to make the objective optical system of this invention compact, it is desirable to satisfy above-mentioned Condition (6). Satisfaction of Condition (6) is important when the pixel size of the image pick-up element is 5

micrometers or less. Moreover, satisfaction of Condition (6) is especially important when the outer diameter of the lens element nearest the image is 3 mm or less. However, in order to make the objective optical system even more compact, it is desirable that the following Condition (6-1) be satisfied in lieu of merely satisfying Condition (6).

$$1.5<Dp/f<7 \qquad \text{Condition (6-1)}$$

When using the objective optical system of this invention with an endoscope system, it may be desirable that the object-side surface of the first lens element be a planar surface. A planar surface is advantageous from the point of view of making the object-side surface of the endoscope easy to clean. However, if priority is given to optical performance, the curvature on the object-side surface of the first lens element should be maintained. Further, in the optical system of this invention, in order to reduce cost, it is desirable to make the surface of one side of at least one positive lens element into a flat surface.

In order to make the objective optical system compact while satisfactorily correcting aberrations generated by the first lens element (i.e., the negative lens element), it is desirable to satisfy the following Condition (7).

$$0.4 \text{ mm}<R_{(1R)}<3 \text{ mm} \qquad \text{Condition (7)}$$

where

$R_{(1R)}$ is as defined above.

If the lower-limit value of Condition (7) is not satisfied, the refractive power of the first lens element will be too strong and it will be difficult to satisfactorily correct aberrations of the objective optical system. Moreover if the upper limit of Condition (7) is not satisfied, the refractive power of the first lens element will be too weak and it will be difficult to make the objective optical system compact. However, it is more desirable to satisfy the following Condition (7-1) in lieu of merely satisfying Condition (7).

$$0.6 \text{ mm}<R_{(1R)}<2 \text{ mm} \qquad \text{Condition (7-1)}$$

Further, when at least one positive lens element includes a flat surface, it is desirable that the following Condition (8) be satisfied:

$$0.5 \text{ mm}<|R(p)|<5 \text{ mm} \qquad \text{Condition (8)}$$

where

R(p) is the radius of curvature of the convex side of the positive lens element having its opposite side planar.

Condition (8) allows for the objective optical system to be compact, while ensuring that the aberrations generated by said positive lens element are small. If the lower-limit value of Condition (8) is not satisfied, the refractive power of the positive lens element will be too strong, and the correction of coma aberration will be difficult. Moreover, if the upper limit of Condition (8) is not satisfied, the refractive power of said positive lens element will be too weak and it will be difficult to make the objective optical system compact. However, it is more desirable if the following Condition (8-1) is satisfied in lieu of merely satisfying Condition (8).

$$0.8 \text{ mm}<|R(p)|<3 \text{ mm} \qquad \text{Condition (8-1)}$$

The objective optical system of this invention is effective when pixel size of the image pick-up element (such as a CCD device) is 5 micrometers or less. However, it becomes more effective as the pixel size is reduced to 4 micrometers or less. Moreover, when the outer diameter of the lens element nearest the image side is 3 mm or less, the optical system of this invention is effective, and it is even more effective when the outer diameter of the lens element is 2.5 mm or less. Also, the objective optical system of this invention is effective when the length, width or height of a visual field conversion optical element is smaller than 5 mm. However, it is even more effective when the length, width, or height of a visual field conversion optical element is smaller than 3 mm.

Next, specific examples of the objective optical system of this invention will be described in the following embodiments of the invention, which are given for purposes of illustration only.

In Tables 1–36 which follow, # is the surface number in order from the object side, R is the radius of curvature (in mm) of the surface, D is the on-axis spacing (in mm) between surfaces, N_d is refractive index and ν_d is the Abbe constant (at the sodium d-line) of each lens element. Moreover, f is the focal length of the objective optical system, 2ω is the image angle, $F_{NO.}$ is the F-number, IH is image height, OB is distance of the object, and the other values listed are as defined above. Various color filters may be used in the objective optical system, depending on the application. Further, various filters for blocking specific laser wavelength ranges may be provided, such as light output by a YAG laser or a semiconductor laser. Such filters may be of the absorbing-type, such as an infrared cut-off filter, or may be of the interference-type. The function of these filters can be provided in, or on, various plane-parallel plates or, alternatively, may be instead be provided in, or on, the materials that form the lens elements.

Embodiment 1

FIG. **1** shows a retro-focus type objective optical system of Embodiment 1 which includes, in relative order from the object side: a first lens element (r_1–r_2) of negative refractive power, a visual field conversion optical element (r_3–r_4), a stop (r_5), a second lens element (r_6–r_7) of positive refractive power, and a third lens element (r_{10}–r_{11}) of positive refractive power. In order from the object side, the first lens element is of a planar-concave shape, the second lens element is of a concave-convex shape, and the third lens element is of a concave-convex shape. Also, various filters which block specific wavelength ranges may be provided. In this embodiment, the plane-parallel plate (r_8–r_9) on the image-side of the second lens element is an interference-type filter, the plane-parallel plate (r_{12}–r_{13}) is an absorbing-type, infrared cut-off filter, and the plane-parallel plate (r_{14}–r_{15}) is an interference-type filter. Further, the two plane-parallel plates nearest the image are a cover glass (r_{16}–r_{17}) of a dust guard, and a cover glass (r_{17}–r_{18}) of an image pick-up element. The outer diameter of the positive lens elements in this embodiment is 2 mm.

Embodiment 2

FIG. **2** shows Embodiment 2 which includes, in relative order from the object side, a first lens element (r_1–r_2) of negative refractive power, a visual field conversion optical element (r_3–r_4), a stop (r_5), a second lens element (r_6–r_7) of positive refractive power, and a third lens element (r_{14}–r_{15}) of positive refractive power. In order from the object side, the first lens element is of a planar-concave shape, the second lens element is of a planar-convex shape, and the third lens element is of a concave-convex shape. Various filters for blocking specific wavelength ranges may be arranged within the objective optical system. For example, the plane-parallel plate (r_8–r_9) is an interference-type filter, the plane-parallel plate (r_{10}–r_{11}) is an absorbing-type, infrared cut-off filter, and the plane-parallel plate (r_{12}–r_{13}) is an interference-type filter. The two plane-parallel plates nearest the image are the cover glass (r_{16}–r_{17}) of a dust guard and the cover glass (r_{17}–r_{18}) of an image pick-up element, such as a CCD device. The outer diameter of the positive lens elements of this embodiment is 1.4 mm.

Embodiment 7

FIG. **7** shows the retro-focus objective optical system of Embodiment 7 which includes, in relative order from the object side, a first lens element (r_1–r_2) of negative refractive power, a visual field conversion optical element (r_3–r_4), a stop (r_5), a second lens element (r_6–r_7) of positive refractive power, and a third lens element (r_{14}–r_{15}) of positive refractive power. In order from the object side, the first lens element is of a planar-concave shape, the second lens element is of a planar-convex shape, and the third lens element is of a planar-convex shape. Three plane-parallel plates are positioned between the second lens element and the third lens element. The plane-parallel plate (r_8–r_9) is an interference-type filter, plane-parallel plate (r_{10}–r_{11}) is an absorbing-type, infrared cut-off filter, and plane-parallel plate (r_{12}–r_{13}) is an interference-type filter. The two plane-parallel plates nearest the image are the cover glass (r_{16}–r_{17}) of a dust guard and the cover glass (r_{17}–r_{18}) of an image pick-up element, such as a CCD device. The visual field conversion optical element is a twice-reflecting prism, similar to the prism shown in FIG. **40**. In this embodiment, each positive lens element includes a side that is planar so as to form an inexpensive objective optical system, and the outer diameter of these positive lens elements is 1.4 mm.

FIG. **10** shows the retro-focus type objective optical system of Embodiment 10, which includes, in relative order from the object side, a first lens element (r_1–r_2) of negative refractive power, a visual field conversion optical element (r_3–r_4), a stop (r_5), a second lens element (r_6–r_7) of positive refractive power, and a third lens element (r_8–r_9) of positive refractive power. In order from the object side, the first lens element is of a planar-concave shape, the second lens element is of a convex-concave shape, and the third lens element is of a planar-convex shape. Two plane-parallel plates are positioned at the image side of the third lens element. The plane-parallel plate (r_{10}–r_{11}) is an interference-type filter, and the plane-parallel plate (r_{13}–r_{14}) is an absorbing-type, infrared cut-off filter. Further, the two plane-parallel plates nearest the image are a cover glass (r_{14}–r_{15}) of a dust guard, and a cover glass (r_{15}–r_{16}) of an image pick-up element. The outer diameter of the positive lens elements of this embodiment is 1.4 mm.

In order from the object side, the first lens element is of a planar-concave shape, and both the second lens element and the third lens element are of a convex-planar shape. The plane-parallel plate (r_8–r_9) adjacent the second lens element is an interference-type filter, the next plane-parallel plate (r_{10}–r_{11}) is an absorbing-type, infrared cut-off filter, and the next plane-parallel plate (r_{12}–r_{13}) is an interference-type filter. Further, the third lens element is joined to the cover glass (r_{15}–r_{16}) of an image pick-up element, such as a CCD. The outer diameter of the positive lens elements of this embodiment is 1.4 mm.

Embodiment 29

FIG. **29** shows the retro-focus type objective optical system of Embodiment 29 which includes, in relative order from the object side, a first lens element (r_1–r_2) of negative refractive power, a visual field conversion optical element (r_3–r_4), a stop (r_5), and a second lens element (r_6–r_7) of positive refractive power. In order from the object side, the first lens element is of a planar-concave shape, and the second lens element is of a convex-planar shape. The plane-parallel plate (r_8–r_9) on the image-side of the second lens element is an interference-type filter, and the plane-parallel plate (r_{10}–r_{11}) is an absorbing-type, infrared cut-off filter. Further, the two plane-parallel plates nearest the image are a cover glass (r_{12}–r_{13}) of a dust guard, and a cover glass (r_{13}–r_{14}) of an image pick-up element. The outer diameter of the positive lens element of this embodiment is 1.4 mm.

Embodiment 31

FIG. **31** shows the retro-focus type objective optical system of Embodiment 31 which includes, in relative order from the object side, a first lens element (r_1–r_2) of negative refractive power, a visual field conversion optical element (r_3–r_4), a stop (r_5), a second lens element (r_6–r_7) of positive refractive power, and a third lens element (r_{12}–r_{13}) of positive refractive power. In order from the object side, the first lens element is of a planar-concave shape, the second lens element is of a planar-convex shape, and the third lens element is of a convex-planar shape. The plane-parallel plate (r_8–r_9) on the image-side of the second lens element is an absorbing-type, infrared cut-off filter, and the next plane-parallel plate (r_{10}–r_{11}) is also an absorbing-type, infrared cut-off filter. Further, the third lens element is joined to the cover glass (r_{13}–r_{14}) of an image pick-up element, such as a CCD device. The outer diameter of the positive lens elements of this embodiment is 1.4 mm. In this example, as shown in FIG. **41**, the visual field conversion optical element uses a one-time reflecting prism. However, although the image detected is a mirror image (in which there is an inversion from left to right), the detected image is then inverted by electronic means, as mentioned above.

Embodiment 33

FIG. **33** shows the retro-focus type objective optical system of Embodiment 33 which includes, in relative order from the object side, a first lens element (r_1–r_2) of negative refractive power, a visual field conversion optical element (r_5–r_6), a stop (r_7), a second lens element (r_8–r_9) of positive refractive power, and a third lens element (r_{12}–r_{13}) of positive refractive power. In order from the object side, the first lens element is of a planar-concave shape, the second lens element is of a planar-convex shape, and the third lens element is of a convex-planar shape. The plane-parallel plate (r_3–r_4) on the image-side of the first lens element is an interference-type filter, and the next plane-parallel plate (r_{10}–r_1) is an absorbing-type, infrared cut-off filter. Further, the two plane-parallel plates nearest the image are a cover glass (r_{14}–r_{15}) of a dust guard, and a cover glass (r_{15}–r_{16}) of

an image pick-up element. The second and third lens elements are both of positive refractive power. The outer diameter of the second lens element is 2 mm, and the outer diameter of the third lens element is 2.4 mm. In this embodiment the visual field conversion optical element uses a twice-reflecting prism which forms an uninverted image of an object field that is centered at about a 45 degree angle to the optical axis of the image. Depending on the design of the twice-reflecting prism, the optical axis of the object field can be any direction from 0 degrees to nearly 180 degrees to the optical axis of the image (i.e., the in-line direction) by choosing a desired design for the visual field conversion optical element.

Embodiment 34

FIG. **34** shows the objective optical system of Embodiment 34 which includes, in relative order from the object side, a first lens element (r_1–r_2) of negative refractive power and plano-concave shape, a visual field conversion optical element (r_3–r_5), a second lens element (r_6–r_7) of positive refractive power and biconvex shape, a stop (r_8), two cover glasses (r_9–r_{10}), (r_{11}–r_{12}), a third lens element (r_{13}–r_{14}) of positive refractive power and plano-convex shape, and an absorbing-type infrared cut-off filter (r_{15}–r_{16}) that is joined to a CCD cover glass (r_{16}–r_{17}). The objective optical system is constructed in two parts, a front part and a back part, and these two parts can be separated between the cover glasses (r_9–r_{10}) and the cover glass (r_{11}–r_{12}), each being formed as plane-parallel plates. The front part (r_1 through r_{10}) is made to be an adaptor unit, the back part (r_{11}–r_{17}) is made to be a master unit, with the adaptor unit being selected according to the particular intended use. Although this embodiment has a watertight construction by arranging a cover glass at the dividing part of each unit, the cover glasses may not be needed depending on the purpose for which it is used. The outer diameter of the lens element of positive refractive power in the master unit in this embodiment is 1 mm.

Embodiment 36

Embodiment 36 is nearly identical to that of Embodiment 35 except that the visual field conversion optical element has

a different design and, in this case, the first lens element (r_3–r_4) has a positive refractive power (thick lens conditions apply). As evident from Embodiments 35 and 36, the power of the first lens element may be either positive or negative.

Image	∞	0.0000		
	F_{NO} = 4.7		IH = 0.9	

The construction of Embodiment 34 is characterized by there being, sequentially from the object side, a first lens element of negative refractive power, a visual field conversion optical element, a second lens element of positive refractive power, a stop, and a third lens element of positive refractive power, with a convex-shaped surface on the image side, wherein the following condition is satisfied:

$$1.5<f_3/IH<5 \qquad \text{Condition (9)}$$

where

f_3 is the focal distance of the third lens element, and

IH is the maximum image height.

In Embodiment 34, the value of f_3/IH equals 4.44, thus satisfying Condition (9).

The construction of Embodiments 35 and 36 is characterized by there being, sequentially from the object side, a visual field conversion optical element, a first lens element of positive or negative refractive power, a stop, and a second lens element of positive refractive power having a convex-shaped surface on the image side, wherein the following condition is satisfied:

$$1.5<f_2/IH<5 \qquad \text{Condition(10)}$$

where

f_2 is the focal distance of the second lens element, and

IH is the maximum image height.

In Embodiments 35 and 36, the value of f_2 /IH equals 1.56, thus satisfying Condition (10).

In Embodiments 34–36, because the master unit includes one positive lens element, the size of the master unit can be made very small Also, because the stop of the adaptor unit is arranged on the master unit side of the lens element more to the master unit side of the lens within the adaptor unit, the outer diameter of the positive lens element inside the master unit can be made small Furthermore, although dust can easily fall on a cover glass between the adaptor unit and the master unit when the two units are detached from each other, thereby influencing the image, by arranging the stop of the adaptor unit on the master unit side of the lens element more to the master unit side of the lens element within the adaptor unit, the light flux diameter in the dividing part can be made large, thereby reducing the influence of dust on the image. Because the adaptor unit also includes one or two lens elements, the adaptor unit size can be made compact.

FIGS. **37**A–**37**E show various aberrations of Embodiment 1. FIG. **37**A shows the longitudinal spherical aberration, for the F, d and C lines. FIG. **37**B shows the astigmatism in the Meridional M (i.e. tangential) and Sagittal S planes. FIG. **37**C illustrates the distortion. FIG. **37**D illustrates the lateral color for the C and F lines, and FIG. **37**E illustrates the transverse spherical aberration for the F, d and C lines.

FIGS. **38**A–**38**E show the same aberrations as discussed in the paragraph above, but the curves are for the aberrations of Embodiment 26.

FIG. **39** shows a visual field conversion optical element having a single reflecting surface 1. Such an arrangement inverts the image once by reflection from the roof surface of the prism However, if the roof prism is manufactured with poor accuracy, there is a disadvantage in that the accuracy of image formation will deteriorate remarkably. This can be a problem, especially when any of the length, width, or height of the visual field conversion optical element is 5 mm or less. In order to avoid such a disadvantage, a twice-reflecting prism as shown in FIG. **40** may be used. When a visual field conversion optical element as shown in FIG. **40** is used, any of the length, width, or height of the visual field conversion element may be smaller than 5 mm without a problem. In addition, such a visual field conversion element does not invert the image from left to right and vice-versa, as is the case in the visual field conversion element of FIG. **39**. Of course, where the incident rays do not undergo total internal reflection, it is necessary to make the prism surface reflective by having, for example, a reflecting coating applied thereto.

Another visual field conversion optical element is illustrated in FIG. **41**. Although a once-reflecting prism is used, the visual field conversion optical element has a favorable image-formation capability by virtue of there being electronic means or software provided to reverse the order of the data read with the image-pickup element.

In the objective optical system of the invention, the visual field conversion optical element allows direct views, side views, and oblique views to be directed to an image pick-up element, as illustrated in, for example, FIGS. **30**, **31**, and **33**, respectively. Further, these views can be readily combined into a single image, as illustrated by the optical system in Japanese Laid Open Patent Application No. 37-9530.

The invention being thus described, it will be obvious that the same may be varied in many ways. Such variations are not to be regarded as a departure from the spirit and scope of the invention. Rather the scope of the invention shall be defined as set forth in the following claims and their legal equivalents. All such modifications as would be obvious to one skilled in the art are intended to be included within the scope of the following claims.

What is claimed is:

1. An objective optical system comprising no more than three lens elements having refractive power, as follows, in relative order from the object side:

a first lens element of negative refractive power;

a visual field conversion optical element which folds light rays incident thereon;

a stop;

a second lens element of positive refractive power; and a third lens element of positive refractive power;

wherein the image side of the third lens element is of a convex shape and satisfies the following condition

$$0.1 <|R_{(3R)}/f<20$$

where

$R_{(3R)}$ is the radius of curvature of the image-side surface of the third lens element, and

f is the focal distance of the objective optical system.

2. An objective optical system comprising, in relative order from the object side:

a first lens element of negative refractive power;

a visual field conversion optical element which folds light rays incident thereon;

a second lens element of positive refractive power; and

a third lens element of positive refractive power;

wherein the object side of the third lens element is of a convex shape, and the objective optical system satisfies the following conditions

$$\nu(p)>42$$

$$N_1>1.6$$

where

ν(p) is the Abbe number at the d-line of one of said second lens element or said third lens element, and

N_1 is the index of refraction of the first lens element.

3. An objective optical system comprising, in relative order from the object side:

a first lens element of negative refractive power;

a visual field conversion optical element which folds light rays incident thereon;

a stop;

a second lens element of positive refractive power; and

a third lens element of positive refractive power;

wherein said first lens element satisfies the following conditions

$$N_1>1.6$$

$$0.1<R_{(1R)}/f<3$$

where

N_1 is the index of refraction of the first lens element.

$R_{(1R)}$ is the radius of curvature of the image-side surface of the first lens element, and

f is the focal distance of the objective optical system.

4. An objective optical system comprising no more than two lens elements having refractive power, as follows, in relative order from the object side:

a first lens element of negative refractive power;

a visual field conversion optical element which folds light rays incident thereon;

a stop; and

a second lens element of positive refractive power;

wherein the first lens element satisfies the following condition

$$0.05<|f/f_1|<5$$

where

f is the focal distance of the objective optical system, and

f_1 is the focal distance of the first lens element.

5. The objective optical system of claim **1**, wherein at least one of the lens elements of positive refractive power includes one surface that is planar and an opposite surface that is convex, with the convex surface thereof satisfying the following condition

$$0.5 \text{ mm}<|R(p)|<5 \text{ mm}$$

where

R(p) is the radius of curvature of said opposite surface that is convex.

6. The objective optical system of claim **2**, wherein at least one of the lens elements of positive refractive power includes one surface that is planar and an opposite surface that is convex, with the convex surface thereof satisfying the following condition

$$0.5 \text{ mm}<|R(p)|<5 \text{ mm}$$

where

R(p) is the radius of curvature of said opposite surface that is convex.

7. The objective optical system of claim **3**, wherein at least one of the lens elements of positive refractive power includes one surface that is planar and an opposite surface that is convex, with the convex surface thereof satisfying the following condition

$$0.5 \text{ mm}<|R(p)|<5 \text{ mm}$$

where

R(p) is the radius of curvature of said opposite surface that is convex.

8. The objective optical system of claim **4**, wherein at least one of the lens elements of positive refractive power includes one surface that is planar and an opposite surface that is convex, with the convex surface thereof satisfying the following condition

$$0.5 \text{ mm}<|R(p)|<5 \text{ mm}$$

where

R(p) is the radius of curvature of said opposite surface that is convex.

9. The objective optical system of claim **1**, in combination with an image pick-up element having a pixel size of 5 micrometers or less.

10. The objective optical system of claim **2**, in combination with an image pick-up element having a pixel size of 5 micrometers or less.

11. The objective optical system of claim **3**, in combination with an image pick-up element having a pixel size of 5 micrometers or less.

12. The objective optical system of claim **4**, in combination with an image pick-up element having a pixel size of 5 micrometers or less.

13. The objective optical system of claim **1**, wherein one of the lens elements of positive refractive power has an outer diameter of 3 mm or less.

14. The objective optical system of claim **2**, wherein one of the lens elements of positive refractive power has an outer diameter of 3 mm or less.

15. The objective optical system of claim **3**, wherein one of the lens elements of positive refractive power has an outer diameter of 3 mm or less.

16. The objective optical system of claim **4**, wherein one of the lens elements of positive refractive power has an outer diameter of 3 mm or less.

17. The objective optical system of claim **4**, wherein the index of refraction of the first lens element is greater than 1.6.

18. An objective optical system, comprising, in relative order from the object side:

a first lens element of negative refractive power;

a visual field conversion optical element which folds light rays incident thereon;

a second lens element of positive refractive power;

a stop;

a third lens element of positive refractive power and having a convex-shaped surface on the image side, wherein the following condition is satisfied

$$1.5<f_3/IH<5$$

where

f_3 is the focal distance of the third lens element, and

IH is the maximum image height.

19. The objective optical system of claim **18**, wherein said objective optical system is formed of two parts comprising, in relative order from the object side:

an adaptor unit formed of

said first lens element,

said visual field conversion optical element,

said second lens element, and

said stop; and

a master unit, detachable from said adaptor unit, formed of

said third lens element.

20. An objective optical system comprising, in relative order from the object side:

a visual field conversion optical element which folds light rays incident thereon;

a first lens element of positive or negative refractive power;

a stop;

a second lens element of positive refractive power and having a convex surface on the image side, wherein the following condition is satisfied

$$1.5<f_2/IH<5$$

where

f_2 is the focal distance of the second lens element, and

IH is the maximum image height.

21. The objective optical system of claim **20**, wherein said objective optical system is formed of two parts comprising, in relative order from the object side:

an adaptor unit formed of

said visual field conversion optical element

said first lens element, and

said stop; and

a master unit, detachable from said adaptor unit, formed of

said second lens element.

(57) **ABSTRACT**

A reduction objective, a projection exposure apparatus with a reduction objective, and a method of use thereof are disclosed. The reduction objective comprises four (primary, secondary, tertiary, and quaternary) mirrors in centered arrangement with respect to an optical axis. The primary mirror is a convex mirror and the second mirror has a positive angular magnification. The reduction objective has an obscuration-free light path and is suitable for annular field scanning operation, such as is used in soft X-ray, i.e. and EUV and UV, lithography.

REDUCTION OBJECTIVE FOR EXTREME ULTRAVIOLET LITHOGRAPHY

FIELD OF THE INVENTION

The invention relates to a reduction objective, a projection exposure apparatus, and method of use thereof for exposing patterned information onto a reduced image plane for use in lithography applications, such as integrated circuit fabrication.

BACKGROUND OF THE INVENTION

The desirability of creating lithography systems which operate with incident light wavelengths below 193 nm to achieve imaging structures or patterns with resolution below 130 nm has been established. In fact, there has been a need for lithography systems using soft X-ray, or so called extreme ultraviolet (EUV), wavelength incident light, such as λ=11 nm or λ=13 nm light, to obtain image resolution in the below 100 nm range. The resolution of a lithography system is described by the following equation:

$$RES=k_1\lambda/NA$$

where k_1 is a specific parameter of the lithography process, λ is the wavelength of the incident light and NA is the numerical aperture of the system on the image side. This equation can be used to establish design criteria for soft X-ray lithography systems. Thus, for a numerical aperture of 0.10, the imaging of 100 nm structures with 13 nm radiation requires a process with k_1=0.77. Alternatively, with k_1=0.64, which occurs with 11 nm radiation, imaging of 70 nm structures is possible with a numerical aperture of 0.10.

For lithography imaging systems in the soft X-ray region, multilayer coated reflective systems, such as Distributed Bragg Reflectors (DBRs) and mirrors, are used as optical components. These multilayer systems employ alternating layers of different indices of refraction. The particular multilayer reflective system depends on the wavelength of incident light used. For example, with incident light of λ=11 nm alternating layers of Mo/Be are preferred and with incident light of λ=13 nm Mo/Si layers are used. In the case of projection objectives used in soft X-ray or EUV microlithography, the reflectivity of these multilayer systems is approximately 70%. It is, therefore, desirable to use as few optical components in the projection objective as possible to ensure sufficient light intensity at the image. With high intensity light, four-mirror projection objective systems were found to be useful in correcting imaging errors at NA=0.10.

Other requirements for soft X-ray projection objectives, in addition to using a limited number of multilayer reflectors, relate to obscuration, image field curvature, distortion, telecentricity on both the image and the object side, free working distance, and aperture stop positioning and accessibility. Obscurations, for example the central obscuration apparent in Schwarzschild systems, create intolerable degradation in image quality. If an obscuration-free light path is required, then, in the case of centered systems, an off-axis image field must be used. In order to provide image formats of 26×34 mm^2 or 26×52 mm^2, it is advantageous to design the projection objective system as an annular field scanner. In such systems, the useful secant length of the scanning slit should be at least 26 mm, and the annular width should lie in the range of 0.5 mm to 2 mm in order to make uniform illumination and illumination-control and dose-control possible.

Regarding distortion, a distinction between static and dynamic or scan distortion is made. Scan distortion is the

effective distortion which is obtained by integration of the static distortion over the scanning path. The limits for magnification-corrected, static distortion follow essentially from the specifications for contrast and CD variation.

Image-side telecentricity is also desired in soft X-ray lithography systems. Whether telecentricity is possible on the object side depends on the type of projection application used. If the projection system uses a reflection mask, then a telecentric optical path on the object side is not possible. If transmission masks, for example stencil masks, are used then a telecentric optical path on the object side can be realized.

In order to enable clean limitations of the beam, the aperture stop should be physically accessible. The image-side telecentricity requirement, referred to above, means that the entrance pupil of the last mirror would lie in or near its focal point. In order to obtain a compact design and maintain an accessible aperture stop, it is recommended that a beam-limiting element be placed before the last mirror. This, preferably, results in the place of the beam-limiting element at the third mirror.

Four-mirror projection or reduction objectives have become known from the following publications:

U.S. Pat. No. 5,315,629

EP 480,617

U.S. Pat. No. 5,063,586

EP 422,853

Donald W. Sweeney, Russ Hudyma, Henry N. Chapman, David Shafer, EUV optical Design for a 100 mm CD Imaging System, 23rd International Symposium of microlithography, SPIE, Santa Clara, Calif., Feb. 22–27, 1998, SPIE Vol. 3331, p. 2ff.

In U.S. Pat. No. 5,315,629, a four-mirror projection objective with NA=0.1, 4×, 31.25×0.5 mm^2 is claimed. The mirror sequence is concave, convex, concave, concave. From EP 480,617, two NA=0.1, 5×, 25×2 mm^2 systems have become known. The mirror sequence is concave, convex, arbitrary/convex, concave.

The systems according to U.S. Pat. No. 5,063,586 and EP 422,853 have a rectangular image field, for example, at least 5×5 mm^2, and use a mirror sequence of convex, concave, convex, concave. These generally decentered systems exhibit very high distortion values. Therefore, the objectives can only be used in steppers with distortion correction on the reticle. However, the high level of distortion makes such objectives impractical in the structural resolution regions discussed here (≦130 nm).

From U.S. Pat. No. 5,153,898, overall arbitrary three to five-multilayer mirror systems have become known. However, the disclosed embodiments all describe three-mirror systems with a rectangular field and small numerical aperture (NA<0.04). Therefore, the systems described therein can only image structures above 0.25 μm in length.

Furthermore, reference is made to T. Jewell: "Optical system design issues in development of projection camera for EUV lithography", Proc. SPIE 2437 (1995) and the citations given there, the entire disclosure of which is incorporated by reference.

In the known systems according to EP 480,617 as well as U.S. Pat. No. 5,315,629 and according to Sweeney, cited above, it was found to be disadvantageous that the outside-axially used part of the primary mirror conflicts with the wafer-side sensor structures of a projection exposure installation when not very large free mechanical working distances greater than 100 mm are realized. By using mirror segments which are placed "near the image field", these conflicts occur only at significantly lower distances (≈10 mm).

Thus, it is desired from the prior art to provide a projection objective arrangement which is suitable for lithography with short wavelengths (at least below 193 nm and preferably below 100 nm) which does not have the disadvantages of the prior art mentioned above, uses as few optical elements as possible and, yet, has a sufficiently large aperture and fulfills the telecentricity requirements as well as all other requirements for a projection system operating with incident light of wavelengths below 193 nm.

SUMMARY OF THE INVENTION

According to an aspect of the invention, the shortcomings of the prior art are overcome by using a reduction objective that includes four mirrors (primary, secondary, tertiary, and quaternary) and is characterized by a convex primary mirror as well as by a positive chief ray angular magnification of the secondary mirror. Using this four-mirror system, high transmission efficiency is achieved at wavelengths in the soft X-ray and EUV region with a multilayer mirror system of 70% reflectivity and an aperture in the range of NA≈0.10. The four-mirror objective according to the invention is thus characterized by high resolution, low manufacturing costs and high throughput.

In a preferred embodiment of the invention, it is provided that an aperture stop lies on or near a mirror, especially on the tertiary mirror. In this embodiment, the aperture stop is physically accessible and the reduction objective is compact and free from vignetting. In a further embodiment, one or two additional mirrors with aspherical surfaces, as derived from a plane, are disposed between selected mirrors of the four-mirror system at grazing angle of incidence. In a further embodiment, at least one of the additional mirrors is an active mirror.

In another embodiment of the reduction objective of the invention, the secondary mirror and the quaternary mirror are concave. In still a further embodiment, the four-mirrors are arranged in the convex-concave-convex-concave sequence.

The asphericities discussed herein refer to the peak-to-peak or peak-to-valley (PV) deviation A of the aspherical surfaces in comparison to the best fitting sphere in the used region of the mirrors. In the embodiments of the invention discussed herein, these are approximated by a sphere, the center of which lies on the figure-axis of the mirror and the meridional plane of the aspherical element intersects in the upper and lower end point of the useful region. The data on the angles of incidence, as provided below in Table II, refer to the angle between the particular incident radiation and the normal to the surface at the point of incidence. The largest angle of incidence of a ray is established by a rim-ray at one of the mirrors.

Preferably, the optically free working distance on the wafer side is 60 mm and the free working distance on the reticle side is at least 100 mm.

As will be appreciated from this disclosure by persons of ordinary skill in the art, the objectives described above can be used not only for soft X-ray lithography, but for other wavelengths, both in the EUV range and outside of this range, without deviation from the invention. Nonetheless, the invention is preferably used at soft X-ray and EUV wavelengths in the region of 193 nm and below. Wavelengths within this range can be generated using excimer lasers.

In order to achieve a diffraction-limited system, it is preferred that the design part of the rms wave front section of the system is at most 0.07λ, and preferably 0.03λ. It is further preferred that the reduction objective is designed so that it is telecentric on the image side. In systems with a transmission mask, the projection objective is also designed to be telecentric on the object side. In projection systems which are operated with a reflection mask, a telecentric beam path without illumination over a beam splitter which reduces transmission greatly, such as is shown in JP-A-95/28 31 16, is not possible on the object side. Therefore, the chief ray angle in the reticle is chosen so that shading-free illumination, that is no obscuration, is possible. Overall, the telecentricity error on the wafer should not exceed 10 mrad, and preferably is in the 5 mrad to below 2 mrad range. This ensures that the change in the image scale or distortion lies within tolerable limits in the depth of field.

According to another aspect of the invention, the reduction objective is used with a mask and a soft X-ray or EUV exposure source, for example, in a projection exposure apparatus, such as those used in lithography for integrated circuit fabrication. In the embodiment, the projection exposure apparatus has a reflection mask and, in an alternative embodiment, it has a transmission mask.

The projection exposure apparatus is preferably designed as an annular-field scanner illuminating an off-axis annular field. Advantageously, it is provided that the secant length of the scanning slit is at least 26 mm and that the annular width is greater than 0.5 mm, so that uniform illumination is made possible.

Another advantage of the objective of the invention, is that the asphericity of the aspherical optical elements is small enough so that the system requirements of being "diffraction-limited" and having high reflectivity multilayer mirrors can be achieved, such that the resulting accuracy requirements on these surfaces in all spatial frequency regions from the free diameter of the mirror to atomic dimensions can be obeyed.

According to another aspect of the invention, a method of integrated circuit fabrication using a projection exposure apparatus including a reduction objective is provided. The method comprises the steps of providing a mask, providing a soft X-ray or EUV, illumination source, and providing four mirrors (primary, secondary, tertiary, and quaternary) in centered arrangement with respect to an optical axis, wherein the primary mirror is a convex mirror and the secondary mirror has a positive angular magnification.

Traditionally, approximately 40 pairs of alternating Mo/Si DBR layers are used to create mirrors with high reflectivity of 13 nm wavelength incident light. Similarly, high reflectivity of 11 nm wavelength radiation, requires approximately 70 pairs of Mo/Be alternating layers. By using large numbers of DBR layers, the acceptance angle of mirrors and thus their objective systems is only a few degrees and decreases with increasing angle of incidence. Furthermore, with this increasing angle of incidence, detrimental phase effects can occur. If the test-point-related mean angle of incidence varies greatly over a system surface, then layer packets with changing thickness must be applied. These disadvantages of existing multilayer mirror objective systems are reduced in the present invention in which the objectives have a low mean angle of incidence and a low surface-specific variation around the mean angle of incidence.

The invention will be explained below with the aid of drawings depicting the preferred embodiments.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a schematic representation of the system classification used in the invention.

FIG. **2** is a lens cross-section of a first four-mirror system (type-e system) according to the prior art.

FIG. **3** is a lens cross-section of a four-mirror system (type-f system) according to the invention.

FIG. **4** is a lens cross-section of another four-mirror system (type-g system) according to the invention.

FIG. **5** is a four-mirror system of type-f with an introduced grazing-incidence mirror according to the invention.

FIG. **6** is a depiction of a four-mirror reduction objective that is telecentric on the object side and used with a transmission mask.

FIG. **7** is a depiction of a four-mirror reduction objective that is telecentric on the object side and used with a reflection mask.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

The practical examples identified in FIGS. **2–5** are centered reduction systems, telecentric on the image side, with an aperture stop (indicated by AS in FIG. **4**, for example) at the third mirror **M3**. In all systems, the same reference numbers are used for the same components and the following nomenclature is employed:

first (primary) mirror (**M1**), second (secondary) mirror (**M2**),

third (tertiary) mirror (**M3**), fourth (quaternary) mirror (**M4**).

Reduction objectives used in lithography are classified by their primary mirror magnification m(**M1**), or convergence ratio ν(**M1**)=−1/m(**M1**), and their secondary-mirror chief ray angular magnification μ(**M2**). This nomenclature is taken from Dietrich Korsch, Reflective optics, Academic Press, 1991, p. 41ff, which is incorporated herein by reference. For the different types of primary mirrors Table I, below, summarizes the different convergence ratio and angular magnification values obtainable.

TABLE I

	M1	ν(M1)	μ(M2)
type-a	concave	$\epsilon]1,\infty[$	$<-\epsilon_4$
type-b	plane, concave	$\epsilon[-1,1]$	$<-\epsilon_4$
type-e	convex	$\epsilon]-\infty,-1[$	$<-\epsilon_4$
type-f	convex	$\epsilon]-\infty,-1[$	$\epsilon]\epsilon_4,1-\epsilon_2[$
type-g	convex	$\epsilon]-\infty,-1[$	$\epsilon]1+\epsilon_3,\infty[$

The following is true for these systems: $\epsilon_i > 0$ increases with the numerical aperture NA of the system, that is, $\epsilon_i = 0 \rightarrow NA = 0$. A schematic representation of the system classification as used below is shown in FIG. 1.

The concept of the chief ray angular magnification or angular magnification refers to the tangents of the chief ray (see Korsch, Reflective Optics, incorporated by reference above). A positive angular magnification means that the slopes of the straight lines identifiable with the incident and reflected chief rays to the optical axis have the same sign, that is, that the entrance and exit pupils of the respective mirror lie on the same physical side of the mirror.

As shown in FIG. **1**, type-a, type-b and type-e are topologically connected components of the two-dimensional parameter space. Therefore, type-a, type-b, and type-e objectives can be transformed continuously into each other. In contrast, this is not possible between each of the two other classes of the three systems shown in FIG. **1**. The class including types-a, -b, and -e, can not be continuously transformed into the type-f class (system) or the type-g class (system). FIG. **1** indicates the forbidden regions F in which, in the case of a finite NA, obscuration of the light beam by the mirror will occur and therefore the objectives will fail to image properly.

The particular topologically-connected component region is determined by μ(**M2**). The annular field systems disclosed in U.S. Pat. No. 5,315,629 and EP 480,617 are type-a systems. Type-b systems provide continuous transition to the type-e system which also include the system known from Donald W. Sweeney et al., 23rd International Symposium of Microlithography. Type-a, type-b, and type-e systems are known in the prior art.

Systems of type-f and type-g are not known from any of the publications referred to above. The systems according to type-f and type-g differ from the systems of U.S. Pat. No. 5,315,629 and EP 480,617 by having a convex primary mirror. The system disclosed in Donald W. Sweeney et al., 23rd International Symposium of Microlithography, loc. cit., has a convex primary mirror but it also has a different angular magnification μ at **M2** and thus a different optical path in the system, which does not overcome the prior art problems described above.

Systems of type-f with ν(**M1**) above approximately −1.5 lead to large chief ray angles on the reticle and to large system diameters. As a result, sensible system design with a concave **M1**, i.e. $\nu(M1) \geqq 1$, is difficult.

In the following Table II, typical functional data are given for some of the embodiments of the various system categories. The distortion values follow from the magnification correction through the annular field. Objective systems belonging to the individual system classes are shown in FIGS. **2–5**.

Explanation of the abbreviations used in Table II are listed in Table III, below.

TABLE III

	Meaning
M1	form of the primary mirror
ν(M1)	"conversion ratio" according to Korsch
μ(M2)	"angular magnification" according to Korsch
NA	image-side numerical aperture
Red	reduction factor = −1/imaging scale
annular field [mm^2]	secant length × annular width in the image field

TABLE III-continued

	Meaning
mean annular field radius [mm]	image field radius in the middle of the annular field
OO[1] [mm]	object-image distance
FWD [mm]	optically free working distance on the image side
CRAO [deg]	chief ray angle in the object space
CRA [mrad]	chief ray angle in the image space
max. asph. [μm]	maximum deviation of the asphere from the best fitting sphere with respect to the used region of the mirror
AOI max. [deg]	maximum angle of incidence
ΔAOI max. [deg]	variation of the angle of incidence over the mirror
WFE max. [λrms]	maximum rms wavefront error in units of λ
distortion [nmPV]	peak-to-peak value over the annular field scale-corrected chief ray distortion

Systems with a convex M1, i.e. primary mirror, show a significantly higher asphericity than the type-a designs with a concave M1.

FIG. **2** shows a cross-section of a type-e system from a reticle plane **2**, or mask, to a wafer plane **4**. The mirror nearest to the wafer is the first mirror **M1**. Type-e systems have the lowest AOI and ΔAOI on mirrors **M1**, **M2**, **M3**, **M4**, which favors the polarization-optical properties of the system. However, the high chief ray angles on the reticle plane **2** requires plane reticles. Conversely, type-g systems, as shown in cross-section in FIG. **4**, have relatively large AOI and ΔAOI on mirrors **M1**, **M2**, **M3**, **M4** with tolerable chief ray angles on the reticle.

As shown in FIG. **3**, type-f systems require the largest aspherical elements, but have favorable angular distributions on mirrors **M1**, **M2**, **M3**, **M4** and on the reticle **2**. The low distortion results in a relatively small image field. Although the constructional length, i.e. the physical length, of the system is larger than in the other systems, the long drift sections within the objective permit the optional use of additional components, such as an alignment system, deflecting mirror, etc. A chief ray CR and an optical axis HA are also shown in FIG. **3**.

The type-f and type-g systems, as shown in FIGS. **3** and **4**, respectively, can be realized with positive and negative chief ray angles on reticle **2**. Thus, an optimal geometry can be selected, especially a comparatively low free working distance to reticle **2**, for imaging the light when using a reflection mask. Furthermore, when using a transmission mask, a telecentric beam path can be realized.

The systems of type-a and type-f have relatively long "drift sections" before or within the actual image system. Therefore, it is possible to introduce grazing-incidence mirrors of high reflectivity as correction elements. These correction elements can include Schmidt corrector-type elements or an active optical correction system. Based on known values for molybdenum-coated mirrors, it is theoretically possible to achieve approximately 85% reflectivity of non-polarized incident light of wavelength 13.3 nm incident at an angle of 75°. Due to the grazing incidence of the beam, the illuminated part of the mirror can be made very large in one direction, in comparison to that on the neighboring mirror, which facilitates the design of the correcting elements. Preferably, the individual mirrors are designed in a pair-wise manner with the normals to the surface being almost perpendicular to one another, in order to be able to manipulate the beams in all spatial directions with the same resolution. FIG. **5** shows such a design of type-f with an introduced grazing-incidence mirror GIM.

The parameters of the system according to FIG. **3** in the code V format are given in Table 1 below.

FIG. **6** shows the four-mirror reduction objective of FIG. **3** or **4** with the reticle plane **2** as a transmission mask. Thus, it can be seen from FIG. **6** that the reduction objective is telecentric on the object side in such a configuration. Similarly, FIG. **7** shows the four-mirror reduction objective of FIG. **3** or **4** with the reticle plane **2** as a reflection mask. In such a configuration, a beam splitter may be used, for example, to ensure the reduction objective is also telecentric on the object side.

Thus, the invention provides for a four-mirror reduction objective with an imaging reduction scale of approximately 4× for use in soft X-ray, i.e. EUV and UV, annular field projection applications, such as lithography. The reduction objection achieves the necessary resolution at the required image field and provides a structural design with optical elements of sufficiently mild asphericity, sufficiently small incident angles for the multilayered optics, and sufficiently large constructional space for the image carriers.

What is claimed is:

1. A reduction objective, with an image side and an object side, comprising:

a primary multilayer mirror, a secondary multilayer mirror, a tertiary multilayer mirror and a quaternary multilayer mirror in centered arrangement with respect to an optical axis situated between the image side and the object side, wherein the primary mirror is convex and the secondary mirror has positive chief ray angular magnification.

2. A reduction objective according to claim **1**, comprising an aperture stop disposed on or near the primary mirror, the secondary mirror, the tertiary mirror, or the quaternary mirror.

3. A reduction objective according to claim **1**, comprising an aperture stop disposed on or near said tertiary mirror.

4. A reduction objective according to claim **1**, comprising a fifth mirror or a sixth mirror disposed at a grazing incidence.

5. A reduction objective according to claim **4**, wherein said fifth mirror or said sixth mirror has an aspherical surface derived from a planar surface.

6. A reduction objective according to claim **4**, wherein at least said fifth mirror or said sixth mirror is an active mirror.

7. A reduction objective according to claim **1**, wherein the secondary mirror and the quaternary mirror are concave.

8. A reduction objective according claim **1**, wherein the primary mirror, the secondary mirror, the tertiary mirror and the quaternary mirror are shaped in a convex-concave-convex-concave sequence.

9. A reduction objective according to claim **1**, wherein the reduction objective is telecentric on the object side.

10. A reduction objective according to claim **1**, wherein a chief ray at the object side is directed away from the optical axis.

11. A reduction objective according to claim **1**, wherein the reduction objective is telecentric on the image side.

12. A reduction objective according to claim **1**, wherein the secondary mirror in centered arrangement with the optical axis has a used area in which rays traveling through the objective are impinging the secondary mirror, and wherein a bundle of rays from the object side to the primary mirror is traveling between the used area of the secondary mirror and the optical axis.

13. A reduction objective according to claim **1**, wherein the primary mirror in centered arrangement with the optical axis has a used area in which rays traveling through the objective are impinging the primary mirror, and wherein a bundle of rays reflected from the secondary mirror and impinging the tertiary mirror is traveling between the used area of the primary mirror and the optical axis.

14. A reduction objective according to claim **1**, wherein the primary mirror in centered arrangement with the optical axis has a used area in which rays traveling through the objective are impinging the primary mirror, and wherein a bundle of rays reflected from the secondary mirror and impinging the tertiary mirror is traveling along a light channel such that the used area of the primary mirror is situated between the light channel and the optical axis.

15. A reduction objective according to claim **1**, wherein the chief ray angular magnification on the second mirror is greater than or equal to 0.6.

16. A projection exposure apparatus including a reduction objective, with an image side and an object side, for annular field scanning operation, comprising:

a mask; and

a primary multilayer mirror, a secondary multilayer mirror, a tertiary multilayer mirror and a quaternary multilayer mirror in centered arrangement with respect to an optical axis situated between the image side and the object side, wherein the primary mirror is convex and the secondary mirror has a positive chief ray angular magnification.

17. A projection exposure apparatus according to claim 16, wherein the mask is a reflection mask.

18. A projection exposure apparatus according to claim 16, wherein the mask is a transmission mask.

19. A method for integrated circuit fabrication using a projection exposure apparatus including a reduction objective, with an image side and an object side, including the steps of:

providing a mask; and

providing a primary multilayer mirror, a secondary multilayer mirror, a tertiary multilayer mirror and a quaternary multilayer mirror in centered arrangement with respect to an optical axis situated between the image side and the object side, wherein the primary mirror is convex and the secondary mirror has a positive chief ray angular magnification.

(57) **ABSTRACT**

A portable TV telephone includes an objective lens system. The objective lens system is configured to form an image of an object. An antenna is configured to transmit and receive at least one of said image of the object, a dial number and a voice carried by radio waves. A display is configured to display at least one of the image of the object and the dial number. The objective lens system includes a first negative lens unit and a second positive lens unit in order from an object side. An aperture stop is disposed between the first lens unit and said second lens unit. In one embodiment, the first lens and the second lens each have a lens barrel configured to position the respective lens units such that circumferences of the lens units contact interior walls of the portable TV telephone. In another embodiment, the first lens unit and the second lens unit are cemented at outer circumferential portions outside an effective diameter through which rays transmit.

OBJECTIVE LENS SYSTEM

This is a division of application Ser. No. 08/713,069, filed Sep. 12, 1996 now U.S. Pat. No. 5,999,327.

BACKGROUND OF THE INVENTION

a) Field of the Invention

The present invention relates to an objective lens system which uses a radial type gradient index lens element.

b) Description of the Prior Art

As conventional examples of lens systems having relatively wide field angles and high optical performance which are used, for example, as objective lens systems for endoscopes, there are known many lens systems such as a lens system disclosed by Japanese Patent Kokoku Publication No. Sho 60-46410 shown in FIG. **1**. A conventional example shown in FIG. **1** is a lens system of the so-called retrofocus type which is composed, in order from the object side, of a front lens unit having negative refractive power, a stop and a rear lens unit having a positive refractive power. In this lens system, the front lens unit has a function to widen a field angle and another function to correct curvature of field by reducing a Petzval's sum of the lens system as a whole, the rear lens unit serves for suppressing production of spherical aberration and coma by distributing refractive powers among three positive lens elements and a cemented lens component, and the cemented lens component corrects lateral chromatic aberration which poses a problem, in particular, in a lens system which has a wide field angle. Though this conventional example favorably corrects aberrations, it is composed of lens elements in a number as large as six, thereby posing a problem of low producibility or a high manufacturing cost. Accordingly, it is expected to develop a retrofocus type objective lens system for endoscopes which is composed of an extremely small number of lens elements and has a high producibility. However, a lens system which favorably corrects aberrations and has high optical performance can hardly be composed of two homogenous spherical lens elements.

Further, an endoscope is generally equipped with a system for illuminating a location to be observed since it is used frequently for observing and photographing dark locations such as interiors of human bodies, aircraft engines, pipings and so on. In addition, an objective lens system for endoscopes has an NA which is not so large for obtaining a large depth of field. Accordingly, axial aberrations do not pose a serious problem, but a wide field angle and a negative-positive asymmetrical composition as shown in FIG. **1** make it difficult to correct offaxial aberrations. When an objective lens system is to be composed of two negative and positive lens elements, it is impossible to use a cemented lens component as in the objective lens system disclosed by Japanese Patent Kokoku Publication No. Sho 60-46410 mentioned above as the conventional example, whereby lateral chromatic aberration can hardly be corrected and offaxial imaging performance is remarkably degraded. It is therefore difficult to favorably correct offaxial aberrations with two homogenous lens elements so as to obtain favorable offaxial imaging performance.

It is therefore conceivable to use a radial type gradient index lens element which is characterized in that it corrects chromatic aberration in particular more favor- ably than a homogenous lens element. As a conventional example of an objective lens system for endoscopes which uses a radial type gradient index lens element and is composed of two lens elements, there is known a lens system disclosed by

Japanese Patent Kokai Publication No. Sho 52-29238. However, this conventional example has a field angle as narrow as 72° which is insufficient for use as an objective lens system for endoscopes.

Further, a lens system disclosed by Japanese Patent Kokai Publication No. Hei 5-107471,for example, is known as a conventional example of an objective lens system having a wide field angle obtained with two lens elements. Though this example uses a radial type gradient index lens element, it does not effectively make use of the chromatic aberration correcting capability of the radial type gradient index lens element and does not sufficiently correct lateral chromatic aberration which poses a problem in a lens system having a wide field angle in particular.

SUMMARY OF THE INVENTION

A primary object of the present invention is to provide an objective lens system which is composed of lens elements in a number on the order of 2, that favorably corrects aberrations and has a wide field angle.

The objective lens system according to the present invention is characterized in that it comprises, in order from the object side, a first lens unit having a negative refractive power and a second lens unit having a positive refractive power; that at least the first lens unit comprises a radial gradient index lens element which has a refractive index distribution in a radial direction of the lens element; and that the first lens unit satisfies the following condition (1):

$$1/V_{10}<1/V_{00} \tag{1}$$

wherein the reference symbols V_{00} and V_{10} represent parameters expressing a dispersing power of the radial type gradient index lens element which are given by the following formulae (b) and (c) respectively:

$$V_{00}=(N_{00d}-1)/(N_{00F}-N_{00C}) \tag{b}$$

$$V_{10}=N_{10d}/(N_{10F}-N_{10C})$$

wherein the reference symbols N_{00d}, N_{00F} and N_{00C} represent refractive indices of the radial type gradient index lens element for the d-line, F-line and C-line respectively, and the reference symbols N_{10d}, N_{10F} and N_{10C} designate values of a coefficient of a term r^2 for the d-line, F-line and C-line respectively when a refractive indices of the radial type gradient index lens element is expressed in a form of a poly-nominal. In embodiments of the present invention which are to be described later, refractive indices of radial type gradient index lens elements are given by the following formula (a):

$$n(r)=N_{00}+N_{10}r^2+N_{20}r^4+ \tag{a}$$

wherein the reference symbol r represents a distance as measured from an optical axis in a radial direction of the radial type gradient index element and the reference symbol n(r) designates a refractive index of a portion of the radial type gradient index lens element located at the distance r.

Further, the objective lens system according to the present invention is characterized in: that it is composed, in order from the object side, of a first lens unit having a negative refractive power, and a second lens unit having a positive refractive power, that at least the second lens unit comprises a radial type gradient index lens element having a refractive index distribution in a radial direction of the lens element,

and that the second lens unit satisfies the following conditions (1) and (3):

$$1/V_{10}<1/V_{00} \quad (1)$$

$$0.05<\phi_{2m}/\phi<1.0 \quad (3)$$

wherein the reference symbol ϕ_{2m} represents a refractive index of a medium of the radial type gradient lens element used in the second lens unit.

Further, it is desirable that the objective lens system according to the present invention described above satisfies the following condition (2):

$$-0.5<\phi_{1m}/\phi<-0.02$$

wherein the reference symbol ϕ_{1m} represents a refractive power of a medium of the radial type gradient index lens element used in the first lens unit and the reference symbol ϕ designates a refractive power of the objective lens system as a whole.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** shows a sectional view illustrating a composition of a conventional objective lens system;

FIG. **2** shows a diagram schematically showing a fundamental composition of the objective lens system according to the present invention;

FIG. **3** shows a diagram schematically showing the fundamental composition of the objective lens system according to the present invention wherein an image surface is positioned in parallel with an optical axis;

FIGS. **4** through **15** show sectional views illustrating compositions of first through twelfth embodiments of the objective lens system according to the present invention;

FIGS. **16**A and **16**B show views illustrating a composition of a thirteenth embodiment of the objective lens system according to the present invention;

FIGS. **17** through **21** show sectional views illustrating composition of fourteenth through eighteenth embodiments of the objective lens system according to the present invention;

FIGS. **22**A, **22**B and **22**C show diagrams exemplifying a shape, before working, of a lens element which is to be used in the objective lens system according to the present invention;

FIGS. **23**A, **23**B and **23**C show diagrams exemplifying a shape, after working, of the lens system which is to be used in the objective lens system according to the present invention;

FIG. **24** is a diagram showing an example of a stop which is to be disposed in the objective lens system according to the present invention;

FIG. **25** is a diagram showing another example of a stop which is to be disposed in the objective lens system according to the present invention;

FIGS. **26** through **31** show sectional views illustrating compositions of nineteenth through twenty-fourth embodiments of the objective lens system according to the present invention;

FIG. **32** shows a perspective view illustrating an endoscope which uses the objective lens system according to the present invention;

FIG. **33** shows a side view of a non-flexible endoscope which uses the objective lens system according to the present invention;

FIG. **34** shows a perspective view illustrating a video camera which uses the objective lens system according to the present invention;

FIG. **35** shows a perspective view illustrating a portable TV telephone which uses the objective lens system according to the present invention; and FIG. **36** shows a perspective view illustrating a portable data input unit which uses the objective lens system according to the present invention.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

It is desirable that an objective lens system which has a relatively wide field angle for use in endoscopes, for example, is configured as the so-called retrofocus type composed, in order from the object side, of a first lens unit having a negative refractive power and a second lens unit having a positive refractive power.

Further, it is desirable that endoscopes, for example, which are inserted into human bodies and pipings for observing interiors thereof use objective lens systems having small diameters. When the lens system according to the present invention is to be used as an objective lens system for endoscopes, it is desirable for reducing a diameter of the lens system to compose it by disposing a stop between a negative lens unit and a positive lens unit. By selecting such a composition, it is possible to lower heights of rays passing through a first lens unit or a second lens unit, thereby reducing the diameter of the lens system. When the lens system has an asymmetrical composition, or is composed of a positive lens unit and a negative lens unit disposed on both sides of a stop, however, offaxial aberrations are apt to be produced in large amounts in the lens system as a whole, or it is difficult to favorably correct lateral chromatic aberration in particular. For favorably correcting lateral chromatic aberration, it is desirable to use a radial type gradient index lens element which has a more excellent characteristic for correcting chromatic aberration than a homogenous lens element.

It is known that lateral chromatic aberration LTC produced by a thin radial type gradient index lens element is expressed by the following formula (d):

$$LTC=K(\phi_s/V_{00}+\phi_m/v_{10}) \quad (d)$$

wherein the reference symbol K represents a constant determined dependently on a height of an offaxial ray and an angle of a final axial ray, the reference symbol ϕ_s designates a refractive power of a surface of the radial type gradient index lens element and the reference symbol ϕ_m denotes a refractive power of a medium of the radial type gradient index lens element which is known to be approximated by the following formula (e):

$$\phi_m \approx 2N_{10}d_G \quad (e)$$

wherein the reference symbol d_G represents thickness of the radial type gradient index lens element.

As is apparent from the formula (d), it is possible to control an amount of chromatic aberration to a desired value by varying V_{10} in the second term of the formula.

Since the objective lens system according to the present invention has an asymmetrical composition, like the model of thin lens elements shown in FIG. **2**, wherein a first negative lens unit L_1 and a second positive lens unit L_2 are disposed in that order from the object side and on both side of a stop S, each of the lens units refracts a ray RO coming

from an offaxial object point, unlike a ray RA coming from an axial object point, in a direction which is the same as a refracted direction (downward in FIG. **2**) of an incident light bundle. Accordingly, lateral chromatic aberration is produced in a very large amount in the objective lens system according to the present invention, thereby making it difficult to compose the objective lens system, in order from the object side, of a negative lens unit and a positive lens unit which consist of two homogenous lens elements.

For solving this problem or favorably correcting lateral chromatic aberration by adopting a radial type gradient index lens element, it is conceivable to select either of two cases: one where the radial index lens element is used in the first negative lens unit and the other where the radial gradient lens element is used in the second positive lens unit.

Description will be made of a first composition of the objective lens system according to the present invention where a radial gradient index element is used in the first negative lens unit.

For allowing a radial type gradient index lens element to produce chromatic aberration in an amount smaller than that of chromatic aberration produced by a homogenous lens element which has the same refractive power as that of the radial type gradient index lens element, it is necessary from the formula (d) to satisfy the following relationship:

$$\phi_s/V_{00}+\phi_m/V_{10}<\phi_t/V_{00}$$

wherein the reference symbol ϕ_t represents a refractive power of the homogenous lens element on an assumption that it has an Abbe's number which is equal to that on the optical axis of the radial type gradient index lens element.

Since the radial type gradient index lens element and the homogenous lens element which are compared with each other have the same refractive power, we obtain:

$$\phi_t=\phi_s+\phi_m$$

From the two formulae mentioned above, there establishes the following relationship:

$$\phi_s/V_{00}+\phi_m/V10<\phi_s/V_{00}+\phi_m/V_{00}$$

The above-mentioned condition (1) is obtained from this formula.

For favorably correcting lateral chromatic aberration in the objective lens system according to the present invention, it is desirable to use a radial type gradient index lens element satisfying the condition (1) as the first lens unit which has the negative refractive power as described above. The condition (1) is required for allowing a radial type gradient index lens element to produce chromatic aberration in an amount smaller than that of chromatic aberration produced by a homogenous lens element which has the same refractive power as that of the radial type gradient index lens element. If the condition (1) is not satisfied, a radial type gradient index lens element cannot correct lateral chromatic aberration more favorably than a homogenous lens element which has the same refractive power as that of the radial type gradient index lens element.

When a radial type gradient index lens element is to be used for correcting lateral chromatic aberration, it is necessary, as apparent from the formula (d), to take into sufficient consideration not only a value of V_{10} but also refractive powers of a surface and a medium. For reducing an amount of lateral chromatic aberration to be produced by the first lens unit in the objective lens system according to the present invention, it is desirable from the formula (d) to meet the following equation:

$$\phi_s/V_{00}+\phi_m/V_{10}\approx 0$$

By using a total refractive power of a surface and a medium $\phi_G(=\phi_s+\phi_m)$ in this formula and developing it, we obtain:

$$\phi_m\approx\phi_G\times V_{10}/(V_{10}-V_{00})$$

Since the Abbe's number V_{00} of a radial type gradient index lens element ordinarily has a value on the order of 30 to 80 on an optical axis and the first lens unit has the negative refractive power, the condition (1) required for correcting chromatic aberration can be transformed as follows:

$$\phi_G\times V_{10}/(V_{10}-V_{00})<0$$

It is desirable as understood from this formula that a medium has a negative refractive power. Taking into consideration this fact and the requirement to correct lateral chromatic aberration favorably in the objective lens system as a whole, it is desirable that a radial type gradient index lens element which is to be used in the objective optical system according to the present invention is made of a medium having a refractive power ϕ_{1m} satisfying the above-mentioned condition (2).

When a ratio of a refractive power of a medium of the first lens unit relative to a refractive power of the objective lens system satisfies the condition (2), it is possible to correct lateral chromatic aberration favorably in the objective lens system as a whole. If the upper limit of −0.02 of the condition (2) is exceeded, a medium of the radial type gradient index lens element will have a weak refractive power, thereby undesirably making it difficult to correct lateral chromatic aberration favorably in the objective lens system as a whole. If the lower limit of −0.5 of the condition (2) is not satisfied, in contrast, a medium will have too strong a refractive power, thereby overcorrecting lateral chromatic aberration.

The objective lens system according to the present invention which has a second composition is composed of a first lens unit having a negative refractive power and a second lens unit having a positive refractive power; a radial type gradient index lens element being used in the second lens unit having the positive refractive power; and the radial type gradient index lens element used in the second lens unit having a refractive index expressed by the above-mentioned formula (a) and satisfying the following conditions (1) and (3):

$$1/V_{10}<1/V_{00} \quad (1)$$

$$0.05<\phi_{2m}/\phi<1.0 \quad (3)$$

wherein the reference symbol ϕ_{2m} represents a refractive power of the gradient index lens element which is used in the second lens unit and the reference symbol ϕ designates a refractive power of the objective lens system as a whole.

Since lateral chromatic aberration is produced in a very large amount in the objective lens system as a whole as described above, it is difficult to compose the lens system, in order from the object side, of two negative and positive homogenous lens elements. When a radial type gradient index lens element is to be used in the second lens lens unit for solving this problem or favorably correcting lateral chromatic aberration, it is desirable to configure this lens element so as to satisfy the condition (1) mentioned above.

The condition (1) is required for allowing the radial type gradient index lens element to produce chromatic aberration in an amount smaller than that of chromatic aberration produced by a homogenous lens element which has the same refractive power as that of the radial type gradient index lens element.

If the condition (1) is not satisfied, the radial type gradient index lens element cannot correct chromatic aberration more favorably than the homogenous lens element having the same refractive power as that of the radial type gradient index lens element.

When a radial type gradient index lens element is to be used for correcting lateral chromatic aberration, it is necessary to take into consideration not only a value of V_1o but also refractive powers of a surface and a medium as described above. When lateral chromatic aberration produced by the second lens unit is to be reduced in the objective lens system according to the present invention, the formula (d) is transformed, as in the case where a radial type gradient index lens element is used in the first lens unit, into the following formula:

$$\phi_m \approx \phi_G \times V_{10}/(V_{10}-V_{00})$$

Since the second lens unit has a positive refractive power, it is desirable that ϕ_m has a positive value. When a radial type gradient index lens element is to be used in the second lens unit for correcting lateral chromatic aberration favorably in the objective lens system as a whole, it is desirable that the refractive power ϕ_m of a medium satisfies the above-mentioned condition (3).

When a ratio of a refractive power of medium relative to a refractive power of the objective lens system as a whole satisfies the condition (3), it is possible to correct lateral chromatic aberration favorably in the objective lens system as a whole.

If the lower limit of 0.05 of the condition (3) is not satisfied, a medium of the radial type gradient index lens element will have a weak refractive power, thereby undesirably making it difficult to correct lateral chromatic aberration favorably in the objective lens system as a whole. If the upper limit of 1.0 of the condition (3) is exceeded, in contrast, a refractive power of medium will be too strong, thereby undesirably overcorrecting lateral chromatic aberration.

The condition (3) is required also for favorably correcting not only chromatic aberration but also the other aberrations.

The objective optical system according to the present invention which has a wide field angle produces a positive Petzval's sum in the lens system as a whole, thereby tending to tilt an image surface toward the object side. For favorably correcting this Petzval's sum, it is desirable to use a radial type gradient index lens element in the second lens unit which has a large positive Petzval's sum.

A Petzval's sum PTZ of a radial type gradient index lens element is expressed by the following formula (f):

$$PTZ=\phi_s/N_{00}+\phi_m/N_{00}^2$$

As is apparent from the formula (f) in which the denominator of the second term on the right side is squared, it is possible to configure a radial type gradient index lens element so as to have a Petzval's sum which is smaller than that of a homogenous lens element having the same refractive power as that of the radial type gradient index lens element.

For reducing a Petzval's sum of the objective lens system with a radial type gradient index lens element, it is desirable from the formula (f) that the radial type gradient index lens element satisfies the following formula:

$$\phi_s/N_{00}+\phi_m/N_{00}^2 \approx 0$$

The formula shown below can be derived by using a total refractive power of surface and medium $\phi_G(=\phi_2+\phi_m)$ in the above formula and developing it.

$$\phi_m \approx \phi_G \times N_{00}/(N_{00}-1)$$

Since refractive indices N_{00} on an optical axis of radial gradient index lens elements ordinarily have values larger than 1, or on the order of 1.45 to 1.85, it is desirable for favorably correcting a Petzval's sum to use a radial type gradient index lens element which has a positive refractive power of medium when it is to be used in the second lens unit having the positive refractive power. If a radial type gradient index lens element which has a negative refractive power of medium is used in the second lens unit, the positive Petzval's sum will be further enlarged, hereby undesirably tilting an image surface toward the object side.

For correcting the Petzval's sum in the objective lens system according to the present invention, it is desirable from the formula (f) that a refractive power of medium is strong to a certain degree or refractive power of medium fm satisfies the condition (3). When a ratio of the refractive power of medium relative to a refractive power of the objective lens system as a whole satisfies the condition (3), it is possible to favorably correct the Petzval's sum in the objective lens system as a whole. If the lower limit of 0.05 of the condition (3) is not satisfied, a refractive power of medium will be weak, thereby making it difficult to correct the Petzval's sum favorably in the objective lens system as a whole. If the upper limit of 1.0 of the condition (3) is exceeded, in contrast, a refractive power of medium will be too strong and the Petzval's sum will be overcorrected, thereby undesirably tilting an image surface in a direction away from the object side.

As understood from the foregoing description, the condition (3) is required for favorably correcting lateral chromatic aberration and Petzval's sum at the same time in the objective lens system according to the present invention (which has the second composition).

Further, an objective lens system for endoscopes is generally used in combination with a solid-state image pickup device such as CCD or an end surface of the so-called image guide composed of an optical fiber bundle which is disposed on an image surface. When an objective lens system is to be combined not with a silver salt photographic film but with a solid-state image pickup device or an image guide, it is desirable for enhancing a light condensing efficiency to configure the objective lens system so as to be telecentric on the image side so that incident rays are as perpendicular as possible to an image surface. For configuring the objective lens system according to the present invention so as to meet this requirement, the second lens unit having the positive refractive power must have an image side surface which has a positive refractive power stronger than that of an object side surface thereof. When the image side surface of the second lens unit on which offaxial rays are relatively high has a strengthened refractive power in the objective lens system according to the present invention having a wide field angle, however, this surface will produce coma in a large amount and it will be difficult to correct this coma favorably with a homogenous lens element.

Accordingly, it was conceived to correct coma favoraly in the objective lens system according to the present invention

with a radial type gradient index lens element used in the second lens unit. For correcting this aberration, it is desirable that the radial type gradient index lens element has such a refractive index distribution as to progressively lower refractive indices from the optical axis toward a marginal portion. An amount of coma to be produced by the image side surface of the second lens unit can be reduced by configuring the radial type gradient index lens element to be used in the second lens unit so as to have such a refractive index distribution. Therefore, the condition (3) serves for favorable correction of coma in addition to favorable correction of lateral chromatic aberration. When the condition (3) is satisfied, the radial type gradient index lens element has a refractive index distribution wherein refractive indices are progressively lowered from the optical axis toward the marginal portion, thereby being capable of favorably correcting coma. If the lower limit of 0.05 of the condition (3) is not satisfied, it will be difficult to favorably correct coma with the radial type gradient index lens element. If the upper limit of 1.0 of the condition (3) is exceeded, in contrast, coma will undesirably be overcorrected.

Since the objective lens system according to the present invention has a wide field angle and the asymmetrical composition which is negative-positive in order from the object side, it tends to produce remarkable barrel form distortion which can hardly be corrected favorably with two homogenous lens elements. For correcting the barrel form distortion favorably in the objective lens system according to the present invention, it is desirable to use, in the second lens unit having the positive refractive power, a radial type gradient index lens element which has a refractive index distribution wherein refractive indices are progressively lowered from the optical axis toward the marginal portion. Distortion to be produced by the second lens unit can be reduced by using a radial type gradient index lens element having such a refractive index distribution. Accordingly, the condition (3) serves for favorable correction of distortion in addition to favorable correction of lateral chromatic aberration. When the contition (3) is satisfied, refractive indices are progressively lowered from the optical axis toward the marginal portion, thereby enabling to favorably correct distortion. If the lower limit of 0.05 of the condition (3) is not satisfied, it will be difficult to favorably correct distortion with a radial type gradient index lens element. If the upper limit of 1.0 of the condition (3) is not satisfied, in contrast, aberrations other than distortion will undesirably be overcorrected.

The objective lens system according to the present invention which has a third composition is characterized in: that it is composed, in order from the object side, of a first lens unit having a negative refractive power and a second lens unit having a positive refractive power; that it uses at least one radial type gradient index lens element having a refractive index distribution in a radial direction from an optical axis which is expressed by the formula (a); and that at least one of the surfaces of lens elements including the radial type gradient index lens element composing the lens system is configured as an aspherical surface which has such a shape as to weaken a refractive power of the lens element having the aspherical surface from the optical axis toward the marginal portion.

Since the objective lens system according to the present invention has a wide field angle and an asymmetrical composition which is negative-positive in order from the object side, it tends to produce remarkable distortion in addition to lateral chromatic aberration. Though distortion can be corrected to a certain degree by using a radial type gradient index lens element in the second lens unit as described above, it is desirable for correcting distortion more favorably to configure the objective optical system according to the present invention so as to comprise at least one surface of at least one lens element which is configured as an aspherical surface having such a shape as to weaken a refractive power of the lens element having the aspherical surface from the optical axis toward the marginal portion. In the objective lens system according to the present invention, barrel form distortion is produced by both the first lens unit having the negative refractive power and the second lens unit having the positive refractive power. When an aspherical surface is to be used in either of the lens units in the objective lens system, it is therefore desirable to configure the aspherical surface so as to have such a shape as to weaken a refractive power from the optical axis toward the marginal portion of the lens element using the aspherical surface. When the second lens unit uses a radial type gradient index lens element, for example, it is desirable to use an aspherical surface in the first lens unit having the negative refractive power and configure the aspherical surface so as to have such a shape as to weaken the negative refractive power from the optical axis toward the marginal portion. Though distortion produced by the second lens unit can be corrected to a certain degree by using a radial type gradient index lens element in the second lens unit as described above, distortion can be corrected more favorably by using an aspherical surface in the first lens unit.

When a radial type gradient index lens element is used in the first lens unit, it is desirable to use, in the second lens unit having a positive refractive power, an aspherical surface which has such a shape as to weaken the positive refractive power toward the optical axis to a marginal portion.

If an aspherical surface has such a shape as to strengthen the refractive power of a lens unit which comprises this aspherical surface, it will undesirably make barrel form distortion more remarkable in the objective lens system as a whole.

It is needless to say that an effect similar to that described above can be obtained by configuring a surface of a radial type gradient index lens element as an aspherical surface.

For correcting lateral chromatic aberration in the objective lens system according to the present invention which has the third composition, it is desirable to configure the radial type gradient index lens element so as to satisfy the condition (1). If the condition (1) is not satisfied, lateral chromatic aberration will undesirably be more remarkable in the objective lens system according to the present invention.

It is needless to say that lateral chromatic aberration can be corrected more favorably by using two radial type gradient index lens elements when the objective lens system according to the present invention is to be composed of two negative and positive lens elements.

It is also needless to say that distortion can be corrected more favorably by using an aspherical surface on each of the lens elements when the objective lens system is to be composed of two negative and positive lens elements.

The objective lens system according to the present invention which has a fourth composition is characterized in that it is composed, in order from the object side, of a first lens unit having a negative refractive power and a second lens unit having a positive refractive power. The second lens unit comprises at least one radial type gradient index lens element which has a refractive index distribution in a radial direction expressed by the formula (a), or wherein refractive indices are progressively lowered from an optical axis toward a marginal portion. The radial type gradient index

lens element has a shape of a positive lens element. The radial type gradient index lens element satisfies the condition (1).

When a radial type gradient index lens element is to be used in the second lens unit, it is desirable for correcting lateral chromatic aberration to configure it so as to satisfy the condition (1) as described above, and it is desirable for correcting a Petzval's sum, coma or distortion that this lens element has a refractive index distribution wherein refractive indices are lowered from the optical axis toward the marginal portion. When not only correction of aberrations but also manufacturing facility are taken into consideration, it is desirable that the radial type gradient index lens element has a shape of a positive lens element.

Since the objective lens system according to the present invention has a wide field angle, it is necessary that the second lens unit has a strong positive refractive power. When a radial type gradient index lens element is to be used in the second lens unit, it is therefore desirable that the radial type gradient index lens element also has a strongly positive refractive power. However, it is undesirable that the radial type gradient index lens element has an extremely strong positive refractive power of medium for a reason described below. As apparent from the formula (e), it is sufficient for strengthening a refractive power of medium of a radial type gradient index lens element to enlarge an absolute value of the refractive index distribution coefficient of the second order N_{10} or thickness d_G of the radial type gradient index lens element. However, an absolute value of the refractive index distribution coefficient of the second order can be enlarged only within a range limited by preparation of materials and enlargement of thickness d_G makes it difficult to configure the objective lens system compactly, thereby making it unusable as an objective lens system for endoscopes, for example, which are desired to be compact. Accordingly, it is desirable not to impart an extremely strong positive refractive power to a medium but to impart refractive powers to both the medium and surfaces, or configure the radial type gradient index lens element so as to have a shape of a positive lens element.

The objective lens system according to the present invention which has a fifth composition is characterized in that it is composed, in order from the object side, of a first lens unit having a negative refractive power and a second lens unit having a positive refractive power; that it uses at least one lens element which is configured as a radial type gradient index lens element having a refractive index distribution in the radial direction from an optical axis expressed by the formula (a); and that a lens unit comprising the radial type gradient index lens element or at least one optical element disposed in the objective lens system has a function to shield components having specific wavelengths.

By using a radial type gradient index lens element, it is possible to obtain an objective lens system which favorably corrects chromatic aberration in particular and has high imaging performance. An objective lens system for endoscopes which comprises a solid-state image pickup device such as a CCD, for example, may use an infrared cut filter for cutting off rays in the infrared region since the image pickup device has high sensitivity at wavelengths in the infrared region. Further, such an optical system may use a low pass filter made, for example, of quartz for eliminating noise components produced due to moiré. Furthermore, such an objective lens system may use a band cut filter for cutting off components having specific wavelengths since endoscopes may be used not only for observing interiors of human bodies but also for cutting off diseased portions of patients with laser knives. It is therefore desirable that the objective lens system according to the present invention uses not only a radial type gradient index lens element but also filters of the kinds mentioned above so that it can exhibit high imaging performance when it is used in optical systems for endoscopes which use, for example, solid-state image pickup devices such as CCD's.

It is desirable that these filters are disposed at locations between a lens element disposed on the image side and an image surface at which offaxial rays, in particular, are nearly in parallel with the optical axis. By disposing the filters as described above, it is possible to prepare approximately equal optical path lengths for axial and offaxial rays, thereby allowing the filters to exhibit their effects uniformly over the entire image pickup surface.

Endoscopes which are to be inserted into human bodies must be compact and require compacter optical systems. When importance is laid on compactness rather than optical performance, it is effective to dispose filters between the first lens unit and the second lens unit. Further, for obtaining an objective lens system which is compact and can be manufactured at a low cost, it is effective to impart filter functions to at least one of the lens elements including a radial type gradient index lens element.

The objective lens system according to the present invention which has a sixth embodiment is characterized in that it is composed, in order from the object side, of a first lens unit having a negative refractive power and a second lens unit having a positive refractive power; that it uses at least one radial type gradient index lens element which has a refractive index distribution in a radial direction expressed by the formula (a); and that it uses a reflecting surface for at least a single reflection disposed on the image side of the second lens unit.

Resolution of an optical system for endoscopes which uses a solid-state image pickup device such as a CCD, for example, can be enhanced by reducing the size of picture elements and arranging these picture elements in a larger number at a higher density on the image pickup device. However, the size of a picture element can be reduced only within a certain manufacturing limit and it is therefore conceivable to enhance resolution by enlarging an image pickup surface. However, it is desirable that endoscopes which may be inserted into human bodies have smaller diameters, or it is undesirable to enlarge image pickup surfaces, thereby enlarging diameters of endoscopes.

For allowing solid-state image pickup devices having larger image pickup surfaces to be used without enlarging diameters of endoscopes, the objective lens system according to the present invention uses a reflecting surface for at least one reflection on the image side of the second lens unit which makes it possible to dispose a solid-state image pickup device, not in parallel with a radial direction of the endoscope, but in a position inclined with regard thereto. FIG. **3** shows a conceptional diagram of the objective lens system according to the present invention which has the sixth composition. In FIG. **3**, the reference symbol L_1 represents the first negative lens unit, the reference symbol L_2 designates the second positive lens unit, the reference symbol RA denotes an axial ray, the reference symbol RO represents an offaxial ray, the reference symbol R designates the reflecting surface and the reference numeral **10** denotes the image pickup device disposed on an image pickup plane. The reflecting surface R disposed on the image side of the second lens unit makes it possible to arrange the solid-state image pickup device which has a large image pickup surface nearly parallel to the optical axis. Though a system for a

single reflection is illustrated in FIG. **3**, it is possible, needless to say, to obtain a similar effect by using a larger number of reflecting surfaces for a plurality of reflections.

When a solid-state image pickup device having a large image pickup surface is used, an image height can be enhanced in a lens system for obtaining a lens system having a wide field angle. However, it is desired for an objective lens system to correct aberrations more favorably over a range from a center to a marginal portion of an image plane. For an objective lens system having a wide field angle in particular, it is desired to favorably correct lateral chromatic aberration.

An objective lens system which has high imaging performance for axial and offaxial rays can therefore be obtained by using a radial gradient index lens element which has high capability to correct chromatic aberration in particular. It is possible to obtain an objective lens system having higher performance by combining an objective lens system which uses a radial type gradient index lens element with a reflection system shown in FIG. **3** which permits enlarging an image pickup surface.

When a radial type gradient index lens element is used in the second lens unit in each of the compositions (first through sixth compositions) of the objective lens system according to the present invention, it is desirable for more favorable correction of lateral chromatic aberration, coma and distortion to satisfy the following condition (4):

$$-0.5<N_{10p}\cdot f^2<-0.01 \tag{4}$$

wherein the reference symbol N_{10p} represents a refractive index distribution coefficient of the second order when a radial type gradient index lens element is used in the second lens unit and the reference symbol f designates a focal length of the objective lens system as a whole.

When the condition (4) is satisfied, a refractive power of medium of the radial type gradient index lens element has a sufficiently large value, thereby making it possible to correct lateral chromatic aberration favorably. Further, refractive indices are progressively lowered from the optical axis toward a marginal portion and a difference in refractive index (An) is large between the optical axis and the marginal portion, thereby making it possible to favorably correct coma produced by an image side surface of the second lens unit and barrel form distortion which poses a problem in the objective lens system as a whole.

If the upper limit of −0.01 of the condition (4) is exceeded, the radial type gradient index lens element will have a weak refractive power of medium, thereby making it difficult to correct lateral chromatic aberration favorably in the objective lens system as a whole, and the difference in refractive indices will be small between the optical axis and the marginal portion, thereby making it difficult to correct coma and distortion. If the lower limit of −0.5 of the condition (4) is not satisfied, in contrast, the radial type gradient index lens element will have a large refractive index difference An, thereby undesirably making it difficult to prepare a material for the radial type gradient index lens element.

When a radial type gradient index lens element is used in the first lens unit in the objective lens system according to the present invention which has one of the compositions described above, it is desirable for correcting lateral chromatic aberration more favorably to satisfy the following condition (5):

$$0.01<N_{10n}\cdot f^2<0.6 \tag{5}$$

wherein the reference symbol N_{10n} represents the refractive index distribution coefficient of the second order of a gradient index lens element when the radial type gradient index lens element is used in the first lens unit and the reference symbol f designates a focal length of the objective lens system as a whole.

When the condition (5) is satisfied, a refractive power of medium of the radial type gradient index lens element has a sufficiently large value, thereby making it possible to correct lateral chromatic aberration favorably.

If the lower limit of 0.01 of the condition (5) is not satisfied, the radial type gradient index lens element will have a weak refractive power of medium, thereby making it difficult to correct lateral chromatic aberration favorably in the objective lens system as a whole. If the upper limit of 0.6 of the condition (5) is exceeded, the radial type gradient index lens element will have a large refractive index difference Δn, thereby making it difficult to prepare a material for the radial type gradient index lens element.

When the radial type gradient index lens element is used in the first lens unit or the second lens unit of the objective lens system according to the present invention, it is desirable for correcting lateral chromatic aberration more favorably in the lens system to satisfy the following condition (6):

$$1/V_{10}<0.01 \tag{6}$$

The objective lens system which satisfies the condition (6) can favorably correct lateral chromatic aberration. Since radial type gradient index lens elements have Abbe's numbers on the order of 30 to 80 as described above, it is desirable from the formula (d), for allowing a radial type gradient index lens element to exhibit a sufficient function for correcting chromatic aberration to satisfy the condition (6). If the condition (6) is not satisfied, it will undesirably be impossible to sufficiently correct lateral chromatic aberration.

When a radial type gradient index lens element is used in the first lens unit of the objective lens system according to the present invention which has any one of the first through sixth compositions, it is desirable for correcting lateral chromatic aberration more favorably to satisfy the following condition (7):

$$0.05<d_{Gn}/f_{Gn}<1.2 \tag{7}$$

wherein the reference symbol d_{Gn} represents thickness of the radial type gradient index lens element used in the first lens unit and the reference symbol f_{Gn} designates a focal length of the radial type gradient index lens element used in the first lens unit.

A radial type gradient index lens element can exhibit its effect to correct chromatic aberration when it has refractive power of medium ϕ_m having a value which is large to a certain degree as described above. When a radial type gradient index lens element has extremely small thickness, for example, the refractive power of medium ϕ_m is weak as judged from the formula (e), thereby making it difficult to favorably correct chromatic aberration. It is therefore desirable that the objective lens system according to the present invention satisfies the condition (7) when a radial type gradient index lens element is used in the first lens unit.

If the lower limit of 0.05 of the condition (7) is not satisfied, the refractive power of medium will be weak, thereby undesirably making it difficult to favorably correct lateral chromatic aberration. If the upper limit of 1.2 of the condition (7) is exceeded, in contrast, the radial type gradient index lens element will have a large thickness, thereby undesirably prolonging a total length of the objective lens system.

When a radial type gradient index lens element is used in the second lens unit of the objective lens system according to the present invention which has any one of the composition described above, it is desirable for correcting lateral chromatic aberration more favorably to satisfy the following condition (8):

$$0.3<d_{Gp}/f_{Gp}<4.0 \quad (8)$$

wherein the reference symbol d_{Gp} represents the thickness of the radial type gradient index lens element used in the second lens unit and the reference symbol f_{Gp} designates a focal length of the radial type gradient index lens element used in the second lens unit.

When a radial type gradient index lens element has extremely small thickness as described above, for example, the refractive power of medium fm is weak, thereby making it difficult to correct chromatic aberration favorably. When a radial type gradient index lens element is to be used in the second lens unit of the objective lens system according to the present invention, the lens system is therefore configured so as to satisfy the condition (8).

If the lower limit of 0.3 of the condition (8) is exceeded, a refractive power of medium will be weak, thereby undesirably making it difficult to favorably correct lateral chromatic aberration. If the upper limit of 4.0 of the condition (8) is exceeded, a radial type gradient index lens element will have large thickness, thereby undesirably enlarging the objective lens system.

When the first lens unit is to be composed of a single negative lens element in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable for favorably correcting aberrations to satisfy the following condition (9):

$$0.1<1H/r_2<1.7 \quad (9)$$

wherein the reference symbol 1H represents an image height and the reference symbol r_2 designates a radius of curvature on an image side surface of the first lens unit having the negative refractive power.

If the lower limit of 0.1 of the condition (9) is not satisfied, the image side surface of the first lens unit will have a weak refractive power and it will be necessary to strengthen a negative refractive power of an object side surface of the first lens unit on which offaxial rays are relatively high, whereby the object side surface will undesirably produce distortion, astigmatism, etc. in larger amounts. If the upper limit of 1.7 of the condition (9) is exceeded, in contrast, the image side surface of the first lens unit will have a strong negative refractive power, thereby undesirably overcorrecting spherical aberration in the objective lens system as a whole.

When the second lens unit is to be composed of a single positive lens element in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable for favorably correcting aberrations to satisfy the following condition (10):

$$-1.5<IH/r_3<0.8 \quad (10)$$

wherein the reference symbol 1H represents an image height and the reference symbol r_3 designates a radius of curvature on an object side surface of the second lens unit having the positive refractive power.

If the lower limit of −1.5 of the condition (10) is not satisfied, the object side surface of the second lens unit will have a strong negative refractive power, thereby undesirably overcorrecting spherical aberration in the objective lens system as a whole. If the upper limit of 0.8 of the condition (10) is exceeded, in contrast, the object side surface will undesirably produce spherical aberration, etc. in larger amounts.

When the second lens unit is to be composed of a single positive lens element in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable for favorably correcting aberrations to satisfy the following condition

$$-1.0<IH/r_4<-0.1 \quad (11)$$

wherein the reference symbol IH represents an image height and the reference symbol r_4 designates a radius of curvature on an image side surface of the second lens unit having the positive refractive power.

If the lower limit of −1.0 of the condition (11) is not satisfied, the image side surface of the second lens unit will have a strong positive refractive power, thereby undesirably aggravating astigmatism and distortion in the objective lens system as a whole. If the upper limit of −0.1 of the condition (11) is exceeded, in contrast, it will be necessary to strengthen a positive refractive power of the object side surface of the second lens unit, whereby the object side surface will undesirably produce astigmatism and distortion in large amounts.

When a radial type gradient index element is to be used in the first lens unit in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable for correcting lateral chromatic aberration more favorably to satisfy the following condition (12):

$$0.05<N_{10n}\cdot f_{Gn}{}^2<1.2 \quad (12)$$

wherein the reference symbol f_{Gn} represents a focal length of the radial type gradient index lens element to be used in the first lens unit.

When the condition (12) is satisfied, the refractive power of medium of the radial type gradient index lens element will have a value which is sufficiently large relative to its total refractive power and can favorably correct lateral chromatic aberration. If the lower limit of 0.05 of the condition (12) is not satisfied, the refractive power of medium will be weak, thereby undesirably making it difficult to correct lateral chromatic aberration favorably with the radial type gradient index lens element. If the upper limit of 1.2 of the condition (12) is exceeded, refractive index difference Δn will be large, thereby undesirably making it difficult to prepare a material for the radial type gradient index lens element.

When a radial type gradient index lens element is to be used in the second lens element in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable for correcting lateral chromatic aberration, a Petzval's sum, coma or distortion more favorably to satisfy the following condition (13):

$$-0.8<N_{10p}\cdot f_{Gp}{}^2<-0.05 \quad (13)$$

wherein the reference symbol f_{Gp} represents a focal length of the radial type gradient index lens element to be used in the second lens unit.

When the condition (13) is satisfied, the refractive power of medium of the radial type gradient index lens will have a value which is sufficiently large relative to its total refractive power and can favorably correct lateral chromatic

aberration. If the upper limit of −0.05 of the condition (13) is not satisfied, the refractive power of medium will be weak, thereby undesirably making it difficult to correct lateral chromatic aberration favorably with the radial type gradient index lens element. If the lower limit of −0.8 of the condition (13) is not satisfied, in contrast, refractive index difference Δn will be large, thereby undesirably making it difficult to prepare a material for the radial type gradient index lens element.

When a radial type gradient index lens element is to be used in the second lens unit in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable, for facilitating preparation of a material in addition to correction of lateral chromatic aberration, to satisfy the following condition (14):

$$0.1<\phi_{2m}/\phi<0.8 \quad (14)$$

When the condition (14) is satisfied, the radial type gradient index lens element will have a strong refractive power of medium and can correct lateral chromatic aberration favorably. If the lower limit of 0.1 of the condition (14) is not reached, the radial type gradient index lens element will have a weak refractive power of medium and can hardly correct lateral chromatic aberration favorably in the objective lens system as a whole, and a difference in refractive indices will be small between a portion of the radial type gradient index lens element located on the optical axis and a marginal portion thereof, thereby making it difficult to correct coma and distortion. If the upper limit of 0.8 of the condition (14) is exceeded, in contrast, the radial type gradient index lens element will have a large refractive index difference An or large thickness, thereby undesirably making it difficult to prepare a material for the radial type gradient index lens element in the former case or undesirably enhancing a manufacturing cost and prolonging a total length of the objective lens system in the latter case.

When a radial type index lens element is to be used in the first lens unit in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable, for facilitating manufacturing of the radial type gradient index lens element in addition to correction of lateral chromatic aberration, to satisfy the following condition (15):

$$-0.25<\phi_{1m}/\phi<-0.05 \quad (15)$$

When the condition (15) is satisfied, the radial type gradient index lens element will have a strong refractive power of medium and can favorably correct lateral chromatic aberration. If the upper limit of −0.05 of the condition (15) is exceeded, the radial type gradient index lens element will undesirably have a weak refractive power of medium and can hardly correct lateral chromatic aberration favorably. If the lower limit of −0.25 of the condition (15) is not reached, the radial type gradient index lens element will undesirably have a large refractive index difference Δn, whereby it can hardly be manufactured or it will be thicker and more expensive to manufacture.

When a radial type gradient index lens element is to be used in the first lens unit in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable, for facilitating manufacturing of the radial type gradient index lens element in addition to correction of lateral chromatic aberration, to satisfy the following condition (16):

$$0.02<N_{10n}\cdot f^2<0.4 \quad (16)$$

When the condition (16) is satisfied, a marginal portion of the radial type gradient index lens element used in the first lens unit may have a refractive index higher than that of a portion thereof on the optical axis, whereby the radial type gradient index lens element has a sufficiently strong refractive power of medium and can correct lateral chromatic aberration favorably.

If the lower limit of 0.02 of the condition (16) is not satisfied, the radial type gradient index lens element will have a weak refractive power of medium, thereby making it difficult to correct lateral chromatic aberration favorably in the objective lens system as a whole. If the upper limit of 0.4 of the condition (16) is exceeded, the radial type gradient index lens element will have a large refractive index difference Δn, thereby undesirable making it difficult to prepare a material therefor.

When a radial type gradient index lens element is to be used in the second lens unit of the objective lens system according to the present invention which has any one of the compositions described above, it is desirable, for facilitating manufacturing of the radial type gradient index lens element in addition to correction of lateral chromatic aberration, to satisfy the following condition (17):

$$-0.25<N_{10p}\cdot f^2<-0.04 \quad (17)$$

When the condition (17) is satisfied, the radial type gradient index lens element has a sufficiently strong refractive power of medium and can favorably correct lateral chromatic aberration.

If the upper limit of −0.04 of the condition (17) is exceeded, the radial type gradient index lens element will have a weak refractive power of medium, thereby making it difficult to correct lateral chromatic aberration favorably in the objective lens system as a whole. If the lower limit of −0.25 of the condition (17) is not satisfied, in contrast, the radial type gradient index lens element will have a large refractive index difference Δn, thereby making it difficult to prepare a material therefor.

For correcting lateral chromatic aberration more favorably in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable to configure a radial type gradient index lens element so as to satisfy the following condition (18):

$$1/V_{10}<0 \quad (18)$$

When the condition (18) is satisfied, the radial type gradient index lens element produces chromatic aberration in a direction opposite to that of chromatic aberration produced by a homogenous lens element having a refractive power which is the same as that of the radial type gradient index lens element. That is to say, when a radial type gradient index lens element which is used in the first lens unit or the second lens unit of the objective lens system according to the present invention satisfies the condition (18), lateral chromatic aberration is overcorrected independently by the radial type gradient index lens element, but this overcorrected chromatic aberration cancels lateral chromatic aberration produced by the other lens element, thereby correcting chromatic aberration favorably in the objective lens system as a whole.

When a radial type gradient index lens element is to be used in the first lens unit of the objective lens system according to the present invention which has any one of the compositions described above, it is desirable, for facilitating manufacturing of the radial type gradient index lens element in addition to correction of lateral chromatic aberration, to satisfy the following condition (19):

$$0.1<d_{Gn}/f_{Gn}<0.9 \quad (19)$$

If the lower limit of 0.1 of the condition (19) is exceeded, the radial type gradient index lens element will undesirably have a weak refractive power of medium, thereby undesirably making it difficult to correct lateral chromatic aberration favorably. If the upper limit of 0.9 of the condition (19) is exceeded, in contrast, the radial type gradient index lens element will be thick, thereby undesirably increasing the manufacturing cost of the objective lens system.

When a radial type gradient index lens element is to be used in the first lens unit of the objective lens system according to the present invention which has any one of the composition described above, it is desirable, for facilitating manufacturing of the radial type gradient index lens element in addition to correction of lateral chromatic aberration, to satisfy the following condition (20):

$$0.7<d_{GP}/f_{GP}<2.8 \tag{20}$$

When a radial type gradient index lens element has extremely small thickness, for example, it has a weak refractive power of medium Am and can hardly correct chromatic aberration favorably. When a radial type gradient index lens element is to be used in the second lens unit of the objective lens system according to the present invention, it is therefore desirable to configure the radial type gradient index lens element so as to satisfy the condition (20).

If the lower limit of 0.7 of the condition (20) is exceeded, the radial type gradient index lens element will undesirably have a weak refractive power of medium, thereby undesirably making it difficult to correct lateral chromatic aberration favorably. If the upper limit of 2.8 of the condition (20) is exceeded, in contrast, the radial type gradient index lens element will have large thickness, thereby undesirably increasing the manufacturing cost of the objective lens system.

When the first lens unit is to be composed of a single negative lens element in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable for more favorable correction of aberrations to configure it so as to satisfy the following condition (21):

$$0.25<IH/r_2<1.4 \tag{21}$$

If the lower limit of 0.25 of the condition (21) is not satisfied, an image side surface of the first lens unit will have a weak negative refractive power and it will be necessary to strengthen a negative refractive power of an object side surface of the first lens unit on which offaxial rays are relatively high, whereby the object side surface will undesirably produce distortion, astigmatism, etc. in large amounts. If the upper limit of 1.4 of the condition (21) is exceeded, in contrast, the image side surface of the first lens unit will have a strong negative refractive power, thereby undesirably overcorrecting spherical aberration in the objective lens system as a whole.

When the second lens unit is to be composed of a single positive lens element in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable for favorably correcting aberrations to satisfy the following condition (22):

$$-0.9<IH/r_3<0.6 \tag{22}$$

If the lower limit of −0.9 of the condition (22) is not reached, an object side surface of the second lens unit will have a strong negative refractive power, thereby undesirably overcorrecting spherical aberration in the objective lens system as a whole. If the upper limit of 0.6 of the condition (22) is exceeded, in contrast, the object side surface will undesirably produce astigmatism, distortion, etc. in large amounts.

When the second lens unit is to be composed of a single positive lens element in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable for favorable correction of aberrations to satisfy the following condition (23):

$$-0.8<IH/r_4<-0.2 \tag{23}$$

If the lower limit of −0.8 of the condition (23) is not reached, the image side surface of the second lens unit will have a strong negative refractive power, thereby undesirably aggravating astigmatism and distortion in the objective lens system as a whole. If the upper limit of −0.2 of the condition (23) is exceeded, in contrast, it will be necessary to strengthen the positive refractive power of the object side surface of the second lens unit, whereby the object side surface will undesirably produce spherical aberrations, etc. in large amounts.

When a radial type gradient index lens element is to be used as the first lens unit of the objective lens system according to the present invention which has any one of the compositions described above, it is desirable, for facilitating manufacturing of the radial type gradient index lens element in addition to correction of lateral chromatic aberration, to satisfy the following condition (24):

$$0.1<N_{10n}f_{Gn}{}^2<0.85 \tag{24}$$

When the condition (24) is satisfied, a refractive power of medium of the radial type gradient index lens element has a value sufficiently large relative to a total refractive power thereof, thereby making it possible to correct lateral chromatic aberration favorably. If the lower limit of 0.1 of the condition (24) is not satisfied, the radial type gradient index lens element will undesirably have a weak refractive power of medium and can hardly correct lateral chromatic aberration favorably. If the upper limit of 0.85 of the condition (24) is exceeded, in contrast, a refractive index difference Δn will undesirably be large, thereby making it difficult to prepare a material for the radial type gradient index lens element.

When a radial type gradient index lens element is to be used as the second lens element of the objective lens system according to the present invention which has any one of the compositions described above, it is desirable, for facilitating manufacturing of the radial type gradient index lens element in addition to correction of lateral chromatic aberration, to satisfy the following condition (25):

$$-0.3<N_{10p}f_{GP}{}^2<-0.1 \tag{25}$$

When the condition (25) is satisfied, a refractive power of medium of the radial type gradient index lens element has a value sufficiently large relative to a total refractive power thereof, whereby the radial type gradient index lens element can correct lateral chromatic aberration favorably. If the upper limit of −0.1 of the condition (25) is exceeded, the refractive power of medium will undesirably be weakened, thereby undesirably making it difficult to correct lateral chromatic aberration with the radial type gradient index lens element. If the lower limit of −0.3 of the condition (25) is not reached, in contrast, the refractive index difference Δn will undesirably be large, thereby making it difficult to prepare a material for the radial type gradient index lens element.

Though it is desirable to satisfy the condition (18) for correcting lateral chromatic aberration more favorably in the objective lens system according to the present invention

which has any one of the compositions described above, lateral chromatic aberration is overcorrected when $1/V_{10}$ has a negative value which is too large. Therefore, it is further desirable to satisfy the following condition (26):

$$-0.5<1/V_{10}<0 \quad (26)$$

When the condition (26) is satisfied, it is possible to correct lateral chromatic aberration favorably. If the upper limit of 0 of the condition (26) is exceeded, lateral chromatic aberration will undesirably be undercorrected. If the lower limit of −0.5 of the condition (26) is not reached, lateral chromatic aberration will undesirably be over-corrected.

From a viewpoint of reducing a manufacturing cost of the objective lens system according to the present invention, it is desirable that a radial type gradient index lens element has a planar surface on one side or planar surfaces on both sides.

The objective lens system according to the present invention which has a seventh composition uses a diffraction type optical element as an optical element which is disposed in the lens system.

The objective lens system according to the present invention which has the seventh composition is composed, for example, of a first lens unit having a negative refractive power, a stop and a second lens unit having a positive refractive power: the first lens unit being composed of a diffractive optical element and the second lens unit being composed of a refractive optical element (lens).

Further, an objective lens system which can accomplish the object of the present invention can be obtained by composing a lens system of a positive lens unit and a positive lens unit: the positive lens unit disposed on the object side being composed of a radial type gradient index lens element and the lens unit disposed on the image side being composed of a diffractive optical element.

The objective lens system which has each of the compositions described above is composed of a small number of optical elements, has a compact size and exhibits favorable optical performance. It is therefore suited for use as an objective lens system for endoscopes, non-flexible endoscopes and video cameras.

Accordingly, endoscopes, non-flexible endoscopes, video cameras, portable TV telephones, portable data input units, etc. which use the objective lens system according to the present invention having the compositions described above are included within the scope of the present invention.

Now, embodiments of the objective lens system according to the present invention will be described below:

Embodiment 1

focal length=1.07 mm, object distance=11.8 mm, image height=0.97 mm, NA=0.0115, 2ω=113.1°

$r_1 = -\infty$
$d_1 = 0.3000$ $n_1 = 1.48749$ $\nu_1 = 70.21$
$r_2 = 1.2764$
$d_2 = 1.2646$
$r_3 = -\infty$ (stop)
$d_3 = 0.5196$
$r_4 = -11.2580$
$d_4 = 1.8811$ n_2 (radial type gradient index lens)
$r_5 = -1.6678$

radial type gradient index lens

wherein the reference symbols r_1, r_2, . . . represent radii of curvature on surfaces of respective lens elements, the reference symbols d_1, d_2, . . . designate thicknesses of the respective lens elements and air-spaces reserved therebetween, the reference symbols n_1, n_2. . . denote refractive indices of the respective lens elements, and the reference symbols υ_1, υ_2, . . . represent Abbe's numbers of the respective lens elements.

The first embodiment of the objective lens system according to the present invention has a composition illustrated in FIG. **4**. Speaking concretely, it is composed of two lens units, i.e., in order from the object side, a first lens unit consisting of a negative lens element, a stop and a second lens unit consisting of a positive lens element. The second lens unit having the positive refractive power is configured as a radial type gradient index lens element. The first lens unit is composed of a homogenous lens element which has a planar surface on the object side and a concave surface on the image side, whereas the second lens unit is composed of a radial type gradient index lens element having a meniscus shape which has a concave surface on the object side.

Though it is ordinarily difficult to favorably correct lateral chromatic aberration in particular with two lens elements, the lens system preferred as the first embodiment is capable of favorably correcting lateral chromatic aberration by using the radial type gradient index lens element as the second lens unit.

Further, distortion and coma produced by the second lens unit are favorably corrected by the radial type gradient index lens element used as the second lens unit which has a refractive index distribution wherein refractive indices are progressively lowered from an optical axis toward a marginal portion.

In the first embodiment, lateral chromatic aberration in particular is corrected favorably by configuring the radial type gradient index lens element used as the second lens unit so as to satisfy the condition (18).

Furthermore, the object side planar surface of the first lens unit is effective for lowering a cost required for polishing the lens element.

Though the first embodiment is composed only of the two lens elements, it favorably corrects aberrations and has high optical performance.

The second embodiment of the present invention is an objective lens system which has a composition illustrated in FIG. **5**. Speaking concretely, it is composed of two lens elements, i.e., in order from the object side, a first lens unit composed of a negative lens element, a stop and a second lens unit composed of a positive lens element. The second lens unit having the positive refractive power is configured as a radial type gradient index lens element.

The second embodiment is an example in which the objective lens system is configured so as to have a total length that is shorter than that of the first embodiment. In the second embodiment also, lateral chromatic aberration in particular is favorably corrected by using the radial type gradient index lens element as the second lens unit.

The radial type gradient index lens element has a meniscus shape which has a concave surface on the object side. When a radial type gradient index lens element has such a meniscus shape, its refractive power of surface and refractive power of medium which are weaker and stronger respectively than a refractive power of surface and a refractive power of medium of a radial type gradient index lens element having a biconvex shape and a refractive power which is the same as that of the radial type gradient index lens element. When a radial type gradient index lens element has a strong refractive power of medium, its effect for correcting chromatic aberration can be effectively utilized as seen from the formula (d). For effectively utilizing the effect of a radial type gradient index lens element, the second embodiment adopts the radial type gradient index lens element which has the meniscus shape. The meniscus shape which has the concave surface on the object side is effective in particular for preventing offaxial aberrations from being aggravated.

In the second embodiment, the outer circumferential portion located outside an effective diameter of the first lens unit and the second lens unit is configured as a nearly planar surfaces on which both the lens units are cemented or kept in contact with each other. By cementing these two lens units into an integrated part, it is possible to simplify a structure of a lens barrel and facilitate assembly of the objective lens system.

The second embodiment also has high optical performance though it is composed only of the two lens elements.

The third embodiment of the present invention is an objective lens system which has a composition illustrated in FIG. **6**. That is to say, the objective lens system is composed of two lens units, in order from the object side, of a first lens unit composed of a negative lens element, a stop, and a second lens unit composed of a positive lens element. The second lens unit having the positive refractive power is configured as a radial type gradient index lens element. The first lens unit is composed of a homogenous lens element having a biconcave shape, whereas the second lens unit is composed of a radial type gradient index lens element having a meniscus shape which has a concave surface on the object side.

Though it is ordinarily difficult to favorably correct lateral chromatic aberration with two lens elements, the objective lens system according to the present invention is capable of favorably correcting lateral chromatic aberration by using the radial type gradient index lens element as the second lens unit.

The third embodiment is an example wherein amounts of aberrations to be produced by the first lens unit are reduced by selecting the biconcave surface for the first lens unit so that a power of this lens unit is shared between the surfaces.

Though $1/V_{10}$ of the radial type gradient index lens element has a positive value, lateral chromatic aberration is favorably corrected by satisfying the condition (1).

The objective lens system preferred as the third embodiment also has high optical performance though it is composed only of the two lens elements.

The fourth embodiment of the present invention is an objective lens system which has a composition shown in FIG. **7**. Concretely, it is composed of two lens units, in order from the object side, a first lens unit composed of a negative lens element, a stop and a second lens unit composed of a positive lens element. The second lens unit having the positive refractive power is configured as a radial type gradient index lens element. The first lens unit has a planar surface on the object side and a concave surface on the image side configured as an aspherical surface which weakens a negative refractive power as portions of the aspherical surface are farther from an optical axis toward a marginal portion. The second lens unit is composed of a radial type gradient index lens element which has a biconvex shape.

The aspherical surface used in this embodiment has a shape expressed by the following formula:

$$x = \frac{y^2/r}{1+\sqrt{1-p(y/r)^2}} + \Sigma A_{2i} y^{2i}$$

wherein a direction along the optical axis is taken as the x axis, a direction perpendicular to the optical axis is taken as the y axis, the reference symbol r represents a radius of curvature on the optical axis, the reference symbol p designates a conical constant and the reference symbol A_{2i} denotes an aspherical surface coefficient.

In the fourth embodiment, the aspherical surface used in the first lens unit is capable of favorably correcting mainly barrel form distortion produced in the lens system as a whole.

Though the first lens unit has the planar surface on the object side in the fourth embodiment, a similar effect can be obtained by using an aspherical surface as the object side surface of the first lens unit.

The fourth embodiment is an example wherein the second lens unit is configured as the biconvex radial type gradient index lens element which has a weakened refractive power of medium and a strengthened refractive power of surface. Accordingly, the radial type gradient index lens element can have a small refractive index difference An contributing to a refractive power of medium, thereby enhancing productibility or shortening a time required for imparting a refractive index distribution at a stage to prepare a material for the radial type gradient index lens element.

In spite of the fact that the fourth embodiment is composed only of the two lens elements, it has high optical performance.

It is possible to obtain a similar effect by using, in place of the aspherical surface disposed in the first lens unit, an axial type gradient index lens element having a refractive index continuously varying in the direction along the optical axis.

The fifth embodiment of the present invention is an objective lens system which has a composition illustrated in FIG. **8**. That is to say, it is composed of two lens elements, in order from the object side, a first lens unit composed of a negative lens element, a stop and a second lens unit composed of a positive lens element configured as a radial type gradient index lens element. The first lens unit has a planar surface on the object side and a concave surface on the image side which is configured as an aspherical surface which has such a shape as to weaken a negative refractive power as portions of the aspherical surface are farther from the optical axis toward a marginal portion, whereas the second lens unit is configured as a radial type gradient index lens element having a biconvex shape. The aspherical surface used in the first lens unit is capable of favorably correcting barrel form distortion which is produced in the objective lens system as a whole as in the fourth embodiment.

For configuring compactly a tip of an endoscope which is to comprise the objective lens system according to the present invention, an outer circumferential portion of the radial type gradient index lens element used as the second lens unit is cut off as shown in FIG. **8**. A tip of the objective lens system can be made thinner since a lens barrel or the like can be disposed, for example, as the slashed location **3** on the cut portion **2**.

The fifth embodiment is an example wherein the objective lens system has a total length that is shorter than that of the fourth embodiment. Though the fifth embodiment is composed only of the two lens elements, it has high optical performance.

The sixth embodiment of the present invention has a composition shown in FIG. **9**. Speaking concretely, it is composed of two lens units, in order from the object side, a first lens unit composed of a negative lens element, a stop and a second lens unit composed of a positive lens element. The first lens unit having the negative refractive power is configured as a radial type gradient index lens element. The first lens unit is a radial type gradient index lens element which has a planar surface on the object side and a concave surface on the image side, whereas the second lens unit is a biconvex homogenous lens element.

Unlike the first through fifth embodiments, the six- th embodiment uses the radial type gradient index lens element as the first lens unit for favorably correcting lateral chromatic aberration which poses a problem in particular in the objective lens system according to the present invention.

The planar surface adopted as the object side surface of the first lens unit makes it possible to reduce the cost for polishing the lens element.

Further, aberrations are reduced by selecting the biconvex shape for the second lens unit so that its power is shared between the two surfaces.

Furthermore, the image side surface of the second lens unit has a refractive power of surface which is stronger than that of the object side surface thereof so that offaxial rays are incident on an image surface nearly at telecentric angles.

The sixth embodiment also has high optical performance though it is composed only of the two lens elements.

The seventh embodiment of the present invention has a composition illustrated in FIG. **10**. That is to say, an objective lens system preferred as the seventh embodiment is composed of two lens units, in order from the object side, a first lens unit composed of a negative lens element, stop and a second lens unit composed of a positive lens element. The first lens unit having the positive refractive power is configured as a radial type gradient index lens element. The first lens unit is a radial type gradient index lens element which has a planar surface on the object side and a concave surface on the image side, whereas the second lens unit is a homogenous lens element which has a biconvex shape.

This embodiment also has high optical performance though it is composed only of the two lens elements.

The eighth embodiment of the present invention is an objective lens system which has a composition shown in FIG. **11**. This lens system is composed of two lens units, in order from the object side, a first lens unit composed of a negative lens element, a stop and a second lens unit composed of a positive lens element. The first lens unit having the positive refractive power is configured as a radial type gradient index lens element. The first lens unit is a radial type gradient index lens element having a meniscus shape which has a concave surface on the image side, whereas the second lens unit is a homogenous lens element which has a biconvex shape.

The composition of the eighth embodiment, in which the radial type gradient index lens element has the meniscus shape which has a concave surface on the image side is advantageous for correcting offaxial aberrations in particular.

The eighth embodiment also has high optical performance in spite of the fact that it is composed only of the two lens elements.

The ninth embodiment of the present invention is an objective lens system which has a composition illustrated in FIG. **12**. Speaking concretely, this lens system is composed of two lens elements, in order from the object side, a first lens unit composed of a negative lens units, a stop and a second lens unit composed of a positive lens element. The first lens unit having the negative refractive power is configured as a radial type gradient index lens element. The first lens unit is a radial type gradient index lens element having a meniscus shape which has a planar surface on the object side and a concave surface on the image side, whereas the second lens unit has aspherical surfaces on both sides.

Owing to a fact that an image side surface of the second lens unit on which offaxial rays are relatively high is configured as an aspherical surface having such a shape as to weaken a positive refractive power as portions of the aspherical surface are farther from an optical axis toward a marginal portion, the ninth embodiment is capable of favorably correcting barrel form distortion produced in the lens system as a whole.

Though the ninth embodiment uses the aspherical surfaces on both sides of the second lens unit, a similar effect can be obtained by using an aspherical surface only on one side.

The ninth embodiment also exhibits high optical performance though it consists only of the two lens elements.

Further, a similar effect can be obtained by adopting, in place of the aspherical surfaces used in the second lens unit, an axial type gradient index lens element which continuously varies a refractive index in a direction along the optical axis.

The tenth embodiment of the present invention is an objective lens system which has a composition shown in FIG. **13**. This lens system consists of two lens units, in order from the object side, a first lens unit composed of a negative lens element, a stop and a second lens unit composed of a positive lens element. The first lens unit having the negative refractive power and the second lens unit having the positive refractive power are configured as radial type gradient index lens elements. The first lens unit is a radial type gradient index lens element which has a planar surface on the object side and a concave surface on the image side, whereas the second lens unit is a radial type gradient index lens element which has a bi-convex shape.

The tenth embodiment is an example wherein lateral chromatic aberration produced in the lens system as a whole is favorably corrected by using radial type gradient index lens elements in both the lens units. In other words, lateral chromatic aberration is favorably corrected by con- figuring the radial type gradient index lens element used in the first lens unit to satisfy the condition (1) and the condition (2), and designing the radial type gradient index lens element used in the second embodiment to satisfy the condition (1) and the condition (3).

Though the tenth embodiment consists only of the two lens elements, it has high optical performance.

Preferred as an eleventh embodiment of the present invention is an objective lens system which has a composition illustrated in FIG. **14**. This lens system comprises two lens units, or is composed, in order from the object side, a first lens unit composed of a negative lens element, a stop, a second lens unit composed of a positive lens element and filters F disposed on the image side of the second positive lens unit. The first lens unit is configured as a homogenous lens element which has a planar surface on the object side and a concave surface on the image side, whereas the second lens unit is configured as a biconcave radial type gradient index lens element which has an object side surface having a weak positive refractive power.

When the objective lens system according to the present invention is used in a video scope or the like which uses a solid-state image pickup device such as a CCD, a low pass filter and an infrared cut filter composed, for example, of quartz or diffraction gratings may be disposed on the object side of an image surface as exemplified in FIG. **14**. The eleventh embodiment is an example comprising such filters. In the objective lens system according to the present invention, the above-mentioned filters can be disposed between the negative lens element and the positive lens element.

Preferred as the twelfth embodiment of the present invention is an objective lens system which has a composition shown in FIG. **15**. Like the eleventh embodiment, the

twelfth embodiment comprises two lens units, or is composed, in order from the object side, of a first lens unit composed of a negative lens element, a stop, a second lens unit composed of a positive lens element, and filters which are disposed between the two lens elements and on the image side of the positive lens element. The first lens unit is configured as a homogenous lens element which has a planar surface on the object side and a concave surface on the image side, whereas the second lens unit is configured as a radial type gradient index lens element which has a biconvex shape.

The thirteenth embodiment of the present invention has a composition illustrated in FIGS. **16**A and 16B: FIG. **16**A being a sectional view showing the thirteenth embodiment as a whole and FIG. **16**B being a diagram illustrating only a portion B on an enlarged scale. The thirteenth embodiment is composed, in order from the object side, of a first lens unit composed of a negative lens element, a stop and a second lens unit composed of a positive lens element. A radial type gradient index lens element is used as the second lens unit. The first lens unit has a planar surface on the object side and a concave surface on the image side, whereas the second lens unit has a planar surface on the object side and a convex surface on the image side.

The thirteen embodiment is an example wherein aberrations are favorably corrected by using a radial type gradient index lens element and a large number of planar surfaces are adopted for reducing a cost required for polishing lens elements, or the object side surface of the first lens unit and the object side surface of the second lens unit are configured to be planar.

Further, for preventing eccentricities of lens elements, in directions along an optical axis and perpendicular thereto in particular, which pose a problem at a stage of assembly, an outer circumferential portion **4** is obliquely chamfered as shown in FIG. **16**B so that a chamfered portion **4** is limited at a location **6** of a lens barrel **5**. Since a radial type gradient index lens element which has a refractive power of medium requires a manufacturing precis-on stricter than that for a homogenous lens element, the thirteenth embodiment provides an effective assembling convenience. A similar effect can, needless to say, be obtained by assembling the first lens unit having the negative refractive power in a similar manner.

Though the thirteenth embodiment uses a large number of planar surfaces, it has high optical performance.

The fourteenth embodiment of the present invention is an objective lens system which has a composition illustrated in FIG. **17**. That is to say, the fourteenth embodiment is composed, in order from the object side, of a first lens unit consisting of a negative lens element, a stop and a second lens unit consisting of a positive lens element which is configured as a radial type gradient index lens element. The first lens unit has a planar surface on the object side and a concave surface on the image side, whereas the second lens unit has a meniscus shape which has a concave surface on the object side.

When a radial type gradient index lens element is used as the second lens unit, it is desirable for correcting aberrations such as spherical aberration that the term of the fourth order N_{20} of a refractive index distribution has a positive value.

The fifteenth embodiment o- the present invention has a composition shown in FIG. **18**. Speaking concretely, the fifteenth embodiment is composed, in order from the object side, of a first lens unit consisting of a negative lens element, a second lens unit consisting of a positive lens element and a reflecting optical element. A radial type gradient index lens element is used as the second lens unit. In this embodiment, a light bundle emerging from the second lens unit is reflected by a reflecting surface **7** of a reflecting optical element P made, for example, of a mirror or a prism so that it is imaged onto a solid-state image pickup device **10** which is disposed nearly parallel to the optical axis. This reflecting surface makes it possible to dispose a solid-state image pickup device such as a CCD that is not parallel to a radial direction of the lens elements but oblique. Though a solid-state image pickup device **10** is disposed nearly parallel to the optical axis in the fifteenth embodiment, the image pickup device can be disposed more obliquely by selecting an adequate inclination angle for the reflecting surface **7** relative to the optical axis. Though the fifteenth embodiment is configured to reflect the light bundle only once, it is possible to reflect the light bundle twice, three times or more times by adopting a larger number of reflecting surfaces.

The sixteenth embodiment of the present invention is an objective lens system which has a composition shown in FIG. **19**. That is to say, the sixteenth embodiment is composed, in order from the object side, of a first lens unit composed of a negative lens element, a second lens unit composed of a positive lens element and a solid-state image pickup device. A radial type gradient index lens element is used as the second lens unit. In this embodiment, the radial type gradient index lens element has a nearly planar image side surface which is cemented or kept in close contact to or with a solid-state image pickup device **10** such as a CCD. Further, disposed in the second lens unit, is a member which extends from an outer circumference toward an optical axis for shielding a light bundle passing through the lens unit or functioning as an aperture stop of the objective lens system. Such a shielding member can be constituted, for example, by forming a cut **8** from the outer circumference toward the optical axis. For preventing the cut from producing flare, it is desirable to color the cut **8**. Further, it is possible to cut the second lens unit along a dashed line **9** shown in FIG. **25** into a front portion La and a rear portion Lb, attach a stop S to a cut surface of the front portion La and cementing the two portions to each other or bringing them into close contact with each other. A similar effect can be obtained by attaching the stop S to the rear portion Lb in place of the front portion La. As means for attaching the stop, it is conceivable to utilize deposition, printing or bonding a stop plate. This means can be utilized for manufacturing not only an aperture stop but also a flare stop.

In the sixteenth embodiment, the aperture stop is disposed at a location 1 mm apart from an object side sur- face of the second lens unit toward an image surface.

It is needless to say that an aperture stop, a flare stop or the like can be manufactured by the means described above in each of the embodiments.

The seventeenth embodiment of the present invention has a composition illustrated in FIG. **20**. That is to say, the seventeenth embodiment is composed, in order from the object side, of a first lens unit composed of a negative lens element, a second lens unit composed of a positive lens element, an optical filter F and a solid-state image pickup device **10**. A radial type gradient index lens element is used as the second lens unit. In the seventeenth embodiment, the second lens unit has planar surfaces on both sides for reducing the cost for polishing the lens unit. The seventeenth embodiment is an example wherein the second lens unit is cemented to the optical filter F for simplifying a structure of a lens barrel and assembly of the objective lens system. Further, the optical filter F is cemented or kept in close contact to or with the solid- state image pickup device **10**.

Furthermore, the first lens unit and the second lens unit are cemented or kept in close contact to or with each other on outer circumferences thereof outside an effective diameter thereof.

In the seventeenth embodiment, an aperture stop is disposed at a location 1 mm apart from an object side surface of the second lens unit toward an image surface.

The eighteenth embodiment of the present invention has a composition shown in FIG. **21**. That is to say, the eighteenth embodiment is composed, in order from the object side, of a first lens unit composed of a negative lens element, a regularly reflecting optical element and a second lens unit composed of a positive lens element. The second lens unit which is disposed on the image side is configured as a radial type gradient index lens element.

Certain endoscopes are specified for oblique observation in directions inclined relative to the optical axis. When the objective lens system according to the present invention is used in an endoscope for oblique observation, a reflecting optical element P composed of a mirror or a prism is disposed between the first lens unit and the second lens unit as shown in FIG. **21** so that a light bundle emerging from the first lens unit is reflected by a reflecting surface **7** of the reflecting optical element and led to the second lens unit.

Though a lens element ordinarily has a circular sectional shape, it may have a different sectional shape. FIGS. **22**A, **22**B, **22**C, **23**A, **23**B and **23**C exemplify lens elements which have external shapes cut or worked in accordance with shapes of image pickup devices for configuring objective lens systems compactly. FIGS. **22**A, **22**B and **22**C schematically show the second lens unit which is used in the first through eighteenth embodiments before being shaped. FIG. **22**A slows a sectional view taken in a direction from an object, FIG. **22**B is a sectional view taken in a direction in parallel with the optical axis, and FIG. **22**C illustrates an image circle **11** of the objective lens system and an image pickup surface **12** of an image pickup device. FIGS. **23**A, **23**B and **23**C schematically show the lens element illustrated in FIGS. **22**A, **22**B and **22**C in another condition after it is shaped. Since a solid-state image pickup device such as a CCD may have a rectangular shape and a lens element ordinarily has a circular shape as shown in FIG. **22**A, there is produced, as slashed in FIG. **22**C, a region which serves for image formation but is not used for image pickup. Since it is desired to configure an objective lens system for endoscopes compacter, it is conceivable to cut off the region of the lens element which is not used for image pickup. The eithteenth embodiment is an example wherein lens portions through which rays to be condensed outside an image pickup surface of an image pickup device are cut off as exemplified by FIGS. **23**A and **23**B so that an image formation range of the lens element is nearly coincident with the image pickup surface of the image pickup device. It is possible to obtain a compacter objective lens system or endoscopes by configuring a lens element so as to occupy a narrower space.

Though the second lens unit is worked for narrowing a lens space in the example described above, it is needless to say that a similar effect can be obtained by working other lens element or optical element, for example, the first lens unit or the reflecting optical element.

The nineteenth embodiment has a composition illustrated in FIG. **26**. Speaking concretely the nineteenth embodiment is a retrofocus type objective lens system which is composed, in order from the object side, of a first negative lens unit, a second positive lens unit and a third positive lens unit. A stop is disposed between the second lens unit and the third lens unit. The nineteenth embodiment is an objective lens system which has a wide field angle and is usable for endoscopes, video cameras, etc. Though the nineteenth embodiment has a wide field angle which makes it rather hard to correct lateral chromatic aberration, it corrects lateral chromatic aberration with a radial type gradient index lens element. In the nineteenth embodiment, the first lens unit has a plano- concave shape and a function to widen a field angle, the second lens unit has a plano-convex shape and a function to correct mainly lateral chromatic aberration produced by the first lens unit, and the third lens unit has a biconvex shape and a main imaging function, and is configured as a radial type gradient index lens element.

Though it is rather hard in the nineteenth embodiment to correct coma which is produced by the third lens unit disposed on the image side of a stop, coma is corrected by configuring the third lens unit as a radial type gradient index lens element which has such a characteristic as to progressively lower a refractive index in a radial direction from an optical axis. In other words, coma is corrected by imparting a positive refractive power to a medium of the radial type gradient index lens element. The composition described above is capable of correcting not only coma but also distortion.

For correcting coma with a medium of a radial type gradient index lens element, it is desirable that terms of high orders of a refractive index distribution satisfy the following condition (27):

$$-0.05 < \sum_{i=2}^{n} N_{iod} e^{2i} < 0.2 \tag{27}$$

wherein the reference symbol e represents an effective diameter of the lens element.

If the lower limit of −0.05 of the condition (27) is not reached, coma will be undercorrected. If the upper limit of 0.2 of the condition (27) is exceeded, in contrast, coma will be overcorrected.

It is desirable for more favorable correction of coma to satisfy the following condition (28):

$$0 < \sum_{i=2}^{n} N_{iod} e^{2i} < 0.1 \tag{28}$$

If the lower limit of 0 of the condition (28) is not reached, coma will be undercorrected. If the upper limit of 0.1 of the condition (28) is exceeded, in contrast, coma will be overcorrected. Either of these cases is undesirable for more favorable correction of coma.

Further, a planar surface used as an object side surface of the lens element disposed on the image side in the nineteenth embodiment has an effect for preventing adhesion of foreign matter such as dust.

In this embodiment, at least one lens element can have a function to cut off components having specific wavelengths, or a radial type gradient index lens element can have such a function.

When an image pickup device such as a CCD which has high sensitivity in the infrared wavelength region is to be disposed on an image pickup surface, for example, it is desirable to provide a function to cut off components having wavelengths in the infrared region. Accordingly, it is desirable that at least one lens element has a function to cut off components having specific wavelengths such as those in the infrared region.

The function to cut off components having specific wavelengths can be obtained by forming, on a flat portion of a

lens element or a flat plate, an interference film which cuts off the components having specific wavelengths.

A stop can be manufactured from a thin plate.

Further, amounts of aberrations produced can be reduced by configuring a radial type gradient index lens element so as to have a biconvex shape, thereby sharing a refractive power between the two surfaces.

Use of a radial type gradient index lens element makes it possible to obtain an optical system which is compact and composed of a small number of lens elements, and has a wide field angle and favorably corrected aberrations such as chromatic aberration and coma. Accordingly, it is effective to use an optical system such as an optical system for image input units for portable TV telephones and portable data input units such as those shown in FIGS. **35** and **36**.

The twentieth embodiment is an optical system which has a composition illustrated in FIG. **27**. It is a retro-focus type optical system which is composed, in order from the object side, of a first lens unit having a negative refractive power, a second lens unit having a positive refractive power and a third lens unit having a positive refractive power. A stop is disposed between the second lens unit and the third lens unit.

The twentieth embodiment is an optical system which has a wide field angle and is usable as an objective lens system for endoscopes or a lens system for video cameras, etc. Though the twentieth embodiment also has a wide field angle and hardly allows correction of Lateral chromatic aberration in particular, aberrations Ere favorably corrected in this embodiment by using a radial type gradient index lens element.

In the twentieth embodiment, the first lens unit is a plano-concave lens element having a function to widen a field angle, the second lens unit is a radial type gradient index lens element having plarar surfaces on both sides and a function to correct lateral chromatic aberration produced by the first lens unit, end the third lens unit has a biconvex shape and a main imaging function. The twentieth embodiment favorably corrects lateral chromatic aberration in particular by using, as the second lens unit disposed on the object side of the stop, a radial type gradient index lens element made of a medium which has a positive refractive power and a relatively strong dispersing power. The medium having the positive refractive power favorably corrects a Petzval's sum.

For correcting lateral chromatic aberration by disposing a radial type gradient index lens element on a stop, it is desirable to satisfy the following condition (29)

$$0.01<1/V_{10}<0.5 \tag{29}$$

If the lower limit of 0.01 of the condition (29) is not reached, lateral chromatic aberration will be undercorrected. If the upper limit of 0.5 of the condition (29) is not satisfied, in contrast, lateral chromatic aberration will be overcorrected.

For correcting lateral chromatic aberration more favorably by disposing a radial type gradient index lens element on the object side of the stop, it is desirable to satisfy the following condition (30):

$$0.015<1/V_{10}<0.1 \tag{30}$$

If the lower limit of 0.015 of the condition (30) is not reached, lateral chromatic aberration will be undercorrected. If the upper limit of 0.1 of the condition (30) is exceeded, lateral chromatic aberration will be overcorrected. Either of these cases is undesirable for correcting lateral chromatic aberration extremely favorably.

When preparation of a material for a radial type gradient index lens element is taken into consideration, it is desirable that $1/V_{10}$ has a value not exceeding 0.05. From viewpoints of manufacturing convenience and cost, it is desirable to configure a radial type gradient index lens element so as to have planar surfaces on both sides. When durability of a radial type gradient index lens element is taken into consideration, it is desirable to make it entirely of a glass material.

The twenty-first embodiment has a composition illustrated in FIG. **28**, or is a retrofocus type optical system which is composed, in order from the object side, of a first lens unit having a negative refractive power and a second lens unit having a positive refractive power. A stop is disposed between the first lens unit and the second lens unit. The twenty-first embodiment which is an optical system having a wide field angle is usable as an objective lens system for endoscopes or video cameras and so on. Though this optical system also has a wide field angle and hardly allows correction of lateral chromatic aberration in particular, lateral chromatic aberration is favorably corrected by using a radial type gradient index lens element.

In the optical system preferred as the twenty-first embodiment, the first lens unit has a negative meniscus shape which has a concave surface on the image side, and the second lens unit has a biconvex shape and a main imaging function. A radial type gradient index lens element is used as the first lens unit.

Offaxial aberrations can be corrected favorably by configuring the radial type gradient index lens element used as the first lens unit so as to have the meniscus shape which has the concave surface on the side of the stop. Lateral chromatic aberration is favorably corrected in particular owing to a fact that the radial type gradient index lens element has a positive refractive power of medium and is configured so as to satisfy the condition (29).

Further, coma is corrected favorably by using an aspherical surface on the lens element disposed on the object side of the stop. This aspherical surface has such a shape as to weaken a positive refractive power as portions of the aspherical surface are farther from an optical axis toward a marginal portion. Owing to this aspherical surface, the twenty-first embodiment is configured as an optical system which is compact and composed of a small number of lens elements, has a wide field angle and favorably corrects aberrations such as coma. It is therefore effective to apply the twenty-first embodiment as an optical system for image intake devices for portable TV telephones and portable date input units.

The twenty-second embodiment has a composition shown in FIG. **29**, or is an optical system composed of a single radial type gradient index lens element. The radial type gradient index lens element has a meniscus shape which has a concave surface on the object side and a positive power of medium. A stop is disposed at a location 0.9471 mm apart from an object side surface of the lens element toward the image side.

The twenty-second embodiment has a wide field angle, and is usable as an objective lens system for endoscopes or a lens system for video cameras and so on. Though the twenty-second embodiment which has the wide field angle hardly allows correction of chromatic aberration, it is corrected with the radial type gradient index lens element. A flat glass plate is disposed on the object side as a cover glass plate. A stop is disposed in the radial type gradient index lens element for obtaining highly symmetrical refractive power of medium, thereby favorably correcting offaxial aberra-

tions. The radial type gradient index lens element satisfies the condition (29) for correcting lateral chromatic aberration produced by an object side concave or convex surface with a medium located on the object side of the stop.

For reducing chromatic aberration to be produced by surfaces of the radial type gradient index lens element, it is desirable that V_{00} has a value of at least 30, or more desirably, at least 40. For reducing aberrations to be produced by the surfaces of the radial type gradient index lens element, it is desirable that N_{00} has a value of at least 1.55, or more desirably, at least 1.6.

The twenty-third embodiment has a composition shown in FIG. **30**, or is composed of two lens units, in order from the object side, a first positive lens unit and a second positive lens unit. The twenty-third embodiment is an example wherein aberrations are corrected favorably by composing an optical system of a radial type gradient index lens element and a diffraction type optical element(DOE). Speaking more concretely, the twenty-third embodiment is composed, in order from the object side, of a first lens unit composed of a radial type gradient index lens element and a second lens unit composed of a diffraction type optical element.

A diffraction type optical element is equivalent to a lens element which has a very high imaginary refractive index as described in literature SPIE, Vol. 126, P46 (1997). For this reason, the diffractive optical element is assumed to be a lens element which is optically equivalent to the optical element including aberrations to be produced thereby, and radii of curvature, thickness, a refractive index, an Abbe's number and aspherical surface coefficients of the lens element are described in the numerical data of the twenty-third embodiment. In the twenty-third embodiment, a stop is disposed on the object side of the optical system (the first lens unit).

In the twenty-third embodiment, the first lens unit composed of the radial type gradient index lens element has a main imaging function and the second lens unit composed of the diffraction type optical element favorably corrects lateral chromatic aberration. The twenty-third embodiment is an example of an optical system which is composed of a small number of optical elements and has a wide field angle, and favorably corrects lateral chromatic aberration with a diffractive optical element disposed on the image side of a stop. The diffraction type optical element has a positive refractive power, is disposed on the image side of the radial type gradient index lens element and has a function to favorably correct lateral chromatic aberration produced by a convex surface of the radial type gradient index lens element. Further, the radial type gradient index lens element has another function to favorably correct a Petzval's sum.

The twenty-third embodiment is usable, as described above, as an objective lens system for endoscopes or an optical system for video cameras and so on. Since the twenty-third embodiment is an optical system which is compact and is composed of a small number of lens elements, and favorably corrects aberrations such as chromatic aberration owing to the fact that it uses the diffraction type optical element, it is effective to apply it as an optical system for image intake devices for portable TV telephones and portable data input units.

The twenty-fourth embodiment has a composition illustrated in FIG. **31**, or is composed, in order from the object side, of a first lens unit having a negative refractive power and a second lens unit having a positive refractive power. A stop is disposed between the first lens unit and the second lens unit. In the twenty-fourth embodiment, the first lens unit having the negative refractive power serves mainly for widening a field angle and the second lens unit having the positive refractive power functions mainly for imaging.

The twenty-fourth embodiment favorably corrects aberrations by using the diffraction type optical element in place of the radial type gradient index lens element adopted for the twenty-first embodiment.

The twenty-fourth embodiment hardly allows correction of offaxial aberrations since it has an asymmetrical refractive power distribution wherein a negative refractive power is disposed on the object side of the stop and a positive refractive power is disposed on the image side of the stop. For this reason, lateral chromatic aberration is corrected favorably by disposing the diffraction type optical element on the object side of the stop and imparting a negative refractive power to this optical element. Coma and distortion in particular can be corrected favorably by using an aspherical surface on a positive lens unit disposed on the image side of the stop and configuring this aspherical surface so as to have such a shape as to weaken a positive refractive power in a radial direction from an optical axis. The negative lens unit has a meniscus shape which has a concave surface on the side of the stop for reducing amounts of offaxial aberrations in particular. Further, the positive lens unit has a biconvex shape so that amounts of aberrations are reduced by sharing a refractive power between two surfaces. Furthermore, the diffraction type optical element is disposed on a surface which is concave toward the stop so that differences between angles of incidence of paraxial rays and offaxial rays are reduced, thereby enhancing a diffraction efficiency.

FIG. **32** is a perspective view illustrating an endoscope according to the present invention which uses an objective lens system such as the embodiment described above. The reference numeral **21** represents the objective lens system.

FIG. **33** is a side view of a non-flexible endoscope according to the present invention which uses an objective lens system such as the embodiment described above. The reference numeral **21** represents the objective lens system.

FIG. **34** shows a video camera according to the present invention which uses an objective lens system such as the embodiment described above. The reference numeral **21** represents the objective lens system.

FIG. **35** shows a perspective view illustrating a portable TV telephone according to the present invention which uses an objective lens system such as the embodiment described above. The reference numeral **21** represents the objective lens system, the reference numeral **22** designates an antenna for transmission and reception, the reference numeral **23** denotes a display, and the reference numeral **24** represents switches.

Further, FIG. **36** shows a perspective view illustrating a portable data input unit according to the present invention which uses an objective lens system such as the embodiment described above. The reference numeral **21** represents the objective lens system, the reference numeral **22** designates an antenna for transmission and reception, the reference numeral **23** denotes a display, and the reference numeral **24** represents switches.

As understood from the foregoing description, the objective lens system for endoscopes according to the present invention is composed of lens elements in a number on the order of 2, and is nevertheless an optical system which favorably corrects aberrations, lateral chromatic aberration in particular, and has high optical performance.

What is claimed is:

1. A portable TV telephone, comprising:

an objective lens system configured to form an image of an object;

an antenna configured to transmit and receive at least one of said image of the object, a dial number and a voice carried by radio waves; and

a display configured to display at least one of said image of the object and the dial number,

wherein said objective lens system comprises a first negative lens unit and a second positive lens unit in order from an object side,

wherein said objective lens system further comprises an aperture stop disposed between said first lens unit and said second lens unit, and

wherein said first lens unit and said second lens unit each have a lens barrel configured to position the respective lens units such that circumferences of the lens units contact interior walls of the portable TV telephone.

2. The portable TV telephone according to claim **1**, further comprising a switch configured to operate at least the dial number.

3. The portable TV telephone according to claim **2**, wherein said first lens unit consists only of a negative lens element and said second lens unit consists only of a positive lens element.

4. The portable TV telephone according to claim **2**, wherein said second lens unit has an outer circumferential portion that has a cutout portion outside an effective diameter through which rays transmit and said lens barrel partially contacts said outer circumferential portion.

5. The portable TV telephone according to claim **2**, wherein said first lens unit consists only of a negative lens element and said second lens unit consists only of a positive lens element, and

wherein said second lens unit has an outer circumferential portion that has a cutout portion outside an effective diameter through which rays transmit and said lens barrel partially contacts said outer circumferential portion.

6. The portable TV telephone according to claim **3** or **5**, wherein said first lens unit is configured to have an aspherical surface.

7. The portable TV telephone according to claim **6**, wherein said aspherical surface is configured to weaken refractive power for rays as portions of the aspherical surface are distanced from an optical axis toward a marginal portion, said optical axis being positioned at a center of the lens unit.

8. A portable TV telephone, comprising:

an objective lens system configured to form an image of an object;

an antenna configured to transmit and receive at least one of said image of the object, a dial number and a voice carried by radio waves; and

a display configured to display at least one of said image of the object and the dial number,

wherein said objective lens system comprises a first negative lens unit and a second positive lens unit in order from an object side,

wherein said objective lens system further comprises an aperture stop disposed between said first lens unit and said second lens unit, and

wherein said first lens unit and said second lens unit are cemented at outer circumferential portions outside an effective diameter through which rays transmit.

9. The portable TV telephone according to claim **8**, further comprising a switch configured to operate at least the dial number.

10. The portable TV telephone according to claim **3**, **5** or **9**, wherein said first lens unit has a planar surface on the object side.

11. The portable TV telephone according to claim **3**, **5** or **9**, wherein said aperture stop and said second lens unit are cemented at outer circumferential portions outside the effective diameter.

12. The portable TV telephone according to any one of claims **2** through **5** and **9**, wherein said objective lens system is disposed on a surface located on the same side as a surface on which said image display is disposed.

13. The portable TV telephone according to any one of claims **2** through **5** and **9**, wherein said objective lens system is disposed on a surface located on the same side as a surface on which said switch is disposed.

14. A portable TV telephone comprising:

an optical system comprising

a first lens unit; and

a second lens unit,

one of the said first and second lens units comprising a lens having at least one aspherical surface, and

wherein said first lens unit and said second lens unit are cemented to each other outside an effective diameter thereof.

15. A portable data input unit comprising:

an optical system comprising

a first lens unit; and

a second lens unit,

one of the said first and second lens units comprising a lens having at least one aspherical surface, and

wherein said first lens unit and said second lens unit are cemented to each other outside an effective diameter thereof.

(57) **ABSTRACT**

In an image-forming lens, an inclined slope or section is provided at a marginal annular region on a surface of an optical member and a light shield is provided on this inclined slope or section. The optical member is mounted longitudinally so that the inclined slope or section is located near where off-field fight (i.e, fight from outside the designed field of view of the lens) reflects off an inner surface of a holding member or at the periphery of an optical member. Thus, the inclined slope or section with light shield acts to shield the reflected off-field light from passing to the image. The invention finds particular advantage in very small lenses that include optical members less than 3 mm in diameter.

OBJECTIVE LENS

BACKGROUND OF THE INVENTION

An endoscope is inserted into narrow spaces such as human internal body parts or the interior of an engine. Therefore it is desirable that the outer diameter of an endoscope be as small as possible, and this requires that the diameter of the lens that is arranged at the tip of an endoscope be as small as possible. An example of a lens of an endoscope that has a comparatively small diameter and wherein the lens is made using only a few lens elements is described in Japanese Laid-Open Patent Applications H9-68647 and H7-84179.

FIG. **9** illustrates the same objective lens element structure as that of Example 1 of Japanese Laid-Open Patent Application H9-68647, but includes different labels and, in addition to showing the objective lens elements themselves, FIG. **9** also illustrates conjectured support structure and flare-reducing structure for these lens elements. The lens comprises, in order from the object side, a first lens element lens **L1**, an aperture stop **5** (ie., a brightness diaphragm), a second lens element **L2** of positive refractive power and a third lens element **L3** of positive refractive power. In one embodiment of Japanese Laid-Open Patent Application H9-68647, lens element **L1**, which in all other embodiments is piano-concave, is replaced by a plane-parallel cover plate. Although no support structure whatsoever for these lens elements is actually shown in Japanese Laid-Open Patent Application H9-68647, FIG. **9** illustrates the assumed support structure for these components based on standard practices in the art, as will now be discussed. Because the first lens element **L1** (or cover plate, as the case may be) and the second lens element **L2** have the same outer diameter, they have been illustrated in FIG. **9** as being fixed to a first support frame **SF1**. An aperture stop **5** lies between the first lens element **L1** and the second lens element **L2**. Thus, the first support frame **SF1**, is shown supporting these three elements. Further, it is likely that the outer diameter of the first support frame **SF1** would be sized to equal the outer diameter of the third lens element **L3**, which in Japanese Laid-Open Patent Application H9-68647 is shown as having an outer diameter that is slightly larger than the outer diameter of the other two lens elements. Having their outer diameters equal would enable the first support frame **SF1** and the second lens element **L2** to each be inserted into a second support frame **SF2**, as illustrated in FIG. **9**. Adjacent lens element **L3** in FIG. **9** is illustrated a conjectured flare diaphragm **7** and a diaphragm receiving member **8**, as would commonly be used in the prior art to form a flare stop.

FIG. **10** illustrates the lens element structure of Example 6 of Japanese Laid Open Patent Application H7-84179. The lens of this example includes, in order from the object side, a plano-concave lens **L1**, an aperture stop **5**, a positive meniscus lens element **L2**, and a positive lens element **L3**.

In image formation lenses generally, in order to remove the light which does not contribute to image formation, a flare stop is often provided. There is no known description in the above-mentioned two patents which relates to a flare stop. However, as shown in prior art FIG. **9** for optical diaphragms generally, a flare diaphragm **7** and a diaphragm receiving member **8** are often provided on the object side of lens element **L3**. In many cases, such a flare stop is provided at this position in order to prevent stray light that has been reflected off the inner surface of the frame from passing through to the observer. The flare stop is positioned before lens element **L3** because stray light rays (i.e., those from a larger angle of view than for which the lens was designed to image) in many cases are incident on the frame between positive lens elements **L2** and **L3**.

However, if the outer diameter of a lens element is made smaller to achieve size reduction, the associated diaphragm receiving member and flare stop member must also be made smaller. Because these members are each shaped as an annular ring which circumscribes an aperture having a diameter that is nearly the same diameter as the lens element itself, as the lens element becomes smaller, the width of the annular ring becomes so small that manufacture and assembly of the ring become difficult.

Although it is known to bevel the edge of a lens element so as to form a sloped surface near the circumference of the lens element and to use this surface to self-center a lens element in lieu of using a spacer ring (as taught, for example, in U.S. Pat. No. 5,589,989) there is no teaching in this reference or any other reference known to applicant which suggests beveling an edge of a lens element and applying a light shielding material (i.e., one which absorbs or attenuates light) to a sloped surface created by the beveling process in order to reduce flare. Nor is there any suggestion that such an approach to reducing flare will result in fewer components and result in an overall cost reduction for assembling a lens system having small diameter components.

BRIEF SUMMARY OF THE INVENTION

The present invention forms an inclined or sloped surface on an optical member (such as a lens element, plane-parallel plate of a filter or cover glass, etc.), near the outer diameter of the optical member and applies a light shielding substance to the sloped surface in order to achieve flare reduction. The sloped or inclined surface, which may be the lens element surface itself, is immediately adjacent a circumferential edge of the optical element, and the circumferential edge is supported by a holding member. Alternatively, the present invention omits forming a separate, planar, sloped surface for the light shield, and instead designs the optical member so a light shielding substance may be easily applied to a sloped surface of a convex lens element near its periphery in order to shield flare from reaching the image. Flare, as used herein, refers to unwanted light which enters an optical system outside the intended field of view and is reflected toward the image plane by one or more surfaces of the optical system. A first object of the invention is to avoid using an annular ring for flare reduction in the case where the diameter of the optical member is small A second object of the invention is to enable the overall manufacturing and assembly cost of an optical system to be reduced by achieving the first object of the invention, while still maintaining adequate flare reduction. Thus, the present invention relates particularly to very small optical members, such as lens elements, filters or cover plates as may be found in endoscopes, or in other applications (e.g., in small electronic cameras, small cameras for monitoring, etc.) where size reduction causes the prior art structures and methods for flare reduction (discussed above) to become unsatisfactory.

BRIEF DESCRIPTION OF THE DRAWINGS

The present invention will become more fully understood from the detailed description given below and the accompanying drawings, which are given by way of illustration only and thus are not limitative ofthe present invention, wherein:

FIG. **1**(*a*) is a side, sectional view of a first embodiment of the invention,

FIG. **1**(*b*) is an end view of the lens element **L2** shown in FIG. **1** (*a*),

FIG. **2**(*a*) is a side, sectional view of a second embodiment of the invention,

FIG. **2**(*b*) is a different sectional view of the second embodiment of the invention, in the case where a square detector is used that eats into the optical surface of lens **L2** from four sides.

FIG. **3** is a side, sectional view of a third embodiment of the invention,

FIG. **4** is a sectional view of a fourth embodiment of the invention,

FIG. **5** is a sectional view of a fifth embodiment of the invention, less the support structure for the optical elements,

FIG. **6** is a sectional view of a sixth embodiment of the invention,

FIG. **7** is a sectional view of a seventh embodiment of the invention,

FIG. **8**(*a*) is a sectional view of an eighth embodiment of the invention,

FIG. **8**(*b*) is an expanded view of the lens element **L2** shown in FIG. **8**(*a*),

FIG. **9** is a sectional view of a conventional lens, and

FIG. **10** is a sectional drawing of another conventional lens, less the support structure for the optical elements.

DETAILED DESCRIPTION

As used herein, the term "optical member" refers to either a single lens element, two lens elements that are cemented together, a plane-parallel plate such as a filter or cover glass, or any combinations of these elements. The present invention relates particularly to optical systems having small diameter optical members. However, the invention may also find utility in other optical systems as well. In optical systems having small diameter optical members, the invention enables such systems to be made and assembled less expensively than previously possible while retaining the same capability of preventing unwanted light from outside the design field of view of the lens from reaching the image plane. Such light is termed flare and, if not shielded, may reach the image surface as a result of undesired reflections of off-axis rays within the lens and cause artifacts in the image.

In the present invention, it is preferable if the following Conditions (1) and (2), below, are satisfied.

$$\Phi 1 < 3 \text{ mm} \qquad \text{Condition (1)}$$

$$0.6 < \Phi 2/\Phi 1 < 0.95 \qquad \text{Condition (2)}$$

where

$\Phi 1$ is the outer diameter of an optical member

$\Phi 2$ is the maximum clear aperture diameter of the optical member (excluding a peripheral region, to which is applied a light shielding substance).

If the upper limit value of 0.95 of Condition (2) is exceeded, there will be too little width to adequately shield the rays that cause flare at the image plane. In other words, the slope becomes smaller, and the effect of flare reduction decreases. Moreover, if the lower limit value (0.6) of Condition (2) is not satisfied, the outer diameter for the portion of the optical member other than the slope will become large. Thus, although flare reduction will be obtained, light throughput of the optical member will become small and the image brightness will decrease.

Moreover, it is better if either of the stricter conditions (3) or (4) is satisfied by at least one of the optical members in the lens of the invention.

$$\Phi 1 < 2 \text{ mm} \qquad \text{Condition (3)}$$

$$0.6 < \Phi 2/\Phi 1 < 0.85 \qquad \text{Condition (4)}$$

In other words, instead of merely satisfying Conditions (1) and (2), it is better if one of the stronger Conditions (3) and (4) is also satisfied by at least one of the optical members in the lens of the invention. Further, it is best if both of the stronger Conditions (3) and (4) are satisfied by at least one of the optical members in the lens of the invention.

A lens according to the invention includes, in order from the object side, an aperture stop, a positive lens element having a convex surface on the image side, and a positive lens element having a convex surface on the object side. Further, the positive lens element with the convex surface on the object side is held by a holding member, a region of the convex surface near the edge of this positive lens has a slope, the slope has a light attenuating or light absorbing material thereon which reduces flare by the slope being near the region (and thus in the path) where a light ray from outside the visual field reflects at the interior of the holding member and is incident on the convex surface side of a positive lens element.

The lens of this invention includes a lens element, plane-parallel plate (such as a filter or cover glass) or other optical member. A slope is provided on the circumference edge of at least one optical member. A fight shield is provided on the slope, and the following condition is satisfied.

$$0.5 < D/f < 2 \qquad \text{Condition (5)}$$

where

D is the air path equivalent length (i.e., the sum of the values d/n) from the on-axis position of the surface of the optical member having the slope formed thereon to an image surface, and

f is the focal length of the lens.

Condition (5) defines the distance from the on-axis position of the surface which includes the slope to the image surface. In other words Condition (5) defines an effective axial position for the slope which removes flare, which also corresponds to the axial position at which flare tends to be generated by light being reflected off a framework surface.

In the objective optical system of the above-mentioned type with two convex surfaces, the principal ray has a tendency to become farther removed from the optical axis as it progresses past the aperture stop. For this reason, since the image surface tends to be close to the aperture stop at the position where the upper limit of Condition (5) is exceeded, the light ray height is low. Removal of flare light, on the other hand, is best achieved where the ray height is high, i.e., where it is so high that it reflects from the frame. For this reason, axial positions near an aperture stop are not suitable as a position for providing a flare stop.

On the other hand, if the lower limit of Condition (5) is exceeded, the flare stop must be too near the image surface, making it impossible to remove flare that is generated before the slope. Moreover, there is a possibility that the image-formation beam for which the height of the light-rays becomes high may be scattered.

The lens of this invention relates particularly to optical members which are inserted and held inside a holding member. A slope is formed on an annular surface of an optical member in a section adjacent to the edge of the

optical surface that is held by the holding member. Usually, the optical member selected for having the flare-reducing slope is the one nearest the image side of the holding member. In the case where a lens has several optical members and holding members, and the optical members are held by different holding members, at least one of the optical members held by the holding member which is nearest the image side should have a flare-reducing slope (either a planar or convex slope) provided.

An important characteristic of the present invention is that a flare stop that is an integral part of the optical member is provided. A conventional flare stop is in many cases inserted and held between optical members. Many optical members, such as a lens element provided at the end of a support frame of a lens, do not have another optical member attached in the same support frame (on one side). Thus, using a conventional flare stop becomes difficult, since there are not the necessary optical components within which the flare stop may be inserted. For this reason, when flare removal is necessary at such a position, it is preferable to employ the slope structure of the present invention for flare reduction.

Furthermore, in forming a light shielding means using adhesives while fixing a lens element to a frame, a specially formed (i.e., planar) slope for supporting the light absorbing or light attenuating adhesive material to shield against flare is not required, provided the following Condition (6) is satisfied:

$$\Phi 1/(2\times|R|)>0.34 \qquad \text{Condition (6)}$$

where Φ1 and R are as defined above.

Condition (6) provides that the angle between a normal to the lens element surface at the periphery of the lens and the optical axis is greater than 20°, thereby ensuring that a groove **4**, as illustrated in FIG. **8**(*b*), is formed at the periphery of the lens element in which a light shielding adhesive may be applied to the sloped, convex surface of a positive lens at the lens periphery for flare reduction.

Several embodiments of the invention will now be described in detail, with reference to the drawings.

Embodiment 1

FIG. **1**(*a*) is a side, sectional view of a first embodiment of the invention. The lens of this embodiment includes two lens elements, and is formed of the following components, in order from the object side: a cover glass C**1**, a film (not visible in this side view), a first lens element L**1** of positive power, a second lens element L**2** of positive power, and a second cover glass C**2**. The cover glass C**1** has film (not visible in this view) deposited on a portion of its image-side surface, and the film thus serves as an aperture stop. A first lens element L**1** is cemented to the film and the remaining portion of the image-side surface of the cover glass C**1**, and all of these elements are inserted within and held by a first frame **1**. The first frame **1** is partially inserted into one end of a second frame **2**, and all of these components are fixed by bonding. A second lens element L**2** having an outer diameter the same as, or nearly the same as, that of the outer diameter of the first frame **1** is inserted within the other end of the second frame **2** and is fixed by being bonded. Second frame **2** maintains a cover glass C**2** of an image pick-up element against its image-side end. Moreover, the image side of the cover glass C**2** is at the position of the image plane I, which coincides with the pick-up face of a detector, such as a CCD array.

For the lens of this first embodiment, the circumference edge of the convex surface on the object side of the second positive lens element L**2** is made to have a planar slope A**1**, as illustrated. The slope A**1** extends to the side of the lens element and provides an annular cone-like surface. The slope A**1** itself provides some assistance in reducing flare by reason of its ability to reflect some of the flare fight reflected off the second frame **2** in a direction away from the image. However, in those embodiments of the present invention which use a separately-formed, planar slope to reduce flare, a light shielding material (not visible in this view) is applied to this slope to prevent the passage of light reflected from second frame **2** from progressing to the image plane at I.

FIG. **1**(*b*) is an end view of the lens element L**2** shown in FIG. **1**(*a*). The outer diameter of this lens element is Φ1 and the maximum clear aperture diameter is Φ2, as illustrated. In this embodiment Φ1 is 1 mm and Φ2 is 0.75 mm; thus, the ratio Φ2/Φ1 is 0.75. This embodiment prevents the sloping surface from eclipsing part of the image-forming beam, and thus enables a maximum image height to pass to the image plane unhindered.

Also, the air path equivalent length D from the on-axis position of the object side surface of the second positive lens element L**2** to the image plane at I is 0.6 mm. The focal distance of the lens is 0.626 mm. Therefore, the ratio of D/f is 0.96, which satisfies Condition (5).

The slope angle θ1 (illustrated in FIG. **1**(*a*)) of the second positive lens element L**2** is 45 degrees. Moreover, this amount is less than 70 degrees, which is advantageous.

In this embodiment, the second positive lens element L**2** is attached to the second frame **2** with a black adhesive. The black adhesive is coated on the periphery surface of the lens (ie., the part supported by the frame) as well as on the slope A**1**. Thus, the adhesive serves to block light from passing through the lens portion having slope A**1**. Alternatively, the bonding of the lens elements to the lens frame can use a more common adhesive that is transparent or translucent, and instead of using adhesive on the slope A**1**, this portion can be coated with black paint to thereby enable the slope A**1** to block off-field light that has been reflected by the frame **2** or the periphery surface of a lens element from passing through to the image plane at I.

The lens of this embodiment can be used for an endoscope, an electronic camera, a surveillance camera, etc.

Table 1 lists the surface # in order from the object side, the radius of curvature R (in mm) of each surface, the on-axis surface spacing d (in mm) of each surface, as well as the index of refraction N_d and the Abbe constant V_d (for the d-line) of each optical member of Embodiment 1. In the bottom portion of the table are listed some of the performance values of the lens of this embodiment.

Embodiment 2

FIG. **2**(*a*) illustrates a second embodiment of the invention. The lens of this embodiment includes a first cover glass C**1**, a first lens element L**1** of positive power, a second lens

element L2 of positive power, and a charge-coupled device (hereinafter CCD) cover glass C2. These optical members are inserted in a single frame **3** having one end bored to a larger diameter than the other end. In this embodiment, a square image pick-up surface of an image pick-up element (not shown) is used. As shown in FIG. **2**(*b*), four sloped surfaces A1 (which correspond to segments ofthe annular ring A1 illustrated in FIG. **1**(*b*)) are visible and a light shield is provided on each of these sloped surfaces.

The outer diameter Φ1 of the second lens element L2 of this embodiment is 1.2 mm, and the diameter Φ2 the part except for the slope (i.e., the maximum clear aperture) is 0.84 mm. Further, Φ2/Φ1 equals 0.7. Moreover, the air equivalent path length D from the on-axis position of the second lens element L2 to the image plane I is 0.466 mm. The focal distance of the lens is 0.66 mm Therefore, D/f is 0.71.

Table 2 lists the surface # in order from the object side, the radius of curvature R (in mm) of each surface, the on-axis surface spacing d (in mm) of each surface, as well as the index of refraction N_d and the Abbe constant V_d (for the d-line) of each optical member of Embodiment 2. In the bottom portion of the table are listed some of the performance values of the lens of this embodiment.

6	∞			
F_{NO} = 5.5 D/f = 0.71	Image height = 0.45		f = 0.66	D = 0.466

Embodiment 3

FIG. **3** illustrates a third embodiment of the lens of the present invention. In this embodiment the lens includes a cover glass C1, a first lens element L1 of positive power, a second lens element L2 of positive power, an infrared cut-off filter F, and a CCD cover glass C2. The cover glass C1 and the first lens L1 of positive power are held by the first frame **1**. The second positive lens element L2 and the infrared cut-off-filter F are joined and held by the second frame **2**, and C2 is the CCD cover glass.

In this third embodiment, the second positive lens element L2 and the infrared cut-off filter F are joined to form an integrated part. A slope A2 is provided on the object side of this optical member, and a light shading means, which may be formed of a light absorbing substance or film, is provided on the slope A2. Therefore, the second lens element L2 does not provide a side for attaching to a support frame **2**. However, if the integrated optical member provides the side, installation is not affected.

In this third embodiment, the outer diameter Φ1 of the optical member is 2.85 mm, and the maximum clear aperture diameter Φ2 is 2.28 mm. Therefore, the ratio of Φ2/Φ1 is 0.8. Moreover, the air path equivalent length from the on-axis convex surface with the slope to the image surface is 1.173 mm. The focal-distance ofthe lens is 1.239 mm. Therefore, the ratio D/f is 0.95.

Table 3 fists the surface # in order from the object side, the radius of curvature R (in mm) of each surface, the on-axis surface spacing d (in mm) of each surface, as well as the index of refraction N_d and the Abbe constant V_d (for the d-line) of each optical member of Embodiment 3. In the bottom portion of the table are listed some of the performance values of the lens of this embodiment.

F_{NO} = 6.9 D/f = 0.95	Image height = 1.23		f = 1.239	D = 1.173

Embodiment 4

FIG. **4** illustrates a fourth embodiment of the lens of the present invention. This embodiment of the invention is an improvement over the conventional optical system shown in FIG. **9**. The lens of FIG. **4** includes a cover glass C3, an aperture stop S, a first lens element L1 of positive power, and a second lens element L2 of positive power. The cover glass C3, the aperture stop S, and the first lens element L1 of positive power are held by the first frame **1**. The second lens element L2 of positive power as well as the first frame **1** are held by the second frame **2**.

In this embodiment, a slope is formed on the circumference part of the surface on the object side of the second lens element L2 of positive power, without employing a flare stop as in the prior art. Black paint or black ink is applied at this slope so as to form a light blocking region or shade.

The outer diameter Φ1 of the second lens element L2 of this embodiment is 0.5 mm, and the maximum clear aperture diameter Φ2 is 0.4 mm. Therefore, Φ2/Φ1=0.8. The air path equivalent length D from the object side of the positive lens element L2 to the image surface at I is 0.214 mm. The focal distance ofthe lens is 0.32 mm. Therefore, the ratio D/f is 0.67.

Table 4 lists the surface # in order from the object side, the radius of curvature R (in mm) of each surface, the on-axis surface spacing d (in mm) of each surface, as well as the index of refraction N_d and the Abbe constant V_d (for the d-line) of each optical member of Embodiment 4. In the bottom portion of the table are listed some of the performance values of the lens of this embodiment.

Embodiment 5

FIG. **5** illustrates a fifth embodiment of the lens of the present invention, which applies the invention to the prior art example shown in FIG. **10**. That is, the lens is formed of, in order from the object side: a negative lens element L1, a

diaphragm S, a first lens element L2 of positive power and a second lens element L3 of positive power. A slope is provided on the object-side surface of the second lens element L3, and a light shield is again provided in this slope.

For this embodiment, the outer diameter Φ1 of the second positive lens element L3 is 1 mm The maximum clear aperture diameter Φ2 of this lens element is 0.85 mm. Therefore, Φ2/Φ1=0.85. The air path equivalent length D from the optical member with the flare stop to the image surface I is 0.798 mm. Further, the focal distance f of the lens is 0.52 mm Therefore, D/f=1.53.

Table 5 lists the surface # in order from the object side, the radius of curvature R (in mm) of each surface, the on-axis surface spacing d (in mm) of each surface, as well as the index of refraction N_d and the Abbe constant V_d (for the d-line) of each optical member of Embodiment 5. In the bottom portion of the table are listed some of the performance values of the lens of this embodiment.

Embodiment 6

FIG. 6 shows the lens element structure of the sixth embodiment of the present invention. In this embodiment, the lens is formed of a first lens element L1 that is a plano-concave lens, a plane-parallel plate P1, a second lens element L2 that is a biconvex lens, two plane-parallel plates P2 and P3, a third lens element L3 that is a piano-convex lens, a plane-parallel plate P4, and CCD cover glass C. The image-side surface of plane-parallel plate P4 is attached to the CCD cover glass C and bonded within the frame 2 to form the CCD sub-assembly. A frame I supports lens element L1 and plane parallel plate P1, which are inserted into the object-side end of the frame 1, which has a larger bore at the object side end The frame 1 also supports the second lens element L2, the plane parallel plates P2, P3 as well as the third lens element L3 at the image side of the frame 1, within the smaller bore. The optical members illustrated in FIG. 6 that are held by the frame 1 are bonded thereto after being inserted in the appropriate end of frame 1 so as to form another sub-assembly. These two sub-assemblies can be attached to one another as illustrated and bonded to form the lens.

The light-rays near the CCD sub-assembly are located far from the optical axis. Therefore, flare is easily generated in this vicinity, and accordingly it is necessary to remove flare near the CCD subassembly. Thus, the present invention can be applied in this vicinity to reduce flare. Moreover, if the plane-parallel plate P4 is provided with a slope (as illustrated) near its circumferential edge, any flare resulting from off-field rays being reflected by the inside surface of the frame 2 can be removed. If a slope is provided on an attached cover glass or on a lens element flare generated by off-field rays being reflected by the circumferential edge of these elements or the inside surface of the frame 1 can be removed

As illustrated, a flare stop FS1 is arranged on the object side of a plane-parallel plate P1. Aperture stop S is arranged on the object side of plane-parallel plate P2. A flare stop FS2 is arranged between the two plane-parallel plates P2 and P3, and a flare stop FS3 is arranged between plane-parallel plate P3 and the third lens element L3.

For this sixth embodiment, a slope is provided at the image-side surface of the third lens element L3, i.e., on the surface supported by frame 1 nearest the image-side. A shading means, such as a light absorbing substance, is provided on this slope. In addition, a slope is also provided on the object-side surface of plate P4, and a shading means, such as a light absorbing substance, is also provided on this slope. Thus, the present invention is advantageous if a flare stop is to be provided at a location where, using a conventional flare stop formed of an annular diaphragm, it would be difficult to locate the support for the annular diaphragm. Thus the present invention is especially suitable at locations, such as the image-side end of frame 1, where it would be especially difficult to hold a conventional flare stop.

The outer diameter Φ1 of the third lens element L3, which is the optical member with the slope in this embodiment, is 1 mm. The maximum clear aperture diameter Φ2 (except for the slope) of this optical member is 0.9 mm. Therefore, Φ2/Φ1=0.9. Moreover, the air path equivalent length D from the image side of the third lens element L3 to the image plane I (i.e., measured on-axis from surface #14 to surface #17) is 0.819. The focal distance f of the lens is 0.573 mm; thus, the ratio D/f is 1.43. Moreover, the angle θ1 of the slope provided at the image side of the third lens element L3 is 40 degrees.

When the third lens element L3 is inserted into the frame 1, the third lens element L3 is fixed by applying an adhesive to which India ink has been added and mixed-in. The adhesive is applied not only to the circumference edge of the third lens element L3, but is also applied to the slope. In this way the adhesive serves as the shading means on the slope. The other optical member having a slope provided for flare reduction is plane parallel plate P4. The outer diameter Φ1 of plane-parallel plate P4 in this embodiment is 1.3 mm, and the maximum clear aperture diameter Φ2 is 1 mm Therefore, the ratio Φ2/Φ1 is 0.77. Moreover, the air path equivalent length D from object side surface of plane-parallel plate P4 to the image surface I (measured from surface #15 to surface #17) is 0.529 mm. Thus, D/f is 0.92. The angle of the slope θ1 on this optical member is 60 degrees.

Table 6 lists the surface # in order from the object side, the radius of curvature R (in mm) of each surface, the on-axis surface spacing d (in mm) of each surface, as well as the index of refraction N_d and the Abbe constant V_d (for the d-fine) of each optical member of Embodiment 6. In the bottom portion of the table are listed some of the performance values of the lens of this embodiment.

Embodiment 7

FIG. **7** illustrates the seventh embodiment of the invention. The lens of this embodiment includes a first lens element **L1** formed of a piano-concave lens with its concave surface on the image side, a plane-parallel plate **P1**, a second lens element **L2** that is biconvex, three plane-parallel plates **P2**–**P4**, a third lens element **L3** formed of a piano-convex lens with its convex surface on the object side, and a CCD cover plate C. The third lens element **L3** and the CCD cover glass C are attached to one another. And, the third lens element **L3**, the CCD cover glass C and the CCD array are integrated to form a CCD sub-assembly. An aperture stop S is arranged at the object-side surface of plane-parallel plate **P2**, a flare stop FSI is arranges at the object-side of plane-parallel plate **P1**, and flare stops **FS2** and **FS3** are arranged and pressed between plane-parallel plates **P2**–**P3** and between plates **P3**–**P4**, respectively.

In this embodiment, the flare-reducing slope is formed on the image-side surface of the plane-parallel plate **P4** , which is the optical member at the image-side of frame **1**. The outer diameter Φ1 of plane-parallel plate **P4** is 1 mm The maximum clear aperture diameter Φ2 is 0.9 mm. Therefore, Φ2/Φ1 is 0.9. The air path equivalent length D from the optical element to the image plane (measured on-axis from surface #14 to #17) is 0.879 mm. The focal-distance of the lens is 0.564 mm. Therefore, D/f=1.56. In addition, flare reduction can be maximized if a slope is also provided on the object side of the third lens element **L3**. Moreover, the inclination angle of the slope at the image side of plane-parallel plate **P4** in this embodiment is 50 degrees.

Table 7 lists the surface # in order from the object side, the radius of curvature R (in mm) of each surface, the on-axis surface spacing d (in mm) of each surface, as well as the index of refraction N_d and the Abbe constant V_d (for the d-line) of each optical member of Embodiment 7. In the bottom portion of the table are listed some of the performance values of the lens of this embodiment.

Embodiment 8

FIG. **8**(*a*) illustrates an eighth embodiment of the lens of the present invention. Embodiment 8 includes, in order from the object side, a field transforming optical element Pr, a first lens element **L1** of positive power, aperture stop S, a plane-parallel cover glass **P1** held in a frame **1**, a plane-parallel cover glass **P2**, a second lens element **L2** of positive power, a plane-parallel absorption-type infrared blocking filter **P3** and a CCD cover glass C held in a frame **2**.

This embodiment has a structure wherein the front and back of an optical system can be separated between the two plane-parallel cover glasses **P1** and **P2**. An adapter unit is placed before the plane-parallel cover glass **P1** and a master unit is placed after the plane-parallel cover glass **P2**. The adapter unit may be selected in accordance with the intended purposes.

The marginal section of a surface of the positive lens element **L2** on the image side is fixed to the frame **2** with adhesives A. The adhesives contain a black, light-absorbing material such as carbon so as to form a light shield. In this embodiment, in lieu of there being an inclined section at the marginal periphery of the positive lens element **L2**, the inclination angle of the lens surface itself at the periphery is made large, so that a groove **4** (FIG. **8**(*b*)) is formed between the optical surface and the frame. The light blocking adhesive is then applied to this slot.

The positive lens element **L2** of this embodiment is arranged nearest the image side among those lens elements of the lens having curvature. It is preferable to provide light shielding at the lens element arranged closest to the image side. This is because, as the position of the lens element approaches the image side of the lens, the ray height of a principal ray gets larger (i.e, the ray is farther from the optical axis) and thus it is more likely that flare is generated.

In this embodiment, the outer diameter Φ1 of the second positive lens element **L2** is 1.4 mm and the radius of curvature R ofthe optical surface on the image side is −1.2362. Thus the right side of Condition (6) is 0.57. The air path equivalent length (D) from the on-axis position of the image side of positive lens element **L2** to the image plane I is 1.34 mm and the focal length ofthe lens is 1.98 mm. Therefore, the ratio D/f equals 0.68.

FIG. **8**(*b*) is an expanded view of the lens element **L2** shown in FIG. **8**(*a*). When the angle a between the normal line at the marginal section of an optical surface and the optical axis is larger than 20°, the groove **4** is formed between the optical surface and a frame, so that it will be easy to apply an adhesive to the marginal section without need for forming a separate annular inclined surface near the circumferential edge of the lens, as done for the previous embodiments. Condition (4) is specifies that the angle α exceeds 20°, and the constant 0.34 on the right side of this

condition represents the value of sin 20°. In this embodiment, the adhesive is mixed with a black light absorbing material, such as carbon.

Moreover, in forming a light shield using adhesive mixtures while fixing a lens element to a frame, it is preferable to form the light shield on the lens element, among those lens elements having curvature, that is arranged in the objective portion of the lens nearest the image side. This is because the ray height (i.e., distance from the optical axis) becomes higher as the lens element position approaches the image side, and thus flare is more likely to occur. Furthermore, in forming a light shield using an adhesive mixture while fixing a lens to a frame, it is preferable to satisfy Condition (3) even when Condition (6) is satisfied and an inclined section is not separately formed at the marginal section of an optical surface.

Table 8 lists the surface # in order from the object side, the radius of curvature R (in mm) of each surface, the on-axis surface spacing d (in mm) of each surface, as well as the index of refraction N_d and the Abbe constant V_d (for the d-line) of each optical member of Embodiment 8. In the bottom portion ofthe table are listed some of the performance values of the lens of this embodiment.

The invention being thus described, it will be obvious that the same may be varied in many ways. For example, the light shield could be modified to be reflective, since the flare rays would in most instances be reflected to an absorbing surface and thereby be greatly attenuated. Such variations are not to be regarded as a departure from the spirit and scope of the invention. Rather the scope of the invention shall defined as set forth in the following claims and their legal equivalents. All such modifications as would be obvious to one skilled in the art are intended to be included within the scope of the following claims.

What is claimed is:

1. In a lens in which an optical member having an optical axis is inserted inside and held by a holding member, the improvement of:

the optical member having a sloped surface that is non-parallel to the optical axis and a circumferential edge, said sloped surface being immediately adjacent the circumferential edge, the circumferential edge being supported by said holding member; and

a light absorbing or light attenuating substance on said sloped surface, so that off-axis light rays from outside the designed angle of view of said lens which strike an inside surface of the holding member or the circumferential edge of the optical member are intercepted by the sloped surface and absorbed or attenuated, thereby reducing flare in an image plane of said lens.

2. The lens of claim **1**, wherein said sloped surface is either planar or convex.

3. The lens of claim **1**, wherein the diameter of the lens is 3 mm or less.

4. In a lens in which an optical member is inserted inside and held by a holding member, the improvement of:

the optical member having a sloped surface outside the circumference of a maximum clear aperture portion of said optical member; and

a light absorbing or light attenuating substance on said sloped surface, so that off-axis light rays from outside the designed angle of view of said lens which strike an inside surface of the holding member or the circumferential edge of an optical member held by the holding member may be intercepted by the sloped surface and absorbed or attenuated, thereby reducing flare in an image plane of said lens, said lens further satisfying the following conditions:

$$\Phi 1<3 \text{ mm}$$

$$0.6<\Phi 2/\Phi 1<0.95$$

where

Φ1 is the outer diameter of an optical member, and

Φ2 is the diameter of the maximum clear aperture portion of said optical member.

5. A lens having an optical axis and comprising, in order from the object side:

an aperture stop;

a first lens element of positive power with a convex surface on the image side;

a second lens element of positive power with a convex surface on the object side; and

a holding member;

wherein

the second lens element is inserted into and is held by the holding member;

the second lens element has a sloped surface that is non-parallel to the optical axis and a circumferential edge, said sloped surface being immediately adjacent the circumferential edge, the circumferential edge being supported by said holding member; and

the sloped surface has a light absorbing or light attenuating substance applied thereto,

whereby

off-axis light rays from outside the designed angle of view of said lens and which strike an inside surface of the holding member or the circumferential edge of an optical member held by the holding member are intercepted by the sloped surface and absorbed or attenuated, thereby reducing flare in an image plane of said lens.

6. The lens of claim **5**, wherein the diameter of the lens is 3 mm or less.

7. In a lens wherein an optical member is inserted within and held by a holding member, the improvement of:

the optical member having a sloped surface at the circumference edge of an optical face, and

a light absorbing or light attenuating substance provided on the slope surface;

wherein

the on-axis position of the optical face which includes the sloped surface satisfies the following condition

$$0.5<D/f<2$$

where

D is the air path equivalent length from the on-axis position of the optical face which includes the sloped surface to the image plane of said lens, and

f is the focal length of said lens.

8. The lens of claim **7**, said lens further satisfying the following condition:

$$0.6<\Phi2/\Phi1<0.95$$

where

Φ1 is the outer diameter of the optical member, and

Φ2 is the diameter of the optical member excluding the sloped surface.

9. The lens of claim **7**, said lens further comprising, in order from the object side:

an aperture stop;

a first lens element of positive power with a convex surface on the image side;

a second lens element of positive power with a convex surface on the object side; and

a holding member;

wherein

the second lens element is inserted into and is held by the holding member;

the second lens element has a sloped surface outside the circumference of a clear aperture portion of the second lens element; and

the sloped surface has a light absorbing or light attenuating substance applied thereto,

whereby

off-axis light rays from outside the designed angle of view of said lens and which strike an inside surface of the holding member or the circumferential edge of an optical member held by the holding member may be intercepted by the sloped surface and absorbed or attenuated, thereby reducing flare in an image plane of said lens.

10. In a lens in which an optical member is inserted inside and held by a holding member, the improvement of:

the optical member having a sloped surface outside the circumference of a maximum clear aperture portion of said optical member said sloped surface being either planar or convex; and

a light absorbing or light attenuating substance on said sloped surface, so that off-axis light rays from outside the designed angle of view of said lens which strike an inside surface of the holding member or the circumferential edge of an optical member held by the holding member may be intercepted by the sloped surface and absorbed or attenuated, thereby reducing flare in an image plane of said lens, said lens further satisfying the following conditions:

$$\Phi1<3 \text{ mm}$$

$$0.6<\Phi2/\Phi1<0.95$$

where

Φ1 is the outer diameter of the optical member, and

Φ2 is the diameter of the optical member excluding the sloped surface.

11. In a lens in which a sub-assembly is inserted within and held by a first holding member and the sub-assembly is formed of a plurality of optical members that are combined and held by a second holding member, the improvement of:

among the optical members that are held by at least one holding member, the optical member nearest the image side having a circumferential edge and an inclined surface, the inclined surface being immediately adjacent the circumferential edge of the optical member, the circumferential edge being supported by said holding member; and

the inclined surface including a light attenuating or light absorbing substance,

whereby

off-field light, which passes through an optical surface and is reflected at an inner surface of a holding member or at a circumferential edge of an optical member, is incident on the inclined surface.

12. The lens of claim **11**, said inclined surface being either planar or convex.

13. The lens of claim **11**, said lens further comprising, in order from the object side:

an aperture stop;

a first lens element of positive power with a convex surface on the image side;

a second lens element of positive power with a convex surface on the object side; and

a holding member;

wherein

the second lens element is inserted within and held by the holding member, said second lens element including an inclined surface at a marginal section of its object-side surface, said inclined surface including a light absorbing or light attenuating substance.

14. The lens of claim **11**, wherein the diameter of the lens is 3 mm or less.

15. In a lens in which a sub-assembly is inserted within and held by a first holding member and the sub-assembly is formed of a plurality of optical members that are combined and held by a second holding member, the improvement of:

among the optical members that are held by at least one holding member, the optical member nearest the image side having an inclined surface outside a clear aperture of an optical surface; and

the inclined surface including a light attenuating or light absorbing substance,

whereby

off-field light which passes through an optical surface and is reflected at an inner surface of a holding member or at a periphery edge of an optical member, is incident on the inclined surface;

said lens further satisfying the following conditions:

$$\Phi1<3 \text{ mm}$$

$$0.6<\Phi2/\Phi1<0.95$$

where

Φ1 is the outer diameter of the optical member, and

Φ2 is the diameter of the optical member excluding the sloped surface.

16. In a lens in which a sub-assembly is inserted within and held by a first holding member and the sub-assembly is formed of a plurality of optical members that are combined and held by a second holding member, the improvement of:

among the optical members that are held by at least one holding member, the optical member nearest the image side having an inclined surface outside a clear aperture of an optical surface; and

the inclined surface being either planar or convex and including a light attenuating or light absorbing substance,

whereby

off-field light which passes through an optical surface and is reflected at an inner surface of a holding member or at a periphery edge of an optical member, is incident on the inclined surface;

said lens further satisfying the following conditions:

$$\Phi 1<3 \text{ mm}$$

$$0.6<\Phi 2/\Phi 1<0.95$$

where

Φ1 is the outer diameter ofthe optical member, and

Φ2 is the diameter of the optical member excluding the sloped surface.

17. In a lens having an optical axis in which a sub-assembly is inserted within and held by a holding member and the sub-assembly includes optical members that are held by a first frame, the improvement of:

at least one of said optical members having an inclined surface that is non-parallel to the optical axis and a circumferential edge, said inclined surface begin a immediately adjacent the circumferential edge, the circumferential edge being supported by said holding member, said inclined surface having an adhesive applied thereto which includes a light absorbing or light attenuating substance.

18. The lens of claim **17**, wherein the diameter of the lens is 3 mm or less.

19. In a lens in which a sub-assembly is inserted within and held by a holding member and the sub-assembly includes optical members that are held by a first frame, the improvement of:

at least one of said optical members having an inclined surface at a marginal section, said inclined surface having an adhesive applied thereto which includes a light absorbing or light attenuating substance;

wherein the optical member having an inclined surface is one of:

a CCD cover glass,

an optical member that is positioned directly in front of a CCD cover glass, or

an optical member directly in front of a CCD unit.

20. In a lens in which a sub-assembly is inserted within and held by a first holding member, said sub-assembly including one or more optical members being held by a second holding member, the improvements comprising:

an optical member having a light absorbing or light attenuating substance on an optical surface that is outside a clear aperture of said optical member;

the light absorbing or light attenuating substance being mixed with an adhesive to form an adhesive mixture, said optical member being fixed by said adhesive mixture to a holding member and applied in a groove near the outer circumference of the optical member, said groove being formed by the optical member satisfying the following condition

$$\Phi 1/(2\times|R|)>0.34$$

where

Φ1 is the outer diameter of the optical member to which the adhesive mixture is applied, and

R is the radius of curvature of the optical surface on which the adhesive mixture is applied.

21. The lens of claim **20**, wherein the optical member on which the adhesive mixture is applied is the lens element arranged closest to the image side of said lens.

22. The lens of claim **20**, wherein the optical surface on which an adhesive mixture is applied is positioned axially so as to satisfy the following condition

$$0.5<D/f<2$$

where

D is the air path equivalent length between the on-axis position of the optical surface having the adhesive mixture applied and the image surface of said lens, and

f is a focal length of the lens.

(57) **ABSTRACT**

An objective lens including first, second, third, and fourth lens units in order from the object side. The first lens unit consists of a first lens of negative refractive power in the shape of a meniscus with a concave surface toward the image field side. The second lens unit consists of a second lens of positive refractive power. The third lens unit consists of a composite lens having joined together a third lens of negative refractive power with a concave surface toward the object side and a fourth lens of positive refractive power with a convex surface toward the image field side, the third lens unit having as a whole negative refractive power. The fourth lens unit consists of a fifth lens of positive refractive power. The objective lens has a predetermined condition for focal length.

OBJECTIVE LENS AND IMAGE PICKUP DEVICE USING THE SAME

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to an objective lens and an image pickup device using the same and is appropriate in particular to a camera system in a device using an image pickup element such as digital still camera, a video camera, a broadcasting camera or a photograph camera with an exit pupil kept far apart from the image field while widening an angle of field devised by employing the retro-focus type.

2. Related Background Art

Recent years, a digital still camera has been spreading out as the image input device. In this digital still camera there is generally carried out a process comprising AD-converting an output signal from a solid image pickup element such as CCD into image data, subjecting them to an image compression such as JPEG and storing the compressed data in a storage medium such as flash memory. After being developed on a computer, the compressed data thus stored are displayed on a monitor or the like.

In such a digital still camera, a higher precision of photographed images and a smaller size of image pickup devices has recently become a task and the compatibility of a high resolution and a smaller size is required therewith. Especially, to attain a thin model camera with stress laid on the portability, shortening the total lens length is required in a photographing lens (objective lens). For shortening the total lens length, it is advantageous to use an objective lens having as small a number of constituent lenses as possible.

Besides, as objective lenses for implementing a wide angle of field, many retro-focus type ones composed of a front lens unit having a negative refractive power and a rear lens unit having a positive refractive power are known. Especially as retro-focus type objective lenses having a small number of constituent lenses, those of the above front lens unit comprising one negative lens are proposed.

As such retro-focus type objective lenses with a front lens unit comprising one negative lens, for example, a 3 group 3 piece configuration comprising a negative lens, a positive lens and a positive lens in sequence from the object side is disclosed in U.S. Pat. No. 5,418,649 and a 3 group 4 piece configuration comprising a negative lens, a positive lens and a positive composite lens in sequence from the object side is disclosed in another embodiment of the same U.S. Pat. No. 5,418,649. As other examples, Japanese Patent Publication No. 7-122692 (corresponding to U.S. Pat. No. 4,984,878), Japanese Patent Publication No. 5-37288, Japanese Patent Publication No. 5-20724, Japanese Patent Publication No. 61-46807, Japanese Patent Publication No. 58-7 and Japanese Patent Application Laid-Open No. 9-189856 (corresponding to U.S. Pat. No. 5,706,141), U.S. Pat. No. 4,146,304, U.S. Pat. No. 4,674,844 and Japanese Patent Publication No. 60-32165 (corresponding to U.S. Pat. No. 4,130,349) disclose a 4 group 4 piece configuration comprising: a negative lens, a positive lens, a positive lens and a positive lens in sequence from the object side; a 4 group 4 piece configuration comprising:

a negative lens, a positive lens, a negative lens and a positive lens in sequence from the object side;

a 4 group 4 piece configuration comprising:

a negative lens, a positive lens, a positive lens and a negative lens in sequence from the object side;

a 4 group 5 piece configuration comprising: a negative lens, a positive lens, a positive lens and a positive composite lens in sequence from the object side;

a 4 group 5 piece configuration comprising:

a negative lens, a positive lens, a negative composite lens and a positive lens in sequence from the object side;

a 4 group 5 piece configuration comprising:

a negative lens, a positive lens, a positive composite lens and a negative lens in sequence from the object side; and

a 5 group 5 piece configuration comprising:

a negative lens, a positive lens, a negative lens, a positive lens, and a positive lens in sequence from the object side, respectively. All of them are of retro-focus model and consist of a negative front lens unit and a positive rear lens unit.

Besides, the focusing approach is divided into the pan focus approach with the pint fixed at an ultrafocal length and a method for focusing by driving the focusing lens for each release. Generally, in a digital still camera of much consumed power, it is desired to lengthen the service life of a battery and the pan focus is effective for saving the power consumption. To obtain an image of high resolution, however, focusing is preferably made so as to make the pint best according to the object distance. Especially, in the case of a macro photographing with an objective lens small in shortest object distance, those of focusing mechanism is better than those of pan focus.

As regards a retro-focus type objective lens, the total thrust method by moving the whole lens system is well known. Besides, as a method of making a partial thrust while making a total thrust and a rear focus method by thrusting a lens on the image side, Japanese Patent Publication No. 45-39875 and Japanese Patent Application Laid-Open No. 55-143517 are referred to.

Besides, as a method for the thinnest possible image pickup device in optical axis, a collapsible mount method comprising moving the objective lens toward the imaging surface side and collapsing it into the front cover of a camera when not using is well known. To minimize the drive mechanism including the actuator of lenses in the collapsible mount method, it is effective to make the focus mechanism and the collapsible mount mechanism into common use by collapsing the focusing lens in a single focus lens.

In the photographing system using a solid image pickup element, the incident angle to the receiving surface of an off-axis ray increases with a smaller distance from the image field to the exit pupil, so that a problem of shading or the like takes place. Thus, the objective lens of a image pickup system using such an image pickup element must be chosen to a telecentric optical system with an exit pupil kept sufficiently apart from the image field. To be specific, the objective lens is so arranged preferably that the off-axis chief ray incident to the optical axis at an angle corresponding to the photographing face angle reaches the image pickup element forming an imaging surface nearly in parallel with the optical axis. The wider the photographing face angle is, the stronger the refractive power required for such a refraction of an off-axis chief ray as to become in parallel with the optical axis is.

Generally, affording a negative refractive power to a group of lenses on the object side from the stop and a positive refractive power to a group of lenses on the image field side from the stop is advantageous to the reduction of an angle of an off-axis chief ray with the optical axis, i.e., to make it nearly parallel to the optical axis. Namely, in a retro-focus type objective lens, the front group of a negative refractive power is generally disposed on the object side with respect to the stop and accordingly the angle of an

off-axis chief ray with the optical axis can be reduced in presence of this front group. In the positive rear group, the angle of an off-axis chief ray with the optical axis can be reduced under action of positive lenses on the image field side with respect to the stop. Since both the front lens unit and the rear lens unit have an effect of making the exit pupil apart from the image field side, the retro-focus type optical system is very effective in the case of a wide photographing face angle.

Furthermore, for making the exit pupil sufficiently apart from the image field by shortening the total lens length, it is preferable to set at least the final lens of the rear group to a positive lens. More preferably, the surface on the image field side of the lens directly in front of the final lens is set to a convex surface. In such a manner, since the action of refracting an off-axis chief ray can be shared between the surfaces of three lenses including the final lens, the refractive power of the final lens cannot be made extremely strong. Too strong a refractive power of the final lens is inadequate because of causing the barrel-shaped aberration and the astigmatism.

From these, it is concluded that to employ the retro-focus type as the whole system and to set only the first lens of the negative front group and the final lens of the positive rear group to positive lenses is effective for making the objective lens telecentric at a wider photographing face angle and in a shortened total lens length and that the surface on the image field side of the lens directly in front of the final lens is preferably convex.

Furthermore, it is necessary for a better planarity of an image field to reduce the Petzval sum to some extent. If there is no negative refractive power in the above rear group, it is necessary for the reduction of the Petzval sum to intensify the refractive power of the first lens in the front group to considerable extent. On intensifying the refractive power of the first lens like this, a very large barrel-shaped aberration occurs as a result. In general cameras including a digital still camera, a large aberration is problematic. If there is a negative refractive power in the rear lens unit, the Petzval term in the rear lens unit can be control to some extent. Since the Petzval term in the front lens unit comprising a single lens is not corrected within the lens unit, it is only necessary to set the Petzval term in the rear lens unit in such a manner as to correct the front lens unit. Thus, for better image field characteristics, it is required that the rear lens unit has at least one concave lens or a group of composite lenses having a negative refractive power.

The configurations of Japanese Patent Publication No. 5-20724 and U.S. Pat. No. 4,674,844 have a problem that the exit pupil cannot be made sufficiently apart from the image field in the case of a shortened back focus because the final lens is not a positive lens.

The 3 group 3 piece configuration of U.S. Pat. No. 5,418,649 and the configuration of Japanese Patent Publication No. 7-122692 have a problem that the exit pupil cannot be made sufficiently apart from the image field while reducing the Petzval sum because there is no concave lens in the rear group.

In the 3 group 4 piece configuration of U.S. Pat. No. 5,418,649 and the configurations of Japanese Patent Publication No. 61-46807 and U.S. Pat. No. 4,146,304, the rear lens unit has a negative lens, which constitutes a positive composite lens. This negative lens is effective in the chromatic aberration, but these configurations have a problem that the exit pupil cannot be made sufficiently apart from the image field while reducing the Petzval sum.

In Japanese Patent Publication No. 5-37288, the rear lens unit has an independent negative lens. However, this negative lens is the lens directly in front of the final lens. Since the surface on the image field is concave, the exit pupil cannot be made sufficiently apart from the image field unless the refractive power of the final lens is made considerably greater. In the configuration of Japanese Patent Publication No. 5-37288, the refractive power of the final lens is not so strong as to make the pupil sufficiently apart from the image field. Besides, on excessively intensifying the refractive power of the final lens for making the pupil sufficiently apart from the image field, a barrel-shaped aberration and a astigmatism occur and therefore this intensification is inappropriate. Also in the configuration of Japanese Patent Publication No. 58-7, the negative composite lens directly in front of the final lens is of meniscus shape having a strongly concave surface on the image field side.

Besides, in Japanese Patent Application Laid-Open No. 9-189856, the composite lens is so constructed as to have a convex surface toward the image field side but to be 48° in the angle of field and does not correspond to an objective lens of a wide angle of field. Furthermore, since the refractive power of the composite system comprising the first lens unit and the second lens unit is weak, the lens back is so long that a compact camera cannot be constructed in the direction of the optical axis.

Besides, on employing the total thrust as a focusing method, the weight of the moving lens unit becomes heavy. In a camera having an autofocus mechanism, a good response of the focusing lens is desired. And, in a camera of much consumed power, a small power needed for the focusing is desired. For this purpose, the focusing lens is preferably as small in size and light in weight as possible and the total thrust is disadvantageous in this respect. Japanese Patent Publication No. 45-39875 has also a similar problem.

The rear focus scheme of Japanese Patent Application Laid-Open No. 55-143517 requires a space for thrust on the side of the focusing lens. Besides, a space for adjusting the shift of a pint due to manufacturing errors or assembling errors is further required in front of or behind the focusing lens, which is disadvantageous to constructing a compact camera in the optical axis direction. And, in an attempt to the compaction at the time of not photographing, it is required to move lenses on the object side rather than the focusing lens and a plurality of drive systems are required.

Besides, on employing the first lens unit as a focusing lens in the configuration of Japanese Patent Publication No. 60-32165, variations in short-distance spherical aberration and curvature of field are marked. Since in a short distance, the spherical aberration varies greatly on the under side and the curvature of field varies greatly on the over side, no focusible construction is formed in the first lens unit.

SUMMARY OF THE INVENTION

It is a first object of the present invention to provide a telecentric objective lens good in optical performance over all the object distance from an infinite object to a near object with an exit pupil kept far apart from the image field while a wider photographing face angle and a shorter total lens length intended by appropriately setting the lens configuration.

Besides, it is a second object to provide an image pickup device excellent in focusing response and small in power consumption.

Furthermore, it is a third object to provide an image pickup device further compact in the direction of optical axis at the time of not photographing.

To attain these objects, an objective lens according to the present invention is featured by the provision of:

a first lens unit consisting of a first lens of negative refractive power in the shape of a meniscus with a concave surface toward the image field side;

a second lens unit consisting of a second lens of positive refractive power;

a third lens unit consisting of a composite lens joined of a third lens of negative refractive power with a concave surface toward the object side and a fourth lens of positive refractive power with a convex surface toward the image field side and totally having negative refractive power; and

a fourth lens unit consisting of a fifth lens of positive refractive power;

in sequence from the object side, wherein on letting fi, f12 and f be the focal length of an i-th lens unit, the composite focal length of the first lens unit and a second lens unit and the focal length of the whole objective lens system, respectively, the conditions of

$$0.7<|f1|/f<3.0,$$

$$0.7<f4/f<3.0, \text{ and}$$

$$0.8<f12/f<2.5$$

are satisfied.

Besides, another objective lens according to the present invention is featured by the provision of:

a front lens unit of negative refractive power consisting of a first lens of negative refractive power in the shape of a meniscus with a convex surface toward the image field side;

and

a rear lens unit comprising a second lens of positive refractive power nearest to the object with a convex surface directed toward the object side; in sequence from the object side, wherein

focusing is carried out by moving the above front lens unit in the direction of the optical axis.

Besides, an image pickup device according to the present invention is featured by the provision of an objective lens comprising the following units in sequence from the object side:

a front lens unit of negative refractive power consisting of a first lens of negative refractive power in the shape of a meniscus with a concave surface directed toward the image field side;

and

a rear lens unit comprising a second lens of positive refractive power nearest to the object with a convex surface directed toward the object side; wherein

focusing is carried out by moving the above front lens unit in the direction of the optical axis;

driving means for moving the above front lens unit in focusing;

and

selecting means for selecting a specific mode from a plurality of modes in possession of the above image pickup device, wherein when a predetermined mode is selected, the above front lens unit is moved by the driving means to a still nearer position of than the focused position for an infinite object.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is an illustration of the basic configuration of an objective lens according to the Embodiment;

FIG. **2** is a sectional lens view of an objective lens according to Numerical Example 1;

FIG. **3** is a sectional lens view of an objective lens according to Numerical Example 2;

FIG. **4** is a sectional lens view of an objective lens according to Numerical Example 3;

FIG. **27** is an illustration of the basic configuration of an image pickup device (during the photographing state); and

FIG. **28** is an illustration of the basic configuration of an image pickup device (during the collapse state).

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

FIG. **1** is an illustration of the basic configuration of one embodiment of objective lens according to the present invention. FIGS. **2** to **8** are sectional views of lenses accord-

ing to the Numerical Examples 1 to 7 mentioned later. FIGS. **9** to **15** are representations of various aberrations in the Numerical Examples 1 to 7. Moreover, FIG. **16**A is a drawing showing the infinite focus state of the objective lens shown in FIG. **1** and FIG. **16**B (not shown) is the collapse state of the objective lens collapsed into the camera body. And, FIGS. **17**A, **18**A, **19**A, **20**A and **21**A are sectional lens views of the objective lens according to Numerical Examples 8 to 12 during the infinite focus state. FIGS. **17**B, **18**B, **19**B, **20**B and **21**B are sectional lens views of the objective lens according to Numerical Examples 8 to 12 during the collapse state. FIGS. **22**A, **23**A, **24**A, **25**A and **26**A are representations of various aberrations of the objective lens according to Numerical Examples 8 to 12 during the infinite focus state. FIGS. **22**B, **23**B, **24**B, **25**B and **26**B are representations of various aberrations of the objective lens according to Numerical Examples 8 to 12 during the state of focused to a short-distance object at a magnification of β=−0.058. Incidentally, the numerical data indicated in pairs of Numerical Examples of 1 and 8, 2 and 9, 4 and 10, 6 and 11 are in common.

In individual drawings, Numerals **101** and **102** denote the front group of negative refractive power and the rear group of positive refractive power. The front lens unit **101** has a first lens unit **103** of negative refractive power, the rear lens unit **102** has a second lens unit **104** of positive refractive power, a third lens unit **105** of negative refractive power and a fourth lens unit **106** of positive refractive power. Numeral **107** denotes a filter unit (glass block) composed of a crystal low-pass filter, an infrared cut filter and like filters. SP denotes a aperture stop, provided between the first lens unit **103** and the second lens unit **104** or between the second lens unit **104** and the third lens unit **105**. Numerals **108**, **109**, **110** and **111** denote an imaging surface on which an image pickup element such as CCD is disposed, an on-axis light flux, an off-axis light flux and the principal ray of an off-axis flux **110**, respectively. Numerals **112** and **113** denote marginal rays of an off-axis light flux **110**, corresponding to the upper and lower rays, respectively.

An objective lens according to this embodiment is a retro-focus type lens configuration comprising a front lens unit **101** of negative refractive power and a rear lens unit **102** of positive refractive power. The first lens unit **103** of negative refractive power consists only of a first negative lens in the shape of a meniscus with the concave surface toward the image field side. The second lens unit **104** of positive refractive power consists only of a second positive lens with the convex surface toward the object side. The third group **105** of negative refractive power consists of a composite lens joined of a third negative lens **105***a* and a fourth positive lens **105***b* in the shape of a meniscus with the concave surface as a whole toward the object side or two independent flat lenses. The fourth lens unit **106** of positive refractive power consists of a single positive fifth lens with both lens surfaces being convex. The total system of an objective lens comprises 4 groups and 5 pieces.

As mentioned above, for widening the photographing field angle and making the exit pupil sufficiently apart from the image field, it is preferable to set the total system to a retro-focus type. Besides, for shortening the total lens length, it is preferable to minimize the number of lenses. The present invention comprises a front lens unit **101** consisting of a single negative lens and a rear lens unit **102** having a positive fifth lens as the final lens. Besides, to keep the exit pupil apart from the image field without intensifying the refractive power of the final lens excessively, a fourth lens **105***b* or a negative composite lens as the lens directly in front of the final lens has the surface on the image field side set to a convex surface.

Besides, to improve the image field characteristics, with the objective lenses shown in Numerical Examples 1 to 11, a negative composite lens is disposed in the rear lens unit **102**. Because of comprising a single lens, the front lens unit **101** has the Petzval sum uncorrected within itself. Consequently, by setting a negative refractive power in the rear lens unit **102**, the front lens unit **101** and the rear lens unit **102** are canceled out to reduce the Petzval sum in the total system. Especially, by pasting the third and fourth lenses from the object side together to make a composite lens among five lenses of a negative, a positive, a negative, a positive and a positive lenses in sequence from the object side, a configuration without a highly eccentrically sensitive air clearance part are implemented. Thereby, the deteriorations of imaging performances due to manufacturing errors, assembling errors or the like is prevented throughout the total system.

Besides, an objective lens according to this embodiment has a stop SP provided between the first lens unit **103** and the second lens unit **104** or between the second lens unit **104** and the third lens unit **105**. For keeping the exit pupil apart from the image field, it is preferable that the front lens unit of retro-focus type is disposed on the object side to the stop SP and an objective lens according to this embodiment has the stop SP disposed on the image field side from the first lens unit. Besides, when the stop is disposed between the third lens unit and the fourth lens unit, an excessively strong refractive power of the fourth lens unit is required for keeping the exit pupil apart from the image field while shortening the total lens length. As a result, the Petzval sum cannot be reduced. Thus, for shortening the total lens length and for keeping the exit pupil apart from the image field, the stop SP is disposed between the first lens unit and the second lens unit or between the second lens unit and the third lens unit.

Besides, the first lens is set to a meniscus lens with a concave surface on the image field side. For keeping the exit pupil far of f from the image field, action of refracting an off-axis chief ray must be afforded to the first lens to some extent. Thus, a certain degree of negative refractive power is necessary for the first lens, but as a result, a barrel-shaped aberration is likely to occur in the first lens. In minimizing the occurrence of this aberration, minimizing the angle of the principal ray of an off-axis light flux incident to a lens surface is effective. For example, if the first lens has a concentric curvature radius, the incident angle of an off-axis ray can be set to 0, but a certain negative refractive power cannot be afforded in this case unlike the above. Thus, in an object lens according to this embodiment, the curvature radius of the surface on the object side is made greater and that of the surface on the image field side is made smaller to intensify the negative refractive power in contrast to a concentric shape, but the occurrence of aberration is minimized by keeping a meniscus shape with a strongly concave surface on the image field side. And correction of aberrations is made so as to cancel this in the rear lens unit **102**.

Besides, in an objective lens according to this embodiment, the total lens length is further shortened by applying an aspherical surface to at least one lens of the fourth lens unit **106** as the final lens and a better imaging performance is obtained. With the above 4 group 5 piece configuration, employing a spherical surface alone has a limit in making the exit pupil sufficiently apart from the image field and shortening the total lens length. In shortening the total lens length with the exit pupil kept apart from

the image field, especially the refractive power of the final lens must be intensified and thereby a barrel-shaped aberration and a under aberration of the image field occur. In an objective lens according to the present invention, shortening the total lens length with the exit pupil kept sufficiently apart from the image is further made easier by applying an aspherical surface to the final lens than in the configuration of a spherical lens alone.

In the case of setting an aspherical surface for the final lens, employing such a shape that the convergent action is weakened from the optical axis toward the marginal portion is effective in correcting a barrel-shaped aberration. This is a shape as slackening the curvature radius in a convex surface. With such an arrangement, both the curvature radius on the surface of lens and the incident angle of a ray act so as to weaken the refraction for an off-axis ray, so that the barrel-shaped aberration is corrected. Besides, since the imaging action is weakened for an off-axis light flux, there is a tendency of correcting the under curvature of field. Thus, in an objective lens according to the present invention, both the aberration and the curvature of field are corrected with the total lens length shortened by applying such an aspherical surface to the final lens. Incidentally, the marginal refractive power is relatively weakened as compared with the neighborhood of the optical axis on account of the above aspherical shape, but the refractive power of the fourth lens unit **106** itself is intensified by introduction of an aspherical surface, so that aberrations can be corrected with the exit pupil kept sufficient apart from the image field.

Besides, in an objective lens according to the present invention, occurrence of comatic aberration is suppressed while the angle of field widened by appropriately setting up the lens shape of the second lens unit **104**. After an off-axis light flux is refracted through the first lens unit **103**, the principal ray is incident to the second lens unit **104** at a certain angle with the optical axis. At this time, a comatic aberration occurs unless the lens surface of the second lens unit **104** has no concentric curvature radius. Thus, in this embodiment, occurrence of a comatic aberration is reduced by making a relatively small curvature radius while the lens surface on the object side of the second group **104** remaining convex.

Furthermore, in an objective lens according to this embodiment, a far better imaging performance is implemented even when the total lens length is shortened while the angle of field widened, by applying at least one aspherical surface to the second lens unit **104**. After an off-axis light flux is refracted through the first lens unit **103**, the principal ray is incident on the second lens unit **104** at a certain angle with the optical axis. At this time, a comatic aberration occurs unless the lens surface of the second lens unit **104** has no concentric curvature radius. Thus, in objective lens of this embodiment, occurrence of a comatic aberration is reduced though the angle of field remains wide by setting the lens surface on the object side of the second lens unit **104** to a relatively small curvature radius. Besides, in an on-axis light flux, a spherical over aberration occurs through the concave surface on the image side of the first lens unit **103**. If the lens surface on the object side of the second lens unit **104** is set to a convex surface, a spherical under aberration occurs and the spherical aberration occurring in the first lens unit **103** can be corrected. If the curvature of the lens surface on the object side of the second lens unit **104**, however, is sharpened for the correction of a comatic aberration with the angle of field kept wide, then a spherical under aberration may occur to greater extent in the second lens unit **104** than required. Though occurring in the concave surface of the third lens unit **105**, the spherical over aberration cannot be corrected too great a degree of spherical under aberration in the second lens unit **104** and accordingly the correction becomes incomplete in the total system. Thus, in this embodiment, the spherical under aberration is corrected by establishing such an aspherical surface that the convergence action is weakened from the optical axis toward the margin in the second lens unit **104**. Since an on-axis land ray is refracted at a position apart from the optical axis on any one surface of the second lens unit **104**, an aspherical surface to be provided for the correction of a spherical aberration is effective even on any lens surface of the second lens unit **104**.

Besides, for a wider photographing field angle, it is effective to apply at least one aspherical surface also to the first lens unit **103** in addition to the fourth lens unit **106**. At a fixed value of total lens length, the refractive power of the first lens unit **103** must be intensified with a wider photographing field angle. In the first lens unit **103**, a barrel-type aberration occurs, but an excessive strength of refractive power results in lack of correction even if an aspherical surface is applied to the fourth lens unit **106**. In such cases, applying an aspherical surface to the first lens unit **103** enables a aberration to be well corrected while the angle of field in the objective lens remaining wider. As mentioned above, the first lens unit **103** consists of a meniscus lens with the negative refractive power intensified in contrast to the concentric shape. Thus, in the lens surface of the first lens unit **103**, the principle ray is refracted at a greater incident angle with more eccentric off-axis light flux. For the correction of a barrel-shaped aberration, it is preferable to employ such an aspherical surface that the divergent action is gradually weakened from the optical axis toward the marginal portion. Namely, it is preferable to make the lens surface on the object side of the first lens unit **103** into an aspherical surface shape with its curvature radius sharpened from the optical axis toward the marginal portion and the one on the image field side into an aspherical surface shape with its curvature radius slackened from the optical axis toward the marginal portion.

Incidentally, even if the composite lens of the third lens unit **105** is separated to make the whole into a 5 piece configuration of simple lenses as shown in FIGS. **21**A and **21**B, shortening the total lens length and improving the optical performance are compatible with the exit pupil remaining sufficiently apart from the image field. In general, however, the air lens formed by separating the third lens unit is highly sensitive and characterized in that curvature of field is likely to occur in the presence of manufacturing errors, assembling errors or the like. Thus, only if manufacturing errors, assembling errors and the like are controllable, the configuration shown in FIGS. **21**A and **21**B is effective as an objective lens.

Besides, in an objective lens according to this embodiment, only a single lens of the first lens unit **103** is used for focusing lens. Thereby, the focusing lens can be constructed at an extremely light weight, so that the focusing performance excellent in response is obtained. In a digital still camera or the like using a solid image pickup element, there is employed a focusing method by positioning a focusing lens at the position of maximum in AF signal after reading an AF signal for each drive distance at definite intervals while driving the focusing lens over the whole focal range extending from an infinite object to a short distance object. In such a focusing method, excellency in the response of a focusing lens is preferable for raising the focusing speed and is important especially where a reversal

motion of driving direction is included. Besides, since the consumed power needed for the drive is small enough, this method leads to a longer life of service in a camera operated with a battery.

Besides, an image pickup device using an objective lens according to this embodiment enables the compaction in the direction of optical axis by collapsing a part of the above objective lens. In the above objective lens, though the total optical length is shortened to the utmost, further shortening the total optical length is implementable by moving the focusing lens toward the image field side as shown in FIG. **16**B during not photographing operation in an image pickup device.

FIG. **27** is a sectional view of the basic configuration of an image pickup device. In FIG. **27**, the image pickup element comprises a lens barrel **221** designated with hatching for retaining the rear lens unit **102**, the filter **107** and the like, a solid image pickup device **222** disposed on the imaging surface of the objective lens comprising the front lens unit **101**, the rear lens unit **102** and the filter **107**, a stepping motor (driving means) **223**, an output axis **224** of the stepping motor **223**, a rack member **225** engaged with the output axis **224**, a moving ring **226** for retaining the front group **101** and a guide bar **227** positioned opposite the output axis **224** across the optical axis. Besides, the solid image pickup element also comprises an unshown guide bar on a section different from that of FIG. **27**.

The moving ring **226**, retained by the guide bar **227** and the unshown guide bar, is so arranged as movable in the direction of optical axis. At this time, the moving ring **226** has an unshown sleeve part for mating with the unshown guide bar and a U-shaped groove (U-shaped, viewed in the direction of optical axis) **226***a* for suppressing the rotation around the optical axis to the guide bar **227**. Besides, by converting the rotation of the output axis **224** into the torque toward the optical axis via the rack member **225**, the moving ring **226** is driven along the optical axis. At this time, the moving ring **226** is driven by the distance corresponding to the number of input steps of the stepping motor **223**. FIG. **27** shows the thrust state of the focusing lens for photographing, whereas FIG. **28** shows the collapse state of the focusing lens **101** by moving the moving ring **226** to the image field side at the not photographing time. Focusing is carried out by moving the focusing lens **101** in the direction of optical axis through the drive of the stepping motor **223** in FIG. **27**. On the other hand, at the not photographing time, the focusing lens **101** is driven toward the image field side from the infinite focus position to reach the collapse state by using the same mechanism. Like this, an image pickup device according to the present invention jointly employs the focusing mechanism for the collapse mechanism and accordingly has no special mechanism for the collapse, the compaction in the direction of optical axis is implemented without making the apparatus greater in size.

Meanwhile, the focusing lens in an image pickup device according to this embodiment is driven to the photographing position shown in FIG. **27** and to the collapse position shown in FIG. **28** corresponding to the mode of a camera. In a digital still camera having display means such as liquid crystal device, for example, the following modes are considered.

<1> Autophotographing mode;

<2> Manual photographing mode;

<3> Power source off;

<4> Playback mode;

<5> Setting mode;

<6> Communicating mode.

MODE <1> is a photographing mode of automatically setting the ON/OFF of focus, exposure or stroboscope for a camera. MODE <2> is a photographing mode of setting the ON/OFF of focus, exposure or stroboscope for a photographer. MODE <3> is a mode of turning OFF the power supply of the total camera. MODE <4> is a mode of playbacking the photographed image by display means. MODE <5> is a mode of setting the level, date or the like of a file compression. MODE <6> is a mode of performing a data communication with a computer. Among these, Modes <1> and <2> are photographing modes and MODES <3> to <6> are not-photographing modes. With Power Supply OFF MODE <3> among MODES <3> to <6>, the focusing lens never fails to become the collapse state. Besides, also when other modes of MODES <3> to <6> are selected, the focusing lens may be collapsed. Especially, from the viewpoint of protecting the focusing lens, it is preferable to keep the collapse state as far as possible at the time of not photographing. Any of these modes can be selected optionally for a photographer by selecting means such as dial provided in the main camera body.

Besides, an objective lens according to the present invention is so arranged as to satisfy the following conditional expressions (1) to (3):

$$0.7<|f1|/f<3.0 \quad (1)$$

$$0.7<f4/f<3.0 \quad (2)$$

$$0.8<f12/f<2.5 \quad (3)$$

Here, fi: focal length of the i-th lens unit,

f12: composite focal length of the first and second lens units

f: focal length of the total objective lens system.

The technical meaning of conditional expressions (1) to (3) will be described.

The conditional expression (1) is an expression for defining the focal length or refractive power of the first lens unit **103**.

When the refractive power weakens beyond the upper limit of the conditional expression (1), the action of holding the exit pupil far off from the image field in the first lens unit **103** weakens. If an attempt is made to hold the exit pupil far off from the image field in such a manner as to compensate this by means of the refractive power in the rear lens unit, the refractive power of a convex surface in the rear lens unit must be intensified, thereby disabling the Petzval sum to be reduced and leading to a frequent occurrence of curvature of field, so that this attempt is not advisable. Besides, if an attempt is made to hold the exit pupil far off from the image field without intensifying the refractive power of the rear lens unit, the total lens length becomes longer, thereby disabling a compact objective lens to be constructed. On the other hand, when the refractive power is intensified beyond the lower limit, an excess of aberration and astigmatism occurs in the first lens unit **103** and the correction becomes impossible even by using an aspherical surface, so that this case is not advisable. Besides, the back focus lengthens and shortening the total optical length becomes difficult.

The conditional expression (2) is an expression for defining the focal length or refractive power of the fourth lens unit **106**.

When the refractive power weakens beyond the upper limit of the conditional expression (2), it becomes impossible to hold the exit pupil sufficiently apart from the image field and accordingly this case is not advisable. On the other hand, when the refractive power is intensified beyond the lower limit, an excess of aberration, curvature of field and astigmatism occur in the fourth lens unit **106** and the correction becomes impossible even by using an aspherical surface.

The conditional expression (3) is an expression for defining the focal length or refractive power of the composite system composed of the first lens unit **103** and the second lens unit **104**.

When the refractive power weakens beyond the upper limit of the conditional expression (3), the back focus lengthens and it becomes difficult to shorten the total optical length. On the other hand, when the refractive power is intensified beyond the lower limit, it becomes difficult to obtain a good optical performance by suppressing the occurrence of various aberrations. Especially an excess of spherical aberration occurs and consequently the correction becomes difficult even by applying an aspherical surface.

Furthermore, in the correction of aberrations, those of satisfying the following conditions is preferable.

Letting r1, r2 and r3 be curvatures of radius in lens surfaces of the first lens of the first lens unit **103** on the object side and on the image field side and that of the second lens of the second lens unit **104** on the object side, it is preferable to satisfy the following relations:

$$0.7<r3/r2<1.5 \quad (4)$$

$$-2.3<(r2+r1)/(r2-r1)<-1.0 \quad (5)$$

The conditional expression (4) is an expression for defining the ratio of curvature radius between the lens surface on the image side of the first lens of the first lens unit and the lens surface on the object side of the second lens of the second lens unit.

When this ratio exceeds the upper limit of the conditional expression (4), the curvature radius in the lens surface on the object side of the second lens unit **104** goes apart from the concentric curvature radius for an off-axis ray and consequently the occurrence of comatic aberration becomes especially excessive often, thus leading to difficulty in the correction even by using an aspherical surface. When this ratio exceeds the lower limit of the conditional expression (4), the correction to the lens surface on the image side of the second lens unit **104** becomes excessive for a spherical over aberration occurring in the lens surface on the image side of the first lens unit **103**, thus leading to difficulty in the correction even by using an aspherical surface.

The conditional expression (5) is an expression for defining the lens shape of the first lens of the first lens unit **103**.

When the relevant ratio exceeds the upper limit of the conditional expression (5), the incident angle of an off-axis light flux on the lens surface on the object side in the first lens unit **103** increase, thus leading to difficulty in a good correction of curvature of field and astigmatism even by using an aspherical surface. When the ratio exceeds the lower limit of the expression (5), the curvature of the lens surface on the image side of the first lens unit **103** is excessively sharpened, thus leading to occurrence of spherical excessively over aberration.

Next, Numerical Examples 1 to 12 of numerical data according to the present invention will be shown. In individual numerical examples, Numerals Ri, Di and Ni and vi denote the curvature radius of the i-th optical part from the object side, the size or air clearance of the i-th optical part from the object side, and the refractive index and Abbe's number of the i-th optical part.

Numerical Expression 1

$$X = \frac{h^2/R}{1+\{1-(h/R)^2\}^{1/2}} + Bh^4 + Ch^6 + Dh^8 + Eh^{10}$$

wherein

X: Coordinate determined from the object toward the image side along the optical axis by setting the vertex of an aspherical surface to the origin;

h: Coordinate vertical to the optical axis by setting the vertex of an aspherical surface to the origin;

R: Paraxial radius of curvature of an aspherical surface; and

B, C, D and E: Aspherical coefficients.

Besides, Table 1 shows the values of individual conditional expressions in individual numerical embodiments.

NUMERICAL EXAMPLE 1

(5)	−1.40	−1.68	−1.21	−1.43	−1.50	−1.88	−2.33	−1.35

By appropriately setting the lens configuration like this, according to this embodiment, telecentric objective lenses can be attained which has a good optical performance over all the object distance from an infinite object to a near object with the exit pupil kept apart from the image field while widening the photographing field angle and shortening the total lens length is intended and moreover a high optical performance of well corrected various aberrations on the whole image at a photographing field angle of about 65–77 and an F number of about 2.5.

Besides, it is possible to provide an image pickup device excellent in focusing response and small in power consumption.

Besides, it is possible to provide an image pickup device still more compact in the direction of optical axis at the time of not photographing.

What is claimed is:

1. An objective lens consisting of the following four lens units in sequence from the object side:

a first lens unit consisting of a first lens of negative refractive power in the shape of a meniscus with a concave surface toward the image field side;

a second lens unit consisting of a second lens of positive refractive power;

a third lens unit consisting of a composite lens having joined together a third lens of negative refractive power with a concave surface toward the object side and a fourth lens of positive refractive power with a convex surface toward the image field side, said third lens unit having, as a whole, negative refractive power; and

a fourth lens unit consisting of a fifth lens of positive refractive power,

wherein on letting fi, f12, and f be the focal length of an i-th lens unit, the composite focal length of the first lens unit and a second lens unit, and the focal length of the whole objective lens system, respectively, the conditions of

$0.7<|f1|/f<3.0$,

$0.7<f4/f<3.0$, and

$0.8<f12/f<2.5$ are satisfied.

2. An objective lens according to claim **1**, wherein said fourth lens unit has at least one aspherical surface.

3. An objective lens according to claim **2**, wherein the aspherical surface of said fourth lens unit is so shaped that the convergent action weakens gradually in a direction from the optical axis to the marginal portion.

4. An objective lens according to claim **2**, wherein said first lens unit has at least one aspherical surface.

5. An objective lens according to claim **4**, wherein the aspherical surface of said first lens unit is so shaped that the divergent action weakens gradually in a direction from the optical axis to the marginal portion.

6. An objective lens comprising the following lens units in sequence from the object side:

a first lens unit consisting of a first lens of negative refractive power in the shape of a meniscus with a concave surface toward the image field side;

a second lens unit consisting of a second lens of positive refractive power;

a third lens unit consisting of a composite lens having joined together a third lens of negative refractive power with a concave surface toward the object side and a fourth lens of positive refractive power with a convex surface toward the image field side, said third lens unit having, as a whole, negative refractive power; and

a fourth lens unit consisting of a fifth lens of positive refractive power,

wherein on letting fi, f12, and f be the focal length of an i-th lens unit, the composite focal length of the first lens unit and a second lens unit, and the focal length of the whole objective lens system, respectively, the conditions of

$0.7<|f1|/f<3.0$,

$0.7<f4/f<3.0$, and

$0.8<f12/f<2.5$ are satisfied,

wherein said second lens unit has at least one aspherical surface.

7. An objective lens according to claim **6**, wherein the aspherical surface of said second lens unit is so shaped that the convergent action weakens gradually in a direction from the optical axis to the marginal portion.

8. An objective lens according to claim **6**, wherein said first lens unit has at least one aspherical surface.

9. An objective lens according to claim **8**, wherein the aspherical surface of said first lens unit is so shaped that the divergent action weakens gradually in a direction from the optical axis to the marginal portion.

10. An objective lens according to claim **1**, wherein said fifth lens is a biconvex lens.

11. An objective lens according to claim **1**, further comprising a stop, wherein said stop is disposed either between said first lens unit and said second lens unit or between said second lens unit and said third lens unit.

12. An objective lens comprising the following lens units in sequence from the object side:

a front lens unit of negative refractive power, said front lens unit consisting of a first lens of negative refractive power in the shape of a meniscus with a concave surface toward the image field side; and

a rear lens unit of positive refractive power, said rear lens unit comprising a second lens of positive refractive power nearest to the object with a convex surface toward the object side,

wherein, a lens free region is provided between said front lens unit and said rear lens unit, and focusing is carried out by moving only said front lens unit in the direction of the optical axis.

13. An objective lens comprising the following lens units in sequence from the object side:

a front lens unit of negative refractive power, said front lens unit consisting of a first lens of negative refractive power in the share of a meniscus with a concave surface toward the image field side; and

a rear lens unit of positive refractive power, said rear lens unit comprising a second lens of positive refractive power nearest to the object with a convex surface toward the object side,

wherein focusing is carried out by moving only said front lens unit in the direction of the optical axis, and

wherein on letting r1 and r2 be radii of curvature of lens surfaces on the object side and the image field side of said first lens and r3 be a radius of lens surface on the object side of said second lens, the conditions of

$$0.7<r3/r2<1.5 \text{ and}$$

$$-2.3<(r2+r1)/(r2-r1)<-1.0 \text{ are satisfied.}$$

14. An objective lens comprising the following lens units in sequence from the object side:

a front lens unit of negative refractive power, said front lens unit consisting of a first lens of negative refractive power in the shape of a meniscus with a concave surface toward the image field side; and

a rear lens unit of positive refractive power, said rear lens unit comprising a second lens of positive refractive power nearest to the object with a convex surface toward the object side,

wherein focusing is carried out by moving only said front lens unit in the direction of the optical axis, and

wherein said rear lens unit has at least one negative lens and consists of 4 lenses or less.

15. An objective lens comprising the following lens units in sequence from the object side:

a front lens unit of negative refractive power, said front lens unit consisting of a first lens of negative refractive power in the shape of a meniscus with a concave surface toward the image field side; and

a rear lens unit of positive refractive power, said rear lens unit comprising a second lens of positive refractive power nearest to the object with a convex surface toward the object side,

wherein focusing is carried out by moving said front lens unit in the direction of the optical axis,

wherein said rear lens unit has at least one negative lens and consists of four lenses or less, and

wherein said rear lens unit consists of the following lenses in order from the object side:

said second lens;

a composite lens of negative refractive power in the shape of a meniscus with a convex surface directed toward the image field side, said composite lens having joined together a negative lens with a concave surface directed toward the object side and a positive lens with a convex surface directed toward the image field side; and

a biconvex positive lens.

16. An objective lens comprising the following lens units in sequence from the object side:

a front lens unit of negative refractive power, said front lens unit consisting of a first lens of negative refractive power in the shape of a meniscus with a concave surface toward the image field side; and

a rear lens unit of positive refractive power, said rear lens unit comprising a second lens of positive refractive power nearest to the object with a convex surface toward the object side,

wherein focusing is carried out by moving said front lens unit in the direction of the optical axis,

wherein said rear lens unit has at least one negative lens and consists of four lenses or less,

wherein said rear lens unit consists of the following lenses in order from the object side:

said second lens;

a negative lens with a concave surface directed toward the object side;

a positive lens with a convex surface directed toward the image field side; and

a biconvex positive lens.

17. An objective lens according to claim **12**, wherein said objective lens has at least one aspherical surface.

18. An image pickup device comprising:

an objective lens as set forth in any of claims **1** to **17** and an image pickup element for receiving an image formed by said objective lens.

19. An image pickup device comprising: an objective lens which comprises the following lens units in sequence from the object side, (a) a front lens of negative refractive power, said front lens unit consisting of a first lens of negative refractive power in the shape of a meniscus with a concave surface toward the image field side, and (b) a rear lens unit of positive refractive power, said rear lens unit comprising a second lens of positive refractive power nearest to the object with a convex surface directed toward the object side, wherein, a lens free region is provided between said front lens unit and said rear lens unit, and focusing is carried out by moving only said front lens unit in the direction of the optical axis;

driving means for moving said front lens unit in focusing; and selecting means for selecting a specific mode from a plurality of modes of said image pickup device, wherein when a predetermined mode is selected, said front lens unit is moved by said driving means to a still nearer position of the image side than the focused position for an infinite object.

20. An image pickup device according to claim **19**, wherein

said predetermined mode is a mode of not photographing for said image pickup device.

21. An objective lens according to claim **12**, wherein light emerging from said front lens unit is directly incident on said rear lens unit.

22. An image pickup device according to claim **19**, wherein light emerging from said front lens unit is directly incident on said rear lens unit.

(57) **ABSTRACT**

A stereoscopic objective lens system for video endoscopes and borescopes includes two full-diameter doublets and two lens pairs forming a stereo lens set. A rotatable dual telescope is disposed between the two doublets and the stereo lens pairs, establishing a Galilean telescope associated with each stereo channel. The Galilean telescopes are each rotatable, preferably in convert, to be in or out of alignment with the system optical axis. When out of alignment, the Galilean telescopes have no effect along the optical path. When in alignment, the Galilean telescopes provide an increase or decrease in magnification, depending on orientation of the telescopes. The full-diameter doublets present equal-angle pairs from symmetrically disposed object points to the lenses of the stereo lens pair. This equal-angle property enables accurate object/image mapping onto the final stereo image pair, such that all parts of each left/right image can be mapped to within a fraction of a video pixel to each other.

MULTIPLE MAGNIFICATION STEREO VIDEO TELESCOPE OBJECTIVE LENS SYSTEM

CROSS-REFERENCE TO RELATED APPLICATIONS

This application is related to and takes priority from U.S. Patent and Trademark Office Provisional Application Ser. No. 60/087,000 filed May 28, 1998, which is incorporated herein by reference.

BACKGROUND OF THE INVENTION

This invention relates generally to optical lens systems, and, more particularly, relates to stereoscopic objective lens designs adapted for use in stereo video telescopes.

Medical endoscopes are a form of telescope which is widely utilized to view internal regions of the human body during diagnostic, surgical, and other medical procedures. Endoscopes typically include a long, thin, rigid or semi-rigid optical cylinder affixed to a viewing mechanism. The cylinder is sufficiently narrow to be inserted through a small opening in the body, which may be natural or surgical. When the endoscope is inserted and positioned for use, an image of the object being viewed is formed at an inserted end of the endoscope by an objective lens. The image passes through a series of relay lenses down the cylinder to an eye lens or video camera at a viewing end of the endoscope.

In recent years, researchers have attempted to improve the imaging available through endoscopic devices by developing stereoscopic video endoscopes. These endoscopes present an apparently three-dimensional image on a video monitor. The stereoscopic effect is created by producing two optical images—a left image and a right image—through the endoscope. The left and right optical images are presented by the endoscope to left and right image sensors, which may be charge-coupled device (CCD) cameras or other image sensing devices. The sensing devices convert the left and right optical images into left and right video images which are then presented as alternating left/right images on a monitor, at a switching rate higher than the flicker-sensing limit of the human eye, so that observed images appear flicker-free.

The images are alternately switched from a left-hand polarization mode to a right-hand polarization mode, such that, for example, the left image has a left-hand polarization and the right image has a right-hand polarization. In accord with this example, the observer wears polarized glasses in which the left lens has the left-hand polarization and the right lens has the right-hand polarization. Thus, the left eye sees only images from the left channel of the endoscope system and the right eye sees only images from the right channel, resulting in stereoscopic viewing.

The following United States and foreign patents disclose examples of stereo endoscopes, some of which utilize video imaging and display elements:

U.S. Pat. No. 4,061,135
U.S. Pat. No. 4,615,332
U.S. Pat. No. 4,651,201
U.S. Pat. No. 4,862,873
U.S. Pat. No. 4,873,572
U.S. Pat. No. 4,895,431
U.S. Pat. No. 5,122,650
U.S. Pat. No. 5,191,203
U.S. Pat. No. 5,673,147
EP Patent No. 211,783

In particular, U.S. Pat. No. 4,061,135 discloses a binocular endoscope in which images are transmitted from the viewed object to the viewing station through an optical system utilizing a dove prism and mechanical linkage to compensate for rotation effects.

U.S. Pat. No. 4,615,332 discloses a binocular endoscope having flexible light guides and binocular eyepieces.

U.S. Pat. No. 4,651,201 discloses a stereoscopic video endoscope including two image guides and an illumination light guide. The image guides are optically coupled to a stereoscopic viewer for three dimensional viewing. The viewer includes couplings for attaching miniature video camera that can be connected to a head mounted stereoscopic video display.

U.S. Pat. No. 4,862,873 discloses a stereo endoscope having two light guides for carrying images of an object an electro-optical imaging assembly. A lens system directs light from the object to the objective end of the light guides. Illuminating light is transmitted to the object from the opposite end of one light guide, thereby illuminating the object. Simultaneously, the image transmitted through the other optical guide is conducted to the imaging assembly.

U.S. Pat. No. 4,873,572 discloses a stereo endoscope having a CCD camera module and two image-forming lens systems that form two object images. The object images are integrated and directed to the CCD camera to provide a stereoscopic output. The lens systems include red, green, and blue color filters disposed at the camera imaging surface.

U.S. Pat. No. 4,895,431 discloses an endoscope apparatus that generates a three-dimensional image of an object from overlapping images recorded by a camera. The endoscope includes an insertion module and a movable end section capable of being deflected through an angle. A first image is recorded with the end section positioned at a first angle. A second image, partially overlapping the first image, is recorded after moving the end section to a second angle. The relative position of the movable end section is detected by an encoder that generates position signals for input to a microprocessor, which utilizes the position signals to generate a three-dimensional image of the object.

U.S. Pat. No. 5,122,650 discloses a stereo video endoscope objective lens system using six doublet lenses to generate pixel mapped left-right images for stereo viewing.

U.S. Pat. No. 5,191,203 discloses a stereo video endoscope objective lens system using lenses having a graded index of refraction to generate pixel mapped left-right images for stereo viewing.

U.S. Pat. No. 5,673,147 discloses a stereo video endoscope objective lens system which uses ball lenses for the left and right stereo lens pair.

European Patent No. 211,783 discloses a stereo video endoscope in which two light pipes deliver two images of the same object. These images are presented by a binocular device to the user's eyes to show a three dimensional image of the target. The apparatus includes two television cameras and video recorders for recording the images. The recorded images can be displayed on separate screens and viewed by a binocular viewing system.

Most conventional stereo endoscopes, however, share a number of deficiencies associated with their objective lens systems. These problems include a bulky and unwieldy configuration; high cost and complexity of fabricating the objective lens system; and the less than optimal optical performance afforded by conventional objective lens systems.

An additional problem associated with conventional stereo video endoscope objectives involves the requirement

that all portions of each left/right image be mapped to within a fraction of a video pixel to each other. This pixel mapping condition is a significant optical design constraint, because the object-to-image ray paths through the lens system are quite different for the left and right image points associated with a common object point.

A further problem is the general characteristic of conventional endoscopes that the magnification is fixed for each such instrument. The present invention is directed to the latter problem.

Accordingly, it is a general object of the present invention to provide improved stereo telescope objective lens systems that selectively provides multiple magnifications.

A more specific object is to provide an improved stereo telescope objective lens system having optical elements that may be selectively placed in the optical train to provide different magnifications.

The above and other objects and advantages of this invention will become more readily apparent when the following description is read in conjunction with the accompanying drawings.

SUMMARY OF THE INVENTION

The foregoing objects are attained by the invention, which provides an improved stereo objective lens system for video imaging for various applications.

One aspect of the invention includes two full-diameter (D) doublets disposed along an optical axis, and a left/right stereo lens pair. A rotatable dual telescope, including two Galilean telescopes, is disposed between the full diameter doublets and the left/right stereo lens pair. The stereo lens pair includes a set of two pairs of doublet lenses.

The full-diameter doublets substantially collimate object points, i.e., image them substantially to infinity. The Galilean telescopes preferably each include a pair of doublets positioned along an optical axis, in a rotatable assembly which permits selectively positioning of the Galilean telescopes of their axes (in a magnifying orientation or a reducing orientation or neither). The stereo lens pair is disposed to collect light from the second doublet, if the Galilean telescope is out of the optical train, or from the Galilean telescope if it is in the optical train, with the optical axis of each lens being substantially parallel, and offset from the optical axis of the doublets.

The doublets and the stereo lens pair cooperate so that the doublets present equal angle light ray pairs from symmetrically disposed object points to the lenses of the stereo lens pair. The left and right stereo lenses generate left and right images respectively, at an image plane, where corresponding portions of those images are mapped to within a selected distance of each other.

In another aspect of the invention, the large collimator doublets provide accurate object/image mapping onto the final stereo image pair. In this design, the larger, and hence easier to fabricate doublets carry the corrective burden, so that the smaller, more difficult to manufacture lenses can be made a simple as possible.

The invention will next be described in connection with certain illustrated embodiments; however, it should be clear to those skilled in the art that various modifications, additions and subtractions can be made without departing from the spirit or scope of the claims.

BRIEF DESCRIPTION OF THE DRAWING

For a fuller understanding of the nature and objects of the invention, reference should be made to the following detailed description and the accompanying drawings, in which:

FIG. **1** is a schematic diagram depicting a stereo video endoscope utilizing an objective lens system constructed in accordance with the invention;

FIGS. **2**A–**2**C is an optical schematic diagram of a stereo objective lens system in accordance with the invention, in "wide angle" mode, "normal" mode and "telephoto" mode, respectively;

FIG. **2**D is an optical schematic diagram of an alternative embodiment of the invention;

FIG. **3**A is an optical schematic layout of the embodiment of FIG. **2**D in wide angle mode;

FIG. **3**B is an optical schematic diagram depicting the objective lens system of FIG. **2**D in wide angle mode, showing light rays transmitted through the system;

FIG. **3**C is an optical schematic diagram depicting the objective lens system of FIG. **2**D in wide angle mode, identifying optical surfaces;

FIG. **3**D shows the polychromatic diffraction modulation transfer function for the objective lens system of FIG. **2**D in wide angle mode;

FIG. **4**A is an optical schematic layout of the embodiment of FIG. **2**D in normal angle mode;

FIG. **4**B is an optical schematic diagram depicting the objective lens system of FIG. **2**D in normal mode, showing light rays transmitted through the system;

FIG. **4**C an optical schematic diagram depicting the objective lens system of FIG. **2**D, in normal mode, identifying optical surfaces;

FIG. **4**D shows the polychromatic diffraction modulation transfer function for the objective lens system of FIG. **2**D in normal mode;

FIGS. **5**A and **5**B set forth Tables A**1** and B**1** respectively, which define exemplary lenses for the embodiment of FIG. **2**D in wide angle mode;

FIGS. **6**A and **6**B set forth Tables A**2** and B**2** respectfully, which define exemplary lenses for the embodiment of FIG. **2**D in narrow mode;

FIG. **7**A is an optical schematic diagram of a stereo objective lens system in accordance with another embodiment of the invention, suitable for relatively long object distances;

FIG. **7**B is an end view of the system of FIG. **7**A;

FIG. **8**A is an optical schematic diagram of a stereo objective lens system in accordance with another embodiment of the invention, showing a third information channel;

FIG. **8**B is an end view of the system of FIG. **8**A; and

FIG. **9** is an end view of a stereo objective lens system similar to that of FIGS. **8**A and **8**B, but being a small, closely packed configuration.

FIGS. **10**A and **10**B show views of a stereo objective system similar to the stereo objective system as illustrated in FIGS. **7**A and **7**B respectively.

In the various figures, corresponding elements are identified with the same reference designations.

DESCRIPTION OF ILLUSTRATED EMBODIMENTS

FIG. **1** depicts the invention, a telescope objective system **100**, utilized in a stereo video optical system **1** for generating stereoscopic images of an object **12**. The system **1** principally includes a stereoscopic telescope **10** containing objective system **100**; sensing modules **152**, **154**; switching module **156**; and a monitor **158**. In addition to objective lens

system **100**, the telescope **10** includes conventional relay lenses or optical fibers **150** for transmitting light collected by the endoscope objective system **100** to light sensing modules **152, 154**.

The telescope objective system **100** generates left and right optical images of the object **12** that are processed by sensing elements **152, 154** and video switching module **156** in a known manner to display an apparently three-dimensional image of the object **12** on video monitor **158**.

The stereoscopic effect is created by producing two optical images—a left image and a right image—through the telescope objective system **100**. The left and right optical images generated by the objective system **100** are presented by the relay lens or optical fiber system **150** to left and right image sensors **152, 154**, which can be conventional charge-coupled device (CCD) cameras or other image sensing devices. The CCD elements operate in a known manner to convert the light collected by the objective system **100**, and transmitted by the relay lenses or optical fibers **150**, into electrical signals representative of the left and right optical images of the object **12**.

Conventional video switching circuitry **156** transmits the electronic signals representative of left and right video images as alternating left-right images on the monitor **158**. In accord with known video practice, these alternating images are presented at a switching rate higher than the flicker-sensing limit of the human eye, so that observed images appear flicker-free.

Moreover, the images can be alternately switched from a left-hand polarization mode to a right-hand polarization mode, such that, for example, the left image has a left-hand polarization and the right image has a right-hand polarization. The observer wears polarized glasses in which the left lens has the left-hand polarization and the right lens has the right-hand polarization. Thus, when the observer views the monitor **158**, the left eye sees only images from the left channel of the endoscope system and the right eye sees only images from the right channel, resulting in stereoscopic viewing. Video switching and display equipment of this type is commercially available from Stereographics, Inc. of San Rafael, Calif.; and from Tektronix Corp., of Beaverton, Oreg.

The accuracy and quality of the image displayed on monitor **158** is controlled by the performance of the telescope objective system **100**, which is the subject of the present invention.

FIGS. **2**A–**2**C and **2**D respectively depict alternate forms of an objective lens system **100** constructed in accordance with the invention.

The objective systems **100** of FIGS. **2**A–**2**C and **2**D include a window **102** followed by a first doublet **110** and a second doublet **112** positioned in sequence along and centered about a common system axis **100***a*, followed by a stereo lens set **113**. Both of the first doublets have circular cross sections with a diameter D**1**. The stereo lens set **113** includes two pairs doublets **114**A/**114**B, **116**A/**116**B, each having a circular cross-section with diameter D**2**, extending along an associated one of lens axes **114***a* and **116***a* which are parallel to, and spaced apart by D**2** from, the system axis **100***a*. The two doublets **110**, **112** cooperate to collimate object points, i.e., image them to infinity. A CCD detector element **152, 154** follows each of the doublet pairs **114, 116**.

A rotatable telescope is positioned between the doublet **112** and stereo lens set **113**. The dual telescope includes a first Galilean telescope **120**A (including doublets **124**A and **125**A extending along an optical axis **120***a*) associated with the axis **114***a* and second Galilean telescope **120**B (including doublets **124**B and **125**B extending along an optical axis **120***b*) associated with the axis **116***a*. Galilean telescope **120**A is selectively rotatable about an axis perpendicular to the axis **114***a* so that (1) its optical axis **120***a* is aligned with axis **114***a* (FIGS. **2**A, **2**C, **2**D, **3**A, **3**B, **3**C), with its components doublets **124**A, **125**A along the system optical axes **100***a*/**114***a*, or (2) its optical axis **120***a* is out of line with axis **114***a* (FIGS. **2**B, **2**D, **4**A, **4**B, **4**C) with its component doublets **124**A, **125**A removed completely from the system optical axes **100***a*, **114***a*.

Similarly, Galilean telescope **120**A is selectively rotatable about an axis perpendicular to the axis **116***a* so that (1) its optical axis **120***b* is aligned with axis **114***a* (FIG. **3**C), with its components doublets **124**B, **125**B along the system optical axes **100***a*/**116***a*, or (2) its optical axis **120***b* is out of line with axis **114***b* (FIGS. **2**B, **2**D, **4**A, **4**B, **4**C) with its component doublets **124**B, **125**B removed completely from the system optical axes **100***a*, **116***a*. Preferably both Galilean telescopes **120**A and **120**B of the dual telescope are mounted in a single carriage so that they may be rotated by a user in a single motion. When in the dual telescope is oriented as shown in FIGS. **2**B, **4**A–**4**C, the telescope has no effect on the magnification and is termed the "normal" mode. When the telescope is oriented as shown in FIGS. **2**A, **3**A–**3**C, the field is increased (with decreased magnification compared with normal mode), and is termed "wide angle" mode. When the telescope is oriented as shown in FIG. **2**C, the field is reduced (with increased magnification compared to the normal mode), and is termed the "narrow angle" mode.

FIGS. **3**D and **4**D show the polychromatic diffraction modulation transfer function for the embodiment of FIG. **2**D, for wide angle mode and normal mode respectively.

Those skilled in the art will appreciate that the lenses of the objective system **100** depicted in FIG. **2**D, define a sequence of optical surfaces. Tables A**1** (FIG. **5**A), A**2** (FIG. **5**B), B**1** (FIG. **5**A) and B**2** (FIG. **6**B) define the exemplary lenses for the embodiment of FIG. **2**D. Reference numerals preceded by S (in FIG. **3**A) and S' (in FIG. **4**A) correspond to the numerals respectively in the "SURFACE" column of Tables A**1** and B**1**. As those skilled in the art will appreciate, surfaces **9** and STO do not correspond to physical surfaces and are indicated in Tables A**2** and B**2** for convenience of analysis.

In Tables A**2** and B**2**, the numerical values in the "RADIUS", "THICKNESS" and "DIAMETER" columns are set forth in millimeters. The "GLASS" descriptions are standard optical glass characterizations as found in the product catalog of the Schott Glass Company of Germany. The "THICKNESS" column refers to the distance to the next optical surface. The "RADIUS" column refers to the radii of curvature of the respective curved surfaces.

The system **100** is designed so that all parts of each left/right image are mapped to within a selected distance of each other such that stereoscopic image quality is maintained. For video applications, this selected distance is typically a fraction of a video pixel. This is a difficult condition to satisfy, because the objectto-image ray paths through the lens system are quite different for the left and right image points of a common object point. The ray paths shown in FIGS. **3**B and **4**B demonstrate how differently an object point is imaged through the lens elements for one of the left and right images.

The objective systems **100** depicted in the above figures are able to map all parts of each left/right image to within a fraction of a video pixel to each other, because the large

collimator doublets present equal-angle pairs from symmetrically disposed object points to the lenses of the stereo lens set **113**. This exact equal-angle solution results in an accurate object/image mapping onto the final stereo image pair.

In the illustrated embodiments, the front full-diameter lenses are essentially a collimator, rendering an object into a virtual image at infinity. This is not essential but rather is a characteristic of the illustrated embodiments.

The collimator provides equal-angle chief rays from symmetrical edges of the field. This equal angle concept, coupled with the symmetry of the system in the left/right channels, insures that the smaller stereo lenses image those field edges at exactly the same positions on the CCD. That is, the right image of the left edge will be at the same position on the left CCD as is the left image of the left edge on the right CCD, and so on. This is an important factor in stress-free 3D viewing.

To obtain such equal-angle chief rays the front lenses have widely separated left-right pupils, so the chief rays of all field bundles are widely separated. As a result, these bundles have non-trivial included angles in object space—i.e. the front lenses are working at some tangible optical speed. In close-up medical use or inspection systems, this optical speed in stereo object space can be considerable, so any aberration of the front lens group will cause a disparity in the chief ray angles in the left-right bundles presented to the stereo lens sets, resulting in left-right image position errors. This stereo mapping error can lead to eyestrain, headaches, and the like, that make stereo visualization difficult.

Objective system **100**, as described in Tables A**1**, A**2**, B**1**, and B**2**, shown in FIG. **2**D, achieves accurate object/image mapping with user selectable field magnification depending on the rotational state of the dual Galilean telescope. Tables A**1** and A**2** in FIGS. **5**A and **5**B respectively, set forth a detailed description of the embodiment of FIG. **2**D in the wide angle mode (FIGS. **3**A–**3**C), and Tables B**1** and B**2** in FIGS. **6**A and **6**B, respectively, set forth a detailed description of the embodiment of FIG. **2**D in the normal mode (FIGS. **4**A–**4**C).

As indicated in FIG. **1**, a telescope constructed using relay lenses **150** or optical fibers or alternatively can employ a conventional CCD array mounted within the same housing as the objective system. The CCD array can include left and right sensing elements **152**, **154**, disposed to receive the optical images generated at the output of the lenses of stereo lens set **113**. The design and construction of CCD elements having more than one photosensitive region in a monolithic package is well known in the art. The electrical signals generated by the CCD array can be conducted from the housing by a conventional conduit. This configuration eliminates the requirement for a relay lens system or optical fibers.

The above described stereo optical systems are particularly well suited for relatively small geometry endoscope systems. However, similar configurations may be used for larger sized systems, such as may be useful for 3-D video teleconferencing or industrial use. By way of example, a system **200** is shown in FIGS. **7**A and **7**B, which includes a full diameter collimating doublet lens assembly **204**, having a relatively large diameter followed by a pair of stereo doublet lenses **206**R, **206**L, each having a relatively small diameter D_S, for the respective right and left channels. The stereo pair is followed by, right and left channel detectors **208**R, **208**L. In the configuration of FIGS. **7**A and **7**B, the front full diameter lens assembly **204** is essentially a collimator, rendering an object into a virtual image at infinity. This is not essential, but is the form of the preferred embodiment.

The collimator lens assembly **204** provides equal-angle chief rays from symmetrical edges of the field. This equal angle concept, coupled with the symmetry of the system in the left/right channels, insures that the small stereo lenses image those field edges at exactly the same positions on the CCD detectors **208**R and **208**L. That is, the left image of the left edge is at the same position on the left CCD **208**L, as is the right image of the left edge on the right CCD **208**R. This aspect enables stress-free viewing for a user.

The front lenses have widely separated left-right pupils, so that the chief rays of all field bundles are widely separated. As a result, these bundles have nontrivial included angles in object space—i.e. the front lenses are working at some tangible optical speed. In close-up medical use or inspection systems, this optical speed in stereo object space is important since any aberration of the front lens group causes a disparity in the chief ray angles in the left-right bundles presented to the stereo lens sets, resulting in left-right image position errors. This stereo mapping error can cause eyestrain, headaches and the like, that are the problematic for stereo visualization.

In prior art configurations for endoscopes, the front lenses have been designated as "full diameter", while the stereo components have been "half-diameter". In many non-medical applications, however, the stereo components **206**R and **206**L are considerably less than half the diameter of the front lens assembly **204**. This sizing of elements is primarily the result of achieving useful stereo parallax angles in object space. Because large, non-medical systems, especially teleconferencing systems, are designed with long object distances, in the order of a meter, stereoscopy requires a relatively wide stereo baseline. The stereo baseline is established by the separation of the stereo lens pairs **206**R, **206**L. Accordingly, these lenses are relatively widely separated with respect to the front components **204**, compared with the short working distance medical designs, such as those in FIGS. **2**A–**2**C and **2**D.

Still another form of the invention is shown in FIGS. **10**A and **10**B. In those figures, a stereo objective system **400** is shown, which is similar the stereo objective system **200** of FIGS. **7**A and **7**B, and includes a collimator doublet lens **404** and a first pair of right/left stereo lenses, **406**R**1**, **406**L**1**, and CCD detectors **408**R, **408**L, and further includes a second right/left stereo lens pair **406**R**2**, **406**L**2** and an optional third "added information", or "AI", channel lens **410**. The lenses **406**R**1**, **406**L**1**, **406**R**2**, **406**L**2** and **410** are all mounted on a base **420** which is selectively rotatable about the axis A of the collimator doublet lens **404**.

In a first state, the base **420** is oriented about axis A (as shown in FIGS. **10**A and **10**B) so that the optical axes of the first stereo lens pair **406**R**1**, **406**L**1** are aligned in the same manner as the corresponding lenses in the system of FIGS. **7**A and **7**B, where those lenses **406**R**1**, **406**L**1** are in the optical path of the overall system, including collimator doublet lens **404** and earlier elements in the optical train; lenses **406**R**2** and **406**L**2** are not in the system optical path in this first state. In a second state (not shown), the base **420** is oriented about axis A so that the optical axes of the second stereo lens pair **406**R**2**, **406**L**2** are aligned in the manner of the system of FIGS. **7**A and **7**B, where those lenses **406**R**2**, **406**L**2** are in the optical path of the overall system, including collimator doublet lens **404**, and earlier elements in the optical train; lenses **406**R**1** and **406**L**1** are not in the system

optical path in this second state. Preferably, lenses **406R1**, **406L1** provide a different magnification train lenses **406R2**, **406L2**, so that switching the orientation of base **420** between the first state and second state provides different magnifications for the optical train of the overall system. This aspect of the invention is useful in a camera, and particularly useful in a digital camera. While shown for two discrete magnifications, in other embodiments, additional stereo lens pairs may be mounted on base **420**, permitting addition magnifications to be selectively used.

In one exemplary configuration, the diameters of lenses **406R1**, **406L1**, **406R2**, **406L2**, and **410** are approximately one fourth the diameter of lens **404**, and the lenses **406R1**, **406L1**, **406R2**, **406L2** and **410** are offset from the axis of lens **404** by approximately one third the diameter of lens **404**. Other dimensions may be used in other embodiments.

The third channel includes a third channel lens **410**. The third channel can be used in many ways—to provide a "viewfinder" for a camera system, to present a "picture-in-picture" display, to provide a 2D image for recording and the like. In addition, with the addition of an external (to the large lens) mirror and/or prism system, the third channel can be steered to view another object. This other object could be another person, in a teleconferencing system "picture-in-picture" (PIP) mode, or an object or a drawing, or just another general scene of interest. The third channel lens **310** need not be the same as the stereo lenses **406R1**, **406L1**, **406R2**, and **406L2**. A different object and image format may be chosen to meet specific system requirements. While shown in FIGS. **10**A and **10**B for large format systems, such as may be useful in cameras, teleconferencing and other large scale industrial applications, the third channel aspect of the invention may be implemented in a closely packed small stereo system, in the same manner as in the system illustrated in FIG. **9**.

The invention may be embodied in other specific forms without departing from the spirit or essential characteristics thereof. The present embodiments are therefore to be considered in all respects as illustrative and not restrictive, the scope of the invention being indicated by the appended claims rather than by the foregoing description, and all changes which come within the meaning and range of equivalency of the claims are therefore intended to be embraced therein.

Having described the invention, what is claimed as new and secured by Letters Patent is:

1. A stereoscopic objective lens system for a stereo video telescope, the objective lens system having elements disposed along an optical path to convert light propagated from an object and received at an objective end of the objective system to pixel-mapped right and left optical images of said object at an image plane end of the objective system, the objective lens system comprising:

A. a first collimator doublet lens disposed along said optical path and proximate to the objective end for collecting light from points on the object, said first collimator doublet lens having a first optical axis, a selected diameter and a selected optical power,

B. a second collimator doublet lens for collecting light from said first collimator doublet lens, said second collimator doublet lens being disposed along said optical path and adjacent to said first collimator doublet lens and having a second optical axis substantially collinear with said first optical axis of the first collimator doublet lens, said second collimator doublet lens having a selected diameter and a selected optical power, whereby said first and second collimator doublet lenses cooperate to image the object points substantially to infinity so that light transmitted by the second collimator doublet lens from the object points is substantially collimated,

C. a multiple field right/left stereo lens pair assembly including on a base:

(i). a first right/left stereo lens pair, said first pair including a first pair right stereo lens and a first pair left stereo lens, said first pair right and first pair left stereo lenses being adjacent to said second collimator doublet lens and disposed for collecting light from said second collimator doublet lens, said first pair right stereo lens and said first pair left stereo lens each having a respective optical axis substantially parallel to said second optical axis of the second collimator doublet lens,

(ii). a second right/left stereo lens pair, said second pair including a second pair right stereo lens and a second pair left stereo lens, said second pair right and second pair left stereo lenses being adjacent to said second collimator doublet lens and disposed for collecting light from said second collimator doublet lens, said second pair right stereo lens and said second pair left stereo lens each having a respective optical axis substantially parallel to said second optical axis of the second collimator doublet lens, wherein the magnifications of said first and second pair right and left stereo lenses are different,

wherein said base and said first and second right/left stereo lens pair are rotatable about a pivot axis parallel to said first optical axis to selectively be in a first state wherein:

said optical axes of said first right/left stereo lens pair are each a parallel sub-component part of said optical path, and said first and second collimator doublet lenses and said first right/left stereo lens pair cooperate so that the first and second collimator doublet lenses present equal-angle chief ray pairs from symmetrically disposed object points to the lenses of said first right/left stereo lens pair, and

whereby said first pair right lens generates a right image at the image plane, and said first pair left lens generates a left image at the image plane, such that corresponding portions of each right/left image are mapped to within a selected distance of each other, or

in a second state wherein

said optical axes of said second right/left stereo lens pair are each a parallel sub-component part of said optical path, and said first and second collimator doublet lenses and said second right/left stereo lens pair cooperate so that the first and second collimator doublet lenses present equal-angle chief ray pairs from symmetrically disposed object points to the lenses of said second right/left stereo lens pair, and whereby said second pair right stereo lens generates a right image at the image plane, and said second pair left stereo lens generates a left image at the image plane, such that corresponding portions of each right/left image are mapped to within a selected distance of each other.

2. A lens system according to claim **1** wherein the diameter of said second collimator doublet lens is approximately equal to the diameter of said first collimator doublet lens.

3. A lens system according to claim **2** wherein said right stereo lens is substantially identical to said left stereo lens.

4. A lens system according to claim **3** wherein said right stereo lens and said left stereo lens each have a circular

cross-section transverse to the respective optical axes of said right stereo lens and said left stereo lens.

5. A lens system according to claim **3** wherein the diameters of said right stereo lens and said left stereo lens are less than or equal to one-half the diameter of said first and second collimator doublet lenses, and said optical axes of said right stereo lens and said left stereo lens are off-set from said first and second optical axes of said first and second collimator doublet lenses by more than one-fourth the diameter of said first and second collimator doublet lenses.

6. A lens system according to claim **5** wherein said right stereo lens and said left stereo lens each have a circular cross-section transverse to the respective optical axes of said right stereo lens and said left stereo lens.

7. A dual telescope including a first Galilean telescope including two doublets extending along a first axis and a second Galilean telescope including two doublets extending along a second axis, said second Galilean telescope being adjacent to a right/left stereo lens pair, said pair including a right stereo lens and a left stereo lens for generating a right image and a left image, respectively of an object, said right stereo lens and said left stereo lens each having a respective optical axis, said optical axes of said right/left stereo lens pair each being a parallel sub-component part of an optical path, wherein said first and second Galilean telescopes are each rotatable about a respective pivot axis perpendicular to said optical axes of said right and left stereo lenses to selectively be in a first state wherein:

said first axis is in alignment with said optical axis of said left stereo lens and said second axis is in alignment with said optical axis of said right stereo lens, whereby said doublets of said first and second Galilean telescopes are in said optical path, or

in a second state wherein:

said first axis is out of alignment with said optical axis of said left stereo lens and said second axis is out of alignment with said optical axis of said right stereo lens, whereby said doublets of said first and second Galilean telescopes are out of said optical path.

8. A stereoscopic objective lens system for a stereo video telescope, the objective lens system having elements disposed along an optical path to convert light propagated from an object and received at an objective end of the objective system to pixel-mapped left and right optical images at an image plane end of the objective system, the objective lens system comprising:

A. a collimator lens system proximate to the objective end for collecting light propagated from points on the object, said collimator lens system being disposed along said optical path and having a defined optical axis, a selected diameter and a selected optical power, whereby said collimator lens system images the object points substantially to infinity so that light transmitted by said collimator lens system from the object points is substantially collimated,

B. a right/left stereo lens pair, said pair including a right stereo lens and a left stereo lens, said right and left stereo lenses being adjacent to said collimator lens system and disposed for collecting light from said collimator lens system, said right stereo lens and said left stereo lens each having a respective optical axis substantially parallel to the optical axis of the collimator lens system, said optical axes of said right/left stereo lens pair each being a parallel sub-component part of said optical path,

wherein said collimator lens system and said right/left stereo lens pair cooperate so that the collimator lens system presents equal-angle chief ray pairs from symmetrically disposed object points to the lenses of said right/left stereo lens pair,

C. a dual telescope including a first Galilean telescope including two doublets extending along a first axis and a second Galilean telescope including two doublets extending along a second axis, wherein said first and second Galilean telescopes are each rotatable about a respective pivot axis perpendicular to said optical axes of said right and left stereo lenses to selectively be in a first state wherein:

said first axis is in alignment with said optical axis of said left stereo lens and said second axis is in alignment with said optical axis of said right stereo lens, whereby said doublets of said first and second Galilean telescopes are in the optical path of said system, or

in a second state wherein

said first axis is out of alignment with said optical axis of said left stereo lens and said second axis is out of alignment with said optical axis of said right stereo lens, whereby said doublets of said first and second Galilean telescopes are out of said optical path of said system,

whereby said right stereo lens generates a right image at the image plane, and

said left stereo lens generates a left image at the image plane, such that corresponding portions of each right/left image are mapped to within a selected distance of each other.

9. A lens system according to claim **8** wherein said collimator lens system comprises:

A. a first collimator doublet lens disposed along said optical path and proximate to the objective end for collecting light from points on the object, said first collimator doublet lens having a first optical axis substantially collinear with said optical axis of said collimator lens system, said first collimator doublet lens having a selected diameter and a selected optical power,

B. a second collimator doublet lens for collecting light from said first collimator doublet lens, said second collimator doublet lens being disposed along said optical path and adjacent to said first collimator doublet lens and having a second optical axis substantially collinear with said first optical axis of said first collimator doublet lens, said second collimator doublet lens having a selected diameter and a selected optical power, whereby said first and second collimator doublet lenses cooperate to image the object points substantially to infinity so that light transmitted by the second collimator doublet lens from the object points is substantially collimated; and

further wherein the diameter of said second collimator doublet lens is approximately equal to the diameter of said first collimator doublet lens.

10. A lens system according to claim **9** wherein said right stereo lens is substantially identical to said left stereo lens.

11. A lens system according to claim **10** wherein said right stereo lens and said left stereo lens each have a circular cross-section transverse to the respective optical axes of said right stereo lens and said left stereo lens.

12. A lens system according to claim **9** wherein the diameters of said right stereo lens and said left stereo lens are less than or equal to one-half the diameter of said first and second collimator doublet lenses, and said optical axes of said right stereo lens and said left stereo lens are off-set from said first and second optical axes of said first and

second collimator doublet lenses by one-fourth the diameter of said first and second collimator doublet lenses.

13. A lens system according to claim **12** wherein said right stereo lens and said left stereo lens each have a circular cross-section transverse to the respective optical axes of said right stereo lens and said left stereo lens.

14. A lens system according to claim **8** wherein first and second Galilean telescopes are mounted in a single carriage whereby said first and second telescopes are rotatable in concert about said pivot axis in response to an applied force.

15. A multiple field stereoscopic objective lens system for a stereo digital camera, the objective lens system having elements disposed along an optical path to convert light propagated from an object and received at an objective end of the objective system to pixel-mapped left and right optical images of said object at an image plane end of the objective system, the objective lens system comprising:

A. a first collimator doublet lens disposed along said optical path and proximate to the objective end for collecting light from points on the object, said first doublet lens having a first optical axis, a selected diameter and a selected optical power,

B. a second collimator doublet lens for collecting light from said first collimator doublet lens, said second collimator doublet lens being disposed along said optical path and adjacent to said first collimator doublet lens and having a second optical axis substantially collinear with said first optical axis of the first collimator doublet lens, said second collimator doublet lens having a selected diameter and a selected optical power, whereby said first and second collimator doublet lenses cooperate to image the object points substantially to infinity so that light transmitted by the second collimator doublet lens from the object points is substantially collimated,

C. a multiple field left/right stereo lens pair assembly including on a base:

i. a first right/left stereo lens pair, said first pair including a first pair right stereo lens and a first pair left stereo lens, said first pair right and first pair left stereo lenses being adapted for positioning adjacent to said second collimator doublet lens and disposed for collecting light from said second collimator doublet lens, said first pair right stereo lens and said first pair left stereo lens each having a respective optical axis substantially parallel to said second optical axis of the second collimator doublet lens,

ii. a second right/left stereo lens pair, said second pair including a second pair right stereo lens and a second pair left stereo lens, said second pair right and second pair left stereo lenses being adapted for positioning adjacent to said second collimator doublet lens and disposed for collecting light from said second collimator doublet lens, said second pair right stereo lens and said second pair left stereo lens each having a respective optical axis substantially parallel to said second optical axis of the second collimator doublet lens, wherein the magnification of said first and second pair right and left stereo lenses are different,

wherein said base and said first and second right/left stereo lens pairs are rotatable about a pivot axis parallel to said first optical axis to selectively be in a first state wherein:

said optical axes of said first right/left stereo lens pair are each a parallel sub-component part of said optical path, and said first and second collimator doublet lenses and said first right/left stereo lens pair cooperate so that the first and second collimator doublet lenses present equal-angle chief ray pairs from symmetrically disposed object points to the lenses of first said right/left stereo lens pair, and whereby said first pair right stereo lens generates a right image at the image plane, and said first pair left stereo lens generates a left image at the image plane, such that corresponding portions of each right/left image are mapped to within a selected distance of each other, and

in a second state wherein

said optical axes of said second right/left stereo lens pair are each a parallel sub-component part of said optical path, and

said first and second collimator doublet lenses and said second right/left stereo lens pair cooperate so that the first and second collimator doublet lenses present equal-angle chief ray pairs from symmetrically disposed object points to the lenses of said second right/left stereo lens pair, and whereby said second pair right stereo lens generates a right image at the image plane, and

said second pair left stereo lens generates a left image at the image plane, such that corresponding portions of each right/left image are mapped to within a selected distance of each other.

16. A lens system according to claim **15** wherein the diameter of said second collimator doublet lens is approximately equal to the diameter of said first collimator doublet lens.

17. A lens system according to claim **16** wherein said first pair right stereo lens is substantially identical to said first pair left stereo lens, and said second pair right stereo lens is substantially identical to said second pair left stereo lens.

18. A lens system according to claim **17** wherein said first and second pair right stereo lens and said first and second left stereo lens each have a circular cross-section transverse to the respective optical axes of said first and second pair right stereo lens and said first and second pair left stereo lens.

19. A lens system according to claim **18** wherein the diameters of said first and second pair right stereo lens and said first and second pair left stereo lens are less than or equal to one-half the diameter of said first and second collimator doublet lenses, and said optical axes of said first and second pair right stereo lens and said first and second pair left stereo lens are off-set from said first and second optical axes of said first and second collimator doublet lenses by more than one-fourth the diameter of said first and second collimator doublet lenses.

20. A lens system according to claim **15** further comprises a third channel lens adjacent to said second collimator doublet lens and disposed for collecting light from said second collimator doublet lens, said third channel lens having an optical axis substantially parallel to the optical axis of said second collimator doublet lens.

21. A lens system according to claim **20** wherein the optical axis of said third channel lens is coaxial with the optical axis of said second collimator doublet lens.

22. A lens system according to claim **19** further comprises a third channel lens adjacent to said second collimator doublet lens and disposed for collecting light from said second collimator doublet lens, said third channel lens having an optical axis substantially parallel to the optical axis of said second collimator doublet lens.

23. A lens system according to claim **22** wherein the optical axis of said third channel lens is coaxial with the optical axis of said second collimator doublet lens.

[57] **ABSTRACT**

A control system for an objective of the camera, in particular a film camera, includes one or several drive units for automatically positioning at least one lens ring, e.g., for adjusting the focus position, the opening of the iris diaphragm and/or the focal length. The drive units can be used to adjust the lens ring(s) to a predefined set position. A device coupled to each of the lens rings determines the actual position of the lens rings relative to the objective and converts this position into a measuring output signal.

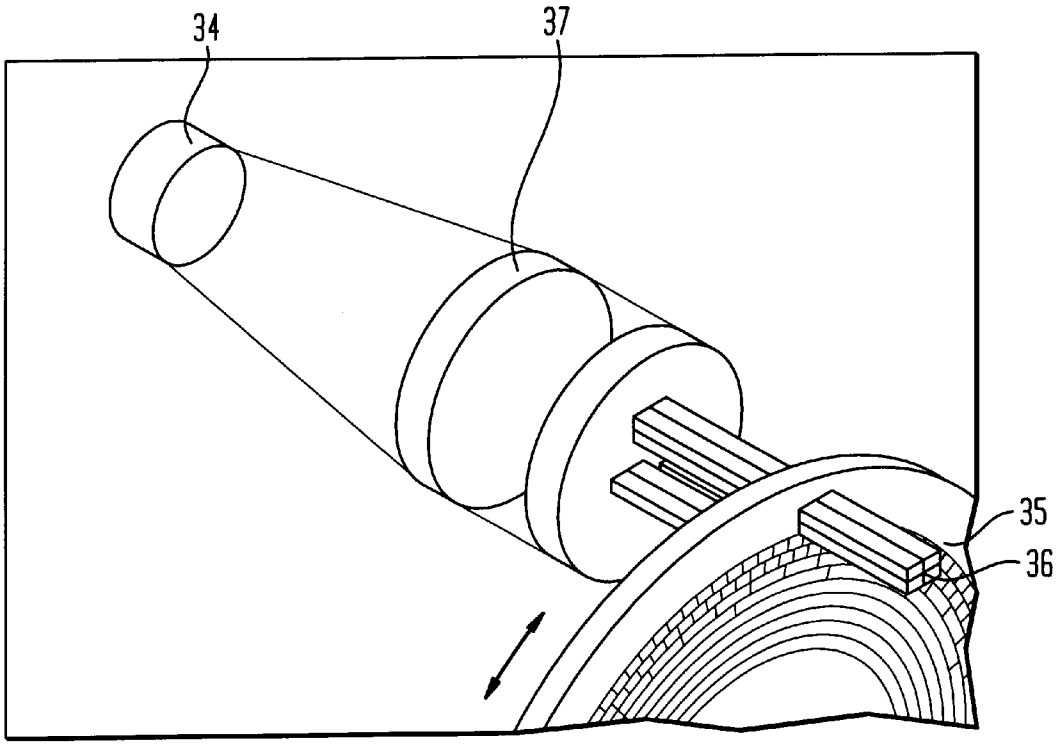

FIG. 3

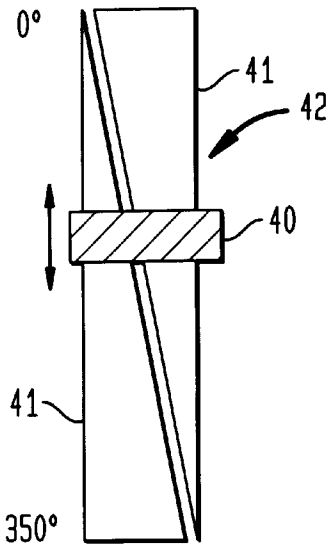

CONTROL SYSTEM FOR AN OBJECTIVE OF A CAMERA

CROSS-REFERENCES TO RELATED APPLICATIONS

This application claims the priority of Austrian Patent Application, Serial No. A 407/98, filed Mar. 9, 1998, the subject matter of which is incorporated herein by reference.

BACKGROUND OF THE INVENTION

The present invention relates in general to a control system for an objective of a camera, in particular a film camera, and in particular to a control system of a type including one or several drive units for automatically adjusting the positions of at least one lens ring, e.g., for focus position, iris diaphragm and focal length. The drive units can adjust the lens rings or rings to a predetermined set position.

Conventional control systems of this type allow remote adjustment of various lens rings of a camera objective. The angular position of the respective lens ring which is preset in an adjusting device, is adjusted by a motor drive that always moves the lens ring from a current position to the next desired position in incremental steps. With this method, however, after several adjustment steps a cumulative error is introduced which can cause a noticeable misalignment. This misalignment interferes with the camera operation and may require a manual fine adjustment in regular intervals.

A larger number of tiltable film cameras that operate completely automatically and are able to attain specific camera positions, are already in use. These cameras are frequently located in areas that cannot be reached by a camera assistant. Movie scenes must then frequently be re-taken because the automatic adjustment of the lens rings is not accurate enough. The film takes then become unusable because the exposure is wrong or the scenes are not in focus.

SUMMARY OF THE INVENTION

It is thus an object of the present invention to provide an improved control system for an objective of a camera, obviating the afore-stated drawbacks.

In particular, it is an object of the present invention to provide an improved control system of the aforedescribed type with allows a precise angular positioning of the lens ring or rings on the camera objective.

These objects, and others which will become apparent hereinafter, are attained in accordance with the present invention by providing a device which is coupled to the lens ring(s) and determines the actual position of the lens ring(s), with the device determining the actual position of the lens ring(s) relative to the camera objective and converts the actual position into a measuring output signal.

By determining the actual position, the deviation from the set position of the respective lens ring can be exactly determined and subsequently corrected. Consequently, the actual values of the lens ring positions are always available, so that an assistant or the cameraman may not have to read the lens ring positions manually which may be difficult. If the camera is located at a remote location, the actual lens ring position may be read remotely and the lens ring position may be corrected by remote control.

According to another feature of the present invention, the device for determining the actual position of the lens ring(s) may include an optical angular encoder in the form of an encoding element that is non-rotatably connected to the lens ring. The encoding element may include encoding tracks that can be read optically through reflection or transmission of light. The encoding element may also include a light transmitter and receiver system, wherein the light receiver produces the measuring output signal.

By applying appropriate encoding methods, the position of the lens ring(s) can be determined with great precision and high-resolution since mechanical friction forces do not interfere with the adjustment of the lens ring(s).

According to still another feature of the present invention, the device for determining the actual position of the lens ring(s) may include a magnetic distance sensor in the form of a tape that is preferably placed on the lens ring and filled with magnetic particles. The tape may be polarized periodically along several parallel tracks. The device may also include a magnetic sensor for sensing the tape without making physical contact with the tape, and for producing the measuring output signal.

This makes it possible to determine the position of the respective lens ring with great precision, without requiring a direct mechanical connection with the lens ring.

Advantageously, the magnetic sensor may be a magneto-resistive magnetic sensor.

According to still another feature of the present invention, the device for determining the actual position of the lens ring(s) may include a waveguide extending around the circumference of the objective in the region of the lens ring and a magnet that is connected to the lens ring at a predetermined location. The magnet may be at least partially movable inside the waveguide. An electromagnetic transmitter element and an acoustic receiver element may be arranged in the waveguide. The measured time difference between the signal transmitted by the transmitter element and the signal received by the receiver element represents the measuring output signal.

This feature also allows a precise and unambiguous measurement of the position of the lens ring.

According to yet another feature of the invention, the device for determining the actual position of the lens ring(s) may include an electrode located on the lens ring. The electrode can be rotated about a two-piece electrode that is located on the objective and increases or decreases in size depending on the position of the lens ring(s), without making physical contact with the electrode. The measuring output signal is produced by the capacitance ratio measured between the two-piece regions of the electrode and the rotatable electrode.

The position can therefore be determined through a capacitance measurement without making physical contact.

According to still another feature of the invention, the two-piece electrode may be represented by a rectangle that is parted along a diagonal. If lens rings are designed to rotate by more than 180°, an electrode that follows the helical path of the rotation, may be placed on the objective.

According to another embodiment of the invention, the measured values of the actual position may be transmitted to a different location for evaluation. Each of the measuring outputs of the device for determining the actual positions may be connected to a respective input of a measuring signal transmitter unit, with the output of the measuring signal transmitter unit connected to a measuring signal receiver unit capable of displaying the actual state of the lens ring(s) via one or several displays arranged in the measuring signal receiver unit.

In order to be able to reliably transmit the measured actual position values even for extreme camera positions, the

measuring signal transmitter unit may include a wireless transmitter section. The measuring signal receiver unit may include a corresponding wireless receiver section. Both sections are capable of exchanging the measuring signal data.

The measuring signal transmitter unit may be attached to the camera that is associated with the objective, Alternatively, the measuring signal transmitter unit may be incorporated in the camera and form a part of the camera. The measuring signal transmitter unit may also be placed at other locations.

According to still another feature of the present invention, the measuring signal transmitter unit may also include a control receiver unit that is electrically connected to the drive(s) for positioning the lens ring(s) and a control transmitter unit that is located in the measuring signal receiver unit and has control actuator elements capable of adjusting the set position of the lens ring(s).

In this way, the control devices and the units which indicate the actual positions, can be functionally combined into a single unit rather than forming separate units.

According to yet another feature of the invention, the measuring signal receiver unit may be connected to a device for determining and displaying the depth of field. With this device, the actual positions of the lens ring(s) can be measured to determine the depth of field that is actually usable with the objective. The actual depth of field range can then be determined for each actual setting of the objective. This may eliminate the need to re-shoot a movie scene because the actors or the backdrop were outside the focal range due to a camera movement. Since is the actual data relating to the position of the lens ring(s) are automatically available, the actual useful depth of field can be automatically determined without to tedium of inspecting tables.

BRIEF DESCRIPTION OF THE DRAWING

The above and other objects, features and advantages of the present invention will now be described in more detail with reference to the accompanying drawing, in which:

FIG. **1** is a schematic overall view of one embodiment of a control system according to the present invention for an objective of a camera;

FIGS. **2** and **3** are schematic illustrations of a device for determining the actual position of the lens ring position.

DETAILED DESCRIPTION OF PREFERRED EMBODIMENTS

Throughout all the Figures, same or corresponding elements are generally indicated by same reference numerals.

Turning now to the drawing, and in particular to FIG. **1**, there is shown a schematic overall view of one embodiment of a control system according to the present invention for an objective **1** of a film camera which includes three lens rings **22, 23, 24** for adjusting the focus position, the aperture of the iris diaphragm and the focal length of the objective. The objective **1** includes a system of optical lenses which are shown as a split elevation view of the objective. The objective is secured to the lens mount of the film camera through a bayonet mount. The system of the invention can also be used with other types of cameras and objectives.

The objective **1** includes several drive units **2, 3, 4** for automatically adjusting the position of the lens rings to predetermined set positions. When a control signal is sent to one of the drives, the drive initiates a rotation of the lens ring through a geared wheel that is driven by a motor, and stops the lens ring at the desired position. The rotation of the lens rings automatically causes a displacement of the optical lenses inside the objective **1** and/or an increase or decrease in the size of the iris diaphragm. The number and the functionality of the lens rings is in no way limited and can be varied in a number of different ways.

The lens ring can still be adjusted manually if a motor-controlled actuation is not desired.

It has been demonstrated in practice that an automatic adjustment of the lens rings, even if performed with great precision, is still inferior to a precise manual adjustment. The reason is that the drive units are not capable of providing the required precision along the entire circumference of the objective and during several adjustments.

In accordance with the invention, this situation can be corrected by providing a device that is coupled to each of the lens rings **22, 23, 24** for determining the actual positions **5, 6, 7** of the lens rings. The device determines the actual position of the lens rings **22, 23, 24** relative to the objective **1** and converts the position into a measuring output signal.

In this way, the adjustment movements that are actually performed by the drive units **2, 3, 4**, can be controlled and, if necessary, corrected.

Various possible methods for coupling the lens rings with the devices that determine the actual positions **5, 6, 7**, are described hereinafter with reference to several exemplified embodiments. In principle, these embodiments are independent of the specific device used to determine the positions.

In accordance with the nonlimiting example of FIG. **2**, the device for determining the actual position includes an optical angular encoder with an encoder element **35** that is non-rotatably connected with the lens ring. The lens ring includes encoding tracks that can be read out optically using transmitted light. The device further includes a light transmitter and receiver system **34, 36**. The measuring output signal is generated by the light receiver **36**. A reflecting encoding disk can also be used, in which case the light receiver would be located on the same side as the light transmitter **34**. To improve illumination of the tracks and to prevent crosstalk between the encoded tracks, a capacitor **37** is connected between the light transmitter **34** and the light receiver **36**. To provide a sufficiently high resolution of the respective angular position, several encoded tracks are arranged on the encoding disk. Accordingly, the light receiver is subdivided into several active elements.

Although not shown in detail in the drawing, a device for determining the actual position of the lens ring may also include a magnetic distance sensor system. The magnetic distance sensor system is formed of a tape that is filled with magnetic particles and preferably attached to the lens ring. The tape is preferably periodically polarized along several parallel tracks. A magnetic sensor which scans the tape without making physical contact with the tape, produces the measuring output signal. The parallel tracks can be polarized periodically in a sinusoidal or rectangular pattern. The magnetic sensor which is preferably a magneto-resistive sensor, is guided across the tape in close proximity thereto according to the angular position of the lens ring and scans the magnetic signatures.

The resistance of the magneto-resistive sensor elements varies as a function of the magnetic fields strength so that under constant current conditions, the elements produce a voltage that is modulated according to the changing magnetic field of the tape. The sensor elements are manufactured using semiconductor technology and can therefore be miniaturized. The output signal of the magnetic sensor is pro-

cessed by signal processing electronics capable of processing digital as well as analog signals, depending on the modulation type of the tape, to determine the position.

In order to provide higher resolution, phase-shifted magnetic tracks with a predetermined pattern are written on the tape. When this pattern is scanned, phase shifted signals are produced which are capable of resolving even those positions on the tape that are located between the magnetization periods. The measuring process operates incrementally and therefore requires that a reference signal be defined. An absolute position can be determined by scanning several parallel tracks.

It is also possible to provide the device for determining the actual position of the lens ring in the form of a waveguide that extends around the circumference of the objective in the region of the lens ring, and a magnet that is connected to the lens ring at a predetermined location.

The magnet is at least partially movable inside the waveguide. An electromagnetic transmitter element and an acoustic receiver element are arranged in the waveguide.

The transmitter element produces an electromagnetic pulse striking the permanent magnetic field of the magnet. The position of the magnet follows the position of the lens ring. This produces an angular momentum or a torsional pulse at the respective location of the waveguide. The latter pulse propagates with a constant sound velocity from the measuring location to the acoustic receiver element which converts the pulse into an electric pulse which is then sensed.

The measured time difference between the signal transmitted by the transmitter element and the signal received by the acoustic receiver element represents the measuring output signal. The measurement of the propagation time corresponds to a distance information between the magnet and the acoustic receiver element and subsequently has to be converted to corresponding angular data.

As shown in FIG. **3**, the device for determining an actual position includes an electrode **40** which is attached to the lens ring **22**, **23**, **24**. The electrode **40** can be pivoted across a split electrode **42** attached to the objective and increasing or decreasing in size depending on the position of the lens ring **22**, **23**, **24**.

The measuring output signal is generated based on the capacitance ratio measured between the two-piece regions **41** of the electrode **42** and the rotatable electrode **40**. The absolute position of the lens ring can be determined from the output signal.

According to the embodiment of FIG. **3**, the split electrode **42**, when in a flat state, represents a rectangle that is divided along a diagonal and composed of the rectangular triangles **41**. However, the electrode **42** can also be selected to have another two-piece shape.

To attain a very high resolution, stray capacitances have to be eliminated by providing adequate shielding. In order to obtain the largest possible capacitance, an intermediate layer with a relatively high dielectric constant, e.g., a Teflon layer, on which the rotatable electrode **40** glides, is preferably placed between the rotatable electrode **40** and the two-piece electrode **42** in situations where these two electrode are separated by a small gap. If the two electrodes are be prevented from contacting each other at all, then the measured signal may have to be amplified.

As also seen in FIG. **1**, each of the measuring outputs of the device for measuring the actual positions **5**, **6**, **7** is connected to a respective input of a measuring signal transmitter unit **8**. This unit receives the measuring signals from the devices determining the actual positions **5**, **6**, **7** and transmits the signals to a measuring signal receiver unit **30** connected thereto.

This connection can be provided in different ways, e.g., via infrared, ultrasound, electrical wires and the like. Illustrated is a wireless connection exemplified by antennas **13**. For this purpose, the measuring signal transmitter unit **8** includes a wireless transmitter section and the measuring signal receiver unit **30** includes a corresponding wireless receiver section which are adapted to transmit the measuring signal data. These data may have already been processed or can alternatively be processed after having been transmitted.

The measuring signal transmitter unit **8** can either be attached to the camera that is associated with the objective or can be a part of the camera. The transmitter unit **8** can also be carried by an assistant accompanying the camera man.

The wireless connection is advantageously implemented at camera locations that have automatic camera control and where the objective cannot be adjusted manually.

Several displays **14**, **15**, **16** capable of displaying the processed measuring signals indicating the actual position of the various lens rings **22**, **23**, **24** are arranged in the measuring signal receiver unit **30**. In the example of FIG. **1**, the focus setting is set to infinity, the iris diaphragm is set to the value 2.3 and the focal length to 180 mm. These values correspond to the values actually indicated on the objective which may be different from the set values inputted earlier.
