In determining the angle of rotation of the pattern illustrated in FIG. **1A** according to the present invention, a circular search region SH_1 is chosen, and a picture in this search region, that is, the letter portion CH,

is extracted as a significant picture. Next, a main axis C of the significant picture is obtained by using the moment of inertia method of calculation of the letter portion CH as shown in FIG. 1B and a rotational angle θ is determined as the angle of the main axis. If the search region SH_1 is set to be logic "1", the letter portion CH is set to be logic "0", and therefore, it is necessary to invert the logic state or the polarity when the letter portion CH is extracted.

This situation also applies in the cases of FIGS. 2A and 2B, and 3A and 3B. In the case of FIG. 2A, the circular hole HL is extracted as a significant picture, a center of gravity P_{G1} of the picture is obtained. The rotational angle θ is determined as the angle of a straight line C passing through the center of gravity P_{G1} of the significant picture and the center of gravity P_G of the entire objective pattern as shown in FIG. 2B.

In the case of FIG. 3A, processing is performed with respect to the notch BL in the same manner as in the case of FIG. 2A to obtain a rotational angle θ as shown in FIG. 3B.

In the case of FIG. 4A, processing is performed in the same manner as in the cases shown in FIGS. 2A and 2B, except that the protrusion PN is extracted without performing an inversion of the polarity or in an inversion of the logic states.

Next, the operation of the system of the present invention will be described with reference to FIG. 5. The system has two modes of operation, one being a judging mode (to be explained in greater detail with reference to FIG. 6) and the other mode being a setting mode (to be explained in greater detail with reference to FIG. 7). As shown in FIG. 5, the system according to the present invention includes a pick-up apparatus, such as a television camera 2, for forming a two-dimensional representation of a sample 1 to be detected; a binary coding circuit 3; a space division circuit 4 a picture memory 5; a change-over circuit 6; a polarity selection circuit 7 switching circuits 8*a* through 8*d*an area extraction circuit 9; a linear moment extraction circuit 10 a quadratic moment extraction circuit 11; a geometric moment extraction circuit 12; a central processing unit (CPU) 13; a memory 14; an address generation circuit 15; a standard search region storage circuit 16; a displacement correction circuit 17; a search region generation circuit 18; and an AND gate 19.

As shown at block 31 in FIG. 6, the detection according to this invention starts with the sample 1 to be detected being sensed by the television camera 2 and converted into binary, that is, black and white, information by the binary coding circuit 3. Next, at block 32, the binary information is spatially divided in two dimensions into picture elements, for example, 256×256 picture elements. These picture elements are then stored in the picture memory 5 which has sufficient capacity to store all of the picture elements. This operation is executed during the period, called the picture take-in period, in which one scene of the picture is scanned by the television camera 2. FIG. 8 shows an example of the relationship between the scanning period and the picture take-in period. FIG. 8(*a*) shows a vertical synchronizing signal and FIG. 8(*b*) shows a picture take-in period.

During the picture take-in period, and also shown by block 32 of FIG. 6 the area and linear moments are obtained. These operations are performed under the control of the CPU 13, which causes the change-over circuit 6 to select an input S_1 rather than an input S_2. The polarity selection circuit 7 selects "forward rotation" thereby turning the switching circuits 8*a* and 8*b* "ON" and the switching circuits 8*c* and 8*d* "OFF." Therefore, the picture information processed by the space division circuit 4 is applied to the area extraction circuit 9 and the linear moment extraction circuit 10, so that an area A and linear moments M_x and M_y are obtained.

Next, at block 33, when the picture take-in is terminated, the CPU 13 obtains coordinates P_{GX} and P_{GY} of the center of gravity of the entire pattern to be inspected. The CPU 13 can make its determination on the basis of expression (2) or on any other acceptable calculation. Then, as shown by block 34, CPU 13 compares the coordinates P_{GX} and P_{GY} with coordinates P_{GXS} and P_{GYS}, which represent the center of gravity of a standard sample obtained in advance during the setting mode. The comparison is performed to obtain a quantity of displacement (Δx, Δy) between the center of gravity coordinates.

Next, as shown by block 35 in FIG. 6, the CPU 13 reads picture polarity information out of the memory 14 corresponding to the shape characteristic of the objective pattern, and applies the information to the polarity selection circuit 7. At the same time, the CPU 13 reads various "ON"/"OFF" switch setting information out of memory 14, and applies that information to the switching circuits 8*a* through 8*d*. The process for initially setting the switches is shown in FIG. 7 and described below in detail. The switch setting information for the switching circuits 8*a* through 8*d* depends on the algorithm which is used for detecting the angle θ and the method of calculation, such as the moment of inertia method or the inter two-gravity center method.

Thus, the setting of the switches is performed in accordance with the shape characteristic of the objective pattern. For example, when the moment of inertia method is employed, the switching circuits 8*a* and 8*b* are turned "OFF" and the switching circuits 8*c* and 8*d* are turned "ON." Information with respect to a circular or ring-like search region to be searched, which had been set in advance by the standard sample, has been stored in the standard-region storage circuit 16 together with the information of the coordinates P_{GXS} and P_{GYS} of the center of gravity of the standard sample.

At this time, as shown by block 35, CPU 13 applies trigger signals to the address generation circuit 15 to scan the picture memory 5 and the search region generation circuit 18. As a result, the address generation circuit 15 generates addresses X and Y to the picture memory 5 to successively scan the picture memory 5 for every picture element in a manner similar to a television, so as to successively read picture information out of picture memory 5. The search region generation circuit 18 is arranged to read search region data (coordinates data) out of the standard search region stored circuit 16 to determine whether addresses generated by the address generation circuit 15 exist in the search region. Accordingly, the search region generation circuit 18 controls the data read out of picture memory 5 through the AND gate 19. Thus, only the picture data in the search region stored in picture memory 5 are read out through the AND gate 19.

Then, at block 36, the quantity of displacement (Δx, Δy) between the respective centers of gravity of the pattern to be detected in the standard sample is applied from CPU 13 to the displacement correction circuit 17. The quantity of displacement is added to the data from

the standard search region storage circuit **16** to thereby shift position of the standard search region by the quantity of displacement so that the position of the search region is normalized.

The change-over circuit **6** is then controlled to select an input S_2 at block **37**, so that the output of the AND gate **19** is applied to the extraction circuits **9** through **12** via the changeover circuit **6**, the polarity selection circuit **7**, and the switching circuits **8**. At this time, as shown in block **37**, the polarity of the picture information is inverted if necessary.

As described above, since the moment of inertia method is to be used in this case, only the switching circuits **8***c* and **8***d* are in the "ON" state, so that the quadratic moments I_x and I_y and the synergistic moment I_{xy} are extracted by the extraction circuits **11** and **12**, respectively (block **38**). FIG. **8**(*c*) shows the timing of the preceding operation. As is apparent from FIG. **8**(*c*), extraction of the area and the moments with respect to the significant picture information is performed after the picture take-in period.

As shown by block **39** of FIG. **6**, the outputs of the extraction circuits **11** and **12** are applied to the CPU **13**, so that the calculation shown in the above-mentioned expression (1) is performed in accordance with the setting of the switches to obtain the rotational angle θ. The timing for the operation which occurs at block **39** is shown in FIG. **8**(*d*).

The rotational angle is thus obtained by using the moment of the inertia method of the preceding example. As described above, there are some shapes of the objective pattern for which the rotational angle can be more accurately obtained by using the inter two-gravity center method and some cases where the rotational angle can be more accurately obtained by using the polarity inversion of the picture information method.

Therefore, the status of the switches is set in advance and stored in memory **14** using a standard sample according to which method should be used and according to whether the polarity of picture information should be inverted. As shown in FIG. **7**, at block **41**, a standard picture sample is obtained and then binary-coded similar to the procedure in block **31** of FIG. **6**. Next, at block **42**, CPU **13** calculates the area and linear moments of the binary-coded picture similar to the procedure in block **32** of FIG. **6**. At block **43**, CPU **13** calculates the center of gravity similar to the procedure in block **33** of FIG. **6**, and at block **44**, CPU **13** determines the search region and stores it in memory **14**. The polarity of the picture information is determined and stored in memory **14** at block **45**, then, at block **46**, the switch states are determined and set and stored in memory **14**.

When the inter two-gravity center method and the polarity inversion of the picture information are to be used, CPU **13** applies a command indicating the polarity inversion to the polarity selection circuit **7**, applies a command turning the switching circuits **8***a* and **8***b* "ON", and applies a command turning the switching circuits **8***c* and **8***d* "OFF." As a result, an area A′ and linear moments M'_x and M'_y are extracted from the information of the significant picture in the search region, and the center of gravity is obtained on the basis of the above-mentioned expression (2).

Therefore, a rotational angle θ can be obtained from the thus-obtained center of gravity of the pattern in the search region and the center of gravity of the entire pattern to be detected on the basis of the following expression (3):

$$\theta = \tan^{-1}\frac{Y_{Gi} - Y'_{Gi}}{X_{Gi} - X'_{Gi}} \quad (3)$$

where X_{Gi} and Y_{Gi} are the respective x- and y- coordinates of the center of gravity of the entire pattern to be detected, and X'_{Gi} and Y'_{Gi} represent the x- and y-coordinates of the center of gravity of the pattern in the search region.

The preceding description of the system in accordance with the present invention has been mainly concerned with objective patterns having only one kind of shape characteristic. If an objective pattern has various shape characteristics, it is possible to use the present invention with respect to portions of such an objective pattern so that data relating to sizes and positions of standard search regions, methods of angle detection, polarity of picture, etc., are set and stored in advance so that the data can be properly selected by CPU **13**.

The following advantages result from the use of the system of the present invention:

(1) Since angle detection with respect to an objective pattern is made by extracting the data of a significant picture in a search region, a correct angle can be detected even where a circular pattern is to be normalized. Accordingly, normalization of rotation in pattern inspection or pattern recognition can be more accurately performed. Furthermore, in a case where angle data are to be detected so as to be utilized for position control, position information can be obtained thereby making it possible to perform highly accurate position control.

(2) Since the angle detection can be performed by using one of several different methods and the picture polarity can be suitably changed, the system according to the present invention can widely apply to various samples with various shape characteristics.

(3) Furthermore, since the size of the search region can be suitably set, the system according to the present invention can deal with various objective samples, so that the system can operate as a flexible manufacturing system (FMS).

(4) Since the displacement of the position where the search region is generated can be corrected, not only can the inspection and recognition be performed with high accuracy independent of the region's displacement, but also the limitation in a carrying system caused by an objective sample is reduced resulting in a reduction in the of cost of the carrying system.

It will be apparent to those skilled in the art that various modifications and variations can be made in the methods and apparatus of the present invention without departing from the scope or spirit of the invention. Thus, it is intended that the present invention cover the modifications and variations of this invention provided they come within the scope of the appended claims and their equivalents.

What is claimed is:

1. A method for detecting a rotational angle of an objective pattern comprising the steps of:

(a) optically sensing an objective pattern by a picture sensor to form a sense signal;

(b) binary coding said sense signal into picture elements;

(c) calculating an area of said objective pattern and a plurality of linear moments of said objective pattern from said picture elements;

(d) calculating a center of gravity of said objective pattern from said area and said linear moments;

(e) storing said area, linear moments, center of gravity and said binary-coded picture elements into a memory;

(f) calculating a displacement of said center of gravity corresponding to a difference between a center of gravity of a predetermined picture sample and said center of gravity of said objective pattern;

(g) determining an appropriate search region from among said binary-coded picture elements and reading out data corresponding to said search region;

(h) normalizing a position of said search region;

(i) calculating a rotational angle for said objective pattern based on predetermined mathematical formulae and utilizing said stored information; and

(j) storing predetermined data for determining whether said logic state of said picture information is to be inverted, and as to which one of said methods of calculation are to be used in detection of said rotational angle of said objective pattern.

2. The method of claim **1**, further including the step of forming a search region by using a normalization process.

3. A system for detecting a rotational angle of a two-dimensional objective pattern converted into binary picture information, said system comprising:

memory means for storing said picture information;

first feature extraction means for extracting an area and a moment of inertia of said objective pattern from said picture information;

center of gravity means for determining a center of gravity of said objective pattern from said area and said moment of inertia of said objective pattern;

region forming means performing a search region having a predetermined shape about said center of gravity of said pattern;

second feature extraction means for extracting a selective portion of said picture information out of said memory means, whereby said rotational angle of said objective pattern is detected on the basis of said extracted portion by using a selected one of a moment of inertia method or an inter two-centers of gravity method of calculation; and

predetermined data storage means for determining whether said logic state of said picture information is to be inverted, and as to which one of said methods of calculation are to be used in detection of said rotational angle of said objective pattern.

4. A system for detecting rotational angle of an objective pattern according to claim **3**, in which said search region is formed by using a normalization process.

[57] **ABSTRACT**

A primary mirror and a secondary mirror are arranged on a lens to form an eccentric radiation path through the mirror objective. The optical axis of the mirror objective follows an N-shaped path through the objective and central diaphragming is avoided. The object and consequently the image are situated outside the geometrical axis of the mirror objective, which shows a short distance between the object and the image. In an optical arrangement comprising two such mirror objectives, one is used for illuminating and the other is used for imaging.

MIRROR OBJECTIVE AND OPTICAL ARRANGEMENT COMPRISING TWO MIRROR OBJECTIVES

BACKGROUND OF THE INVENTION

The invention relates to a monolithic mirror objective comprising a lens having a primary mirror on the output surface of the lens and a secondary mirror on the input surface of the lens to form an N-shaped radiation path through the mirror objective. In this case all of the N-shaped radiation path is within the lens and possible further lenses. The invention also relates to an optical arrangement comprising two such mirror objectives.

All standard mirror objectives consist of a primary mirror and a secondary mirror, which may be disposed in connection to one or a number of combined lenses. U.S. Pat. No. 2,378,301 shows such a mirror objective in the form of a camera objective. In a mirror objective of the prior art, the primary mirror images the object in its focal plane, the rays are caught by the secondary mirror and the rays are reflected through an aperture in the primary mirror and into the image plane of the camera of the field glass. The optical axis of the mirror objective coincides with the geometrical axis of the objective which passes through the central part of the objective. The aperture in the primary mirror causes a central obscuration on the entrance pupil of the objective (diaphragming in the centre), that is to say, light cones emanating from each object point become hollowed. In order to reach a given desired strength of light, the outer rays of the cone must be given a large angle with respect to the geometrical axis of the mirror objective. Furthermore, if it is desired to adapt the mirror objective to a small magnification, the diameter of the secondary mirror increases and hence the angle of outer rays increases further. When transferring symbols from a material of, for example, paper to a detector, such an objective is unusable because a depth movement of the material which may be very small results in an unacceptable defocus.

SUMMARY OF THE INVENTION

It is an object of the invention to use the advantages of mirror optics over lens optics, namely to obtain the same image quality and short length of the construction by using fewer elements whilst avoiding the great disadvantage of the mirror objective, namely the central diaphraming. This is obtained by putting the object and consequently the image outside the geometrical axis of the mirror objective. The optical axis is reflected between the mirrors as an N and there is no need for an aperture in the primary mirror. The imaged radiation beam assumes the same appearance as with a lens objective and the depth of focus will only be dependent on the entrance pupil and the object distance.

According to the invention the first mirror is arranged to cover the central part of the output surface, while the second mirror is arranged to cover a part of the input surface which is displaced aside relative to the center of the input surface, so that the first mirror and the second mirror together with the lens and possible further lenses can follow an eccentric, N-shaped path through the objective, the object and the image situated on each side of the geometrical axis of the mirror objective.

The mirror objective according to the invention is suitable for reading bar symbols, letters and digits having one detector line (array) and for reading optical discs and similar storage media. Until now a microobjective or a miniaturized photo objective have been used in connection with the examples of application. These objectives, however, have inconvenient dimensions. For example, in order to transfer a letter having a size of 10 mm to a detector having a size of 5 mm an astigmate having four lenses is needed and an overall length from the object to the detector of 40 to 60 mm. This length may be compared with the overall length of at least 20 mm in connection with the mirror objective according to the invention.

In its simplest form the mirror objective consists of two reflecting surfaces applied to a lens. In order to improve the image sharpness and adapt the mirror objective to different magnifications (the ratio of the object and the image dimensions), however, further lenses may be disposed which are preferably glued together with the lens. According to an advantageous embodiment of the mirror objective a further lens is disposed adjacent to the lens, one of the reflecting surfaces being enclosed between the two lenses.

According to another advantageous embodmient a collimator lens is disposed near the object. The collimator lens ensures that radiation beams which are mutually parallel are chosen for imaging. If the variations of the object distance are small, the image dimension by means of this arrangement remains unchanged. The mirror objective according to this embodiment is characterized in that a collimator lens is disposed near the object plane of the mirror objective.

The invention also relates to an arrangement comprising two mirror objectives according to the invention. One of the objectives is used for illuminating, while the other is used for reading. Normally the illuminating is carried out by means of a miniature lamp or a so called vertical illuminator. In the first case a large field is illuminated but only a narrow strip is used for reading. In the other case the light is reflected in an inclined transparent mirror, passes the objective and illuminates the object, the object being imaged by the objective by means of the mirror on the detector. Both of these illuminating systems require a lot of light and a great deal is lost and may also give rise to disturbing reflections. The eccentric radiation path causes the object to be situated at the periphery of the optics. Accordingly, two identical mirror objectives may be situated adjacent to one another and one of them may be used for projecting a light source on the object, which light source is shaped in accordance with the object, for example, a straight incandescent filament, if a line or a band on the object is to be read. The radiation paths for illuminating and reading are totally separated in this case, whilst no reflections occur and only the field to be read is illuminated.

The optical arrangement consisting of two mirror objectives is characterized in that the two mirror objectives are arranged with two parallel geometrical axes and adjacent to each other, and in that one of the mirror objectives is used for illuminating an object, while the other mirror objective is used for imaging the object in question.

BRIEF DESCRIPTION OF THE DRAWING

FIG. 1 shows a simple embodiment of a mirror objective,

FIG. 2 shows a second embodiment of a mirror objective according to the invention comprising one further lens,

FIG. 3 shows a third embodiment of the mirror objective according to the invention,

FIG. 4 shows a fourth embodiment of the mirror objective according to the invention comprising a collimator lens, and

FIG. 5*a* is a side view an optical arrangement comprising two mirror objectives;

FIG. 5*b* is a top view of the arrangement show in FIG. 5*a*.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENT

The mirror objective of FIG. 1 consists of a plano-convex lens 1 provided with a primary mirror 2 and a secondary mirror 3. The object 5 is imaged by means of a radiation beam 6 on the detector or the detector line 7. In the Figure only the radiation path of the central ray is indicated. An input slot 10 is disposed between the object 5 and the lens 1 and an output slot 11 is disposed between the lens body 1 and the detector line 7. The mirror objective according to FIG. 1 is suitable for a magnification of 0.5. The magnification is not limited to this value, but it may assume other values, preferably by changing the refractive index. The lenses mentioned above and below are preferably of synthetic resin or glass material.

In the following description with reference to FIGS. 2–4 corresponding elements have been given the same reference numerals as in FIG. 1.

In addition to the lens 1, which in this case is convex, the embodiment shown in FIG. 2 comprises a further lens 4. These two lenses 1, 4 are disposed in such a way that the secondary mirror 3 is enclosed by the adjacent surfaces of the lenses. The second surface of the lens 4 facing the input slot 10 has a spherical shape permitting the radiation beam 6 to hit the last-mentioned surface at an essentially right angle.

FIG. 3 shows an embodiment in which the lens 1 is convex-concave and a further lens 4 is arranged to enclose the secondary mirror 3 together with the convex surface of the lens 1. As in FIG. 1, only the radiation path of the central ray is indicated.

FIG. 4 shows a mirror objective according to FIG. 2 which is provided with a collimator lens 14 close to the object. The collimator lens shows that radiation beams being mutually parallel are selected for the imaging.

An optical arrangement consisting of two mirror objectives of the above described kind is shown in FIGS. 5*a* and 5*b*. The two mirror objectives, the bodies, are disposed adjacent to each other and one of them (on the left) is used for illuminating an object 5, while the other one (on the right) is used for imaging the object 5 in question. The illuminating body as well as the imaging body each consist of a convex lens 1 and a further lens 4 which together enclose a secondary mirror 3, and a primary mirror 2 arranged in connection to the convex lens 1. Furthermore the bodies are provided with input and output slots 10, 11. The reference numeral 8 denotes a light body whose light is projected onto the object 5 and is then imaged on the detector line 9. As is shown in FIG. 5*b* the aperture of the primary mirror 2 in the illuminating body, the mirror objective on the left, may be larger than the primary mirror 2 in the imaging body, the mirror objective on the right. In the embodiment according to FIG. 5, the adjacent surfaces of the illuminating body and the imaging body consist of flat surfaces 12, 13. However, as in the case of the optical mirror systems described with reference to FIGS. 1–4, the bodies may be circular cylindrical. The object 5 is disposed in alignment with the flat surfaces 12, 13 in the embodiment shown.

What is claimed is:

1. An optical arrangement having a mirror objective for imaging a planar object onto an image plane, comprising

a lens having an input surface toward the object, an output surface toward the image plane, and a geometric axis extending between said surfaces,

a primary mirror arranged on the output surface and centrally located on the geometric axis,

a secondary mirror on the input surface and displaced from the geometric axis so that the first and second mirrors together with the lens establish an eccentric N-shaped radiation path, the object and the image being situated on opposite sides of the geometric axis.

2. An optical arrangement as claimed in claim 1, characterized in that an input slot is disposed in front of the input surface and an output slot is disposed after the output surface in order to together with the shaping of the mirrors delimit the radiation beam passing through the mirror objective.

3. An optical arrangement as claimed in claim 1, characterized in that a further lens is disposed adjacent to said lens, one of the reflecting surfaces being enclosed between the two lenses.

4. An optical arrangement as claimed in claim 1, characterized in that a collimator lens is disposed near the object plane of the mirror objective.

5. An optical arrangement as claimed in cliam 1, having the further including a second mirror objective said two mirror objectives arranged with parallel geometrical axes and adjacent to each other, and in that one of the mirror objectives is used for illuminating the object while the other mirror objective is used for imaging the object.

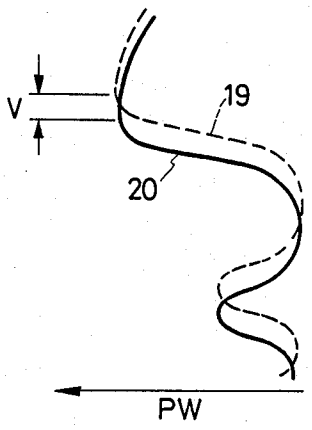

FIG. 11

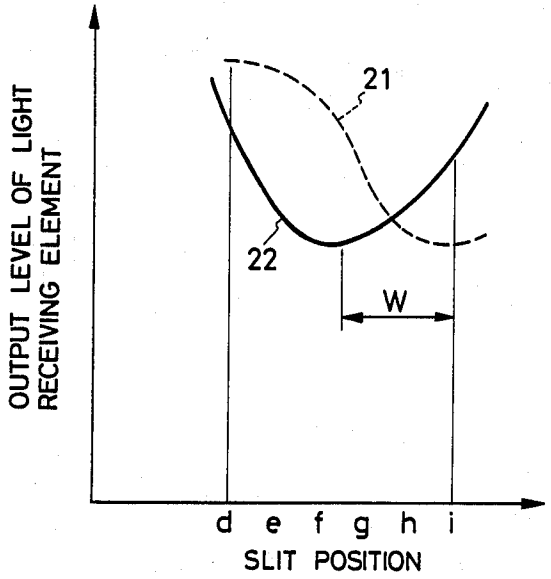

APPARATUS FOR DETECTING THE FOCUS ADJUSTED STATE OF AN OBJECTIVE LENS

BACKGROUND OF THE INVENTION

Field of the Invention

This invention relates to a focus detecting apparatus, and in particular to a focus detecting apparatus suitable for a photographic camera, a video camera or the like in which distance measurement can be accomplished at any position of an object.

Focus detecting apparatuses of various types have heretofore been proposed, and in principle, in any of them, distance measurement has been effected at the center of the picture plane of the finder field, i.e., on the optic axis of the objective lens, irrespective of the size of the distance measuring area. Therefore, there has been no problem when the main portion of an object to which the objective lens is to be focused is set at the center of the picture plane. However, when it is desired to set the main portion of the object at a position other than the center of the picture plane, it has been necessary to turn the camera so that the main portion of the object lies at the center of the picture plane and focus the objective lens, and then return the object to a desired position on the picture plane and re-set the picture plane. So, if a focus detecting apparatus which enables the distance measuring field to be moved is constructed, the above-noted problem will be solved, but in such case, the range in which distance measurement is possible, i.e., the length of the distance measuring field, must naturally be made great.

For example, when a light flux passed through the photo-taking lens is utilized and a light-receiving element for focus detection is fixed and focus detection is to be effected within this length of the distance measuring field, it is necessary to form the object image on the light-receiving element even if the imaged point of the object image moves. This has led to the problem that the light-receiving surface of the light-receiving element must have a wide area.

On the other hand, U.S. Pat. No. 3,553,455 shows an apparatus in which two images of an object (which have a parallax) are scanned by a slit. In addition, an apparatus in which two images formed by a light flux passed through an objective lens are scanned by a slit is known from Japanese Patent Publication No. 37957/1971. However, any of these apparatuses is such that the center of the distance measuring field coincides with the optic axis of the objective lens. That is, distance measurement is effected in the central region of the picture plane of the viewfinder.

Also, German Patent No. 2156617 discloses a technique in which the image is scanned, but distance measurement is effected at the center of the picture plane. As other focus detecting apparatuses, there are known U.S. Pat. Nos. 4,636,627, 4,634,255, 4,634,557, 4,670,645, 4,632,532 and 4,560,863.

SUMMARY OF THE INVENTION

It is an object of the present invention to enable the focus detection of an objective lens to be accomplished for an object at a desired position in the field of view.

It is another object of the present invention to enable a desired one of a plurality of detecting methods to be selected.

BRIEF DESCRIPTION OF THE DRAWINGS

FIGS. **1A** and **1B** and FIGS. **3** to **11** illustrate various elements in an embodiment of the present invention.

FIG. **1A** is a perspective view of the optical system of a focus detecting apparatus.

FIG. **1B** illustrates the divided condition of the exit pupil of an objective lens.

FIG. **2** illustrates the effective light fluxes when a focus detecting system according to the prior art is used with the focus detecting system of the present invention.

FIG. **3** illustrates the effective light fluxes of the focus detecting system.

FIG. **4** illustrates the exit pupil position of a popular interchangeable objective lens for a single-lens reflex camera.

FIG. **5** illustrates the effective light fluxes when the position of the stop of the focus detecting system is changed.

FIG. **6** illustrates the optical path when the distance measuring field of the focus detecting system is on the optic axis.

FIG. **7** illustrates the optical path when the distance measuring field of the focus detecting system is off the optic axis.

FIGS. **8** and **9** illustrate the image positions by defocus in the focus detecting system, FIG. **8** showing a case where the distance measuring field is on the optic axis, and FIG. **9** showing a case where the distance measuring field is off the optic axis.

FIGS. **10A** and **10B** illustrate the relative positional relation between two object images and slits.

FIG. **11** illustrates the relation between the slits and the output values from two light-receiving elements.

DESCRIPTION OF THE PREFFERRED EMBODIMENT

FIG. **1** is a perspective view of an embodiment of a focus detecting apparatus according to the present invention. In FIG. **1**, there is shown a first focus detecting system according to the present invention and also an auxiliary second focus detecting system. In the figure, the reference numeral **1** designates an objective lens for forming an object image, and X denotes the optic axis thereof. The first and second focus detecting systems are provided rearwardly of the predetermined imaging plane of the objective lens **1**. The predetermined imaging plane may be either a primary imaging plane or a re-imaging plane relaying it. The reference numeral **2** designates a slit member having, for example, a rectangular opening portion **2***b* and a grating portion having a plurality of slits **2***a* and movable in the scanning direction of arrow C. The slit member **2** is positioned substantially on the predetermined imaging plane of the objective lens **1**. A rack **4***a* is secured to the slit member **2** and is driven by a motor **6** through a pinion gear **4***b* and a gear box **5**. The reference numeral **7** denotes a control circuit for reciprocally moving the member **2** so that the slits **2***a* scan the image and setting the member **2** so that the rectangular opening **2***b* is positioned on the optic axis of the objective lens. The reference numeral **3** designates a field mask having, for example, a rectangular aperture **3***a* and movable in the directions of arrows A and B.

The rectangular aperture **3***a* of the field mask **3** is designed such that the length thereof in the direction of arrangement of the slits **2***a* of the slit member **2** is about

an integer times the length of one pitch of the slits, said integer including 1.

The reference numeral 8 denotes a field lens disposed near the predetermined imaging plane, the reference numerals 12 and 13 designate the stops of the first focus detecting system, the reference numeral 9 denotes the stop of the second focus detecting system, and the reference numerals 14 and 15 designate light-receiving elements constituting first light-receiving means. The light-receiving elements 14 and 15 are arranged in the scanning direction with the optic axis X interposed therebetween. The reference numeral 17 denotes second light-receiving means, i.e., a light-receiving device, having two light-receiving element arrays 17*a* and 17*b*. Instead of two light-receiving element arrays, two ranges of a single element array may be electrically designated. The reference numeral 16 designates a secondary imaging lens having convex lenses behind stop openings 9*a* and 9*b*, respectively. The reference numerals 10 and 11 denote reflecting members for bending the optical path to make the apparatus compact.

The reference numeral 18 designates a calculating circuit using the output signals from the light-receiving elements 14 and 15 and the output signal of the light-receiving device 17 to calculate information indicative of the focus adjusted state of the objective lens.

The reference numeral 100 denotes a transparent finder field member, the reference numeral 101 designates the finder field, the reference numeral 102 denotes a frame for indicating the range of distance measurement in the finder field, and the reference numeral 103 designates a distance measuring position selecting lever which can be moved by the operator from the outside of a casing, not shown. The reference numeral 104 denotes a connecting member for connection with the field mask 3, and the reference numeral 105 designates an eyepiece. A viewfinder optical system for directing a light flux from the view field to the finder field is not shown.

The finder field member 100 may be moved through the connecting member 104 in response to the movement of the field mask 3 so as to display the range of distance measurement in the finder field.

Instead of the field mask 3 being moved, a plurality of ranges of distance measurement may be set on a liquid crystal display plate and one of these ranges may be selectively made transparent and the surroundings thereof may be made opaque, whereby the distance measuring field may be designated.

The first focus detecting system according to the present invention will now be described. The first focus detecting system is for effecting the distance measument at any position in the finder field, and functions when the aperture 3*a* of the field mask 3 is set at any position in the effective aperture of the field lens, particularly, a position off the optic axis, and the aperture 3*a* overlaps the slits 2*a* of the slit member 2. The constituent members of the first focus detecting system disposed subsequently to the field mask 3 are the field lens 8 common to the second focus detecting system, the reflecting members 10 and 11 disposed outside the openings 9*a* and 9*b* of the second stop 9 and each having a trigonal inclined surface as a reflecting surface, the stop 12 for limiting the light flux reflected by the reflecting member 10, the stop 13 for limiting the light flux reflected by the reflecting member 11, and the light-receiving elements 14 and 15.

In the first focus detecting system, as will be described later, the slit member 2 is scanned in the direction of arrow C and at this time, correspondingly to said scanning, the phases of the variations in the output signals from the light-receiving elements 14 and 15 are detected to thereby accomplish focus detection.

FIG. 1B illustrates the divided condition of the exit pupil of the objective lens 1 in the present invention. In the figure, the reference character 1*a* designates the exit pupil of the objective lens 1, the reference characters 12*a*′ and 13*a*′ denote the inversely projected images of the stop openings 12*a* and 13*a*, respectively, of the stops 12 and 13 onto the surface of the exit pupil 1*a* by the field lens 8, and the reference characters 9*a*′ and 9*b*′ designate the inversely projected images of the stop openings 9*a* and 9*b*, respectively, of the stop 9 onto the surface of the exit pupil 1*a* by the field lens 8.

In the present embodiment, the exit pupil 1*a* of the objective lens 1 is divided into two pairs of areas as previously described by disposing the stop openings 12*a* and 13*a* of the stops 12 and 13 in more spaced apart relationship with the optic axis than the stop openings 9*a* and 9*b* of the stop 9.

The second focus detecting system will now be described. The second focus detecting system functions only when the rectangular opening 2*b* of the slit member 2 and the aperture 3*a* of the field mask 3 are both set on the optic axis of the objective lens 1. At this time, the light flux of the second focus detecting system is limited by the aperture 3*a* of the field mask 3 because the rectangular aperture 3*a* of the field mask 3 is made smaller than the opening 2*b* of the slit member 2.

The constituent members of the second focus detecting system disposed subsequently to the field mask 3 are the field lens 8, the stop 9 having two openings 9*a* and 9*b*, the secondary imaging lens 16 and the second light-receiving means 17 having two light-receiving element arrays 17*a* and 17*b*.

The second focus detecting system is particularly suitable for effecting focus detection highly accurately when the defocus amount of the objective lens 1 is great. The focus detection of the second focus detecting system is accomplished by the already known method proposed, for example, in Japanese Laid-Open patent application No. 101513/1985.

In the present embodiment, the first focus detecting system and the second focus detecting system share the field lens 8.

In many objective lenses used in photographic cameras, video cameras, etc., when the focal length is short and the lens is bright, the exit pupil position from the imaging plane is generally short, and when the focal length is long and the lens is dark, the exit pupil position from the imaging plane is long. Therefore, the first stop openings 12*a* and 13*a* in the first focus detecting system chiefly directed to bright objective lenses and having a variable distance measuring field are set so as to lie more outwardly relative to the optic axis than the second stop openings 9*a* and 9*b* in the second focus detecting system having a fixed distance measuring field, thereby achieving effective utilization of a light beam.

Also, the distance from the principal point of the image space of the field lens 8 to the first stop openings 12*a*, 13*a* is set so as to be longer than the distance from the pincipal point of the image space of the field lens 8 to the second stop openings 9*a*, 9*b*.

Thus, the inversely projected images of the first and second stop openings onto the objective lens side by the

field lens **8** may be formed near the exit pupil position of the objective lens, and even if an objective lens of any focal length is mounted, effective utilization of the light flux can be ensured and improved accuracy of focus detection is achieved.

That is, the first stop openings **12***a* and **13***a* are such that the inversely projected images thereof are formed at positions near the predetermined imaging plane of the objective lens **1**, and the second stop openings **9***a* and **9***b* are such that the inversely projected images thereof are formed at positions far from said predetermined imaging plane.

A description will now be given of effective light fluxes entering the light-receiving means in the first and second focus detecting systems. FIGS. **2** to **5** are optical path diagrams showing the light fluxes from the exit pupil of the objective lens **1** which enter the stops **9**, **12** and **13** disposed in the front faces of the light-receiving means in the respective focus detecting systems. FIG. **2** shows the case of the second focus detecting system, and FIG. **3** shows the case of the first focus detecting system.

In these figures, P1 and P2 designate the positions of the light rays passing through the centers of the openings **12***a* and **13***a* of the stops **12** and **13** in the exit pupil of the objective lens **1**. F.P denotes the predetermined imaging plane of the objective lens **1**, and the objective lens is positioned at the left side thereof and the first and second focus detecting systems are positioned at the right side thereof.

In the present embodiment, it is to be understood that the object image is formed near the predetermined imaging plane. The stops **9**, **12** and **13** are designed so as to be conjugate with the vicinity of the exit pupil position of the objective lens **1** with respect to the field lens **8**.

In FIG. **2**, a surface D designates a surface conjugate with the stop **1**, and in FIG. **3**, a surface E denotes a surface conjugate with the stops **12** and **13**.

In the present embodiment, the surface D is positioned more distantly from the predetermined imaging plane F.P than the surface E by setting the first stop openings **12***a*, **13***a* and the second stop openings **9***a*, **9***b* as previously described. J represents the length of the distance measuring field of the second focus detecting system, and K represents the length of the distance measuring field of the first focus detecting system. In FIGS. **2** and **3**, the portions indicated by hatching represent the effective light fluxes in the respective focus detecting systems. Generally, in order that focus detection maybe accurately accomplished in the first and second focus detecting systems when the phase difference between two images is detected to thereby effect focus detection, it is necessary that the exit pupil of the objective lens **1** have a width including the range of the effective light fluxes represented by hatching in FIGS. **2** and **3**. Therefore, the length K of the distance measuring field of the first focus detecting system in FIG. **3** means the total range over which the opening **3***a* of the field mask **3** is movable, and is relatively great as compared with that of the second focus detecting system. Thus, in the first focus detecting system, it becomes necessary to use an objective lens of small F-number which is relatively bright, that is, has a large exit pupil.

FIG. **4** shows, for information, the exit pupil position of an objective lens for a single-lens reflex camera such as a popular photographic camera and the size thereof.

In the figure, F.P indicates the predetermined imaging plane of the objective lens, the horizontal axis represents the optic axis, the scale indicates the distance from the predetermined imaging plane, and the vertical axis represents the size of the exit pupil. Ranges L, M and N represent areas in which the exit pupil of the objective lens in present. Depicting the effective light fluxes of the first and second focus detecting systems shown in FIGS. **3** and **2** while superposing them upon these areas, the effective light fluxes are present inside a straight line **0** in the second focus detecting system, and the effective light fluxes are present inside a straight line P in the first focus detecting system. That is, the second focus detecting system permits the use of an objective lens of the total range of the areas L, M and N, among objective lenses having an exit pupil within the range shown in FIG. **4**, and the first focus detecting system permits the use of a photo-taking lens having an exit pupil in the areas M and N in FIG. **4**.

In FIG. **4**, broken line Q indicates the effective light flux in a case where the position when the stop in the first focus detecting system has been projected onto the exit pupil of the objective lens is indentical to the projection position when the stop in the second focus detecting system has been projected onto the exit pupil of the objective lens. In this case, if use is made of an objective lens having an exit pupil position in the area N, the light flux is eclipsed and thus, the accuracy of distance measurement is reduced.

FIG. **5** shows the optical path of the then effective light flux. In this figure, the distance from the surface D conjugate with the stops **12** and **13** near the exit pupil position of the objective lens to the predetermined imaging plane F.P is shown as a distance G identical to that in the second focus detecting system shown in FIG. **2**.

FIGS. **6** to **11** illustrate the principle of distance measurement of the first focus detecting system of the present invention. Of these figures, FIGS. **6** and **7** are developed cross-sectional views of the first focus detecting system when the objective lens **1** is in the in-focus state. FIG. **6** depicts the principal ray passing through the center of the opening **3** *a* in the field mask **3** in a case where the opening **3***a* in the field mask **3***a* is positioned on the optic axis. FIG. **7** depicts the principal ray in a case where the opening **3***a* in the field mask **3** is positioned off the optic axis. In these figures, P1 and P2 are similar to those in the optical path diagram shown in FIG. **3**, that is, the projection positions of the light rays passing through the centers of the openings **12***a* and **13***a* of the stop on the exit pupil of the objective lens.

That is, P1 and P2 indicate the positions of the center of light intensity when the openings **12***a* and **13***a* of the stop have been projected onto the exit pupil. The surfaces of the stops **12** and **13** and the surface containing the points P1 and P2 are at positions conjugate with each other with respect to the field lens **8** and therefore, irrespective of the position of the opening **3***a* in the field mask **3**, the light rays from the points P1 and P2 arrive at the light-receiving elements **14** and **15**, respectively. Accordingly, even if the position of the opening **3***a* in the field mask **3** is set anywhere in the range of the length K of the distance measuring field shown in FIG. **3**, that is, even if distance measurement is effected anywhere with the opening **3***a* moved, the light flux from the object image enters the light-receiving elements **14** and **15** and therefore, distance measurement can be accomplished with the locations of the light-receiving elements fixed.

FIGS. 8 and 9 are developed cross-sectional views of the focus detecting system when the objective lens 1 is defocused by a predetermined amount DF. FIG. 8 is an illustration depicting the principal ray passing through the imaging point R on the optic axis, and FIG. 9 is an illustration depicting the principal ray passing through the imaging point S off the optic axis. The focus detecting system for detecting the phase difference between two images to thereby detect the in-focus state calculates the defocus amount from the spacing between the centers of light intensity of two object images on the predetermined imaging plane F.P. Therefore, it is necessary that irrespective of the position of the opening 3*a* in the field mask 3, the spacing between the centers of light intensity of two object images (for example, in FIG. 8, $\overline{T1, T2}$) be constant for a predetermined defocus amount. The relation between the then defocus amount DF and the spacing $\overline{T1, T2}$ will now be described with reference to FIGS. 8 and 9.

In FIG. 8,

$\angle P2, R, P1 = \angle T2, R, T1$ and $\angle R, P2, P1 = \angle R, T2, T1$.

Accordingly, $\Delta P2, p1, R \infty \Delta T2, T1, R$ and when the distance from the exit pupil of the objective lens 1 to the predetermined imaging plane F.P is I, the following equation is established:

$$\overline{T1, T2} = \frac{DF}{I - DF} \overline{P1, P2} \quad (1)$$

Likewise, in FIG. 9,

$\angle P2, S, P1 = \angle U2, S, U1$ and $\angle S, P2, P1 = \angle S, U2, U1$.

Accordingly, $\Delta P2, P1, S \infty \Delta U2, U1, S$ and the following equation is established:

$$\overline{U1, U2} = \frac{DF}{I - DF} \overline{P1, P2} \quad (2)$$

From equations (1) and (2),

$$\overline{T1, T2} = \overline{U1, U2}.$$

That is, when the defocus amount DF is constant, the spacing between the centers of light intensity of two images does not vary for any of the imaging points R and S. Accordingly, even if the opening 3*a* in the field mask 3 is moved to any position in the distance measuring field, the defocus amount can be found with good accuracy. That is, in the present embodiment, the opening 3*a* in the field mask 3 may be located anywhere, and it is not necessary to use a different focus detecting system depending on the difference in the distance measuring field, and stable focus detection can be accomplished by only the first focus detecting system.

FIGS. 10A, 10B and 11 illustrate output signals obtained from the light-receiving elements 14 and 15 which have received the light flux passing through the slits 2*a* of the slit member 2 and the opening 3*a* in the field mask 3 when the slit member 2 is scanned. The basic principle of the detecting method shown in these figures in the heretofore practised method of detecting the amount of deviation between two images.

In the present embodiment, the length of the opening 3*a* the field mask 3 in the direction of arrangement of the slits 2*a* is constructed in such rectangular shape which is, for example, about four times the length of a slit 2*a* (the sum of the area transmitting the light beam therethrough and the area not transmitting the light beam therethrough), whereby the output signals from the light-receiving elements 14 and 15 when the slit member 2 is moved are obtained in a stable state.

In FIG. 10A, d, e, f, g, h and i indicate the moved positions of the slits 2*a* , and in FIG. 10B, there are schematically shown the distributions of quantity of light of two object images 19 and 20 in the opening 3*a*. In FIG. 10B, the reference numerals 19 and 20 indicate the illumination distributions of the object images on the predetermined imaging plane F.P of the objective lens formed by the light fluxes passing through the openings 12*a* and 13*a*, respectively, of the stops 12 and 13.

In FIG. 10B, the horizontal axis represents illumination PW and the vertical axis represents the position on the predetermined imaging plane. The object images 19 and 20 having such illumination distributions are sampled by the slits 2*a* of the slit member 2 disposed substantially on the predetermined imaging plane and the opening 3*a* in the field mask 3, and enter the light-receiving elements 14 and 15, respectively. As shown in FIG. 1, the slit member 2 is moved in the direction of arrow C by the motor 7, and the then positional relations thereof with the object images are as indicated by d to i in FIGS. 10A and 10B. The width of the opening 3*a* in the field mask 3 is designed so as to be an integer times (in FIG. 10A, four times) the slit pitch and therefore, in any of the positions d to i, the area of the light-transmitting area formed by the opening 3*a* in the field mask 3 and the slits 2*a* is kept constant. Accordingly, the outputs from the respective light-receiving elements 14 and 15 conforming to the positions d to i of the slits vary with a phase difference corresponding to the amount of deviation between the two object images. In the case of the object images having the illumination distributions shown in FIG. 10B, the outputs from the light-receiving elements 14 and 15 conforming to the positions d to i of the slits are as indicated by curves 21 and 22 in FIG. 11. In FIG. 11, the horizontal axis represents the position of the slits 2*a* and the vertical axis represents the output values from the light-receiving elements 14 and 15. The curve 21 indicated by broken line corresponds to the illumination distribution 19 of the object image in FIG. 10B, and the curve 22 indicated by solid line corresponds to the illumination distribution 20 of the object image in FIG. 10B. Also, the amount of deviation V between the object images in FIG. 10B is equal to the phase difference W between the output distributions 21 and 22 from the light-receiving elements 14 and 15 in FIG. 11.

The calculation of the defocus amount of the objective lens 1 can be accomplished in the following manner. When the defocus amount is *DF*, $\overline{T1, T2} = V$ in FIG. 8 and there is the relation that $V: \overline{P1, P2} = DF:(I - DF)$. Accordingly, the following equation is derived:

$$DF = \frac{VI}{P1, P2 + V} \quad (3)$$

Accordingly, the defocus amount DF can be found from equation (3).

As a method of detecting the amount of image deviation in the present embodiment, the outputs from the light-receiving elements 14 and 15 corresponding to the position of the slit member 2 may be dealt with instead of the outputs from the light-receiving elements 17*a* and 17*b* of the second focus detecting system, and according

to this, the first focus detecting system and the second focus detecting system can utilize a single method of detecting and calculating the amount of image deviation.

As described above, in the present embodiment, the focus detection at any position in the finder field is possible by the first focus detecting system. Alternatively, by using the first and second focus detecting systems together, the design may be made such that for example, in the second focus detecting system, detection of great defocus of the order of 30 mm is effected chiefly on the optic axis and in the first focus detecting system, movement of the distance measuring field is effected. From these features of the respective focus detecting systems, for example, the following application is conceivable. Where this focus detecting apparatus is applied to a single-lens reflex camera or the like, the second focus detecting system is used to focus the photo-taking lens to a main object at the center of the picture plane, and then the main object is framed to any position on the picture plane, whereafter the main object is pursued by the first focus detecting system to thereby accomplish photographing.

According to the present invention, there can be achieved a focus detecting apparatus which can move the distance measuring field to any position to accomplish focus detection by a very simple construction in which the slit member having a plurality of slits is scanned and the opening in the field mask is made movable to any position in the finder field and the light beam passed through the slits and the opening is received by two light-receiving elements through a stop.

Also, according to the present invention, there can be achieved a focus detecting apparatus which uses the two first and second focus detecting systems set as previously described, whereby for example, in the first focus detecting system, focus detection of small defocus is possible in any distance measuring field and in the second focus detecting system, focus detection of great defocus is possible in a predetermined distance measuring field on the optic axis.

Particularly, there can be achieved a focus detecting apparatus in which the exit pupil of the objective lens is divided into four areas forming two pairs and used as previously described, whereby in the second focus detecting system, focus detection of great defocus in a predetermined field in a dark objective lens of great F-number to a bright objective lens of small F-number is accomplished and in the first focus detecting system, focus detection of small defocus of a variable distance measuring field chiefly in a bright objective lens of small F-number is accomplished.

Further, there can be achieved a focus detecting apparatus of simple construction in which some optical members of the first and second focus detecting systems are made common, whereby bulkiness of the entire apparatus is effectively prevented in spite of the two focus detecting systems being used.

I claim:

1. An apparatus for detecting the focus adjusted state of an objective lens, comprising:

scanning means having optical slits and disposed on or near a predetermined imaging plane of said objective lens for scanning the image of an object in a predetermined scanning direction;

aperture setting means disposed on or near said predetermined imaging plane for (1) providing an aperture which determines a range for detection, (2) moving the aperture to a desired position in the field of view, and (3) masking a light beam from entering portions other than the aperture;

a plurality of light-receiving device for receiving light fluxes passed through said optical slits and said aperture, and for outputting a signal regarding the focus adjusted state of said objective lens; and

means for relating the light fluxes entering said light-receiving devices with each other so that they pass through different areas of the exit pupil of said objective lens.

2. An apparatus according to claim **1**, wherein the length of said aperture is substantially an integer times the pitch of the optical slits arranged in the scanning direction.

3. An apparatus according to claim **1**, wherein said means for relating has a field lens.

4. An apparatus according to claim **1**, wherein said scanning means has an opaque plate having slits arranged in the scanning direction, and drive means for reciprocally moving said opaque plate.

5. An apparatus according to claim **1**, wherein said aperture setting means has a mask provided with said aperture, and displacing means for displacing said mask in a direction perpendicular to the optic axis of said objective lens.

6. An apparatus according to claim **1**, wherein said light-receiving devices are disposed with the optic axis of said objective lens interposed therebetween.

7. An apparatus according to claim **6**, wherein each of said light-receiving devices is a single light-receiving element.

8. An apparatus according to claim **1**, further comprising with a viewfinder, display means for displaying said range for detection in the field of said viewfinder, and changing means for changing the position of the display by said display means in conformity with the movement of the position of said aperture.

9. An apparatus for detecting the focus adjusted state of an objective lens, comprising:

a first focus detecting system, including first and second photodetector means, for receiving light fluxes passed through first and second areas of the exit pupil of said objective lens onto said first and second photodetector means, and for forming a signal regarding the focus adjusted state of said objective lens, said first focus detecting system being capable of changing a detection range;

a second focus detecting system, including third and fourth photodetector means, for receiving light fluxes passed through third and fourth areas of the exit pupil of said objective lens onto said third and fourth photodetector means, and for forming a signal regarding the focus adjusted state of said objective lens, said second focus detecting system having a fixed detection range;

optical means for relating the light flux entering said first photodetector means and passed through said first area, the light flux entering said second photodetector means and passed through said second area, the light flux entering said third photodetector means and passed through said third area, and the light flux entering said fourth photodetector means and passed through said fourth area; and

means for causing said first focus detecting system and said second focus detecting system to function alternatively.

10. An apparatus according to claim 9, wherein said optical means comprises a field lens disposed on or near the predetermined imaging plane of said objective lens.

11. An apparatus according to claim 9, wherein said means for causing said first and second focus detecting systems to function alternatively has a mask provided with a grating structure for scanning the light fluxes entering said first and second photodetector means and an aperture for regulating the light fluxes entering said third and fourth photodetector means.

12. An apparatus according to claim 9, wherein said first and second areas are set more inside than said third and fourth areas.

13. An apparatus according to claim 9, wherein said first and second photodetector means comprise photosensors, and said third and fourth photodetector means comprise arrays of photosensors.

14. An apparatus according to claim 10, wherein said first focus detecting system has first and second stops for regulating the light fluxes entering said first and second photodetector means, said second focus detecting system has third and fourth stops for regulating the light fluxes entering said third and fourth photodetector means, and the distance from the image field side principal point of said field lens to said first and second stops is longer than the distance from the image field side principal point of said field lens to said third and fourth stops.

[57] **ABSTRACT**

Two movable groups of lenses forming a variator are controlled by means of a computer and these groups are accordingly subjected not only to the necessary displacements of each group for the progressive variations of focal length but also to a complementary longitudinal displacement for applying to the objective-lens system a focal-length multiplier coefficient having a value chosen by the operator. The device in accordance with the invention comprises a control system associated with a computer and capable of subjecting the two movable groups of lenses to a complementary longitudinal displacement in order to apply a focal length multiplier coefficient to the objective-lens system, another function of the computer being to produce the desired variation of the iris and the complementary displacements of the focusing groups in respect of each focal length. The longest possible focal length can thus be chosen as a function either of the selected numerical aperture or of the field to be covered.

VARIABLE-FOCUS OBJECTIVE-LENS DEVICE AND A METHOD FOR THE CONTROL OF SAID DEVICE

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to variablefocus objective lenses which are more particularly intended to be employed in television studios.

2. Description of the Prior Art

Devices of this type are made up of several groups of lens elements, the displacements of which make it possible to obtain a variation of field at the same time as a still picture on the receiver irrespective of the focusing distance chosen. As a general rule, the function of variation of focal lengths is performed by two movable groups of lenses constituting a so-called "variator" whilst the other groups undergo suitable displacements in order to adjust focusing under the best possible conditions of picture quality up to minimal distances, that is, practically against the front element. In order to obtain the still picture, the laws of displacements of the movable groups are computed and applied in real time as a function of the desired focal length and distance.

In the majority of objective-lens systems employed in television studios, a system is provided in addition for carrying out multiplication of the basic focal length. This system consists of a rotary lens turret placed behind the iris and adapted to carry a number of quasi-afocal lens elements, each of which may thus be put into service in order to obtain a different multiplier coefficient.

This makes it possible to obtain a constant variation ratio and to choose the basic focal length as a function of the field angles which can be employed. However, since the maximum available f-number is proportional to the basic focal length, this must be taken into account in the choice of the multiplier. In fact, by choosing a situation which is conducive to long focal lengths, it may happen that the lens aperture is stopped-down too far. The ideal arrangement, in the event that the quantity of light is critical and that it is therefore desired to give priority to the lens aperture, would be to have a large number of multipliers and to be in a position to choose the best compromise. This is not possible, however, with current systems consisting of a lens turret which carries a limited number of quasi-afocal lens elements corresponding to as many different multiplier coefficients.

Another characteristic of existing objective-lens systems of the type under consideration is that the multiplier system thus provided is located in a quasi-afocal region behind the iris. This actually has the effect of significantly changing the position of the exit pupil and therefore the distribution of colors in the picture (colored spot) as a result of the changes in angle of incidence of the principal beams on the dichroic mirrors of the camera separator. This phenomenon is aggravated when the exit pupil is relatively close to the image and also when "ramping" occurs or in other words when the f-number varies with the focal length. In this case, the exit pupil is in fact the image of the diameter of any one group of the variator and often of the front element, the dimensions of which are always limited so as to reduce the weight and volume, and is no longer the image of the iris. Furthermore, the spectrum transmission is modified by introduction of additional lenses.

It is for the reasons given above that the object of the invention is to permit the application of multiplier coefficients for multiplication of the basic focal length of an objective-lens system of the type considered while removing the disadvantages of the system discussed in the foregoing.

SUMMARY OF THE INVENTION

To this end, the invention has for its primary object a particular method of control of an objective-lens system of this type which is so designed as to permit application of a plurality of multiplier coefficients for multiplication of the basic focal length without any need to have recourse to a lens-turret system of the type recalled earlier. This method is designed for the control of a variable-focus objective-lens system consisting of at least two movable groups of lenses forming a variator and at least two other groups which have the function of focusing by displacement and the position of which is defined as a function of the two variables consisting of focal length and focusing distance.

The distinctive feature of this method lies in the fact that, since the displacements of the two movable groups forming a variator are controlled by means of a computer, these groups are subjected not only to the necessary displacements of each group for the variations of focal length but also to a complementary longitudinal displacement for applying to the objective-lens system a focal-length multiplier coefficient having a value chosen by the operator, another function of the computer being accordingly to produce the required variation of the iris and the complementary displacements of the focusing groups in respect of each focal length.

Thus the multiplier function is performed by means of complementary displacements of the movable groups which also serve as a variator. As will become apparent hereinafter, this offers considerable advantage over the system used in the prior art.

However, it is another object of the invention to provide an objective-lens device designed for implementation of the method defined in the foregoing. This device is distinguished by the following features:

(1) the two movable groups of lenses forming a variator have characteristics such that, in addition to the ability to produce variations in focal length of the lens system, they are capable under the action of a complementary longitudinal displacement of carrying out multiplication of the basic focal length and the arrangement is such that, in their end positions, these two groups are still capable of undergoing a similar complementary displacement;

(2) in combination with this lens system, the device under consideration is provided for the purpose of producing displacements of the movable groups of lens elements with a control system associated with a compute and capable of subjecting these two movable groups of lenses not only to the displacements required for each group in order to produce a progressive variation in focal length but also to a complementary longitudinal displacement in order to apply to the objective-lens system a focal length multiplier coefficient having a value chosen by the operator, another function of said computer being to produce the desire variation of the iris and the complementary displacements of the focusing groups in respect of each focal length.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a longitudinal sectional view of an objective-lens system according to the invention in its normal situation in which the groups of lenses are shown in a position of short focal length.

FIG. 2 is a similar view showing the groups of lenses of said objective-lens system in a position of long focal length, said lens system being again shown in its normal situation.

FIG. 3 is a similar view showing the same objective-lens system in a situation of multiplication of its basic focal length by a coefficient of 1.4, the groups of lenses being shown in a position of short focal length.

FIG. 4 is a view illustrating said objective-lens system in the same situation but in this case the groups of lenses are in a position of long focal length.

FIG. 5 is a similar view showing the objective-lens system in a different situation, namely a multiplication of the basic focal length corresponding to the coefficient 2, the groups of lenses being shown in a position of short focal length.

FIG. 6 is a similar view showing the objective-lens system in the same situation but in this case said groups of lenses are in a position of long focal length.

FIG. 7 is a table indicating the different possible apertures as a function of the focal length of the objective-lens system.

DETAILED DESCRIPTION OF THE INVENTION

The objective-lens system illustrated in FIGS. 1 to 6 is made up of five groups of lenses I, II, III, IV, V. Among these latter, the two groups II and III are movable and have the function of constituting the "variator" element for varying the focal length of the objective-lens system as a function of a predetermined optical law. The two groups I and V are also movable but do not take part in the variation in focal length of the objective-lens system. The function of these two groups is in fact to adjust focusing by means of their displacements, their positions being defined as a function of the two variables consisting of focal length and focusing distance.

Group I is convergent as is also the case with groups III and V. In regard to groups II and IV, they are divergent.

In the lens system being considered, and proceeding from left to right as in the drawings, group I comprises a first divergent lens **1** and three other convergent lenses **2, 3** and **4**. Group II comprises a divergent lens **5**, a divergent doublet **6–7**, a divergent lens **8** and a divergent doublet **9–10**.

So far as group III is concerned, this group is constituted from the front end to the rear end by a first convergent doublet **11–12**, a second convergent doublet **13–14** and a convergent lens **15**.

Group IV comprises a convergent doublet **16–17**, a divergent lens **18** and a convergent meniscus lens **19**.

Finally, group V comprises a convergent meniscus lens **20**, a first convergent doublet **21–22**, a second convergent doublet **23–24** and a convergent lens **25**.

The objective-lens system thus constituted is a variable-focus lens system having a basic focal length of 8.5 and a coefficient of variation of twenty times this focal length. Its maximum aperture is accordingly f-1.3.

The four groups I, II, III and IV and the various lenses of these groups comply with the following inequalities in which:

F'1, F'2, F'3 and F'4 each correspond to the focal length of a group considered from front to rear,

f'1, f'2 . . . f'5 each correspond to the focal length of a lens considered from front to rear,

R1, R2 . . . correspond to the radius of each surface of curvature considered from front to rear,

(a) General relations

$$2(F'2) < (F'3) < 3(F'2)$$
$$2(F'3) < (F'1) < 3(F'3)$$

(b) Relations in Group I

$$\frac{1}{2}F'1 < R2 < \frac{3}{2}F'1$$
$$\frac{1}{2}F'1 < R5 < \frac{3}{2}F'1$$
$$\frac{1}{2}F'1 < R7 < 2(F'1)$$
$$(F'1)\,(f'4) < 2(F'1)$$

(c) Relations in Group II

$$(F'2) < R10 < 3(F'2)$$
$$(F'2 < (f'5) < 3(F'2)$$
$$(F'2) < (f'6) < 3(F'2)$$
$$(F'2) < (f'6) < 3(F'2)$$
$$1.65 < n9 < 1.85$$

(d) Relations in Group III

$$(F'3) < (R21) < 2(F'3)$$
$$(F'3) < (R25) < 2(F'3)$$
$$(F'3) < (f'12) < 3(F'3)$$
$$(F'3) < (f'13) < 3(F'3)$$
$$(F'3) < (f'15) < 3(F'3)$$

In regard to the numerical values of the radii of the different lenses as well as the intermediate air spaces existing in each group, they are indicated in the table given hereinafter. In this table, the radii of curvatures are designated by the indications R1, R2, R3 . . . following the order of the different surface areas of lenses from the front end to the rear end. In regard to the air spaces, they are designated by the indications E1, E2, E3 . . . , these latter being numbered according to their position from the front end to the rear end.

As already mentioned earlier, FIGS. **1** and **2** illustrate the objective-lens system in its normal situation, that is to say in the case of a basic focal length of 8.5. In FIG. **1**, the movable groups II and III are shown in their positions corresponding to a short focal length. On the other hand, in FIG. **2**, the same two groups are shown in their position of short focal length.

In the last-mentioned position, groups II and III are not in closely spaced relation but there exists a relatively large gap which permits closer spacing in other cases at the time of multiplication of the basic focal length. This is made possible by suitably determining the characteristics of the different elements of the objective-lens system and especially a judicious reduction in overall length of groups II and III. The reduction of overall length is obtained by making use of glasses having high refractive indices in certain lenses of elements II and III, thus having the effect of reducing the curvatures and therefore the volume.

The essential characteristic of the objective lens system in accordance with the invention lies in the fact that the two groups II and III have configurations and characteristics such that they are capable of performing two separate and distinct functions as follows:

(1) their normal function of variator for progressively varying the focal length of the objective-lens system;

(2) a function of multiplier for multiplying the basic focal length in accordance with a very large number of possible multiplication coefficients.

Moreover, the different movable groups of the objective-lens system considered are made dependent on a control device comprising a computer and capable of subjecting the two movable groups II and III not only to the displacements required for progressive variation in focal length but also to a complementary longitudinal displacement for applying to the objective-lens system a focal length multiplication coefficient having a value chosen by the operator. Accordingly, the operator need only depress a push-button of this control device in order to obtain a multiplication of the basic focal length in accordance with a predetermined coefficient. This accordingly produces the desired complementary displacements of the two groups II and III in order to carry out the corresponding multiplication of focal length. In such a case, however, the computer also determines the requisite variation of the iris and the complementary displacements of the focusing groups in respect of each focal length.

Thus FIGS. **3** and **4** represent the movable groups II and III of the present objective-lens system, respectively in their position of short focal length and in their position of long focal length in the case considered in which a multiplication coefficient g of 1.4× has been applied to the objective-lens system by means of a suitable complementary displacement of the two groups II and III. In consequence, the basic focal length now becomes 1.9 and the objective-lens system is thus a variable-focus lens system of 20×11.9.

In regard to FIGS. **5** and **6**, they illustrate the movable groups II and III of the objective-lens system under consideration, respectively in their position of short focal length and in the long focal length position whereas a multiplier coefficient g of 2×a has been applied to this latter. In consequence, the basic focal length of this objective-lens system now becomes 17, with the result that it constitutes a variable-focus objective of 20×17. It is worthy of note that, in this case, there exists in the long focal-length position a relatively substantial spacing both between groups I and II on the one hand and between groups III and IV on the other hand. This is necessary to permit a close spacing in the short focal-length position in the case of the normal situation of the objective-lens system (as shown in FIG. **1**). The characteristics of the different groups and of their lenses are therefore determine accordingly.

However, the two cases illustrated respectively in FIGS. **3** and **4** and in FIGS. **5** and **6** constitute only examples which are given by way of indication. It is in fact possible to apply to the objective-lens system a large number of multiplier coefficients having different values subject to the condition that the control device is determined in consequence and that the computer has a program which is also established for this purpose.

The essential feature of the device in accordance with the invention therefore lies in the fact that the multiplying function which had thus far been performed by a turret of quasi-afocal lenses located in the rear stationary portion of the objective-lens system and usually limited to one or two positions is replaced in this device by a complementary longitudinal displacement of the elements of the variator.

It thus becomes possible to choose very precisely the longest focal length desired as a function of the numerical aperture chosen or of the field to be covered Thereupon, the variation in focal length always takes place in the same maximum ratio with a constant aperture. It is thus possible in actual fact to give priority of choice to the aperture and to improve the compromise.

This novel situation in fact consists in making provision for an unlimited number of multipliers between the two end values. Management of these positions, of the iris whose aperture is adapted to each situation and of the complementary displacements of the focusing groups which are adapted to each focal length is accordingly performed by the computer provided in the control device.

The basic concept of this device is such that an operator has the possibility of controlling the focal length exactly in dependence on the level of light chosen. He may accordingly place the objective in the position

which corresponds most effectively to the useful field, the aperture being determined by the maximum aperture which is permissible for the longest variable focal length chosen.

The table of FIG. 7 in any case indicates the variations in values of aperture of the objective as a function of the different focal lengths. The operator should therefore consult this table in order to adopt any coefficient of multiplication of the basic focal length which is best suited to his particular case of utilization. The variation in focal length may thus be centered with accuracy as a function of the extreme field angles chosen.

In addition to this essential advantage of utilization, the present device offers a certain number of other advantages.

One of these advantages lies in the fact that the exit pupil is not affected by the application of a coefficient of multiplication of the basic focal length and that the image is not impaired by any colored spot. This is due to the fact that no optical element is added behind the iris in the case under consideration and that the focal length ratio is chosen so as to ensure that there is no "ramping" or in other words no variation of the numerical aperture with the focal length. The light spectrum transmission is therefore unchanged.

Yet another advantage arises from the fact that the objective in accordance with the invention has a smaller number of lenses than in the objectives at present used for the application considered. This produces a reduction in absorption of light at the time of application of a focal-length multiplier by virtue of the fact that, in the present instance, the number of surfaces traversed accordingly remains the same. This also achieves a reduction in cost price. Yet a further advantage lies in the reduction in weight of the assembly as a result of elimination of the afocal-lens turret provided in current objectives of the type recalled earlier.

What is claimed is:

1. A method of control of a variable-focus objective lens system comprising two groups of lenses which are capable of moving along the optic axis so as to produce variations in the focal lengths as initiated by the operator while the final image remains stationary during these variations, and also comprising two other groups which carry out focusing by displacement and the position of which is defined as a function of two variables consisting of focal length and focusing distance, wherein the displacements of the two movable groups forming a variator are controlled by means of a computer and these groups are accordingly subjected not only to the necessary displacements of each group for the progressive variations of focal length but also to a complementary longitudinal displacement for applying to the objective-lens system a focal-length multiplier coefficient having a value chosen by the operator, another function of the computer being accordingly to produce the required variation of the iris and the complementary displacements of the focusing groups in respect of each focal length.

2. An objective-lens device according to claim 1, wherein the four groups of lenses and the various lenses of these groups comply with the following inequalities in which:

F'1, F'2, F'3 and F'4 each correspond to the focal length of one group in a direction away from the object viewed,

f'1, f'2, . . . f'25 each correspond to the focal length of one lens in a direction away from the object viewed,

R1, R2, . . . correspond to the radius of each surface of curvature in a direction away from the object viewed,

(a) General relations

$2(F'2) < (F'3) < 3(F'2)$

$2(F'3) < (F'1) < 3(F'3)$

(b) Relations in Group I

$\frac{1}{2} F'1 < R2 < \frac{3}{2} F'1$

3. An objective-lens device for a variable-focus objective lens system comprised by two groups of lenses which are capable of moving along the optic axis so as to produce variations in focal lengths as initiated by the operator while the final image remains stationary during these variations, and also comprised by two other groups which carry out focusing by displacement and the position of which is defined as a function of the two variables consisting of focal length and focusing distance, wherein

(1) the two movable groups of lenses forming a variator have characteristics such that, in addition to the ability to produce variations in focal length of the lens system, they are capable under the action of a complementary longitudinal displacement of carrying out multiplication of the basic focal length and the arrangement is such that, in their end positions, these two groups are still capable of undergoing a similar complementary displacement; combination with this lens system, the device in

(2) in combination with this lens system, the device in accordance with the invention is provided for the purpose of producing displacements of the movable groups of lens elements with a control system associated with a computer and capable of subjecting these two movable groups of lenses not only to the displacements required for each group in order to produce variations in focal length but also to a complementary longitudinal displacement in order to apply to the objective-lens system a focal length multiplier coefficient having a value chosen by the operator, another function of said computer being to produce the desired variation of the iris and the complementary displacements of the focusing groups in respect of each focal length.

[57] **ABSTRACT**

A variable focal length objective having a plurality of lens units with at least one unit separation being varied to vary the focal length of the entire system, in which at least one of the plurality of lens units has at least gradient-index lens having a refractive index distribution of the form: $N(h)=N_0+N_1h^2+N_2h^4+N_3h^6+\ldots$ where h is the height from the optical axis, N_0 is the refractive index on the optical axis, and N_1, N_2, N_3, . . . are constants, satisfying the following conditions:

$$\phi_G \cdot N_1 < 0$$

$$K \cdot \phi_G \cdot N_2 < 0$$

where ϕ_G is the refractive power of that lens unit which has that gradient-index lens, and K is $+1$ or -1 when the stronger of the curvatures of both surfaces of that gradient-index lens is convex or concave to the air respectively.

VARIABLE FOCAL LENGTH OBJECTIVE

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to variable focal length objectives, and more particularly to such objective which has a plurality of lens units with the separation between the first and second lens units being varied to vary the focal length of the entire system.

2. Description of the Related Art

The aberration problem of the variable focal length objective, especially the zoom lens that varies its focal length continuously, must be solved, besides the good correction of aberrations in the standard setting, for as far minimized variation with zooming of the aberrations as possible. To achieve this, all the lens units are required to be at least individually corrected well for spherical aberration, coma and astigmatism in each unit. It has, therefore, been the prior art practice that each lens unit is made up by using several lens elements.

Because the total sum of the lens elements of all the units became enormous, the weight and size of the entire system were very heavy and very long in the longitudinal direction, and the assembly and adjustment of the lens elements in each unit was very difficult to perform with high accuracy in respect to the axial alignment and the spacing.

Recently, much interest has aroused in developing a variable focal length objective of more compact form with an increased range of magnifications. Yet, from the obstacle of the above-described problem of aberration correction it was also very difficult to achieve it by relying on the method of trimming some lenses from each lens unit.

For example, in the type of zoom lens comprising a plurality of lens units of which the first and second counting from the front are respectively positive and negative in power and the separation between the first and second lens units, its bulk and size can be reduced, speaking in the concept of Gauss theory, either by strengthening the power of each lens unit, or by shortening the intervals between the principal points of the successive two of the lens units. As to extend the zooming range, the method of strengthening the power of each lens unit may also be employed. There is another method of increasing the total zooming movement. When the requirements of reducing the size of the zoom lens of the type described above and of increasing the zoom ratio are to be fulfilled simultaneously, it is certainly natural in the concept of Gauss theory to choose the method of increasing the power of each lens unit. In an actual lens system, however, the increase in the power of the lens unit calls for an increase in the number of constituent lens elements in order to achieve good stability of aberration correction over the entire zooming range. This may otherwise be achieved by increasing the power per one lens element with its surface curvatures being strengthened. To allow for the minimum acceptable edge thickness of every lens element, the central thickness of the positive lens and the axial air separation between the adjacent concave surfaces are caused to become very large. In either case, therefore, the physical length of each of the lens units increases. Also since the principal point interval has to be increased, the optical total length of the entire system can no longer be shortened. Such an increase of the length of the lens unit gives rise to another problem that as the space in which the lens unit movable for zooming makes excursion becomes small, a desired increase of the zoom ratio can no longer be achieved.

Further with the first or second lens unit having an increased overall thickness due to the increase of the number of constituent elements, to admit of the oblique pencile, the diameter of the first or front lens unit must be increased. Thus, the attempt to advance the compactness was frustrated. Therefore, the use of any of the prior known methods, because of effecting the result of such a vicious cycle, could not filfill both requirements of achieving a much-desired reduction of the bulk and size of the zoom lens and of achieving a much desired increase of the zoom ratio while preserving good stability of aberration correction throughout the entire zooming range.

SUMMARY OF THE INVENTION

An object of the present invention is to eliminate the above-described drawbacks of the prior art, and to provide a variable focal length objective of extended range with a lessened total number of lens elements while still permitting good stability of aberration correction to be achieved throughout the zooming range.

BRIEF DESCRIPTION OF THE DRAWINGS

Odd numbered FIGS. **1** to **11** are longitudinal section views of six examples of specific zoom lenses of the invention.

Even numbered FIGS. **2** to **12** are graphic representations of the aberrations of the first to the sixth lenses respectively.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

The present invention is applied to the variable focal length objective comprising a plurality of lens units of which the first and second counting from front are a positive lens unit and a negative lens unit respectively, and in which when varying the image magnification, the air separation between the first and second lens units is varied. A feature of the invention in such objective is that at least one of the plurality of lens units is included with at least one gradient-index lens having a refractive index distribution over the radius given by the expression:

$$N(h)=N_0+N_1h^2+N_2h^4+N_3h^6+ \quad (1)$$

where h is the radial distance from the optical axis, N_0 is the refractive index on the optical axis, and N_1, N_2, N_3, . . . are constants, and is made with a refractive power ϕ_G satisfying the following conditions:

$$\phi_G \cdot N_1 < 0 \quad (2)$$

$$K \cdot \phi_G \cdot N_2 < 0 \quad (3)$$

where K is the coefficient representing the sign-convention for the one of the surfaces of the gradient-index lens which has a stronger curvature than the other, in which when that surface is convex, $K=+1$, and, for the concave surface, $K=-1$.

As is understandable from the equation (1), the gradient-index lens herein used has a distribution of refractive indices along the radial direction of the lens, or so-called radial gradient of refractive index. Particularly when such a gradient-index lens is introduced to

that lens unit which contributes to variation of the image magnification, or, in the usual zoom lens concept, the variator, or to that lens unit which contributes to compensate for the image shift, or, in the usual zoom lens concept, the compensator, it becomes possible to realize a variable focal length objective in which the bulk and size and weight are reduced in such a manner that a good stability of aberration correction over the extended range of variation of the focal length is achieved.

The radial gradient-index lens differs from the ordinary lens of homogeneous material in that its interior has a converging action (hereinafter referred to as "positive transition of power"), or a diverging action (hereinafter referred to as "negative transition of power"). Further since a refractive index pattern appears from the lens surface, the refracting action of that surface on the rays of light also becomes different from that of the usual lens.

Here, if, as the inequality (2) is to be satisfied, the aforesaid gradient-index lens is given such a refractive index distribution that $\phi_G \cdot N_1 < 0$ results, it exerts a surplus power of $\phi = -2N_1D$ owing to the gradient of refractive index, where D is the axial thickness of the lens. This implies that the medium of the gradient-index lens shares the required power of that lens unit which contains that gradient-index lens by the amount ϕ. Therefore, the curvatures of each of the lenses constituting that lens unit can be weakened with an advantage of reducing the aberrations.

When the inequality (3) or $K \cdot \phi_G \cdot N_2 < 0$ is satisfied simultaneously, the refracting action at the surface of the gradient-index lens in cooperation with the above-described power of the gradient permits a higher degree of aberration correction to be obtained.

The rules of design of the invention are next discussed based on the aberration theory in detail below.

Whilst P. J. Sands et al. have derived the third order aberration coefficients for the gradient-index lens, the terminology in "Lens Design Method" by Yoshiya Matsui (published from Kyoritsu Shuppan Co. 1962) is used here for defining the third-order aberration coefficients by the following formulae (4) to (18). For note, the aberration coefficients of the gradient-index lens are grouped to three sets of terms: (A) the terms of refraction arising when it is assumed to be a sphare of homogeneous medium are exposed by the formulae (4) to (8); (B) the terms of refraction due to the refractive index distribution over the surface of the gradient-index lens are exposed by the formulae (9) to (13); and (C) the terms of aberrations ascribable to the power of gradient of the medium of the gradient-index lens (hereinafter referred to as the "terms of gradient") are expressed by the formulae (14) to (18).

$$\text{(A): } I_\nu = h_\nu^4 Q_\nu^2 \Delta\left(\frac{1}{Ns}\right) \tag{4}$$

$$IV_\nu = III_\nu + P_\nu \tag{12}$$

$$V = h_\nu \bar{h}_\nu^3 \Psi_{in,\nu} \tag{13}$$

where

$$\Psi_{in,\nu} = \frac{4}{r_\nu}(\Delta N_{1\nu}) + \frac{1}{r_\nu^2}\left(\Delta \frac{dN_{0\nu}}{dx}\right) \tag{14}$$

$$\text{(C): } I_\nu^t = V_\nu\left(\frac{h\alpha^3}{N_0^2}\right) - \int_{\nu \to \nu+1}\left[8 N_2 h^4 + \frac{4N_1 h^2 \alpha^2}{N_0^2} - \frac{\alpha^4}{N_0^3}\right]dx \tag{15}$$

$$II_\nu^t = V_\nu\left(\frac{h\alpha^2\bar{\alpha}}{N_0^2}\right) - \int_{\nu \to \nu+1}\left[8 N_2 h^3 \bar{h} + \frac{2N_1 h\alpha}{N_0^2}(h\bar{\alpha} + \bar{h}\alpha) - \frac{\alpha^3\bar{\alpha}}{N_0^3}\right]dx \tag{16}$$

$$III_\nu^t = V_\nu\left(\frac{h\alpha\bar{\alpha}^2}{N_0^2}\right) - \int_{\nu \to \nu+1}\left[8 N_2 h^2 \bar{h}^2 + \frac{4N_1 h\bar{h}\alpha\bar{\alpha}}{N_0^2} - \frac{\alpha^2\bar{\alpha}^2}{N_0^3}\right]dx$$

$$IV_\nu^t = III_\nu^t + P_\nu^t ; P_\nu^t = -2\int_{\nu \to \nu+1}(N_1/N_0^2)dx \tag{17}$$

$$V_\nu^t = V_\nu \frac{h\bar{d}^3}{N_0^2} - \int_{\nu \to \nu+1}\left[8 N_2 h\bar{h}^3 = \frac{2 N_1 \bar{h}\bar{\alpha}}{N_0^2}(h\bar{\alpha} + \bar{h}\alpha) - \frac{\alpha\bar{\alpha}^3}{N_0^3}\right]dx \tag{18}$$

Taking an example of spherical aberration, in what way it is corrected is explained below. Since the gradient-index lens adopted in the invention is of the radial type, $\Psi_{in,\nu}$ in the terms for refraction due to the refractive index distribution, or the formulae (9) to (13) reduces to

$$\Psi_{in,\nu} = 4(\Delta N_{1\nu})/r\nu \tag{19}$$

It follows from (9) and (19) that, for, as the medium surrounding the front or rear surface of the gradient-index lens is homogeneous, the distribution coefficient N_1 in the equation (1) is of negative sign, when the surface of stronger curvature is convex, $\Psi_{in,\nu} < 0$ (hereinafter the suffix ν will be omitted), so that the value of $h^4\Psi_{in}$ in the formula (9) is negative. Hence the spherical aberration is produced in direction to over-correction. When that surface is concave, $\Psi_{in} > 0$, so that $h^4\Psi_{in}$ has

a positive value. Hence the spherical aberration is produced in direction to under-correction. For the distribution coefficient N_1 is of positive sign, on the other hand, when that surface is convex, $\Psi_{in}<0$, so that the value of $h^4\Psi_{in}$ is positive. Hence the spherical aberration is produced in direction to under-correction. When that surface is concave, $\Psi_{in}<0$, so that the value $h^4\Psi_{in}$ is negative. Hence the spherical aberration is produced in direction to over-correction. In summary, depending on whether the sign of the power of that lens unit which is selected for incorporation of the gradient-index lens is positive or negative, and, because the sign of the distribution coefficient N_1 is determined according to the above-stated inequality (2), depending on whether that surface of the gradient-index lens whose curvature is stronger than the other is convex or concave, which correction of spherical aberration that surface gives can be discriminated by finding the sign of the coefficient for spherical aberration as shown in the following table.

Lens Unit	Equation (1)	Spherical Aberration: Gradient-Index Lens, Convex (K = +1)	Spherical Aberration: Gradient-Index Lens, Concave (K = −1)
$\phi_G > 0$	$N_1 < 0$	$h^4\Psi_{in} < 0$	$h^4\Psi_{in} > 0$
$\phi_G < 0$	$N_1 > 0$	$h^4\Psi_{in} > 0$	$h^4\Psi_{in} < 0$

Next, the term of the gradient for spherical aberration given by the expression of the equation (14) is of the very complicated form including terms of integrations. But, in the case of the radial type of gradient-index lens, N_0, N_1 and N_2 when to integrate with respect to X or the axial direction can be treated as constants. Further, on assumption that the ray of light travelling in interior of the gradient-index lens does not largely change its height h or $\bar{h}$, the equation (14) can be simplified to and approximated by

$$It \approx \frac{h}{N_0^2}\nabla(\alpha^3) - 8N_2h^4D - \frac{4N_1h^2}{N_0}\int \alpha^2\,dx + \frac{1}{N_0^3}\int \alpha^4\,dx \quad (20)$$

Of the four terms of the equation (20) it is in the usual zoom lens that the second one gives a largest contribution to spherical aberration, and is, therefore, predominant. For this reason, the term of gradient for the spherical aberration of the gradient-index lens has an important parameter as a function of the value of the distribution coefficient N_2 of the equation (1).

In other words, by choosing an appropriate value of the distrubution coefficient N_2, the term of gradient for the spherical aberration can be controlled. For example, when $N_2>0$, the spherical aberration is produced in direction to over-correction. For $N_2<0$, the spherical aberration is produced in direction to under-correction.

The present invention sets forth the conditions under which the third-order aberrations of the gradient-index lens in terms of refraction and gradient of the above-described refractive index distribution cancel out each other for a higher degree of correction. The simple expression of these conditions is of the above-described form of the inequalities (2) and (3). The combination of these inequalities (2) and (3) means that the direction of production of the aberrations ascribable to the refractive index pattern on that surface of the gradient-index lens which has a stronger curvature than the other has is made opposite to the direction of production of the aberrations ascribable to the gradient of refractive index. For example, in the case of spherical aberration, with the lens unit containing the gradient-index lens when being of positive power $\phi_G>0$, the inequality (2) determines $N_1<0$. If the surface of stronger curvature of the gradient-index lens is convex (K = +1), the term of refraction for spherical aberration is $h^4\Psi_{in}<0$. As it then follows that the term of gradient for spherical aberration should be $I^t>0$, the value of N_2 is determined to be $N_2<0$, according to the inequality (3). If that surface is concave (K = −1), after the same reasoning, the opposite sign for N_2 should be chosen. Conversely when the lens unit is of negative power: $\phi_G<0$, the sign for N_1 should be changed to $N_1>0$ according to the inequality (2). If that surface is convex (K = +1), $h^4\Psi_{in}>0$. Then, the inequality (3) determines $N_2>0$ so that the term of gradient for spherical aberration becomes $I^t<0$. If that surface is concave (K = −1), the sign for N_2 should be changed to $N_2<0$ according to the inequality (3).

As has been described above, in the present invention, the choosing of which sign to determine the coefficients N_1 and N_2 of the equation for the refractive index distribution of the gradient-index lens is made controlled in accordance with the critical conditions set forth above, when a higher degree of aberration correction is obtained. It is to be noted that what is referred to by the term radial type gradient-index lens in the invention must be taken that the radial gradient of refractive index is dominant on the performance of the lens itself. Therefore, regardless of the inclusion of another or longitudinal gradient of refractive index, if its effect is far weaker than that of the radial type, it should be understood that it falls within the scope and spirit of the invention.

The invention will next be described in connection with specific embodiments thereof in great detail.

FIG. 1 in longitudinal section view illustrates the construction and arrangement of the elements of an example of a specific zoom lens according to the present invention, and FIG. 2 shows its aberrations. The zoom lens comprises, from front to rear, a first lens unit A, a second lens unit B, a third lens unit C and a fourth lens unit D with the surfaces denoted by Ri (i=1, 2, 3, . . .) for the i-th surface counting from front, and the axial thicknesses or air separations denoted by Di (i=1, 2, 3, . . .) for the one between the i-th and (i+1)th surfaces. The spherical aberrations d and g for spectral d- and g-lines respectively, the astigmatisms M and S in the meridional and sagittal planes respectively, and the distortion of the lens of FIG. 1 are shown in different zooming positions of f=100, 200 and 286 mm.

The first lens unit A is of positive power and is held stationary during zooming. The second lens unit B is of negative power and axially moves with zooming to contribute to variation of the image magnification, and the third lens unit C is of positive power and also axially moves with zooming to compensate for the image shift. The fourth lens unit D of positive power remains stationary during zooming. The positive first lens unit A is constructed in the form of a singlet defined by surfaces R_1 and R_2 and having a radial gradient of refractive index defined by the equation (1) where the coefficients N_1 and N_2 take the signs: $N_1<0$, and $N_2<0$.

The above-defined gradient-index lens, unlike the usual lens of homogeneous medium, gives a converging function at the medium as it has a positive transition of power. Letting the overall power and thickness of the

gradient-index lens A be denoted by ϕ_I and D respectively, since the gradient of refractive index is made of $N_1<0$ according to the inequality of condition (2) or $\phi_I \cdot N_1<0$, because the power ϕ in terms of the gradient of the gradient-index lens A then takes a value of $\phi=-2N_1D$, the positive power assigned to the first lens unit A is shared by the medium of the gradient-index lens with its refracting surfaces. In the zoom lens of FIG. 1, due to the weakened curvatures of both surfaces of one lens constituting the positive first lens unit A, the aberrations are, therefore, primarily reduced remarkably.

The use of the convex form in the positive first lens unit in combination with such a gradient of refractive index as to give a positive transition of power as in this zoom lens is advantageous at correcting spherical aberrations in the telephoto positions. Other aberrations, for example, coma and astigmatism, can be also well corrected. Thus, it is made possible that only one gradient-index lens suffices for making up the positive first lens unit A.

In more detail, since the front and rear surfaces of the positive first lens unit A or the gradient-index lens are both convex, and the coefficient N_1 is of negative sign, the third-order spherical aberration in terms of refraction in the telephoto positions is largely over-corrected. Further since, as $K=+1$, the sign of the coefficient N_2 is made negative according to the inequality of condition (3), the spherical aberration in terms of gradient is under-corrected. Thus, a possibility of achieving a good balance is provided. In such a manner, by controlling the values of the terms of refraction and gradient for the third-order aberrations, not only the spherical aberration but also coma and astigmatism can be corrected as well.

The numerical data in accordance with which the zoom lens of FIG. 1 can be constructed are given in Tables 1-1 to 1-3 for the focal length f of the entire system, F-number FNO, the image angle 2ω, the radii of curvature, R, the axial thicknesses or air separations, D, and the refractive indices, N, and Abbe numbers, ν, of the glasses of the lens elements with the subscripts numbered consecutively from front to rear, along with the values for the spectral d- and g-lines of the refractive index distribution coefficients N_0 to N_4.

FIG. 3 illustrates another specific zoom lens of the invention whose aberrations are shown in FIG. 4. The symbols in these figures have the same meanings as those in FIGS. 1 and 2. The aberration curves represent the spherical aberration, astigmatism and distortion in different zooming positions of the focal length f=100, 200 and 304.5 mm.

The zoom lens comprises, from front to rear, a positive first lens unit A which is held stationary during zooming, a negative second lens unit B which axially moves with zooming to contribute to variation of the image magnification, a positive third lens unit C which axially moves with zooming to compensate for the image shift, and a positive fourth lens unit D which remains stationary during zooming. The second lens unit B, usually called the variator, is constructed with a gradient-index lens of the radial type with the surfaces R_6 and R_7. The gradient-index lens is made of a gradient of refractive index defined by the equation (1) where the coefficients N_1 and N_2 are of opposite sign such that $N_1>0$, and $N_2<0$.

The above-defined gradient-index lens, unlike the usual lens of homogeneous medium, gives a diverging function at its medium, and has a negative transition of power. Letting ϕ_{II} denote the required power of the negative second lens unit B and D the thickness of the gradient-index lens, it follows from the inequality of condition (2) that as $\phi_{II} \cdot N_1<0$, the gradient-index lens should be made with a gradient of refractive index of $N_1>0$. Then, the power ϕ owing to the term of gradient of the gradient-index lens is $\phi=-2N_1D$. This implies that the negative power of the lens unit B is partly borne by the term of gradient of the gradient-index lens. In this zoom lens, the negative second lens unit B can be constructed with one lens whose surfaces both are weak in curvature. Therefore, the zoom lens is fundamentally corrected to minimums of aberrations produced.

When the second lens unit B is constructed in the form of a bi-concave lens having a gradient of refractive index for the negative transition of power, the spherical aberration in the telephoto positions can be advanta-

geously corrected. And, other various aberrations, for example, coma and astigmatism, can also be corrected well. This permits only one gradient-index lens to suffice for constituting the negative second lens unit.

Both surfaces of the aforesaid gradient-index lens of the negative second lens unit B are concave, and the coefficient N_1 in the equation for the gradient of refractive index is made $N_1>0$, so that the third-order spherical aberration in terms of refraction at the concave surface is largely over-corrected in the telephoto positions. Since both surfaces of the gradient-index lens of the negative second lens unit B are concave, because $K=-1$, the gradient of refractive index is made with $N_2<0$, according to the inequality of condition (3), thereby the spherical aberration in terms of the gradient is produced in the opposite direction to that in which the spherical aberration in terms of the refraction is produced. Thus, a possibility of taking a balance is provided.

In such a manner the spherical aberration can be corrected by controlling the terms of the gradient and refraction for the third-order aberration. Similarly the coma and astisgmatism can be corrected.

Whilst it has been usual in the prior art that the negative second lens unit B is constructed by using three lens elements and that the spherical aberration is corrected by the cemented surface of the cemented lens, it is in the zoom lens of the invention that despite the negative second lens unit B is constructed by using only one lens element, the spherical aberration can be well corrected.

Further, the Petzval sum can be corrected when the gradient-index lens of the negative second lens unit B is made of the gradient of refractive index that satisfies the inequality of condition (2), or the gradient of refractive index of $N_1>0$ as in the zoom lens of FIG. 3. Letting ϕ denote the power owing to the converging or diverging effect of the medium of the gradient-index lens referred to the normalized focal length of the entire system to unity, and N_0 the basic refractive index, the Petzval sum varies as a function of $P=\phi/N_2{}^0$, being inversely proportional to the square of N_0, while the Petzval sum of the spherical system produces a larger Petzval sum, because the latter is expressed by $P=\phi/N_0$. Therefore, in the case of the zoom lens of the invention, a smaller Petzval sum is produced in the negative sense. On assumption that the power arrangement is the same as that of the zoom lens of the invention, the variator of the spherical system produces a Petzval sum of -1.25 to 1.3 in contrast to the negative second lens unit B as the variator of FIG. 3 which has a Petzval sum of -1.025 from the reason described above.

This means that the power of the zoom section may be strengthened or the telephoto ratio of the relay section may be reduced in order to shorten the optical total length of the entire system as compared with the spherical system. That is, the largest drawback of the conventional method for shortening the total length by strengthening the power of the zoom section, or by reducing the telephoto ratio of the relay section was that the Petzval sum became too large in the negative sense to be corrected. In the zoom lens of the invention, however, the variator produces a smaller Petzval sum in the negative sense, thus increasing the possibility of shortening the optical total length of the entire system by the above-described method.

In the zoom lens of the invention, the telephoto ratio of the relay section comprised of the positive fourth lens unit D is reduced so that the ratio of the total length of the entire system of 254.8 mm to the longest focal length of the entire ratio, or the telephoto ratio of the entire system can be reduced to a very small value of 0.836. Further, by the room for freedom created in the Petzval sum, the power of the positive first lens of the surfaces R_{11} and R_{12} in the positive fourth lens unit D is made higher to permit a higher degree of spherical aberration correction to be achieved.

Usually the variator of the zoom lens is constructed with three to five lens elements of strong power, and the tolerances for the thicknesses of the lens elements, the air spacings and the decentering of the lens elements from the common axis must be very rigorous. But, now that it can be constructed with only one element as in the zoom lens of the invention, the assembly and the adjusting operation becomes extremely easy.

The numerical data of the zoom lens of FIG. 3 along with the separations between the lens units during zooming, and the values of the coefficients for the gradient-index lens ar given in Tables 2-1 to 2-3 below. For note, the symbols in the tables have the same meanings as those stated in connection with the first example.

FIG. 5 is a longitudinal section view illustrating another specific zoom lens of the invention, and FIG. 6 shows its aberrations. The symbols in these figures have the same meanings as in the foregoing examples. The aberration curves are of the spherical aberration, astigmatism and distortions at the focal lengths of f=100, 167 and 283 mm.

The zoom lens comprises, from front to rear, a positive first lens unit A which axially moves with zooming to contribute to variation of the image magnification, a negative second lens unit B which is held stationary during zooming, a positive third lens unit C which axially moves with zooming to contribute to a variation of the image magnification and also to compensate for the image shift, and a positive fourth lens unit D which remains stationary during zooming. The negative second lens unit B is constructed with a first radial gradient-index lens having surfaces R_6 and R_7 and a second radial gradient-index lens having surfaces R_8 and R_9. Since, in this zoom lens, the negative second lens unit which is most sensitive to decentering is held stationary, it becomes possible to improve the assembly accuracy.

The above-described two gradient-index lenses, unlike the usual lens, have diverging actions at the interiors thereof, providing a negative transition power. Letting the refractive power of the negative second lens unit be denoted by ϕ_{II} and the sum of the thicknesses of the gradient-index lenses by D, since, according to the inequality of condition (2), $\phi_{II} \cdot N_1 < 0$, that is, $\phi_{II} < 0$, for the gradient-index lenses are made with refractive index gradients of $N_1 > 0$, they produce a power $\phi = -2N_1D$ owing to the term of gradient. This implies that the negative power of the lens unit B is partly borne by the term of gradient of the gradient-index lenses. Whilst the prior art would necessitate four to five lens elements, it is in the zoom lens of FIG. 5 that only two lens elements suffice for constituting the negative second lens unit B.

For example, the first gradient-index lens R_6, R_7, has its rear surface R_7 made of a stronger concave curvature. This concave surface R_7 in combination with $N_1 > 0$ produce over-corrected third-order spherical aberration in terms of refraction in the telephoto positions.

On this account, the direction in which the spherical aberration in terms of gradient is produced should be made opposite to that of the spherical aberration in terms of refraction so that a balance can be taken. Since the rear surface of the first gradient-index lens is of stronger curvature than the front surface, because it is concave or $K = -1$, when the inequality of condition (3) is satisfied by making the gradient of refractive index with $N_2 < 0$, the spherical aberration in terms of gradient can be produced as opposed to that in terms of refraction to permit the balance to be obtained.

Therefore, the term of refraction for third-order spherical aberration, the term of gradient for third-order spherical aberration and the term of refraction for fifth-order spherical aberration allow the spherical aberrations to be balanced out, thus making it possible to correct the spherical aberration for a higher grade of imagery as the coma and astigmatism also can be well corrected in a similar manner.

The zoom lens of FIG. 5 can be constructed in accordance with the numerical data given in Tables 3-1 to 3-3 below.

A third example of the specific zoom lens of the invention is illustrated in FIG. 7, and its spherical aberration, astigmatism and distortion are shown in different focal length positions of f=100, 170 and 278 mm.

This zoom lens comprises, from front to rear, a positive first lens unit A which axially moves with zooming, a negative second lens unit B which axially moves with zooming to contribute to variation of the image magnification, and positive third lens unit C which remains stationary during zooming. The positive first lens unit A consists of a radial gradient-index lens having surfaces R_1 and R_2. The negative second lens unit B consists of a radial gradient-index lens having surfaces R_3 and R_4 front part of the third lens unit C includes a radial gradient lens of bi-convex form having surfaces R_5 and R_6 at the frontmost position, followed rearwardly after a very short spacing by an axial gradient-index lens of bi-convex form having surfaces R_7 and R_8, and a rear part

includes a radial gradient-index lens of convex form having surfaces R_{10} and R_{11}.

When the positive first lens unit is constructed in the form of a convex lens, and is made with such a gradient of refractive index that a positive transition power is produced as in the zoom lens of the invention, an advantage of correcting spherical aberration in the telephoto positions is produced. And, because other various aberrations can be well corrected, it has been made possible that only one lens element having the gradient of refractive index sufficies for contructing the positive first lens unit A.

Also, the radial gradient-index lens having the negative transition power in the negative second lens unit B, because the negative transition power of the interior thereof can partly bear the power of the lens unit B, enables the curvature of the surfaces of the lens to be weakened with an advantage of correcting spherical aberration and Petzval sum.

For example, if the power arrangement is the same, the negative lens unit B which would otherwise be made of homogeneous material only would produce a Petzval sum of -1.45 to -1.6 referred to the normalized focal length of the entire system to unity. But, in the zoom lens of the invention, as it is constructed with the radial gradient-index lens, the Petzval sum is reduced to a very small value of -1.06.

Thus, the adoption of the gradient-index lens as the second lens unit B enables the Petzval sum to be suppressed. This permits the telephoto ratio of the relay lens, that is, the positive third lens unit C to be minimized with an advantage of shortening the optical total length of the entire system.

The third lens unit C is divided into the front and rear parts spaced apart by a longest distance D_9 in that lens unit. As the frontmost lens in the front part use is made of a gradient-index lens of bi-convex form. At the same time, as the frontmost lens in the rear part also, use is made of a gradient-index lens which is also of bi-convex form. The first-named and second-named gradient-index lenses have positive and negative transition powers respectively, and their gradients of refractive index are formed so as to satisfy the inequalities (2) and (3). By using such a construction and arrangement, the spherical aberration and coma of the front part and the spherical aberration, curvature of field and distortion of the rear part which would usually by deteriorated when the powers of the front and rear parts are strengthened in order to achieve a shortening of the entire system, are made possible to correct well.

Next explanation is given to how such advantages are produced by the adoption of the gradient-index lens as the positive first lens unit A.

The above-described gradient-index lens, unlike the usual lens of homogeneous medium, has a converging action even at its medium, getting a positive transition power. Letting the refractive power of the positive first lens unit A be denoted by ϕ_I and the thickness of the gradient-index lens by D, since, according to the inequality of condition (2), or $\phi_I \cdot N_1 < 0$, as $\phi_I > 0$, the gradient of refractive index is made with $N_1 < 0$, because such a gradient-index lens produces a power ϕ in terms of gradient given by the expression $\phi = -2N_1D$, it should be understood that the positive power of the lens unit A is partly borne by the term of gradient of that gradient-index lens.

As the curvatures of both convex surfaces of the positive first lens unit A, therefore, become weaker, smaller spherical aberrations are produced. A good result of the other aberrations, for example, coma and astigmatism, can also be attained. These facts enable the positive first lens unit A to be constructed with only one gradient-index lens.

Since both surfaces of the gradient-index lens constituting the positive first lens unit A are convex, and $N_1 < 0$, the third-order spherical aberration in terms of refraction is over-corrected in the telephoto positions. Further since, as both surfaces of the gradient-index lens in the positive first lens unit A are convex, $K = +1$, for, as the inequality of condition (3) is satisfied, the gradient of refractive index is made with $N_2 < 0$, the spherical aberration in terms of gradient is produced as opposed to that in terms of refraction, thus permitting a balance of them to be taken.

Further, with the gradient of refractive index of $N_2 < 0$, the fifth-order spherical aberration in terms of refraction is over-corrected. Thus, the third-order spherical aberrations in terms of refraction and gradient and the fifth order spherical aberration in terms of refraction are balanced out with one another to achieve a higher degree of correction of spherical aberration. In a similar manner, higher degrees of correction of coma and astigmatism can be obtained.

Next, concerning the advantages arising from the use of a gradient-index lens as the negative second lens unit B, letting the refractive power of the negative second lens unit B be denoted by ϕ_{II} and the thickness of the aforesaid gradient-index lens by D, since, according to the inequality of condition (2), or $\phi_{II} \cdot N_1 < 0$, as $\phi_{II} < 0$, the gradient of refractive index is made with $N_1 > 0$, for the aforesaid gradient-index lens produces a power ϕ owing to the gradient given by the expression $\phi = -2N_1D$ the negative power of the lens unit B is partly borne by the term of gradient. Therefore, it is in the zoom lens of the invention that the negative second lens unit can be constructed by using one lens element whose both surfaces are of weaker curvature.

Since both surfaces of the gradient-index lens constituting the negative second lens unit B are convex, for a refractive index pattern with $N_1 > 0$ appears at that surface, the third-order spherical aberration in terms of refraction is under-corrected in the telephoto positions. Further since, as both surfaces of the aforesaid gradient-index lens are convex, $K = +1$, because the gradient of refractive index is made with $N_2 > 0$, according to the inequality of condition (3), the spherical aberrations in terms of gradient and refraction are produced as opposed to each other to permit a balance to be taken.

Further, with the gradient of refractive index of $N_2 > 0$, the fifth-order spherical aberration in terms of refraction is under-corrected. Therefore, the third-order spherical aberrations in terms of gradient and refraction and the fifth-order spherical aberration in terms of refraction are balanced out with one another to achieve a higher degree of correction of spherical aberration. In a similar manner, higher degrees of corection of coma and astigmatism can be achieved.

Usually, the negative second lens unit B is constructed with three lens elements, and the spherical aberration is corrected by the cemented surface of them. In the present invention, on the other hand, despite the number of constituent lens elements is only one, the various aberrations can be corrected.

Next, concerning the advantages arising the incorporation of the gradient-index lens into the front part of the positive third lens unit C, letting the refractive

power of the front part of the third lens unit C be denoted by $\phi_{III\text{-}1}$, and the thickness of the radial gradient-index lens by D_1, since, as $\phi_{III\text{-}1}>0$, $N_1<0$, or since, as the inequality of condition (2) is satisfied, the gradient of refractive index is made with $N_1<0$, for that gradient-index lens produces a transition power $\phi=-2N_1D_1$ which is positive, the positive power of the front part is partly borne by the transition power of the gradient-index lens. Also since, as both surfaces of that gradient-index lens are convex, $K=+1$, the gradient of refractive index is made also according to the inequality of condition (3).

Therefore, the spherical aberration can be well corrected, and other aberrations for example, coma and astigmatism, can also be well corrected. Therefore, the total length can be shortened by strengthening the power of the front part. That is, regarding the correction of spherical aberration, for the gradient of refractive index is made of $N_1<0$, the third-order spherical aberration in terms of refraction is over-corrected in the telephoto positions, and the spherical aberration in terms of gradient is produced as opposed to that in terms of refraction to permit a balance to be taken. Further since the gradient of refractive index is made of $N_2<0$, the fifth-order spherical aberration in terms of refraction is over-corrected. The third-order spherical aberrations in terms of refraction and gradient and the fifth-order spherical aberration in terms of refraction are delicately balanced out with one another to permit a higher degree of correction of spherical aberration to be obtained. In a similar manner, higher degrees of correction of coma and astigmatism can also be obtained.

Next, concerning the advantages arising from the incorporation of the gradient-index lens in the rear part of the positive third lens unit C, letting the refractive power of the rear part be denoted by $\phi_{III\text{-}2}$, and the thickness of the gradient-index lens by D_2, since, according to the inequality of condition (2), as $\phi_{III\text{-}2}<0$, $N_1>0$, for the gradient of refractive index is made with $N_1>0$, that gradient-index lens produces a negative transition power $\phi=-2N_1D_2$ which is to partly bear the power of the rear part. Therefore, even if the negative refractive power of the rear part of the positive third lens unit C is strengthened, the various aberrations can be well corrected to permit the total length to be shortened. Since both refracting surfaces of the gradient-index lens, similarly to the front part, are convex, because $N_1>0$, the third-order spherical aberration in terms of refraction is under-corrected. Also since $K=+1$, for the inequality of condition (3) is satisfied, the spherical aberration in terms of gradient is produced as opposed to that in terms of refraction to permit a balance to be taken.

Further since the gradient of refractive index is made of $N_2>0$, the fifth-order spherical aberration in terms of refraction is under-corrected. Similarly to the gradient-index lens in the front part, the third-order spherical aberration and the fifth-order spherical aberration in terms of refraction are balanced out to achieve a higher degree of correction of spherical aberration. Also, higher degrees of correction of coma, astigmatism, and distortion can be obtained.

It will be appreciated that a great reduction of the size of the entire system can be achieved by incorporating the gradient-index leses into the last lens unit while maintaining a good stability of aberration correction throughout the entire system when the inequalities of condition (2) and (3) are satisfied.

Though this specific example has been described in connection with the last or positive third lens unit C which is held stationary during zooming, it is to be understood that the present invention is applicable to another zoom type in which the last or third lens unit axially moves with zooming, while preserving the above-described advantages to obtain a compact zoom lens.

The fourth example of the specific zoom lens can be constructed in accordance with the numerical data given in Tables 4-1 to 4-3. As the fourth lens counting from front in the zoom lens is a gradient-index lens of the axial type, the gradient of refractive index $N_4(x)$ can be expressed by the following equation in terms of the distance x measured from the front vertex toward the rear in the direction parallel to the optical axis.

$$N4\ (x)=N_0+N_1x+N_2x^2+N_3x^3+N_4x^4+\ldots$$

where N_0 is the refractive index at the front vertex, and N_1, N_2, N_3, . . . are coefficients similarly to the radial type.

A fifth example of the specific zoom lens of the invention is illustrated in FIG. **9** and its spherical aberration, astigmatism and distortion in the focal length positions of f=100, 167 and 283 mm are shown in FIG. **10**.

This zoom lens comprises, from front to rear, a positive first lens unit A which axially moves with zooming to contribute to variation of the image magnification, a negative second lens unit B which is held stationary during zooming, a positive third lens unit C which axially moves with zooming to contribute to a variation of the image magnification and to compensate for the image shift, and a positive fourth lens unit D which remains stationary during zooming. The third lens unit C comprises, front from to rear, positive, negative and positive lenses, of which the first positive is a radial gradient-index lens having a positive transition power with the surfaces R_{14} and R_{15}, and the second positive is a radial gradient-index lens having a negative transition power with the surfaces R_{18} and R_{19}. Because, in this zoom lens, the position of the negative second lens unit B relative to the image plane does not change, this type is suited to facilitate simplification of the structure of the operating mechanism.

The rays of light emerging from the negative second lens unit B are divergent on the positive first lens of the third lens unit C. As the height of incidence of the principal ray is higher than in the other types of zoom lens, under-correction of spherical aberration is liable to result. On this account, use is made of the gradient-index lens so that it is corrected in direction to over-correction. And, since the positive first or gradient-index lens has a positive transition power, for, as the positive power of that lens is so much strengthened, the principal point of the positive third lens unit C is brought to a more forward position, the interval between the principal points of the negative second and positive third lenses can be reduced, contributing to a shortening of the entire system.

Also, as the height of incidence of the oblique pencile on the positive third lens is high, the use of another gradient-index lens as this lens allows for correcting particularly astigmatism.

It has been customary that the positive third lens unit C in this kind of zoom lens is constructed with at least five lens elements. In the invention, on the other hand, only three lens elements suffice, contributing to a compactness of the entire system. Another advantage arising from the reduction of the number of lens elements is that the assembly and the adjusting operation become easier, making it possible to simplify the structure of the operating mechanism.

In more detail, letting the refractive power of the positive third lens unit C be denoted by ϕ_{III} and the thickness of the gradient-index lens by D, since, according to the inequality of condition (2), or $\phi_{III} \cdot N_1 < 0$, as $\phi_{III} > 0$, $N_1 < 0$, for the gradient-index lens made of such a gradient of refractive index gets a power $\phi = -2N_1D$ owing to the term of gradient, the positive power of the lens unit C is partly borne by the term of gradient of that gradient-index lens.

With both convex surfaces of the gradient-index lens, for the gradient of refractive index is made of $N_1 < 0$, the third-order spherical aberration in terms of refraction is over-corrected in the telephoto positions. Since, as both surfaces of the gradient-index lens are convex, $K = +1$, for, according to the inequality of condition (3), the gradient of refractive index is further made of $N_2 < 0$, the spherical aberration in terms of the gradient is produced as opposed in direction to that in terms of the refraction, to permit a balance to be taken.

Further, with the gradient of refractive index of $N_2 < 0$, over-correction of the fifth-order spherical aberration in terms of the refraction results. So, the third-order spherical aberration in terms of the refraction, the third-order spherical aberration in terms of the gradient and the fifth-order spherical aberration in terms of the refraction are balanced out to permit a higher correction of spherical aberration to be obtained. In a similar manner, higher degrees of correction of coma and astigmatism can also be obtained.

The zoom lens of FIG. **9** can be constructed in accordance with the numerical data given in Tables 5-1 to 5-3 below.

A sixth example of the specific zoom lens of the invention is illustrated in FIG. **11**, whose spherical aberration, astigmatism and distortion in the focal length positions of f=100, 280 and 570 mm are shown in FIG. **12**.

This zoom lens comprises, from front to rear, a positive first lens unit A which is held stationary during zooming, a negative second lens unit B which axially moves with zooming to contribute to variation of the image magnification, a negative third lens unit C which axially moves with zooming to compensate for the image shift, and a positive fourth lens unit D which is held stationary during zooming. As this zoom lens is adapted to be used with an image pickup device, the fourth lens unit D is usually included with a positive lens for making afocal the arriving rays of divergence in passing therethrough at the front most position and a prism (not shown) as a beam splitter for the finder, and, in many cases, also with a diaphragm. Also, since the image plane is immediately preceded by a low pass filter, a stripe filter and a face plate, the rays emerging from the positive fourth lens unit D are almost telecentric.

In the invention, a lens group of positive power which is usually constructed with three or four lens elements just behind the diaphragm is replaced by one gradient-index lens having surfaces R_{17} and R_{18}. For the medium of the gradient-index lens as having a positive transition power bears part of the overall positive power of that lens, the curvature of its surfaces can be weakened to suppress aberrations to minimum. Also, the surfaces R_{17} and R_{18} each have lower refractive indices from the paraxial region toward the margin. So, the more marginal the incident ray, the smaller it refracts as compared with the lens of homogeneous material, and the smaller the spherical aberration and coma produced become. Further, for $N_2>0$, the excessively undercorrected spherical aberration by the presence of the refractive index pattern over the surface R_{18} can be corrected when the rays pass through the interior thereof.

In such a manner, the aberrations can be corrected. Whilst the conventional relay section has had many troubles due to the optical misalignment, the positive fourth lens unit D as the relay section can be constructed with only one lens element for the positive lens group just behind the diaphragm, thereby giving an advantage of facilitating the assembly and the adjusting operation. Also, as the residual aberrations of the front part of the relay section become small, the curvatures of the surfaces of the lens elements constituting the rear part of the relay section can be weakened. So, the assembly and adjusting operation become easier.

Concerning the advantages produced by incorporating the gradient-index lens into the positive fourth lens unit D, a more detailed explanation is given below.

Since the gradient-index lens with the surfaces R_{17} and R_{18} satisfies the inequality of condition (2), or $\phi_G \cdot N_1 < 0$, the power of the positive fourth lens unit D is partly borne by the term of gradient of that gradient-index lens. Therefore, the surface curvature of each of the lens elements constituting the fourth lens unit D can be weakened, thereby it being made possible to decrease the aberrations. Another advantage is that when the minimum acceptable edge thickness or marginal separation is taken, the axial air spacing can be minimized, thereby it being made possible to shorten the fourth lens unit D and therefore to achieve an advance in the compactness of the entire system.

Further since the inequality of condition (3) or $K \cdot \phi_G \cdot N_2 < 0$, is simultaneously satisfied, the direction of correction of aberrations by the surface of stronger curvature is made opposed to that of correction of those aberrations by the gradient of refractive index. This implies that the convex gradient-index lens though being only one is equivalent in the aberration correcting effect to several number of convex and concave lenses in combination. Thus, the spherical aberration, coma and astigmatism can be well corrected.

The sixth example of the zoom lens of the invention can be constructed in accordance with the numerical data given in Tables 6-1 to 6-3 below.

TABLE 6-3

Ni (h)	λ	N_0	N_1	N_2	N_3	N_4	N_5
N 10 (h)	d	1.8457	-5.76408×10^{-6}	6.72888×10^{-11}	1.83029×10^{-15}	6.51016×10^{-20}	6.69015×10^{-24}
	g	1.86557	-5.45905×10^{-6}	8.8922×10^{-11}	8.24188×10^{-16}	1.50515×10^{-20}	1.51127×10^{-23}

It is to be understood from the above-described specific embodiments of the invention that when a gradient-index lens that satisfies the inequalities (2) and (3) is incorporated into a desired one or ones of the lens units, for the lens unit is of positive power, the gradient-index lens has an almost equivalent effect to that of a lens system of two positive lenses and one negative lens which are of homogeneous medium, and for the lens unit is of negative power, it has an almost equivalent effect to that of a lens system of two negative lenses and one positive lens.

Therefore, the above-described advantages on the aberration correction can be obtained when at least one of the plurality of lens units of the zoom lens is included with at least one gradient-index lens provided that the above-stated conditions (2) and (3) are satisfied. Further, the necessary number of constituent lens elements in that lens unit can be remarkably reduced. It is, therefore, obvious that as the number of gradient-index lenses used and the number of lens units employing those gradient-index lenses increase, a further improvement of the performance and compactness of the zoom lens can be achieved.

What is claimed is:

1. A variable focal length objective comprising a plurality of lens units of which the first from the object side is a positive lens unit, the second from the object side is a negative lens unit, and in which when varying the image magnification, the separation between said first and said second lens units varies, wherein at least one of the plurality of lens units has at least one gradient-index lens having a gradient of refractive index defined by the following equation:

$$N(h)=N_0+N_1h^2+N_2h^4+\ldots$$

wherein h is the height from the optical axis; N_0 is the refractive index on the optical axis, and N_1, N_2, . . . are constants, and wherein when the refractive power of said at least one lens unit is denoted by ϕ_G, and when the sign of the strongest curvature surface of said gradient-index lens is denoted by K such that $K=+1$ when said strongest curvature surface is convex, and $K=-1$ when said strongest curvature surface is concave, the following conditions are satisfied:

$$\phi_G \cdot N_1 < 0$$

$$K \cdot \phi_G \cdot N_2 < 0.$$

2. A variable focal length objective according to claim **1**, wherein said gradient-index lens is provided in said first lens unit.

3. A variable focal length objective according to claim **1**, wherein said gradient-index lens is arranged in at least a lens unit which moves to effect variation of the image magnification.

4. A variable focal length objective according to claim **1**, wherein of said plurality of lens units, there is a last lens unit that is furthest from the object side and comprises a front part and a rear part that are separated from each other by a distance that is larger than the distance separating a front and a rear part of any other of the plurality of lens units, and wherein at least one of said front and said rear parts of said last lens unit has at least one gradient-index lens that satisfies said equation and conditions.

[57] **ABSTRACT**

A focus detecting apparatus is provided with a plurality of pattern forming lenses for forming light patterns whose relative positional relation varies in conformity with the focus adjusted state of an objective optical system from lights passed through different areas on the pupil of the objective optical a sensing device is included for sensing the light patterns and producing a signal regarding the relative positional relation between the light patterns. A light divider is inclined along an optical path passing through the areas on the pupil and has a light-transmitting area through which light is refracted and transmitted. The light divider is disposed between the objective optical system and the pattern forming lenses. The pattern forming lenses are different in shape and are formed asymmetrically with respect to the optic axis of the objective optical system to correct the destruction of the light patterns caused by the light divider.

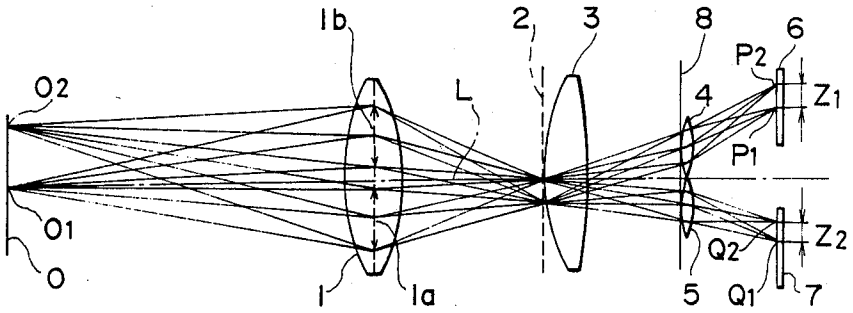

FIG.8

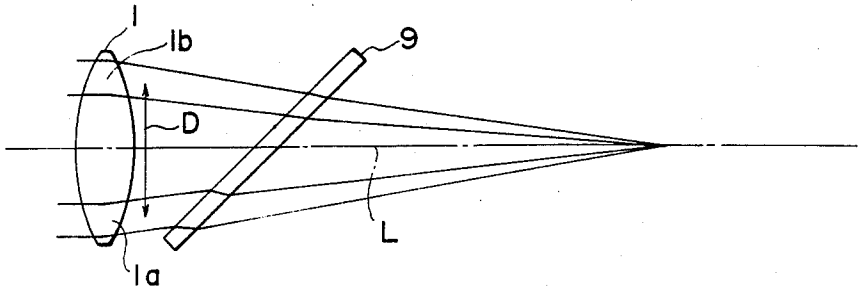

FIG.9

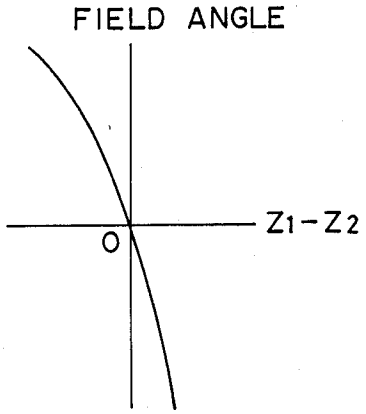

APPARATUS FOR DETECTING THE FOCUS ADJUSTED STATE OF AN OBJECTIVE OPTICAL SYSTEM

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to a focus detecting apparatus suitable for an optical machine such as a camera, and in particular to a focus detecting apparatus for detecting the focus adjusted state of an objective lens.

2. Related Background Art

In single-lens reflex cameras or the like, a focus detecting system of the so-called image deviation type is known in which light distributions regarding two object images are formed from light beams from two different portions of the pupil of the photo-taking lens and the focus state of the photo-taking lens is detected from the relative positional relation between the light distributions.

FIG. **5** of the accompanying drawings depicts a longitudinal sectional shape of a single-lens reflex camera provided with a focus detecting unit of the image deviation type, and FIG. **6** of the accompanying drawings is a transverse sectional view in which only the optical system is developed and depicted to illustrate the focus detecting action.

In these figures, the reference numeral **1** designates an interchangeably mounted or fixed photo-taking lens, the reference numeral **3** denotes a field lens provided near the predetermined imaging plane **2** of the photo-taking lens **1** (the focal plane in a camera), the reference numerals **4** and **5** designate secondary imaging lenses disposed symmetrically about the optic axis L of the photo-taking lens **1** for forming two object images on the basis of light beams passing through different portions **1***a* and **1***b* of the pupil of the photo-taking lens **1**, and the reference numerals **6** and **7** denote photoelectric conversion arrays for detecting the respective object images formed by the secondary imaging lenses **4** and **5**. The arrays **6** and **7** are constructed, for example, of CCDs (charge coupled devices) or the like on a chip.

The reference numeral **8** designates a mask provided near the secondary imaging lenses. The field lens **3** causes the opening portions **8***a* and **8***b* of the mask **8** to be imaged on the different portions **1***a* and **1***b* on the pupil of the photo-taking lens **1**.

The reference numeral **9** denotes a quick return mirror which is mirror-surface-treated on a light-transmitting substrate except for the aperture near the optic axis, and which is obliquely disposed in the photo-taking optical path during observation and is retracted out of the optical path during photographing. A pentaprism P and an eyepiece E are successively disposed on the reflecting optical path of the quick return mirror **9**, and a sub-mirror M, the field lens **3**, an optical path inverting mirror M2, the secondary imaging lenses **4** and **5** and the photoelectric conversion arrays **6** and **7** are successively disposed on the transmitting optical path of the quick return mirror **9**. PC designates a signal processing circuit which calculates a value indicative of the focus adjusted state of the objective lens **1** on the basis of the signals of the arrays **6** and **7**. F denotes the imaging plane on which a silver chloride film or an image pickup element is disposed.

In such an apparatus, when for example, the photo-taking lens **1** is moved leftwardly as viewed in FIG. **6** to provide the so-called forward focusing, light patterns, for example, object images, formed on the light-receiving surfaces of the respective photoelectric conversion arrays **6** and **7** by the secondary imaging lenses **4** and **5** deviate in the direction of arrow and thus, the fact of forward focusing and the amount thereof are detected from the variation in the outputs of the photoelectric conversion arrays **6** and **7** corresponding to the relative deviation of the pair of light patterns. Also, in the case of backward focusing, the respective images deviate in the direction opposite to that in the case of forward focusing and therefore, the fact of backward focusing and the amount thereof are detected.

FIG. **7** of the accompanying drawings depicts the optical action during in-focus in greater detail. The point of intersection between the optic axis L and the surface O of an object to be photographed is O1, and a point off the axis is O2. A light beam emitted from the point O1 is imaged on the photoelectric conversion arrays **6** and **7** by the action of the secondary imaging lenses **4** and **5**, and the points at which the light beam is imaged on the arrays are P1 and Q1.

Paying attention to the light beam emitted from the point O2 off the axis, this light beam having a field angle is once imaged on or near the predetermined imaging plane, whereafter it is re-imaged on the photoelectric conversion arrays **6** and **7** by the secondary imaging lenses **4** and **5**. The points at which the light beam is re-imaged on the arrays are P2 and Q2. The spacing Z1 between the points P1 and P2 and the spacing Z2 between the points Q1 and Q2 correspond to the images linking the points O1 and O2 together and must therefore be equal to each other.

However, as can be seen from FIG. **5**, if an attempt is made to provide a focus detecting unit at the bottom of a camera, the light beam refracted and passed through the substrate of the quick return mirror **9** will be measured. If, at that time, the direction of arrangement of the secondary imaging lenses is made orthogonal to the direction of arrangement shown in FIG. **5**, it means that as shown in FIG. **8** of the accompanying drawings, the quick return mirror **9** is disposed in the optical path while being inclined with respect to the direction of division D of the pupil of the photo-taking lens **1**. The imaged states of the light beams passed through the portions **1***a* and **1***b* of the pupil differ from each other and therefore, even if the various aberrations of the optical system are corrected well, the position of the imaging plane which provides the reference differs depending on the field angle and the aforementioned spacings Z1 and Z2 become unequal. More specifically, as shown in FIG. **9** of the accompanying drawings, Z1–Z2 by the field angle exhibits an inclined characteristic and therefore, even in the case of objects at the same object distance, there arises an inconvenience that the discrimination of the focus state of the lens differs between the central area and marginal area of the distance measurement field.

Accordingly, in the case of an ordinary single-lens reflex camera, optical elements must avoidably be disposed so that the direction of division of the pupil becomes horizontal, and this has been a limitation in the optical arrangement.

SUMMARY OF THE INVENTION

It is the object of the present invention to realize accurate detection even in the case of a detecting optical system including optical elements asymmetrical

disposed with respect to the direction of division of the pupil.

To achieve this object, an optical system for forming a pair of light distributions based on an object having their relative spacing varied in conformity with the focus adjusted state of an objective lens is a system optically asymmetrical with respect to the direction of division of the pupil of the objective lens.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is an optical sectional view showing a first embodiment of the present invention.

FIG. **2** is a partial sectional view of a modification of the first embodiment.

FIG. **3** is an optical sectional view showing another embodiment of the present invention.

FIG. **4** is a front view of the FIG. **3** embodiment,

FIG. **5** is a cross-sectional view of a single-lens reflex camera.

FIGS. **6**, **7** and **8** illustrate the optical action.

FIG. **9** is a graph of the performance.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

An embodiment of the present invention will hereinafter be described with reference to FIG. **1**.

Left in FIG. **1**, there lies a photo-taking lens, although not shown. Letter L designates the optic axis of the photo-taking lens. The reference numeral **9** denotes a quick return mirror similar to that described previously. That portion of the quick return mirror **9** which is near the optic axis L is a light-transmitting area.

The reference numeral **12** designates the predetermined imaging plane of the photo-taking lens, and the reference numeral **13** denotes a field lens. In the present embodiment, the field lens **13** is somewhat spaced apart from the predetermined imaging plane **12**, but alternatively, it may be disposed on the predetermined imaging plane **12**. The reference numerals **14** and **15** designate secondary imaging lenses arranged in the direction of inclination of the mirror **9**. In the present embodiment, the secondary imaging lenses **14** and **15** are formed as a unit of plastics with the sides of the two lenses cut off and joined together. The reference numerals **16** and **17** denote photoelectric conversion arrays. In FIG. **1**, they are shown divided into two rows, but alternatively, they may be used with a single row being divided into two detecting areas. The reference numeral **18** designates a two-aperture stop. The centers of the respective apertures of this stop **18** are coincident with the optic axes of the secondary imaging lenses, respectively.

The front surfaces of the secondary imaging lenses **14** and **15** provide spherical surfaces **14***a* and **15***a* and the rear surfaces provide planar surfaces **14***b* and **15***b*. In the present embodiment, the planar surfaces **14***b* and **15***b* are both inclined in the direction of arrangement of the photoelectric conversion arrays, and this has been caused due to two angles overlapping each other, and for the matters so far called in question, correction can be made simply by inclining one of these two surfaces. In FIG. **2**, the rear surface **14'***b* of one of secondary imaging lenses, **14'**, is optically parallel to the light-receiving surface of the photoelectric conversion array **16**, while the rear surface **15'***b* of the other photoelectric conversion array **15'** is inclined with respect to the light-receiving surface of the photoelectric conversion array **17**. To correct the deviation of the imaging plane shown in FIG. **8**, correction can be made with the angle put either upward or downward, and in the arrangement of FIG. **2**, correction is made by the rear surface **15'***b*. Only a light beam of one field angle is depicted in FIG. **8**, but actually, it is necessary to correct light beams of various field angles and therefore, the form of the inclined surface like the planar surface **15'***b* is taken. In this embodiment, the surface **15'***b* assumes a gentle rightwardly downward inclination, but this is determined by an optical arrangement including other optical elements such as a field lens, etc., and a leftwardly downward inclination is also possible.

The reason why the rear surfaces **14***b* and **15***b* of the secondary imaging lenses of FIG. **1** are both inclined will now be mentioned. This correction is already proposed in Japanese Patent Application No. 143126/1985 (U.S. application Ser. No. 877,850), and in the optical action illustration of FIG. **7**, paying attention to light rays travelling from a point lying on the predetermined imaging plane **2** and deviating downwardly from the optic axis L toward the photoelectric conversion arrays **6** and **7**, the angle of incidence differs between the secondary imaging lenses **4** and **5** and therefore, a delicate difference occurs between spacings Z1 and Z2 under the influence of the residual aberrations of the lenses. In order to correct this difference, one surface of each of the two secondary imaging lenses is made into a planar surface and these surfaces are equally inclined in the direction of arrangement of the photoelectric conversion arrays. Again in this case, however, the direction of inclination is varied by the optical arrangement.

It is of course more convenient to improvement in accuracy that this correction is used in all the focus detecting systems, but actually, this correction can be adopted in conformity with the practical tolerance limits required of each camera, and there is also an electrically correcting method and in that case, it will suffice to incline one planar surface alone.

In the embodiment of FIG. **1**, the correction of both surfaces is adopted to achieve highly accurate detection and avoid the burden of the electrical system and therefore, both planar surfaces **14***b* and **15***b* are inclined with respect to the direction of arrangement of the photoelectric conversion arrays and are asymmetrical with respect to the extension of the optic axis L of the objective lens. Also in the present embodiment, the rear surfaces of the secondary imaging lenses are planar surfaces, but alternatively, the front surfaces may be planar surfaces and the rear surfaces may be spherical surfaces.

An example of numerical values will be shown below.

First, the thickness of the quick return mirror **9** disposed in the camera body is 1 mm. Hereinafter, the unit is mm. The imaging plane lies at a distance of **21** from the entrance surface of the mirror **9** along the optic axis, and the first surface of the field lens **13** lies at a distance of 4.6 therefrom.

In the table below, R1 and R2 correspond to the first and second surfaces, respectively, of the field lens, and R3 corresponds to the first surface of the secondary imaging lenses. R is the radius of curvature, D is the spacing between lens surfaces, Nd is the refractive index for d-line, and νd is the abbe number.

TABLE

	R	D	Nd	νd
1	18.8	2	1.492	57.4
2	−12.8	16.5	1	
3	2.7	5	1.583	30.2

TABLE-continued

	R	D	Nd	νd
4	∞		1	

However, the R4 planar surfaces of the two secondary imaging lenses are valley-shaped, the surface **14***b* is inclined by 2°10′, and the surface **15***b* is inclined by 2°45′. The spacing between the optic axes of the two secondary imaging lenses **14** and **15** is 3.6.

The vertically asymmetrical bend of the Z1–Z2 shown in FIG. **8** by the field angle has been corrected by the above-described construction.

FIG. **3** shows another embodiment of the present invention, in which optical elements identical to those in the embodiment of FIG. **1** are given identical reference numerals. The reference numerals **24** and **25** designate secondary imaging lenses whose front surfaces are spherical surfaces. The optic axes of these front surfaces are designated by **24**L and **25**L, respectively. The rear surfaces of the secondary imaging lenses **24** and **25** are also spherical surfaces, but have a radius of curvature differing from that of the front surfaces, and their respective optic axes are designated by **24**L′ and **25**L′. The optic axis **24**L′ is optically parallel-displaced relative to the optic axis **24**L in the direction of arrangement of the photoelectric conversion arrays, and the optic axis **25**L′ is likewise parallel-displaced relative to the optic axis **25**L. The amounts of displacement are asymmetrical with respect to the extension of the optic axis L of the photo-taking lens. However, again in the present embodiment, it is for the aforedescribed two kinds of corrections that both optic axes are displaced, and if the influence of the quick return mirror **9** which the present application calls in question is eliminated, correction can be made by displacing only one of the optic axes. Alternatively, the optic axes may be displaced in the front surfaces of the secondary imaging lenses.

Further, the secondary imaging lenses each may be comprised of a plurality of lenses. A method of correcting the reduction in performance by displacing lens surfaces is proposed in U.S. application Ser. No. 907,588.

In the above-described embodiment, the apertures of the stop **18**, the secondary imaging lenses **24** and **25** and the photoelectric conversion arrays **16** and **17** have been shown vertically disposed in pairs, respectively, but if combination is made with a system in which secondary imaging lenses are horizontally disposed as in the conventional focus detecting system, accurate detection can be realized without being affected by the directionality of an object to be photographed. Such an optical system is proposed in U.S. application Ser. No. 919,506. FIG. **4** depicts the front form of only the unit of secondary imaging lenses, and as shown there, the displacement of the optic axes of the front and rear surfaces of secondary imaging lenses **26** and **27** arranged horizontally is symmetrical.

According to the present invention described above, highly accurate detection can be realized without being affected by an optical member which is rotation-asymmetrical with respect to the optic axis like the quick return mirror, and the inconvenience that the arrangement of the focus detecting system is limited by such kind of optical member can be eliminated.

We claim:

1. An apparatus for detecting the focus adjusted state of an objective optical system, comprising:

a plurality of pattern forming optical means for forming energy patterns whose relative positional relation varies in conformity with the focus adjusted state by the use of energy passed through different areas of a pupil of the objective optical system;

sensing means having a plurality of portions and producing a signal regarding a relative positional relation between the energy patterns; and

optical means disposed between the objective optical system and said pattern forming optical means for asymmetrically varying optical paths passing through said areas of the pupil;

said pattern forming optical means being arranged in the direction passing through said areas on the pupil and forming an asymmetrical shape with respect to the optic axis of said objective optical system, a first pattern forming optical means having a different shape from a second pattern forming optical means.

2. An apparatus according to claim **1**, wherein said optical means comprises a light-transmitting plane parallel plate inclined with respect to the optical paths passing through said areas on the pupil.

3. An apparatus according to claim **2**, wherein said light-transmitting plane parallel plate comprises a portion of a quick return mirror incorporated in a camera body.

4. An apparatus according to claim **1**, wherein said plurality of pattern forming optical means comprise a plurality of convexo-planar lenses which differ in the inclination of their planar surfaces.

5. An apparatus according to claim **1**, wherein each of said plurality of pattern forming optical means includes a biconvex lens having a second lens surface displaced relative to a first lens surface, the biconvex lenses each being different in a magnitude of displacement between the two lens surfaces.

6. An apparatus according to claim **1**, wherein each of said plurality of pattern forming optical means has a stop and a lens.

7. An apparatus according to claim **1**, further having another plurality of pattern forming optical means arranged in a direction differing from a direction of arrangement of said pattern forming optical means and forming separate energy patterns whose relative positional relation varies in conformity with the focus adjusted state of the objective optical system, and wherein said sensing means further has third and fourth portions each having a plurality of sensors and sensing said separate energy patterns.

8. A camera body used with an objective lens, comprising:

a quick return mirror having a reflecting area for reflecting a part of a light beam from the objective lens toward a viewfinder and a transmitting area for refracting and transmitting another part of the light beam therethrough;

an optical assembly having secondary imaging lenses optically arranged in a direction in which said quick return mirror is inclined for receiving the light beam transmitted through said transmitting area and forming energy patterns whose relative positional relation varies in conformity with the focus adjusted state of the objective lens; and

sensing means for receiving said energy patterns, said sensing means having two portions each having a

plurality of sensors, said sensing means producing a signal regarding the relative positional relation between said energy patterns;

said secondary imaging lenses being of an asymmetrical shape with respect to the optic axis of said objective lens, a first secondary imaging lens having a different shape from a second secondary imaging lens.

9. A camera body according to claim **9**, wherein said second imaging lenses include convexo-planar lenses which differ in the inclination of their planar surfaces.

10. A camera body according to claim **8**, wherein said secondary imaging lenses each include a biconvex lens having a second lens surface displaced relative to a first lens surface, said biconvex lenses differing in the magnitude of the displacement between the lens surfaces.

11. A camera body according to claim **8**, wherein said optical assembly has separate secondary imaging lenses arranged in a direction orthogonal to the direction of arrangement of said secondary imaging lenses.

12. An apparatus for detecting the focus adjusted state of an objective optical system, comprising:

a plurality of pattern forming optical means for forming energy patterns whose relative positional relation varies in conformity with the focus adjusted state by the use of energy passed through different areas of a pupil of the objective optical system;

sensing means having a plurality of portions and producing a signal regarding a relative positional relation between the energy patterns; and

optical means disposed between the objective optical system and said pattern forming optical means for asymmetrically varying optical paths passing through said areas of the pupil, said optical means comprising a light-transmitting plane parallel plate inclined with respect to the optical paths passing through said areas of the pupil; and

said pattern forming optical means being arranged in the direction passing through said areas of the pupil and forming an asymmetrical shape with respect to the optic axis of said objective optical system, a first pattern forming optical means having a different shape from a second pattern forming optical means, said plurality of pattern forming optical means comprising a plurality of convexo-planar lenses which differ in the inclination of their planar surfaces.

13. An apparatus for detecting the focus adjusted state of an objective optical system, comprising:

a plurality of pattern forming optical means for forming energy patterns whose relative positional relation varies in conformity with the focus adjusted state by the use of energy passed through different areas of a pupil of the objective optical system;

sensing means having a plurality of portions and producing a signal regarding a relative positional relation between the energy patterns; and

optical means disposed between the objective optical system and said pattern forming optical means for asymmetrically varying optical paths passing through said areas of the pupil, said optical means comprising a light-transmitting plane parallel plate inclined with respect to the optical paths passing through said areas of the pupil; and

said pattern forming optical means being arranged in the direction passing through said areas of the pupil and forming an asymmetrical shape with respect to the optic axis of said objective optical system, a first pattern forming optical means having a different shape from a second pattern forming optical means, each of said plurality of pattern forming optical means including a biconvex lens having a second lens surface displaced relative to a first lens surface, the biconvex lenses each being different in a magnitude of displacement between the two lens surfaces.

OBJECTIVE LENS

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to improvements in a triplet objective lens, and in particular to a behind stop modified Tessar type objective lens of compact three-group four-lens construction in which the angle of view amounts to 60° or greater and the brightness amounts to F3.5.

2. Related Background Art

A so-called Tessar type lens which is an objective lens comprising three components, i.e., a diverging biconcave lens and two converging portions with the diverging biconcave lens interposed therebetween has the features that its full length is relatively short and that the fluctuations of aberrations by the object distance are relatively small, and is known as a compact objective lens optical system. Particularly, a lens of the behind stop type in which a stop is provided rearwardly (on the image side) of the lens system permits distance adjustment to be accomplished by fixing the stop on the optic axis and axially moving only the lens and therefore is most suitable for the distance adjusting mechanism of a compact auto focus camera, and has often been put into practical use. In the ordinary Tessar type lens, a third component has a cemented surface convex relative to the object side, but many modified Tessar type lenses in which the third component has a cemented surface concave relative to the object side are also known. In such modified Tessar type, the sagittal plane is somewhat flat and the full length of the lens can be balanced to a slightly short length.

Generally, however, in the case of an objective lens provided with a behind stop, the light ray of an oblique light flux which passes through the marginal portion of a first lens passes through a location near the center of the stop and therefore, a decrease in the marginal light is liable to become conspicuous, and this leads to the disadvantage that it is difficult to correct the deficiency of the quantity of marginal light even if the variable stop is stopped down. In a Tessar type lens comprised of three components, it is possible to reduce the decrease in the marginal light considerably by making the effective diameter of the first lens large, but occurrence of coma and chromatic coma is conspicuous. Particularly, in the conventional modified Tessar type lens in which a third component has a cemented surface concave relative to the object side, occurrence of chromatic coma has been remarkable.

SUMMARY OF THE INVENTION

It is therefore an object of the present invention to provide a behind stop objective lens in which a compact form is kept and yet various aberrations, particularly, coma and astigmatism, are corrected better than in the conventional lens and moreover chromatic coma which is the above-noted disadvantage is corrected well in a modified Tessar type lens system of three-group four-lens construction.

The objective lens according to the present invention is a behind stop lens which comprises, in succession from the object side, a first lens L1 which is a positive meniscus lens having its convex surface facing the object side, a second lens L2 which is a biconcave lens, and a positive composite lens comprising a third lens L3 which is a biconvex lens and a fourth lens L4 which is a negative meniscus lens having its convex surface facing the image side, said third and fourth lenses L3 and L4 being cemented together, and in which is stop is provided most adjacent to the image side, and is characterized in that the values of the full length Σd of the lens system from that surface of the first lens L1 which is adjacent to the object side to that surface of the fourth lens L4 which is adjacent to the image side, the refractive index n2 of the second lens L2, the difference n3−n4 between the refractive indices of the third lens L3 and the fourth lens L4, the focal length f1 of the first lens L1, the radius of curvature r4 of that surface of the first lens L1 which is adjacent to the object side, the radius of curvature r6 of the cemented surface of the third lens L3 and the fourth lens L4, the radius of curvature r7 of that surface of the fourth lens L4 which is adjacent to the image side, the difference $\nu 4-\nu 3$ between the Abbe numbers of the fourth lens L4 and the third lens L3, the ratio (d5+d6)/d3 of the thickness (d5+d6) of the composite lens L3, L4 to the thickness (d3) of the second lens L2, and the sum d1+d5+d6 of the thicknesses of the first lens L1 and the composite lens L3, L4 are limited within ranges which will hereinafter be described.

According to the present invention, there is provided a behind stop modified Tessar type lens which is a compact lens in which the angle of view is 60° or greater and the brightness amounts to F3.5 and yet various aberrations are corrected well and particularly, coma and astigmatism are corrected better than in the conventional lens and at the same time, chromatic coma is also corrected well and further, distortion is small.

Other objects, features and effects of the present invention will become more fully apparent from the following description.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is the optical path diagram of a behind stop objective lens showing a first embodiment of the present invention.

FIG. 2 is a cross-sectional view of a second embodiment of the present invention.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

The objective lens of the present invention is a behind stop lens which, as shown in FIGS. 1 and 2, comprises in succession from the object side a first lens L1 which is a positive meniscus lens having its convex surface facing the object side, a second lens L2 which is a biconcave lens, a third lens L3 which is a biconvex lens, and a fourth lens L4 which is a negative meniscus lens having its convex surface facing the image side, said third lens L3 and said fourth lens L4 being joined together and form into a compositely positive cemented lens, and which further has a stop S on the side most adjacent to the image side of the lens system, and which satisfies the following conditions:

(1) $0.28f<\Sigma d<0.36f$
(2) $1.58<n2<1.745$
(3) $n1>n2$
(4) $0.24<n3-n4<0.30$
(5) $0.6f<f1<1.0f$
(6) $0.30f<-r6<0.40f$
(7) $f<-r7<2f$
(8) $10<\nu 4-\nu 3<25$
(9) $2<(d5+d6)/d3<9.9$

(10) $0.18f < d1 + d5 + d6 < 0.24f$

(11) $0.28f < r1 < 0.31f$

where

Σd: the full length of the lens system, i.e., the distance from the foremost lens surface to the last lens surface

f: the combined focal length of the lens system

ri: the radius of curvature of the ith surface from the object side

di: the spacing of the ith surface from the object side

ni: the refractive index of the ith lens from the object side

νi: the Abbe number of the ith lens from the object side

f1: the focal length of the first lens.

The above-mentioned conditions will hereinafter be described in detail.

Condition (1) is a condition for correcting coma and the quantity of marginal light well. If the full length is great beyond the upper limit of this condition, to secure a predetermined quantity of marginal light, it becomes necessary that an oblique light ray enter from a height distant from the optic axis. Thus, the light flux necessarily passes through the portions of the first lens L1 and the second lens L2 which are nearer to the edges thereof, and high-order aberrations occur and particularly coma is aggravated. If the full length exceeds the lower limit of this condition, the aggravation of coma tends to decrease, but the lens thickness and the air thickness become small and therefore, the effective diameter of each lens becomes small and the oblique light flux is intercepted by the first lens L1 and the second lens L2, and the quantity of marginal light becomes insufficient.

Conditions (2), (3) and (4) are conditions for correcting the Petzval sum well. In a popular phototaking lens, the entire system has a positive power and therefore has a positive Petzval sum, and to correct this, it is effective to make the convex lens high in refractive index and make the concave lens low in refractive index. The condition (3) that $n2 < n1$ is a condition necessary to correct the Petzval sum. If the refractive index n2 of the second lens L2 which is a negative lens exceeds the upper limit of condition (2), the refractive index is too high relative to the convex lens and therefore, correction of the Petzval sum is not done. If n2 exceeds the lower limit of condition (2), it is effective for the correction of the Petzval sum, but the radius of curvature of the second lens L2 becomes small to keep the focal length and therefore, high-order aberrations of divergent property occur in the marginal portion of the lens and coma is aggravated and good correction is not accomplished.

If the difference between the refractive indices of the third lens L3 and the fourth lens L4, i.e., the value of condition (4), exceeds the lower limit, the Petzval sum is also under-corrected. Also, as the difference in refractive index between the third lens L3 which is a positive lens and the fourth lens L4 which is a negative lens ($n3 - n4$) is greater, it is more advantageous for the correction of the Petzval sum, but if the upper limit of condition (4) is exceeded, the converging action in the cemented surface becomes too strong with a result that the bulge of spherical aberration increases and this cannot be corrected.

Condition (5) is a condition effective for the correction of distortion. In the behind aperture lens, positive distortion is usually liable to occur. Particularly, if the focal length of the positive lens (e.g. L1) farthest from the stop becomes short and the refractive power thereof increases, positive distortion is increased. If the power limit of condition (5) is exceeded, positive distortion becomes strong and is not corrected well. As the value of the focal length fl of the first lens L1 is greater, correction of distortion is easier, but the focal length of the composite positive lens comprising the third lens L3 and the fourth lens L4 cemented together becomes short in order that the focal length as the entire system may be of a predetermined value. If the value of the focal length f1 of the first lens L1 exceeds the upper limit of condition (5), the converging action of the cemented positive lens comprising the third lens L3 and the fourth lens L4 becomes too strong, and particularly, as the angle of view becomes greater, the coma above the principal ray is sharply aggravated and becomes difficult to correct.

Conditions (6) and (7), with condition (5), are conditions for correcting coma well. First, condition (6) prescribes the direction and curvature of the cemented surface between the third and fourth lenses L3 and L4. This cemented surface has its sharper concave surface facing the object side and particularly has the strong action of converging the light flux below the principal ray of the oblique light flux. By well balancing the strong converging property of this cemented surface with the strong diverging property in the second lens L2, the coma below the principal ray can be well balanced. If the radius of curvature r6 of the cemented surface exceeds the upper limit of condition (6), the converging action of the cemented surface weakens and the diverging property in the second lens L2 is relatively strongly influenced and coma, particularly, the lower coma, is aggravated and is not corrected. Also, the second lens L2 is a flint lens having a high dispersing power and therefore, causes a light of short wavelength (g-line) to diverge sharply, and chromatic coma becomes aggravated and is not corrected. If the lower limit of condition (6) is exceeded, the converging property of the cemented surface becomes relatively strong and the lower coma occurs in the opposite direction and is not corrected well.

Condition (7) prescribes the range of the radius of curvature of the last lens surface, which is a surface for converging the light rays. This converging action converges the light flux below the principal ray of the oblique light flux more effectively, but the last surface does not cause high-order aberrations to occur so much as the cemented surface between the third and fourth lenses L3 and L4. Therefore it has the effect of converging the lower light flux in the entire picture plane. Accordingly, by well balancing the converging action which affects the entire picture plane of the last surface with the converging action of the cemented surface between the third and fourth lenses L3 and L4 which works particularly remarkably at a great angle of view and the diverging action of the second lens L2, it becomes possible to correct the coma below the principal ray of the oblique light flux well. If the radius of curvature r7 of the last surface of the fourth lens L4 exceeds the upper limit of condition (7) and the converging action thereof weakens, the lower coma of a small angle of view becomes negative and aggravated and good correction thereof is not accomplished. Also, if the converging action strengthens beyond the lower limit of condition (7), the lower coma of a small angle of view conversely becomes positive and aggravated and again, good correction thereof is not accomplished.

Condition (8) is a condition for correcting chromatic coma better. The second lens L2 is flint glass and therefore, in a Tessar type lens, a light of short wavelength (g-line) is made excessively divergent by the second lens L2 and chromatic coma occurs. To correct this more effectively, it is better to utilize the converging action of the cemented positive lens comprising the third and fourth lenses L3 and L4, and the light of short wavelength (g-line) can be converged sharply by the surfaces of these lenses. Condition (8) is a condition effective for this, and as the difference ($\nu 4 - \nu 3$) between the Abbe numbers of the third lens L3 and the fourth lens L4 has a greater value, the influence of high-order aberrations strengthens and good correction is ensured. If the upper limit of condition (8) is exceeded, the dispersion of the third lens L3 becomes relatively great and therefore, the on-axis chromatic aberration becomes under-corrected and cannot be corrected well. On the other hand, if the lower limit of this condition (8) is exceeded, the correcting effect for chromatic coma becomes small and good correction of chromatic coma becomes difficult.

Condition (9) regards the center thickness of the composite positive lens comprising the third lens L3 and the fourth lens L4 cemented together. In a positive lens, generally, spherical aberration and curvature of meridional image field have negative values. In the rearward cemented positive lens component in a popular Tessar type lens, the cemented surface has a converging action and therefore, spherical aberration and curvature of meridional image field are caused to occur more negatively. These are corrected chiefly by a negative lens, but when the aberrations by the negative lens are great, the influence of high-order aberrations resulting from correction becomes strong and the bending of spherical aberration and the bending of curvature of meriodional image field become remarkable. Also, to reduce the occurrence of negative spherical aberration and negative curvature of image field caused by the positive lens, it is generally known that it is effective to increase the center thickness of the positive lens. So, in the present invention, by prescribing the combined center thickness (d5+d6) of the third and fourth lenses L3 and L4 forming the composite positive lens as shown in condition (9) relative to the center thickness d3 of the negative lens L2, the bulge of spherical aberration and the bending of curvature of meridional image field are corrected. As the value of condition (9) is greater, it is possible to reduce the bulge of spherical aberration and the bending of curvature of meridional image field, but as the thickness of the cemented positive lens comprising the third and fourth lenses L3 and L4 becomes greater, the oblique light ray tends to become farther from the optic axis at the position of the stop and at last, deficiency of the quantity of marginal light results. If the upper limit of condition (9) is exceeded, the quantity of marginal light is insufficient, and if the lower limit of condition (9) is exceeded, the bulge of spherical aberration and the bending of curvature of meridional image field become great and good correction of aberrations cannot be accomplished.

Condition (10) prescribes the total center thickness of the positive lens components of the lens system in the present invention. If the upper limit of condition (10) is exceeded, the quantity of marginal light decreases, and if the lower limit of condition (10) is exceeded, curvature of image field becomes remarkable. Also, condition (11) prescribes an appropriate radius of curvature of the foremost lens surface. If the upper limit of this condition (11) is exceeded, curvature of image field increases, and if the lower limit of this condition is exceeded, spherical aberration becomes remarkable and good correction thereof becomes difficult. In the aforedescribed condition (10), it is desirable that the thickness d1 of the first lens L1 satisfy the following condition:

(12) $0.08f < d1 < 0.1f$

Further, in the present invention, the quantity of marginal light of the lens is secured sufficiently and moreover, the first lens L1 and the second lens L2 contact with each other at the marginal portions thereof as shown in FIG. 1 and the second lens L2 and the third lens L3 contact with each other at the marginal portions thereof as shown in FIG. 1, whereby the objective lens can be constructed without the use of a spacer. As the condition therefor, it is desirable that

(13) $d2 > d4$.

Also, as a condition for keeping the upper coma good, it is desirable that the radius of curvature r5 of that surface of the third lens L3 which is adjacent to the object side satisfy the following condition:

(14) $0.45f < r5 < 0.70f$

Furthermore, as a condition for keeping astigmatism good, it is desirable that the radius of curvature r2 of that surface of the first lens L1 which is adjacent to the image side satisfy the following condition:

(15) $0.45f < r2 < 0.75f$

Tables 1 and 2 below show the data of two embodiments, respectively, of the present invention. The first embodiment shown in Table 1 and the second embodiment shown in Table 2 are ones in which the focal length f=100 and F-number is 3.5. In the tables below, the numbers at the left end represent the order from the object side. Also, Bf represents the back focal length, f1 represents the focal length of the first lens, f2 represents the focal length of the second lens, and f3 represents the combined focal length of the third and fourth lenses.

TABLE 1

(First Embodiment)
Focal length f = 100, F3.5

No.	Radius of curvature r	Center thickness and space d of the lens	Refractive index n	Abbe number ν
1	30.652	9.860	1.76684	46.76

6	−33.811	2.499	1.51680	64.12
7	−85.944			

TABLE 2-continued

(Second Embodiment)
Focal length f = 100, F3.5

No.	Radius of curvature r	Center thickness and space d of the lens	Refractive index n	Abbe number ν
		Bf = 81.140		
		Σd = 28.602		
		f1 = 63.397		
		f2 = −33.907		
		f3 = 47.495		

These embodiments are ones in which positive distortion liable to occur in a behind stop modified Tessar type lens like the lens according to the present invention is corrected to a further smaller value. As a condition for correcting distortion to a smaller value as in the embodiments, it is desirable that the following condition be satisfied:

(16) $1.3<(f1/f3)<2.6$,

where f1 is the focal length of the first lens, and f3 is the combined focal length of the third lens L3 and the fourth lens L4. If the upper limit of condition (16) is exceeded, distortion becomes negative, and if the lower limit of condition (16) is exceeded, distortion becomes positive.

I claim:

1. An objective lens having a stop provided most adjacent to the image side, comprising, in succession from the object side, a first lens which is a positive meniscus lens having its convex surface facing the object side, a second lens which is a biconcave lens, a third lens which is a biconvex lens, and a fourth lens which is a negative meniscus lens having its convex surface facing the image side and is joined to said third lens and formed into a compositely positive cemented lens, characterized in that said objective lens satisfies the following conditions:

(1) $0.28f<\Sigma d<0.36f$
(2) $1.58<n2<1.745$
(3) $n1>n2$
(4) $0.24<n3-n4<0.30$
(5) $0.6f<f1<1.0f$
(6) $0.30f<-r6<0.40f$
(7) $f<-r7<2f$
(8) $10<\nu4-\nu3<25$
(9) $2<(d5+d6)/d3<9.9$
(10) $0.18f<d1+d5+d6<0.24f$
(11) $0.28f<r1<0.31f$

where

Σd: the full length of the lens system
f: the focal length of the lens system
ri: the radius of curvature of the ith surface from the object side
di: the spacing of the ith surface from the object side
ni: the refractive index of the ith lens from the object side
νi: the Abbe number of the ith lens from the object side
f1: the focal length of the first lens.

2. An objective lens according to claim 1, characterized in that the thickness d1 of said first lens satisfies the following condition:

$0.08f<d1<0.1f$.

3. An objective lens according to claim 1, characterized in that the spacing d2 between said first lens and said second lens and the spacing d4 between said second lens and said third lens satisfy the following condition:

$d2>d4$.

4. An objective lens according to claim 1, characterized in that the radius of curvature r5 of that surface of said third lens which is adjacent to the object side satisfies the following condition:

$0.45f<r5<0.70f$.

5. An objective lens according to claim 1, characterized in that the radius of curvature r2 of that surface of said first lens which is adjacent to the image side satisfies the following condition:

$0.45f<r2<0.75f$.

6. An objective lens according to claim 1, characterized in that the ratio (f1/f3) of the focal length f1 of said first lens to the combined focal length f3 of said third lens and said fourth lens satisfies the following condition:

$1.3<(f1/f3)<2.6$.

7. An objective lens according to claim 1, characterized by the following data:

Focal length f=100, F3.5

No.	Radius of curvature r	Center thickness and space d of the lens	Refractive index n	Abbe number ν
1	30.652	9.860	1.76684	46.76

[57] **ABSTRACT**

An objective for a photographic camera is mounted on a carrier having a squeezable handle by which the focusing device can be actuated. The objective has a zoom facility and may also have a macro facility which is actuated by the camera acting on the zoom facility or the macro facility by means of a sliding or a turning movement.

FIG. 1

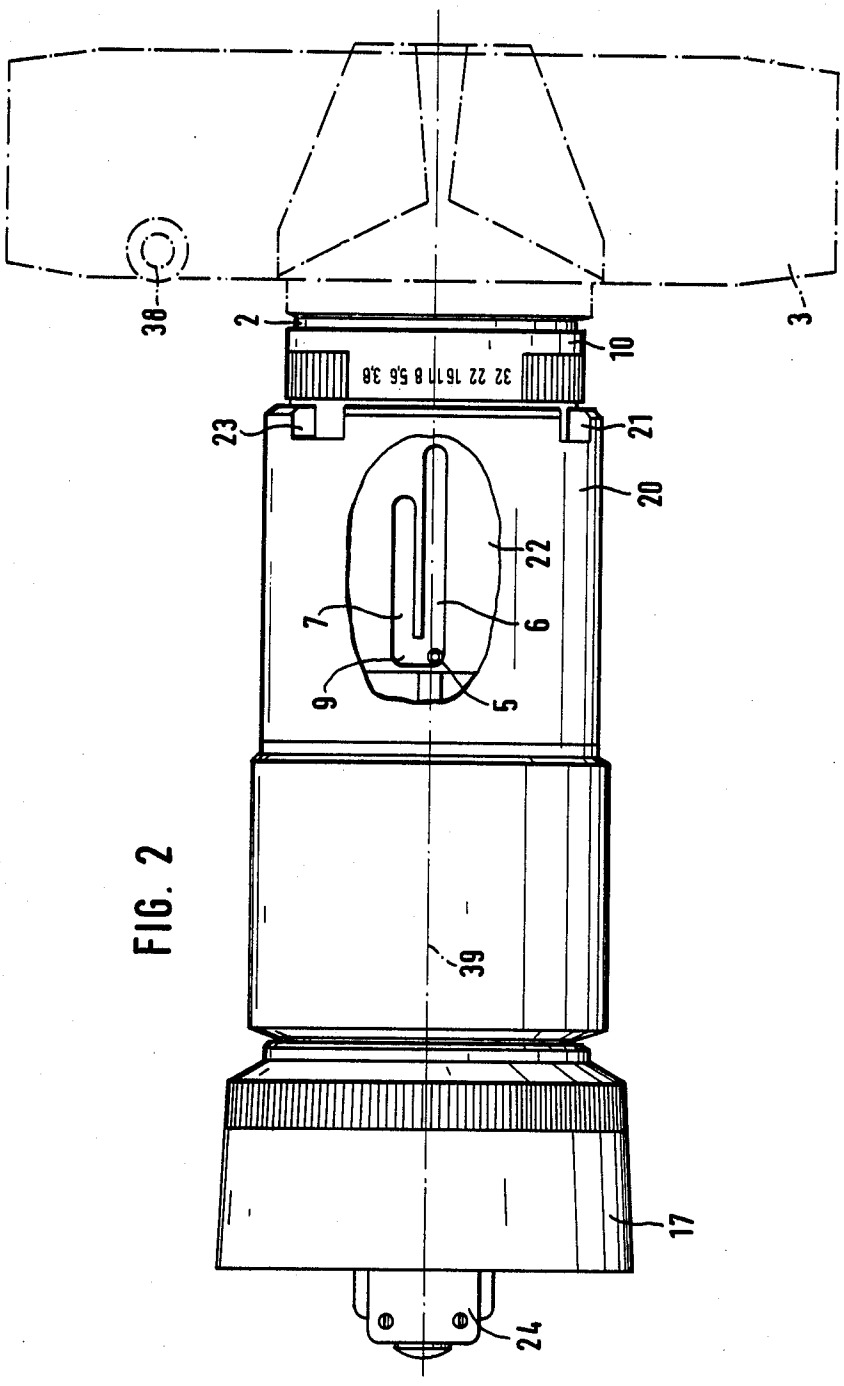

FIG. 2

OBJECTIVE FOR PHOTOGRAPHIC CAMERAS

FIELD OF THE INVENTION

The invention concerns an objective (by which is meant a lens assembly, and herein termed an "objective") for photographic cameras, having an objective housing, a focusing device on the front part of the objective and having a zoom facility, and if required also a macro facility, controllable by a sliding movement, in the direction of the optical axis of the objective relative to the objective housing, of a connecting element arranged at the end of the objective nearer the camera, which element serves to connect the objective with the camera.

DESCRIPTION OF THE PRIOR ART

Objectives having a zoom facility, and if required also a macro facility, of the type set out hereinbefore, are known. Such objectives are used in the following way: the objective is supported by one hand at the objective housing, while the other hand of the operator operates the camera. Adjustment of the desired focal distance when using a zoom facility, or of the desired enlargement when using a macro facility, is performed by a sliding movement of the camera towards the objective housing. In order to change from operation of the zoom facility to operation of the macro facility, the camera is turned through a small angle relative to the objective housing, so that in each case the facility being used becomes effective and the other facility becomes inoperative.

For the purpose of focusing, these known objetives have at the front end of the objective an adjusting ring which permits screw movement. This screw movement is indirectly or directly transferred to the focusing part of the objective lenses, thus enabling fine adjustment.

These known objectives and their relevant cameras are troublesome to use. While one hand supports the camera, the other hand has to operate not only the focusing device at the front end but also the shutter and the release, and possibly also the zoom facility at the rearward end of the objective. In the case of moving objects, fine adjustment can become impossible, particularly when e.g., the zoom facility has to be adjusted subsequently.

The invention has as an object to find an arrangement which considerably facilitates and accelerates operation of such an objective and its relevant camera.

SUMMARY OF THE INVENTION

To solve this problem, a start is made from an objective of the kind set out in the opening paragraph of this specification. According to the invention it is proposed that the objective housing be mounted on a carrier having a handle consisting of two parts which are compressible together against a restoring force and which acts on a slidable sleeve of the objective movable in the direction of the optical axis and carrying the focusing part of the objective lenses.

This problem is solved by the invention in a surprisingly simple way. One hand of the operator supports the objective by means of the carrier and also actuates the focusing device while the other hand of the operator actuates the zoom facility or the macro facility and also operates the camera. This hand can also actuate the shutter without any substantial change in the position of the hand on the camera being necessary.

Thus both hands can support the camera and the objective, since the position of the hand on the camera need not be changed substantially and in particular need not actuate the focusing device.

In the practical use of such an objective and a camera it is further found that the focusing device can be operated at the same time that the zoom facility is actuated, thus enabling a sharply-defined picture to be quickly obtained. As the camera cn be released without changing the hand position, operating time is considerably shortened. This has a considerable advantage when photographing moving objects, for example when taking sports pictures and the like.

There is a further advantage which has an effect particularly with regard to the taking of macro photographs. In taking macro photographs, the distance between the object and the objective is relatively small. If living animals are to be photographed, movement of the hand to the front end of the objective or to a device for fine adjustment often spoils the picture.

Use of a carrier for supporting an objective, and actuating a focusing device by a compressible handle, is known per se. Hitherto, however, such a device has been used with objectives having relatively long focal distances and corresponding weight, and has served merely to accelerate focusing. This invention however has a further advantage, that, when using a relatively light objective, such objectives having a zoom facility can be provided with a sliding arrangement which actuates both the focusing and the zoom or macro facility.

A further feature of the invention provides a sliding sleeve enclosing the objective housing. Although this means that a part of the length of the objective housing is lost for the purpose of support by the carrier, this mode of construction permits a simple coupling of the movement of the movable handling part with the slidable sleeve of the focusing part.

In particular, the invention proposes that one part of the handle be connected with a carriage which is movable on the carrier and acts on the slidable sleeve with a pin extending from the carriage and engaging said one part of the handle; and preferably two spaced stops are mounted on the outside of the slidable sleeve, between which the pin engages.

BRIEF DESCRIPTION OF THE DRAWINGS

The drawing is a diagrammatic representation of an embodiment of an objective for use on a camera in accordance with the invention. In the drawing,

FIG. 1 is a side view, partly in section, of the objective according to the invention, and

FIG. 2 shows a top view of the objective shown in FIG. 1.

DESCRIPTION OF THE PREFERRED EMBODIMENT

In the drawing, the camera 3 is indicated by chain lines. The camera is attached to the connecting ring 2 of the objective 1, for example by being screwed into this ring or else held by means of a bayonet attachment. A ring 10 for adjusting the automatic shutter 40 of the objective 1 is arranged on the connecting ring 2.

The objective 1 shown has, as is known per se, a zoom facility and also a macro facility. The objective 1 consists of a total of five sets of lenses. The lens set 11

serves for focusing. It is carried by a sliding sleeve **16** to which is also secured a sun shield **17**.

In the central region of the objective **1** there are lens sets **12** and **13** which are displaceable relative to each other and also to the other sets of lenses. The lens sets **14** and **15** are accommodated together in a displaceable sleeve **18**. The lens setse **12**, **13**, **14** and **15** represent essentially the zoom facility and serve to alter the focal distance.

An objective structure of the type described so far is known per se. If the zoom facility is to be used, the lens sets **12**, **13** and the sleeve **18** with the lens sets **14** and **15** are displaced relative to each other. If the macro facility is actuated, the camera **3** only is displaced towards the rear in the direction of the optical axis **39**, the focal distance being unchangeable. The mechanical elements for actuating the zoom or the macro facility are however not fully represented in the drawing. These mechanical elements, which, regarded separately, are known, are driven in the embodiment of this invention, via the connecting ring **2** or the sleeve-shaped extension **19**. On this extension **19** there are two guide pins **5** (see also FIG. **2**) which are each movable in longitudinal slots **6** and **7**. By a rotary movement on the camera **3**, the connecting ring **2**, which is firmly connected therewith, can be turned so that each guide pin **5** is aligned with either a slot **6** or a slot **7**. When the guide pins **5** move in the slots **6**, the macro facility is actuated. When the guide pins **5** move in the slots **7**, the zoom facility is actuated.

On the housing **20**, which encloses both the extension **19** and the sleeve **22** in which the longitudinal slots **6** and **7** are provided, there are recesses **21** and **23**. If the guide pins **5** are aligned with the slots **6**, a marking is visible in the recess **21** to indicate that the macro facility is actuated. If however the guide pins **5** are aligned with the slots **7**, the relevant focal distance of the lens can for example be read in the recess **23**.

In the embodiment shown, the longitudinal slots **6** and **7** are joined together at their ends **9** in such a way that, in the appropriate position of the objective, a change can be made from actuation of the macro facility to actuation of the zoom facility. In the embodiment shown, the zoom facility is in the position having the shortest focal distance. In the case of other objectives the arrangement may be different. This is not essential for an understanding of the invention.

The objective **1** with its housing **20** is mounted on a carrier **24** which has a handle consisting of two parts **25** and **26**. The part **26** of the handle is held on a guide rod **27** which is displaceably mounted with its two ends in the carrier **24**. One mounting, which is shown in section, consists essentially of a fixed sleeve **28** in which the rod **27** with a sliding member **29** slides.

On a collar **31** of the guide rod **27** there is supported a spring **32** which is located on an abutment in the interior of the carrier **24**.

When the parts **25** and **26** of the handle squeezed together, the guide rod **27** is displaced against the force of the spring **32** and the spring **32** pushes the guide rod **27** forward in a direction paralell to the optical axis when the handle is released.

The guide rod **27** is connected with a carriage **33**. A pin **34** is mounted in the carriage **33** and is pressed towards the objective **1** by a small spring **35**. The pin **34** thereby engages in a recess **36** between two stops **37** on the sliding sleeve **16** of the lens. By compression of the handle which consists of the parts **25** and **26**, the sliding sleeve **16** together with the first lens set **11** is moved and the objective **1** can be focused.

In use of the objective according to the invention, the operator holds the handle comprising the parts **25** and **26** with one hand and thus is able to actuate the focusing device, that is to say the sliding sleeve **16** for the first lens set **11**, and grasps the camera **3** with the other hand with one finger on the release **38**. With the hand holding the camera **3**, the operator by a pushing or a turning movement is able to actuate the macro facility or the zoom facility of the objective **1** as desired.

What we claim as our invention and desire to secure by Letters Patent of the U.S. is:

1. An objective for a photographic camera, the objective including an objective housing; a focusing device in said objective; means in said objective providing a zoom facility and a connecting element at one end of said objective for connecting said objective to a camera, said connecting element being movable in the direction of an optical axis of the objective relative to said objective housing to enable said zoom facility to be actuated, a carrier on which said objective housing is mounted; a two-part handle having one part fixed to said carrier and the other part movable towards said one part when said handle is gripped in one hand by an operator; a slidable sleeve surrounding the objective housing, said sleeve being movable in the direction of the optical axis and carrying said focusing device, restoring means acting to urge said two parts of said handle apart, said two parts of said handle being squeezable in said one hand against the action of said restoring means to effect sliding of said sleeve and actuation of said focusing device; a carriage on which said one part of the handle is mounted, the carriage being movable with respect to said carrier, a pin mounted in said carriage and extending therefrom, two spaced stops mounted on the outside of said sleeve, said pin engaging between said stops for sliding the sleeve to provide actuation of the focussing device, and the objective also including means providing a macro facility, said connecting element being movable in the direction of the optical axis of said objective relative to said objective housing to enable said macro facility to be actuated, and selector means in said objective housing having two alternative settings of which one corresponds to said zoom facility and the other corresponds to said macro facility, said selector means being selectively movable into each of said settings whereby one only of said zoom and macro facilities is actuated for each setting.

2. An objective as claimed in claim **1** in which said selector means comprises a further sleeve positioned coaxially within said objective housing and having thereon two altenrative slots of unequal length and each extending parallel to said optical axis of said objective and spaced apart in the circumferential direction of said further sleeve and a pin fixed with respect to said connecting element and selectively engageable in one or other of said slots on turning said connecting element with respect to said objective housing about said optical axis.

[57] **ABSTRACT**

The present invention can be applied to a control device wherein the probability of giving the proper exposure to the primary object photographed is high even when the regions to be found in range within the photographing distance are plural, thereby to being capable of more positively judging the backlight condition, an automatic focus adjusting apparatus capable of more reflecting the photographing intention of the photographer, an exposure control apparatus capable of normally providing the proper exposure amount with respect to the photographed object independently of the distance to the object photographed even when the daylight synchronized flash photographing operation is performed, and a control device which does not need a switching circuit and the switching operation by it.

CONTROL DEVICE FOR USE IN A CAMERA HAVING AN OBJECTIVE LENS

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to a control device for use in a camera, and more particularly to a control device which controls both the focusing operation of an objective lens of the camera and exposure operation of the camera.

2. Description of the Prior Art

There has been proposed, in U.S. Pat. No. 4,423,936, a control device in which distance detection for the focusing operation and a light measuring for the exposure operation are performed with respect to a plurality of regions in an object area to be photographed, and a distance is selected among the detected distances for the focusing operation. If the selected distance is detected with respect to a single region, a light measurement value measured with respect to the single region is used for exposure operation to control exposure value. On the other hand, if the selected distance is detected with respect to plural regions, plural light measurement values measured with respect to the detected regions are averaged to be used for the exposure operation to control exposure value.

However, in the conventional device as described above, since a primary object to be focused is not always positioned at the detected plural regions, the possibility for obtaining proper exposure for the primary object is relatively low.

Furthermore, in the conventional device, backlight condition is detected in the case that, difference between a first light measurement value measured with respect to the region in which the selected distance is detected and a second light measurement value calculated by averaging all of other light measurement values, is over a predetermined value. Here, if the selected distance is detected with respect to plural regions, the first light measurement value is calculated by averaging plural light measurement values of the plural regions. However, the difference is not always indicating whether the backlight condition or not in the latter case. Fore example, if the selected distance is detected in two regions arranged symmetrically with an optical axis of the objective lens, it is impossible to judge at which region a primary object is positioned in the device. In such case, it would be improper to detect the backlight condition.

There has been proposed, in Japanese Laid-Open patent application No. 60-129732, another control device in which a common ligh receiving device is used for the light measuring and for the distance detection. In the device, one calculating circuit for distance detection and the other calculating circuit for light measuring are provided, and the output of the common light receiving device is sent to two calculating circuits in time-sharing manner or in time-dividing manner. The distance detection calculation and exposure calculation are performed in respective circuits. However, such device has disadvantages that the construction thereof becomes comples since two calculating circuits and switching circuit for selectively transmitting the output of the light receiving device to the two calculating circuits are necessary, and that the operation of the entire device becomes complex since switching operation of the switching means is necessary.

SUMMARY OF THE INVENTION

Accordingly, an object of the present invention is to provide a control device for use in a camera having an objective lens wherein the probability of giving the proper exposure to the primary object photographed is high even when the selected distance is detected with respect to plural regions.

Also, another object of the invention is to provide a control device for use in a camera having an objective lens which is capable of more positively judging the backlight condition.

An additional object is to provide a control device for use in a camera having an objective lens which does not need a switching circuit for finding a range even when regions to be found in the range within the photographing distance are plural.

In accomplishing these and other objects, according to the present invention, there is provided a control device for use in a camera having an objective lens, comprising means for producing a plurality of distance signals necessary for focusing the objective lens on a plurality of first regions of an object area to be photographed; means for determining a distance on the basis of the plurality of distance signals to produce a determined distance signal for focusing the objective lens; means for driving the objective lens in accordance with the determined distance signal; means for measuring a plurality of brightnesses of second regions of the object area to produce a plularity of brightness signal each corresponding to the measured brightnesses respectively, each of the second regions being substantially similar to each of the first regions, respectively; means for counting the number of the distance signals used in the distance determining means for determining the distance; means for discriminating whether the number counted by the counting means is single or plural; means for determining a light measuring value by a first calculation when the discriminating number is single, while determining the light measuring value by a second calculation which is different from the first calculation and which is independent of the discriminated number when the discriminated number is plural; and means for calculating exposure value of the camera in accordance with the light measuring value, so that satisfactory exposure may be provided, judging from the experiences even when the selected distance is detected with respect to plural regions.

BRIEF DESCRIPTION OF THE DRAWINGS

These and other objects and features of the present invention will become apparent from the following description taken in conjunction with the preferred embodiments thereof with reference to the accompanying drawings, in which:

FIG. 1 is an illustrating view showing one arrangement of a light measuring optical system to be used in a first embodiment of the present invention;

FIG. 2 is an illustrating view showing the construction of a liquid-crystal filter of transmission wavelength switch type;

FIG. 3 is an illustrating view showing the light measuring range;

FIG. 4 is a block diagram showing a light measuring circuit employed in the first embodiment of the present invention;

FIG. 5 is a circuit diagram showing the switch groups in FIG. 4;

FIG. 6 is a further detailed block diagram of the light measuring circuit in FIG. 4;

FIG. 7 is a circuit diagram showing the construction of the light measuring circuit and the timing circuit thereof;

FIG. 8 is a block diagram showing the circuit construction of an electronic flashing apparatus in the first embodiment of the present invention;

FIG. 9 is a graph showing the relationship among the distance region of the photographed object, the focusing range and the aperture value (so-called lens opening);

FIGS. 10 through 14 are flow charts showing the operation of the microcomputer of FIG. 4; and

FIGS. 15 and 16 are flow charts showing about the decision of the distance region for the photographing operation in the second embodiment of the present invention.

DETAILED DESCRIPTION OF THE INVENTION

Before the description of the present invention proceeds, it is to be noted that like parts are designated by like reference numerals throughout the accompanying drawings.

The embodiment wherein the present invention has been applied upon the lens shutter camera will be described with reference to the accompanying drawings. First, the distance detection and the light measurement to be used in the embodiment will be described in principle. The distance detecting apparatus is composed of a projecting means for projecting the light onto the entire region of the photographed field to be detected in distance, a light-receiving means for receiving the light to be reflected from the object, and a circuit for processing the signals from the light-receiving means to detect the distance.

The light-receiving means is composed of a plurality of light-receiving elements, by which the photographed field is divided into a plurality of regions to detect the respective distances. And one of the distances is selected as a distance where the photographing lens is focused, thereby the brightness of the selected region is detected as supposing that a primary object is positioned in the selected distance. In the present embodiment, the common light-receiving elements are used for both the distance detection and the brightness detection.

Referring now to FIG. 1, there is shown a concrete example of the optical system with the light-receiving element being provided for common use. An electronic flashing apparatus FL2 is the projecting means which projects the light on the entire region of the photographed field through the filter IRF1 provided on the front face, through which the infrared light of particular wavelength or wavelength range is transmitted. The light-quantity emitted by the electronic flashing apparatus FL2 is by far less than the light-quantity emitted by the electronic flashing apparatus for object illumination use to be employed in the photographing operation. A condenser lens LE collects the light reflected from the object OB to guide into the light receiving element SPC. A filter LCDF1 which is adapted to be capable of switching to a filter for transmitting the infrared light of particular wavelength or wavelength range through it, and a filter having the characteristics of visual sensitivity is provided between the condenser lens LE and the light-receiving element SPC.

This filter is constructed as shown in FIG. 2. Namely, the filter LCDF1 is composed of a guest-host type liquid crystal devices LCD1 and LCD2. When the signal of the "High" level (hereinafter referred to as "H") is outputted from a terminal OP1 of a microcomputer MC shown in FIG. 4, a predetermined voltage V2 is applied upon a first liquid crystal device LCD1 through a buffer BUF, and the first liquid crystal device LCD1 comes to let the infrared light of the particular wavelength or wavelength range pass through it. On the other hand, when the signal of the "Low" level (hereinafter referred to as "L") is outputted from the output terminal OP1 of the microcomputer MC, the predetermined voltage V2 is applied upon a second liquid crystal device LCD2 through a buffer BUF and an inverter IN2, so that the second liquid crystal device LCD2 comes to operate as a visible-sensitivity filter through which the light of the visible sensitivity range may pass. The buffer BUF and the inverter IN2 are adapted to be fed by the power voltage to be described later. Accordingly, when the release button (not shown) is not depressed, both the liquid crystal devices remain colorless in light transmission condition without application of the voltage.

The light-receiving element SPC shown in FIG. 1 is composed of a plurality of elements as described hereinabove and is adapted to measure each of a plurality of regions ① through ⑨ of the object field shown by rectangular frame in FIG. 3. A plurality of the light-receiving elements are arranged to measure the region which is deviated a little downwardly of the object field as a whole, and are composed of nine elements in total arranged symmetrically in the horizontal, vertical relation with the No. 1 light-receiving element as a center being provided to measure the region a little lower than the center of the object field. They are adapted to detect the distance and brightness of the regions ① through ⑨ shown in the oblique-line portions. The reason where they are arranged somewhat downwardly with respect to the field to be photographed is that the object or the person regarded as the primary object is often provided in the lower portion, but in the upper portion with the lens shutter camera having a comparatively wide-angle lens.

The camera system which performs the above-described described distance detection and brightness detection will be described hereinafter. In the block diagram of FIG. 4 showing the circuit construction of the entire camera, a power battery E consists of direct connection of two lithium cells each producing 3 V. A diode D1 is provided for preventing the voltage applied to the microcomputer MC from becoming lowered during the operation of the boosting circuit in the electronic flashing apparatus FL. A capacitor C0 is provided to prevent the noises and to hasten the charging operation to the main capacitor in the electronic flashing apparatus FL. A capacitor C1 has comparatively large in capacity for the back-up operation of the microcomputer MC. A resistor R1 and a capacitor C2 for resetting use are adapted to reset the microcomputer MC when the power batter E is mounted. A group of switches SW have a plurality of switches which are required for the operation of the apparatus of the present embodiemnt. The group of switches will be described in detail with reference to FIG. 5.

A display circuit DI displays the photographing information. A liquid-crystal filter FI, which is shown in FIG. 2, becomes an infrared filter or a visible-light filter. The microcomputer MC is provided to control the entire circuit. A film sensitivity setting circuit IS converts the film sensitivity, which is read from the code pattern provided on the film container or is manually set, into the film sensitivity value represented by A.P.E.X. system to output it into the microcomputer MC. A light measuring circuit LM is composed of a distance detection circuit for receiving the light, which are emitted from the electronic flashing apparatus FL for distance detection to be described later and are reflected from the object to detect the distance of the object, and a light measuring circuit for measuring the brightness BV of the object. An exposure control circuit AE for controlling the exposure in accordance with the exposure value EV to be outputted from the microcomputer MC outputs the flash starting signal X1 to the electronic flashing apparatus FL at a given timing. An AF controlling circuit AFC drives the objective lens to an in-focus position in accordance with the AF data to be outputted from the microcomputer MC. A motor controlling circuit MO controls the motor M for the winding operation of the film. The electronic flashing apparatus FL is composed of the electronic flashing apparatus FL2 for distance detection use and the electronic flashing apparatus FL1 for object illumination use during the exposure. A transistor Tr1 feeds the power voltage to the filter FI, the film sensitivity setting circuit IS, the light measuring circuit LM, the exposure controlling circuit AE, the AF control circuit AFC, and the motor control circuit MO in accordance with a signal from the microcomputer MC.

FIG. 5 shows the concrete example of a group of switches SW in FIG. 4. A lens cover switch S0 turns on and off through the operative cooperation of the opening, closing operations of a lens cover (not shown). The pulse signal is outputted into the interruption terminal INT0 of the microcomputer MC through a circuit composed of a delay circuit DEL and an exclusive OR circuit EOR by turning on and off of the switch SO. When it is inputted into the microcomputer MC, the microcomputer executes a given interruption routine INT0. A photograph preparing switch S1 turns on when the release button (not shown) is depressed as far as the first stroke. If the switch S1 is turned on when the lens cover is open, the interruption routine INT1 is executed. A release switch S2 turns on when the release button is depressed as far as a second stroke provided deeper than the first stroke. An exposure completion switch S3 turns off at the charging completion of the shutter charging member (not shown) and turns on at the exposure completion.

A one frame winding switch S4 turns off at the exposure completion and turns on at the completion of one frame winding completion. A switch S5 turns on when the objective lens is driven to the given position corresponding to the control signal and turns off at the charge completion of the shutter charging member.

The details of the light measuring circuit LM of the distance detection and the brightness detection to be used in the present embodiment will be described hereinafter with reference to the block diagram of FIG. 6.

The light measuring circuits LM1 through LM9 perform the distance detection and the brightness detection of the regions ① through ⑨ shown in FIG. 3, respectively. Each of the circuits for the distance detection latches the signals from the light-receiving element, i.e., the distance signal in response to a signal of the timing circuit TM, so that the signals from the light-receiving elements are latched at the timing when the intensity of the light projected from the electronic flashing apparatus FL2 becomes maximum in the variation thereof, thereby to output the signal to the selector SEL. The selectro SEL selects the signals from the light measuring circuits LM1 through LM9 by the signal from a decoder DE2, which is adapted to decode the signal from the microcomputer MC to output the selected signals to the encoder ED. The encoder ED converts the inputted signals into given forms to output them into the microcomputer MC. The distance signals of the light measuring circuis LM1 through LM9 are outputted to the microcomputer, by the signal from the microcomputer MC, sequentially through the selector SEL and the encoder DE1.

On the other hand, signals of the detected brightnesses are outputted as analog signals to the analog switch ANSW. The analog switch ANSW is composed of nine FETs, which are connected with the light measuring circuits LM1 through LM9 respectively, so that the respective brightness signals may be inputted, all the outputs being integrated into one, and are connected with the A/D converting circuit A/D. The selection of the analog switch ANSW is performed by the signal of the decoder DE2, which is adapted to decode the signal from the microcomputer MC as in the distance signal, and is sequentially performed from the light measuring circuits LM1 through LM9. The brightness signal which has been outputted to the A/D converting circuit A/D through the analog switch ANSW is converted into digital forms and is outputted into the microcomputer MC.

The details of the light measuring circuit LM1 and the timing circuit TM1 are the above-described diagram will be described in FIG. 7. The portion surrounded by the dotted lines in the drawing shows the timing circuit, and the portion except for it shows the light measuring circuit.

First, the timing circuit TM1 will be described. When the release button is depressed, the signal of "H" is outputted from the terminal OP8 of the microcomputer MC before the electronic flashing apparatus FL2 starts to emit the light, and the transistor Tr2 turns on to discharge the capacitor C3. The transistor Tr2 is turned off immediately before the light emission to wait therefor. A phototransistor PHT1 which charges the capacitor C3 is disposed near the light emitting portion of the electronic flash apparatus FL2 and is adapted to directly receive the emitted light. When the electronic flashing apparatus FL2 emits the light in this condition, the current corresponding to the intensity of the light received by the phototransistor PHT1 is charged into the timing capacitor C3 through the phototransistor PHT1. When the voltage of the capacitor C3 exceeds a reference voltage Vr1, the comparator COMP1 is reversed to output the signal of the "H". The signal of the "H" is pulsed by the one-shot circuit OS1 and is outputted into the terminals T of the D flip-flops to be described later to latch the amplification signal from the light-receiving element SPC1. The reference voltage Vr1 is adapted to reverse the comparator COMP1 at the time point when the intensity of light emitted by the electronic flashing apparatus FL2 is slightly lower from the maximum intensity.

The light measuring circuit LM1 will be described hereinafter. The voltage is applied through the power supply line V2 by the depression of the first stroke of the release button to feed the power to each circuit. At once, the signal of the "H" is outputted from the terminal OP9 of the microcomputer MC to turn on the analog switches AS1, AS2 so that constant current circuits I1, I2 start to flow constant currents, respectively. After the lapse of a predetermined time (as the lowest 20 msec is assigned to that time in the present embodiment), the light measuring circuit LM1 remains stable.

The circuit operation before the stability of the circuit LM1 will be briefly described. As the voltage of the capacitor C4 is extremely low when the constant current circuits I1, I2 start to flow constant currents, the transistor Tr3 does not turn on. Constant current I1 flown by the constant current circuit I1 and the photocurrent IP which corresponds to the brightness of the particular wavelength light passing through the filter flow to the base of the transistor Tr4 to be amplified there. The amplified current flows through the transistor Tr6, and the equivalent current flows through the transistor Tr7 which constitutes a known current mirror circuit with the transistor 6. One part of the current becomes current of the constant current circuit I2 and the remaining current flows through the diodes D2, D3 to cause the voltage VD corresponding to two steps of the diode. The operation amplification OP1 has a reference voltage Vref inputted into the inversion input terminal, and has the voltage VD inputted into the non-inversion input terminal, and the negative feedback is applied upon the transistor Tr3 so that the voltage VD may become always constant.

As the current flowing through the transistor Tr7 corresponds to the current which has amplified most of all the photocurrent IP and the constant current I1, the voltage VD to be caused by this current becomes higher than the reference voltage Vref. Accordingly, the operation amplifier OP1 charges the capacitor C4 to boost the base voltage of the transistor Tr3. This capacitor C4 is charged through the transistor Tr4. When the voltage of the capacitor C4 is boosted to turn on the transistor Tr3, the constant current I1 and the photocurrent IP flow through the collector of the transistor Tr3 to reduce the current flowing through the base of the transistor Tr4. Thus, the current flowing through the transistor Tr6 and the transistor Tr7 is reduced to lower the voltage VD, so that the above-described operation is performed until the voltage VD becomes equal to the reference voltage Vref. During this operation, the voltage VD may become lower than the reference voltage Vref. At this time, the operation amplifier OP1 operates for discharging the charge of the capacitor C4 to reduce the voltage thereof, which reduces the current through the transistor Tr3 within the constant current I1 and the photocurrent IP so as to increase the base current of the transistor Tr4. Accordingly, the current which flows through the transistors Tr6 and Tr7 increases to boost the voltage VD.

This circuit is stabilized by the above-described operation to flow the current almost equal to the total of the constant current I1 and the photocurrent IP through the transistor Tr3, so that the voltage of the capacitor C4 for becomes equal to the base voltage corresponding to the current.

When the electronic flashing apparatus FL2 emits the light, the light reflected from the object is received by the light-receiving element SPC1 to cause the photocurrent IP' (which is referred to as IP' hereinafter to distinguish it from the above-described ambient photocurrent IP) corresponding to the light including a reflected light component reflected by the object and the ambient light component. The current IP of the ambient light component within the photocurrent flows through the collector of the transistor Tr3, and the current IP'-IP corresponding to the reflected light component flow as the base current of the transistor Tr4. At this time, the capacitor C4 has the capacity, in which the transistor Tr4 does not respond by the current while the reflected light is received by the light receiving element. And the current IP-IP' is amplified by the transistor Tr4 to flow the diodes D2, D3 through the transistors Tr6, Tr7. Thus, the voltage VD is increased to compare the voltage VD with the reference voltage determined by the constant current circuit I3 and the resistors R11 through R14, so that the distance signal is represented as the outputs of the comparators COMP2 through COMP5. The output signals of the comparators COMP2 through COMP5 are latched into the D flip-flops DFF1 through DFF4 by the signal from the timing circuit TM to output the latch signal to the selector SEL.

After the distance detection has been performed in the above-described way, the filter arranged in front of the light-receiving element SPC1 is changed from a characteristic for permitting that the infrared light having the particular wavelength pass therethrough to the other characteristic for permitting that the visual light pass therethrough. Furthermore, the constant current circuit I1 is switched off to remove the voltage of the constant current I1 with respect to the charging voltage of the capacitor C4. The constant current circuit I2 is also turned off to cut off the route of the feedback of the transistor Tr3 through this constant current I2 so that the voltage of the capacitor C4 may become only the voltage which depends upon only the intensity of the ambient light component received by the light-receiving element SPC1. The voltage is outputted into the analog-switch ANSW through the buffer BUF1.

The other light measuring circuits LM2 through LM9 shown in FIG. 6 are also completely the same in construction as in FIG. 7.

The electronic flashing apparatus FL1 for photograph use and the electronic flashing apparatus FL2 for distance detection use to be used in the embodiment will be described hereinafter with reference to FIG. 8. Except for the point that the electronic flashing apparatus FL2 for distance detection use is much smaller (approximately 1/25 in the maximum light emitting amount) than the electronic flashing apparatus FL1 for photographing use, the former is completely the same in the circuit construction as the latter FL1, thus removing the illustration of the concrete construction of the former with the circuit being shown simply in block.

In the circuit of the electronic flashing apparatus FL1 for photographing use, a boost controlling circuit DCC receives the boost controlling signal FLC1 from the microcomputer MC and produces the changing completion signal B.C1 to be described later to control the transistor Tr8 for boosting circuit DC. The rectification diode is represented by D4. A charge detecting circuit B.C detects the charging condition of a main capacitor C5. An emission control circuit EC energizes a xenon tube Xe in accordance with the emission signal X1 from the exposure control circuit AE to illuminate the object area. The emission signal X2 of the electronic flashing

apparatus FL2 for distance detection use is fed through the buffer BUF10 from the microcomputer MC.

The operation of the electronic flashing apparatus FL1 for photographing use will be described. When the charging operation to the main capacitor C5 has not been completed, the charge completion signal B.C1 is in the "L" level. When the boosting control signal FLC1 of the "L" showing the boosting start is sent from the microcomputer MC, the NOR circuit NOR1 outputs the signal of "H", and the boost controlling circuit DCC receives it to control the transistor Tr8 to turn it on and starts the boosting operation. When the charging completion signal B.C1 becomes "H" level by the completion of the charging operation to the main capacitor C5 or the boosting control signal FLC1 from the microcomputer MC becomes "H" level, the NOR circuit NOR1 outputs "L" level, so that the boost controlling circuit DCC turns off the transistor Tr8 to stop the boosting operation of the boosting circuit DC. It is to be noted that a neon tube showing this condition lights on independently of the control circuit and the microcomputer MC when the charging operation of the main capacitor C5 is completed.

The entire operation of the camera in the embodiment will be described hereinafter. Before it, the number of the distance zones detected by the distance detection, the in-focus range in each region, and how to determine it will be described.

The distances to the objects located at each of the regions are detected in accordance with the absolute amounts of the light reflected by the objects as described hereinabove. However, as each of the objects has a reflectance different from that of the other objects, the distance detected by the detection apparatus is not always equal to the distance to the object. In the present embodiment, the in-focus range of each region is provided wider or the range is provided across two regions so that the focusing operation may be performed without fail on the object. However, if the distance range from the nearest focusing distance such as 0.6 m to the infinity distance is divided into five ranges, it is impossible to achieve the in-focus condition of the objective lens with respect to any object located within the distance range in the condition in which the aperture of the objective lens is fully opened, due to the focusing performance of the objective lens. Thus, in the embodiment the maximum aperture value is decreased in accordance with the decrease of the distance. Therefore, an in-focus range of particular distance zone can be extended to achieve the in-focus condition with respect to any object within the distance range, by dividing the latter into five ranges.

Here, since the embodiment uses a shutter serving as an aperture diaphragm, the reduction of the aperture value causes the shutter speed to shorten. Therefore, the brightness range in which the natural light photographing may be performed becomes narrower, the underexposure is likely to be caused. In this case, the flash photographing operation is performed to compensate for it. The shutter, also serving as an aperture diaphragm, which is used in the present embodiment, is a type showing the triangular waveform in time-variation characteristics of the opening degree. The shutter gradually opens to reach the given aperture value, and is adapted to move to the closed operation.

Five ranges determined in accordance with the above-described idea and their in-focus ranges, the maximum aperture value of the use limit at this time, and the aperture value at the flash photographing operation will be described in FIG. 9.

In the drawing, the axis of ordinates shows the regions 1, 2, 3, 4, 5 arranged in order from the near distance side. The axis of abscissa shows the distance as far as 0.6 m through ∞. The focusing range of each region will be described. As shown in FIG. 9, in the region 1, the open aperture value is limited to F/8, and the object distance of the objective lens is set to 0.75 m. Thus, the object positioned within a distance range from 0.56 m to 1.1 m can be in-focus condition on the predetermined focal plane by the objective lens. In the region 2, the open aperture value is limited to F/5.6, and the object distance is set to 1.0 m, thereby the objective lens is set to be in in-focus condition with respect to an object positioned within a distance range from 0.77 m to 1.5 m. In the region 3, the open aperture value is limited to F/4, and the object distance is set to 1.5 m, thereby the objective lens is set to be in in-focus condition with respect to an object positioned within a range from 1.1 m to 2.2 m. In the region 4, the open aperture value is limited to F/3.5, and the object distance is set to 2.1 m, thereby the objective lens is set to be in in-focus condition with respect to an object positioned within a distance range from 1.5 m to 3.6 m. In the region 5, the open aperture value is limited to F/3.5 and the object distance is set to 5 m, thereby the objective lens is set to be in in-focus condition with respect to an object positioned within a distance range from 2.7 m to ∞.

The aperture value used in flash photographing operation is determined as shown in "FM" in FIG. 9. The guide number of the flashing apparatus is determined to be 10 with respect to a film sensitivity of ISO=100. In the region 1, the aperture value in flash photographing operation is set to F/13, so that under- or over-exposure is provided by 1 step with respect to the object located at the nearest or farthest distance within the distance range of region 1. Only the same exposure amount is designed to become over or under with respect to both the ends. In the region 5, the flash photographing operation is adapted to be performed as far as possible with F/3.5 in the open aperture value.

FIGS. 10 through 14 show the flow charts of the microcomputer MC. The controlling operation of the camera will be described with reference to the flow charts.

The operation with the battery E being mounted on the camera will be described with reference to FIG. 10. When the battery E is mounted thereon, the signal which changes from "L" to "H" is inputted into the reset terminal RES, the microcomputer MC executes the flow to prohibit the interruption (#5) and to initially set (#10) the output terminals, the registers. Then, the signal of the terminal IP6 shown in FIG. 5 is inputted and the microcomputer MC allows the interruption to decide whether or not the lens cover is open. When it is closed, the interruption to the interruption terminal INT1 to be described later is prohibited to come to a stop (#25 through #27). On the other hand, the program proceeds to step #45 to be described later when the lens cover is open.

The interruption INT0 which is executed through the opening and closing operation of the lens cover will be described hereinafter. If the lens cover is opened or closed in the condition where the interruption to the flow is allowed, the pulse is inputted into the terminal INT0, so that the microcomputer MC executes the interruption INT0 operation from the step #32. At first,

the decision is made as to whether the lens cover has been opened or closed (#35). When the lens cover has been closed, the interruption of the flow of the interruption to the flow of the interruptions INT1 to be described later is prohibited (#57) to proceed to the step #60 (§35, 37). When the lens cover has been opened, the interruption to the terminal INT1 is allowed (#40), the signals of "H" to the output terminals FLC1, FLC2 are outputted (#40 through 50) to start the boosting operation of the electronic flashing apparatus FL1, FL2 for photographing use and distance detecting use so as to decide whether the charging operation of the main capacitor of the electronic flashing apparatus FL1 for photographing use has been completed through the output signal BC1 (#55). Even when the lens cover is open with the battery being mounted on, the program proceeds to the step #45. When the charging completion of the main capacitor is decided at the step #55, the signals of "L" are outputted to the terminals FLC1, FLC2 (#60, 65) to stop the boosting operation of both the electronic flashing apparatuses FL1, FL2 for photographing use and distance detection use. And all the flags are reset at the step #70. The counting timer started in the interruption flow ot the INT1 shown in FIG. 11 is stopped to turn off the display, and the microcomputer MC becomes halt condition (#70 through 85).

Then, in FIG. 11, when the release button is depressed to the first stroke with the lens cover being opened, the signal which changes from "H" to "L" is inputted to the terminal INT1 and the microcomputer MC executes the flow of the interruption INT1 from the step #90.

In order to perform the distance detection and the brightness detection, the boosting operation of the electronic flashing apparatus FL1 for photographing use is stopped operation and the decrease in the battery voltage (#95). Then, the transistor Tr1 is turned on to supply the power supply to each control circuits (#100). The analog switches AS1, AS2 are turned on to flow the constant current for distance detection use (#105), and the output of the terminal OP1 is turned into "H" so that the filter is switched for infrared ray use to detect the distance (#110). The timer for counting the time required for the circuit stability is reset and started (#115), and the transistor Tr2 for timing use is turned on (#120) to discharge the timing capacitor C3 for the determination of the timing to latch the output of the distance detecting circuit. Then, the controlling operation is performed to start the boosting operation of the electronic flashing apparatus FL2 for distance detection use to wait for the completion of the charging operation of the capacitor C5 (#125, 130). After the charging operation of the capacitor C5 completes, the boosting operation is stopped (#132). And the decision is made whether or not 20 msec have passed from the timer start of the step #115. If they have not passed, the lapse is waited for. If they have passed, the transistor Tr2 for timing use is turned off (#135, 140). The signal of "H" is outputted into the terminal X2 to detect the distance and thereby the flashing apparatus FL2 for distance detection use is energized (#145). The signal from the timing circuit is inputted to detect whether or not the data of the result of the distance detection has been latched to wait for the data to be latched (#150). When the detection is performed that the data has been latched, the terminal OP1 is turned into "L" to detect the brightness to put the filter into the visible sensitivity use (#155). The analog switches AS1, AS2 are turned off (#160), and the subroutine for taking in the data for the latched distance detection use comes in preparation for the following brightness detection.

The subroutine will be described with reference to FIG. 12. The microcomputer MC sets variables N, N1, N2 into 0, and D0 into 5 (#1000 through 1015). This variable N is outputted into the decoder DE2 shown in FIG. 6 (#1020). The distance data detected by the light measuring circuit selected by the selector SEL which receives the output of the decoder DE2 are converted into a given coded data D1 by the encoder ED, and the coded data are inputted into the microcomputer MC at the step #1025. This data D1 corresponds to the detected distance region, that is either of the regions 1 through 5. For example, the coded data D1 shows 1 if the detected distance region is the region 1, while the data D1 shows 5 if the detected distance region is the region 5.

The nearest distance region among the distance regions detected by each of the light receiving circuits LM1 through LM5 is selected in accordance with the data D1. First, a decision is made as to whether or not the data D0, wherein the data corresponding to the distance region 5 is set, are equal to the input data D1. If they are equal to each other, 1 is added to the variable N1 (#1030, 1035). This variable N1 is provided for deciding if the number of the light measuring circuits which detect if the nearest distance region is single or plural. The data D0 are set in D1 to add 1 to the variable N (#1045, 1065). On the other hand, in the step #1030, the program proceeds to the step #1050 when the set data D0 are not equal to the input data D1 to decide whether or not the input data D1 is in the distance region nearer than the set data D0. The program proceeds to the step #1045 when it is not in the nearer distance region. When it is in the nearer distance region, the variable N1 is set in 1, and the variable N2 is set to the variable N to proceed to #1040 (#1055, 1060). This variable N2 shows either of the light receiving regions ① through ⑨ shown in FIG. 3. In the step #1065, the decision is made whether or not the variable N is 9, i.e., whether or not the distance data of the light-receiving regions①through⑨have been inputted after the addition of 1 to the variable N at the step #1045. If the inputting operation of the distance data has not been finished, the step returns to the step #1020 to repeat the loop. If the inputting operation of the distance data has been finished, the program returns to the original flow of FIG. 11 at the step #1067 to proceed to the next light measuring data subroutine of the step #1070.

The subroutine is shown from the step #1070 of FIG. 12(*b*). In the step #1070, the decision is made as to whether or not the variable N1 is 1, i.e., the number of the light receiving regions in which the nearest distance region is detected is single. If it is single (N1=1), the program proceeds to the spot light measurement subroutine of the step #1075. When the number of the light receiving regions in which the nearest distance region is detected is plural, the program proceeds to the step #1080 to decide whether or not the light receiving region ① of the central portion is included in the plurality of regions in which the nearest distance region is detected. Even when it is included, the program proceeds to the step #1075. When the light receiving region of the central portion is not included at the step #1080, the average light measurement flag AVRE is set at the step #1085. The program proceeds to the average

light measurement subroutine, and returns to the original flow with BV2 (average light measurement value) as the light measurement data BV.

The spot light measurement and average light measurement subroutine among the light measuring data subroutine will be described with reference to FIG. **13**. First, in the spot light measurement subroutine shown in FIG. **13**(*b*), the microcomputer MC outputs the variable N2, showing the number of the light receiving regions, to the decoder DE2 (#**1160**). The decoder DE2 decodes the inputted variable N2, and controls to turn on one of the analog switches ANSW in order to output the analog light measuring signal which corresponds to the brightness of the region related to the variable N2, to the A/D converting circuit A/D. The microcomputer MC outputs the A/D conversion start signal from the terminal OP6 to convert the light measuring signal of this analog form into the digital form at the step #**1165**, and decides with the signal of the terminal OP7 whether or not this A/D conversion has been completed at the step #**1170**. After the completion of the A/D conversion, the A/D completion signal is outputted from the terminal OP6 at the step #**1175** and the digital-converter light measuring data are inputted to the microcomputer MC as the brightness value BV.

The average light measurement subroutine shown in FIG. **13**(*a*) will be described hereinafter. The variables BV2 and I are set to 0 (#**1105**, **1110**) and this variable I is outputted to the decoder DE2. As in the case of the above-described spot light measurement operation, the light measuring output of the analog form showing the brightness of the light receiving region corresponding to this variable I is converted in digital form by the A/D converter A/D to input the light measuring data as BV1 (#**1120** through **1135**). The data BV1 are added to the data BV2 at the step #**1180** and 1 is added to the variable I at the step #**1145**. And it is decided whether or not the variable I has reached 9 (#**1150**). If it reaches 9, it is assumed that the light measuring data showing the brightness has been inputted from all the light-receiving regions ① through ⑨, and the program goes to the next step. If it is not 9, the program returns to the step #**1115** to repeat this loop to perform the data inputting operation. After the inputting operation of all the data is over, the microcomputer MC divides the data BV2, i.e., the light measuring data of all of the respective light-receiving regions, by 9 to obtain the average brightness data at the step #**1155**. It may be modified to obtain the average brightness data by averaging all of the light measuring data, even if a plurality of light receiving regions detect the nearest distance region. The step #**1080** should be omitted for this modification.

Returning to the flow of FIG. **11**, the film-sensitivity data SV from the film sensitivity setting circuit IS are read in A.P.E.X. system at the step #**175** to add the brightness data BV to this value SV to obtain the exposure value EV (#**180**). The limited exposure value (EV) for switching from the natural light photographing mode to the flash photographing mode will be explained. The limited exposure value (EV) is changed in accordance with the detected distance region. In the step #**185**, the decision is made as to whether or not the distance region is region **1**. If it is 1, the program goes to the step #**190** to decide whether or not the exposure value EV is 13.5 or more. If the exposure value EV is less than 13.5, the exposure value EV is fixed to 13.5 (#**235**) to go to the step #**270**. If the distance region is region **2**, the exposure value is secured to 11.5 when the exposure value EV is less than 11.5 at the step #**230**. If the distance region is region **3**, the exposure value EV is secured to 9.5 when the exposure value EV is less than 9.5 at the step #**225**. If the distance region is region **4** or **5**, the exposure value EV is fixed to 8.5 when the exposure value EV is less than 8.5 at the step #**230**. The program moves to the step #**270** respectively to enter into the flash photographing mode (#**195** through **235**).

If the exposure value EV is 13.5 or more when the distance region is region **1**, if the exposure value is 11.5 or more when the distance region is region **2**, if the exposure value EV is 9.5 or more when the distance region is region **3**, and if the exposure value EV is 8.5 or more when the distance region is region **4** or **5**, the program moves to the step #**240** to decide whether or not the average light measurement flag AVRF is set. When this flag AVRF is not set, the program goes to the step #**245** to execute the average light measurement subroutine to obtain the average brightness data BV2 for getting the difference between the obtained spot brightness data BV and it so as to decide whether or not the difference is 2EV or more at the step #**255**. If this difference is 2EV or more, the daylight synchronous flag FILF is set because a primary object is in backlight condition. The program moves to the step #**270** to enter the flash photographing mode (#**250** through **260**).

When the average light measurement flag AVRF is set in the step #**240**, or when the difference between the average brightness data and the spot brightness data value is less than 2EV, the program moves to the step #**265**, and moves to the step #**390** to be described later to calculate the aperture value AV to move to the flow of the shutter release operation.

The flash photography mode from the step #**270** will be described hereinafter. The decision is made as to whether or not the charging operation of the main capacitor of the electronic flashing apparatus FL1 for photographing use has been completed at the step #**270**. If it has been completed, the program moves to the step #**310** to display the completion of the photograph preparation. If the charging operation has not been completed, the decision is made as to whether or not the release button is depressed to the first stroke. When the release button is depressed to the first stroke, it is displayed that the charging operation of the electronic flashing apparatus FL1 is not completed. Then, the removal of the depression of the release button is waited for (#**275**, **280**). After the depression of the release button is removed, the microcomputer MC turns off the transistor Tr1 to cut out the power supply to the control circuit to start the boosting operation of the electronic flashing apparatus FL1 for photographing use (#**285**, **290**). And the timer for battery check use is reset and is started to decide whether or not the charging operation has been completed within ten seconds. When the charging operation has not been completed within ten seconds, the boosting operation is stopped at the step #**320**, the timer for warning display use is reset and is started at the step #**325**, the battery check warning is performed for five minutes at the steps #**330** and **335**. Then, all of the displays are turned off at the step #**340**, and the flags are reset at the step #**345**. Thereafter, the microcomputer MC becomes in halt condition at the step #**350**. If the charging operation is completed within ten seconds, the program moves to the step #**310** to display the completion of the photographing preparation, and moves to the step #**355**.

In the step #355, the aperture value AV1 used in the flash photographing mode is calculated. The distance value DV in the step #355 is the value which becomes 5, 4, . . . 1 in response to the distance regions 1, 2, . . . 5. For example, supposing that the guide number of the electronic flashing apparatus FL1 is 10 with respect to the film sensitivity of ISO 100, and that the distance region detected is the region 2, the distance value DV is 4 and the film sensitivity SV is 5, respectively, if the amount of light emitted by the flashing apparatus FL1. In the case, the calculated aperture value AV1 is 6.5, that is, the F-number of F/9.3. Then, the decision is made as to whether or not this calculated aperture value AV1 is less than 3.5 at the step #357. When it is less than 3.5, it is secured to 3.5 at the step #360 and the program goes to step #362. And the decision is made as to whether or not the daylight synchronous flag FILF is set. When the flag FILF is not set, the aperture value for exposure use is calculated from the exposure value EV fixed by each region to output the data of the aperture value AV1 showing the light emitting timing of the flash photographing operation (#385). When the flag FILF is set, the aperture value AV2 based on the average brightness data BV2 is obtained at the step #370 to compare it with the aperture value AV1 of the flash photographing operation (#375). Here, the decision is made whether or not the exposure amount of the primary object becomes proper in the daylight synchronized flash mode.

Generally, the exposure amount of the primary object becomes proper by the flash light while the background thereof becomes in proper exposure by the natural light, in the daylight synchronized flash mode. In the case where the aperture value is determined for the natural light photographing condition, the aperture value AV1 for flash photographing should be compared with the aperture value AV for discriminating whether the primary object located at the detected distance region becomes in proper exposure by the flash light whose intensity is constant. Since the shutter serving also as an aperture diaphragm is gradually opening, the start of flash light emission can be performed at any timing during the opening. Therefore, if the aperture value AV1 is equal to or greater than the aperture value AV, proper exposure can be reproduced with respect to the primary object. Namely, when the aperture value AV1 for the flash photographing operation is equal to or greater than the aperture value AV for the natural-light photographing operation, the proper daylight synchronized flash photographing is performed. In the daylight synchronized flash mode, the microcomputer MC outputs the data of the aperture value AV1 as the light emitting timing data of the flash apparatus at the step #385 with the aperture value AV2 of the average light measurement as the control aperture value AV at the step #380. When the primary object is not exposed to the proper exposure by the flash photographing operation even in the backlight condition, the control aperture value AV is obtained in accordance with the brightness value in the spot light measurement to perform the natural-light photographing operation only (#390).

At this time, the microcomputer MC decides whether or not the release operation, i.e., the depression of the release button as far as the second stroke is effected at the step #392. When the release operation is not effected, the program moves to the step #395 to decide whether or not the release button is depressed as far as the first stroke. When the release button is in its depressed position, it returns to the step #390 to wait for the release operation. When the release button is not depressed as far as the first stroke, the program moves to the step #450 to be described later.

When the computer decides, at the step #392, that the release operation is affected, the program enters the release control operation to, first, prohibit the interruption to this flow at the step #397, and the microcomputer MC outputs the distance region data to the AF control circuit AFC at the step #400. Then, the microcomputer MC outputs the start signal to start the driving operation of the objective lens. When the objective lens is driven to the given position in accordance with the data, the switch (S5) showing the AF control completion is turned on, so that the microcomputer MC detects the AF control completion (#410). Then, the date of the control aperture value AV is outputted to the AE control circuit AE, and the AE control start signal is outputted (#415, #420) to the AE control circuit AE. When the light emitting timing data of the flash during the flash photographing operation is sent from the microcomputer MC in the AE control circuit AE, a flash signal is outputted to the electronic flashing apparatus FL1 for photographing use at the given timing in accordance with the data.

When the exposure control is performed in the AE control circuit and the switch S3 showing the exposure completion is turned on, the motor is driven to wind up one frame of the film. When the film is wound up by one frame, the motor is stopped (#425 through 440). The microcomputer MC permits the interruption to this flow at the step #445, and turns off the control circuit at the step #450. Then, the microcomputer MC starts the boosting operation of the electronic flashing apparatuses FL1, FL2 in preparation for the next photographing operation, and the timer for the boosting control use is reset and started at the step #470. The respective boosting operations are stopped when the charging operation is completed in five seconds or five seconds pass, and the display is turned off thereafter. Then, all the flags are reset and the microcomputer MC is in halt condition.

Though the first embodiment of the present invention is described hereinabove in such a manner that, the nearest distance region among the plurality of detected distance regions is provided as the distance region for the focusing operation, in the second embodiment described hereinafter, each light-receiving region is weighted when the distance region is obtained, and the weighted value is added for each distance region to detect which distance region is the most frequent. And the interval between the most frequent distance region and the nearest distance region, for example, in the case of the distance region 1 and the distance region 3 the intermediate distance region, that is, the distance region 2 in the above-described example, is applied as the distance for focusing operation. In the intervals except for it, the nearest distance is provided as the distance for the focusing operation. The brightness detection and the backlight detection are performed as in the first embodiment.

The flow chart for the operation of the microcomputer MC which executes the second embodiment is shown in FIG. 15, FIG. 16. This flow chart shows the modified example of the AF data subroutine shown in FIG. 12(*a*), and the light measurement data subroutine

shown in FIG. 12(*b*) with the entire flow being completely the same as FIG. 11, FIG. 13 and FIG. 14.

The flow chart will be described hereinafter. First, the microcomputer MC sets variables N0 through N4, N10 through N14, and N to 0 at all (#1500 through 1510). The variable N is outputted to the decoder DE2, and the data D1 of the distance region coming from the given light receiving region is inputted (#1515, 1520). Then, the microcomputer MC operates the weighting operation of 3, 2, 1 respectively to the light receiving regions 1, 2 through 5, 6 through 9 with respect to each light-receiving region. When the light-receiving region is 1 (N=0), the α as the weighting data is assumed as 3 (#1535) with this input data D1 being as the data D2 (#1530). If the light-receiving region is 2 through 5 likewise, the α is set to 2. If the light-receiving region is 6 through 9, the α is set to 1 (#1540 through 1550).

Then, the microcomputer MC adds the sum of the number of light receiving regions belonging to each distance region and the weighting data. When the distance region of the light receiving region is 1, 2, . . . 5, the weighting data are added respectively to N0, N1, . . . N4, and the number of the light-receiving regions are added to N10, N11 . . . N14 (#1555 through 1640). The decision is made as to whether or not N has become 9 through addition of 1 to the N. If the N has not become 9, the program returns to the step #1515 to repeat this loop until the N becomes 9. If the N is 9, the program moves to the step #1655 (#1645, #1650), considering that all the distance data have been inputted, and the microcomputer MC obtains the distance region including the light receiving region of the most frequent. In the step #1655, the value of the N0 showing the addition value of the weighted data of the distance region 1 is shifted to the N5, then the data showing that the distance region is 1 is inputted into the variable D3 and the variable I is set to 1 (#1660, 1665). Then, the weighted data N5 established is compared with the NI (I is the established value), for example, the addition value of the weighted value corresponding to the distance region 2 if I=1. If the NI is larger, the value of the N5 is changed to the value NI and the distance region at this time is inputted into D3 (#1670 through 1680).

Even when the NI is equal to or less than N5, the program goes to the next step #1685 to add 1 to the I. And the decision is made whether or not the I has become 5. If the I has not become 5, the program returns to the step #1670. If the I becomes 5, the microcomputer MC obtains the nearest distance region and the distance between this region and the distance region of the most frequent value to obtain the distance region for the focusing operation. The microcomputer MC obtains the distance region where the value of the weighted data is not 0 in order from the distance region 1 to the distance region 4. The data showing this distance region at a time when the value of the weighted data not been 0 is inputted into D0 to input the number of the light receiving regions in that region into N7 (#1695 through 1760).

When the nearest distance region is one of the regions 1 through 3, the decision is made whether or not the distance between the nearest distance region and the distance region of the most frequent value is only one region. When the distance is one region, the data in the middle region is inputted into the D0 (#1765, #1770), and the program proceeds to the step #1775 of the light measurement data subroutine. When the nearest distance region is the region 4 or 5, the distance between the nearest distance region and the distance region of the the most frequent value does not become 1, the program moves to the step #1775 as soon as the inputting operation to D0, N7 is completed. In the light measurement data subroutine as compared with FIG. 12, the processed content of the microcomputer MC is completely the same except for the N1 being changed into N7.

The present invention is not restricted to this embodiment described hereinabove. The following modified embodiments may be applied.

(1) In the first and second embodiments, the brightness data obtained by the average light measurement of all regions are used for controlling the exposure amount, when the number of light receiving regions in which the nearest distance region is detected or when the central region is not included for detecting the distance region for the focusing operation. However, the exposure amount may be controlled in accordance with the average of the brightness data in all the light receiving regions showing the nearest distance region may be used. Thus, the number of the light receiving region in which the nearest distance region is detected is required to be memorized. The brightness data of the light receiving region are required to be inputted in accordance with this number to provided this average. Also, when the number of the light receiving regions in which the nearest distance region is detected are plural, the average light measurement value of all the regions may be used.

(2) Though the electronic flashing apparatus which is disposed separately from the electronic flashing apparatus for the photographing use is provided as the light emitting means for the distance detection means of the present embodiment, this may use the electronic flashing apparatus for photographing use in common. In the case of the distance detection, the infrared transmission filter of the particular wavelength is required to be provided on the entire face of the light emitting portion. In the case of the photographing operation, such mechanical construction as to remove this filter is required to be provided. Also, the light emitting means may be such a plurality of LEDs as shown in Japanese Patent Application Laid-open Publication Tokkaisho No. 59-146032. Also, one LED may be required with being sequentially scanned.

(3) If the primary object does not become proper with the flashing photographing operation only in the embodiment when the backlight light condition is detected, the photographing operation is switched from the flash photographing mode to the natural-light photographing mode. In addition, in the natural-light photographing operation, the light measuring operation is switched from the average light measurement to the spot one. However, since the film has a latitude, there is no necessity to provide the most proper exposure amount of the primary object. Concretely, if the exposure amount of the primary object is low by 1.5 steps than the most proper exposure amount, the image of the primary object can be reproduced sufficiently by the latitude of the film. Thus, it may be permitted that the exposure amount of the primary object by the flash light is lower by 1.5 steps than the calculated proper exposure amount in daylight synchronized flash photographing.

(4) In addition, the (1) through (3) of the above-described examples may be properly combined with the first, and second embodiments.

(5) Though the distance from the camera to the object is detected with a plurality of regions in the object area to be photographed in the embodiments, the defocus amount of the objective lens may be detected with the plurality of regions.

(6) Since the distance detection and the brightness detection use the common light measuring circuits LM1 through LM9 in the embodiments, the distance detection regions are completely similar to the brightness detection regions, respectively. However, both of the regions may be deviated from each other, or the size of both regions may be different from each other.

Although the present invention has been fully described by way of example with reference to the accompanying drawings, it is to be noted here that various changes and modifications will be apparent to those skilled in the art. Therefore, unless otherwise such changes and modifications depart from the scope of the present invention, they should be constructed as included therein.

What is claimed is:

1. Control device for use in a camera having an objective lens, comprising:
- means for producing a plurality of distance signals on a plurality of first regions of an object area to be photographed;
- means for determining a distance on the basis of the plurality of distance signals to produce a determined distance signal for focusing the objective lens;
- means for driving the objective lens in accordance with the determined distance signal;
- means for measuring a plurality of brightnesses of second regions of the object area to produce a plurality of brightness signals each corresponding to the measured brightness respectively, each of the second regions being substantially similar to each of the first regions, respectively;
- means for counting the number of the distance signals representing an identical distance to a distance represented by the determined distance signal;
- means for discriminating whether the number counted by the counting means is single or plural;
- means for determining a light measuring value on the basis of a brightness signal of a single second region corresponding to a single first region whose corresponding distance signal represents an identical distance to a distance represented by the determined distance signal when the discriminated number is single, while determining a light measuring value which corresponds to a brightness of almost the entire object area when the discriminated number is plural; and,
- means for calculating exposure value of the camera in accordance with the light measuring value.

2. Control device as claimed in claim 1, wherein the light measuring value determining means includes means for averging the plurality of brightness signals to determine a light measuring value, when the discriminated number is plural.

3. Control device as claimed in claim 1, wherein the distance signals producing means includes a plurality of light receiving elements each corresponding to each of first regions, and the brightnesses measuring means includes means for measuring a plurality of brighnesses on the basis of output signals of the light receiving elements.

4. Control device for use in a camera having an objective lens, comprising:
- means for producing a plurality of distance signals on a plurality of first regions of an object area to be photographed;
- means for determining a distance on the basis of the plurality of distance signals to produce a determined distance signal for focusing the objective lens;
- means for driving the objective lens in accordance with the determined distance signal;
- means for measuring a plurality of brightnesses of second regions of the object area to produce a plurality of brightness signals each corresponding to the measured brightnesses respectively, each of the second regions being substantially similar to each of the first regions, respectively;
- means for counting the number of the distance signals representing an identical distance to a distance represented by the determined distance signal;
- means for discriminating whether the number counted by the counting means is single or plural;
- means for determining a light measuring value on the basis of a single brightness signal of a single second region corresponding to a single first region whose corresponding distance signal represents an identical distance to a distance represented by the determined distance signal when the discriminated number is single, while determining the light measuring value on the basis of a plurality of brightness signals of at least a plurality of second regions corresponding to a plurality of first regions whose corresponding distance signals represent an identical distance to a distance represented by the determined distance signal when the discriminated number is plural; and,
- means for calculating exposure value of a camera in accordance with the light measuring value.

5. Control device as claimed in claim 4, wherein the light measuring value determining means includes means for determining a light measuring value which corresponds to a brightness of almost the entire object area, when the discriminated number is plural.

6. Control device as claimed in claim 5, wherein the light measuring value determining means includes means for averaging the plurality of brightness signals to determine a light measuring value, when the discriminated number is plural.

7. Control device as claimed in claim 4, wherein the distance signals producing means includes a plurality of light receiving elements each corresponding to each of first regions, and the brightnesses measuring means includes means for measuring a plurality of brightnesses on the basis of output signals of the light receiving elements.

8. Control device for use in a camera having an objective lens, comprising:
- means for producing a plurality of distance signals on a plurality of first regions of an object area to be photographed, the plurality of first regions including a central region of the object area and the plurality of distance signals corresponding to respective ones of the first regions;
- means for determining a distance on the basis of a selected group of the plurality of distance signals to produce a determined distance signal for focusing the objective lens;

means for driving the objective lens in accordance with the predetermined distance signal;

means for measuring a plurality of brightnesses of second regions of the object area to produce a plurality of brightness signals each corresponding to the measured brightnesses respectively, each of the second regions being substantially similar to each of the first regions, respectively;

means for discriminating whether the selected group includes the distance signal corresponding to the central region;

means for determining a light measuring value by a first calculation when the distance signal corresponding to the central region is discriminated to be included in the selected group, while determiningthe light measuring value by a second calculation different from the first calculation when the distance signal corresponding to the central region is discriminated not to be included in the selected group; and

means for calculating exposure value of the camera in accordance with the light measuring value.

9. Control device as claimed in claim **8**, wherein the light measuring value determining means includes means for averaging the brightness signals of the second regions corresponding to the first regions whose corresponding distance signals are included in the selected group used for producing the determined distance signal when the distance signal corresponding to the central region is discriminated not to be included in the selected group.

10. Control device as claimed in claim **8**, wherein the light measuring value determining means includes means for determining the light measuring value on the basis of all of the plurality of brightness signals when the distance signal corresponding to the central region is discriminated not to be included in the selected group.

11. Control device as claimed in claim **10**, wherein the light measuring value determining means includes means for averaging the plurality of brightness signals to determine a light measuring value.

12. Control device as claimed in claim **8**, wherein the distance signals producing means includes a plurality of light receiving elements each corresponding to each of first regions, and the brightnesses measuring means includes means for measuring a plurality of brightnesses on the basis of output signals of the light receiving elements.

13. Control device for use in a camera having an objective lens, comprising:

means for producing a plurality of distance signals necessary for focusing the objective lens on a plurality of first regions of an object area to be photographed;

means for determining a distance on the basis of the plurality of distance signals to produce a determined distance signal for focusing the objective lens;

means for driving the objective lens in accordance with the determined distance signal;

means for measuring a plurality of brightnesses of second regions of the object area to produce a plurality of brightness signals each corresponding to the measured brightnesses respectively, each of the second regions being substantially similar to each of the first regions, respectively;

means for counting the number of the distance signals representing an identical distance to a distance represented by the determined distance signal;

means for discriminating whether the number counted by the counting means is single or not;

means for determining a first light measuring value on the basis of the brightness signals of the second regions corresponding to the first regions whose corresponding distance signals represent an identical distance to a distance represented by the determined distance signal;

means for determining a second light measuring value corresponding to a brightness of almost the entire object area;

means for detecting whether a primary object is in backlight condition or not in accordance with the first and second light measuring signals; and

means for controlling exposure of the camera in accordance with the result of the detecting means when the discriminated number is single, while controlling the exposure independently of the result of the detecting means when the discriminated number is plural.

14. Control device as claimed in claim **13**, wherein the second light measuring value determining means includes means for determining the second light measuring value on the basis of the brightness signals of at least the second regions corresponding to the first regions whose corresponding distance signals do not represent an identical distance to a distance represented by the determined distance signal.

15. Control device as claimed in claim **13**, wherein the second light measuring value determining means includes means for determining the second light measuring value on the basis of all of the brightness signals of the second regions.

16. Control device as claimed in claim **13**, further comprising means for interruping operation of the detecting means when the discriminating number is plural.

17. Control device as claimed in claim **13**, further comprising means for illuminating the object area for photographing, and wherein the exposure controlling means includes means for controlling the illuminating means to energize the illuminating means for flash photography when the discriminated number is single, while de-energizing the illuminating means when the discriminated number is plural.

18. Control device as claimed in claim **13**, wherein the distance signals producing means includes a plurality of light receiving elements each corresponding to each of first regions, and the brightnesses measuring means includes means for measuring a plurality of brightnesses on the basis of output signals of the light receiving elements.

19. Control device for use in a camera having an objective lens, comprising:

means for producing a plurality of distance signals on a plurality of first regions of an object area to be photographed, the plurality of first regions including a central region of the object area and the plurality of distance signals corresponding to respective ones of the first regions;

means for determining a distance on the basis of a selected group of the plurality of distance signals to produce a determined distance signal for focusing the objective lens;

means for driving the objective lens in accordance with the determined distance signal;

means for measuring a plurality of brightnesses of second regions of the object area to produce a plurality of brightness signals each corresponding to the measured brightnesses respectively, each of the second regions being substantially similar to each of the first regions, respectively;

means for discriminating whether the selected group includes the distance signal corresponding to the central region;

means for determining a first light measuring value on the basis of the brightness signals of the second regions corresponding to the first regions whose corresponding distance signals are included in the selected group used for producing the determined distance signal;

means for determining a second light measuring value corresponding to a brightness of substantially the entire object area;

means for detecting whether a primary object to be photographed is in backlight condition or not in accordance with the first and second light measuring signals; and

means for controlling exposure of the camera in accordance with a result of the detecting means when the distance signal corresponding to the central region is discriminated to be included in the selected group, while controlling the exposure independently of the result of the detecting means when the distance signal corresponding to the central region is discriminated not to be included in the selected group.

20. Control device as claimed in claim **19**, wherein the second light measuring value determining means determines the second light measuring value on the basis of the brightness signals of at least the second regions corresponding to the first regions whose corresponding distance signals are not used to produce the determined distance signal.

21. Control as claimed in claim **20**, wherein the second light measuring value determining means determines the second light measuring value on the basis of all of the brightness signals of the second regions.

22. Control device as claimed in claim **20**, further comprising means for counting a number of the distance signals in the selected group, means for discriminating whether the number counted by the counting means is single or plural; and means for interrupting operation of the detecting means when the discriminated number is plural.

23. Control device as claimed in claim **20**, wherein the exposure controlling means includes:

means for calculating a first aperture value for a normal photographing on the basis of the second light measuring value,

means for calculating a second aperture value for a flash photographing on the basis of the determined distance signal,

means for comparing the first aperture value with the second aperture value,

means for controlling exposure operation of the camera on the basis of the first light measuring value when the second aperture value is less than the first aperture value, while controlling the exposure operation on the basis of the second light measuring value when the first aperture value is less than the second aperture value,

means for illuminating the object area in flash photographing, and

means for energizing the illuminating means when the first aperture value is less than the second aperture value.

24. Control device as claimed in claim **20**, wherein the distance signals producing means includes a plurality of light receiving elements each corresponding to each of first regions, and the brightnesses measuring means includes means for measuring a plurality of brightnesses on the basis of output signals of the light receiving elements.

[57] **ABSTRACT**

Light intensity distributions of object images whose relative positions vary with a focusing state of an objective lens are formed by a lens assembly based on light fluxes transmitted through the objective lens, and the distributions are sensed by sensing devices having a plurality of photo-sensors to produce first and second signals for the respective light intensity distributions. The first and second signals are processed by relatively displacing the first and second signals under a first relationship and by relatively displacing the first and second signals under a second relationship different from the first relationship to determine a relative positional relationship of the light intensity distributions. If there is identical or essentially identical portion is found in the processing of the first signal and the second signal, the previous processing result is utilized to shorten the processing time.

APPARATUS FOR DETECTING FOCUSING STATE OF OBJECTIVE LENS

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to an improvement in a focusing state detection system which detects a focusing state by a relative positional relationship of two images of an object.

2. Related Background Art

In a prior art focus state detection apparatus for a camera, an exit pupil of an imaging lens is divided into two pupil areas and relative positional displacement of two images formed by light fluxes transmitted through the pupil areas are observed to determine an in-focus state. For example, Japanese Laid-open Patent Application Nos. 118019/1980 and 155331/1985 disclose a secondary focusing system in which a spatial image formed on a predetermined focus plane (corresponding to a film plane) by two secondary focusing optical systems is guided to two sensor planes so that relative positional displacement of the two images is detected.

The secondary focusing type focusing state detection apparatus is shown in FIG. 4. A field lens 3 is arranged coaxially with an optical axis 2 of an imaging lens 1 whose focusing state is to be detected. Two secondary focusing lenses 4*a* and 4*b* are arranged behind the field lens 3 symmetrically with respect to the optical axis 2. Photo-electric conversion element arrays 5*a* and 5*b* are arranged behind the lenses 4*a* and 4*b*. Diaphragms 6*a* and 6*b* are arranged in the vicinity of the secondary focusing lenses 4*a* and 4*b*. The field lens 3 essentially focuses an exit pupil of the imaging lens 1 onto pupil planes of the two secondary focusing lenses 4*a* and 4*b*. As a result, light fluxes applied to the secondary focusing lenses 4*a* and 4*b* correspond to those light fluxes which are emitted from non-overlapping equi-space areas on the exit pupil plane of the imaging lens 1, corresponding to the secondary focusing lenses 4*a* and 4*b*. When a spatial image formed in a vicinity of the field lens 3 is refocused on the planes of the photo-electric conversion element arrays 5*a* and 5*b* by the secondary focusing lenses 4*a* and 4*b*, the positions of the two images on the photo-electric conversion element arrays 5*a* and 5*b* change in accordance with the displacement of the spatial image along the optical axis. FIG. 5 shows this. In FIG. 5A which shows an in-focus state, the two images are positioned at the centers of the photo-electric conversion element arrays 5*a* and 5*b*, in FIG. 5B which shows a near-focus state, the two images are moved away from the optical axis 2, and in FIG. 5C which shows a far-focus state, the two images are moved toward the optical axis 2. This image intensity distribution is photo-electrically converted and the converted electrical signal is processed to detect a relative positional deviation of the two images. In this manner, the focus state of the imaging lens 1 can be detected.

Methods for processing the photo-electrically converted signal from the photo-electric conversion element arrays 5*a* and 5*b* are disclosed in Japanese Laid-open Patent Application No. 142306/1983 (U.S. Pat. No. 4,559,446) and U.S. Pat. No. 4,333,007. Specifically, the following formula is operated for $k_1 \leqq k \leqq k_2$ (for example, $k_1 = -N/2$, $k_2 = N/2$).

$$V(k) = \sum_{i=0}^{M-1} A(i) \square B(i + |K| + 1) - \sum_{i=0}^{M-1} A(i+1) \square B(i + |k|) \quad (k < 0)$$

$$= \sum_{i=0}^{M-1} A(i + k) \square B(i+1) - \sum_{i=0}^{M-1} A(i + k + 1) \square B(i) \quad (k \geqq 0)$$

$$= V_1(k) - V_2(k) \tag{1}$$

where N is the number of photo-electric conversion elements of the photo-electric conversion element array 5*a* or 5*b*, A(i) and B(i) are image signals from the i-th elements of the photo-electric conversion element arrays 5*a* and 5*b*, and M is the number of pixels processed ($M = N - |k| - 1$). $A(i) \square B(j)$ is an operator for A(i) and B(j). For example,

$$A(i) \square B(j) = |A(i) - B(j)| \tag{2}$$

$$A(i) \square B(j) = |A(i) - B(j)|^n \tag{3}$$

$$A(i) \square B(j) = \max[A(i), B(j)] \tag{4}$$

$$A(i) \square B(j) = \min[A(i), B(j)] \tag{5}$$

The formula (2) represents an absolute value of a difference between A(i) and B(i), the formula (3) represents accumulated product, the formula (4) represents a larger one of A(i) and B(j), and the formula (5) represents a smaller one. By the above definition, $V_1(k)$ and $V_2(k)$ can be considered as correlation amounts in a broad sense. From the formula (1), $V_1(k)$ represents the correlation amount at a displacement $(k-1)$ and $V_2(k)$ represents the correlation amount at a displacement $(k+1)$. Accordingly, an evaluation amount V(k) which is the difference between $V_1(k)$ and $V_2(k)$ represents a change of correlation amount of the image signals A(i) and B(i) at a relative displacement k. Since a change is zero at the peak of the correlation amount, it is assumed that the peak of the correlation amount exists in a section [k, k+1] represented by

$$V(k) \cdot V(k+1) < 0 \tag{6}$$

and V(k) and V(k+1) are interpolated to detect the deviations of the image signals A(i) and B(i). FIG. 6 shows the image signals A(i) and B(i) for the two images formed when the number of photo-electric elements is 16 (N=16). There is a deviation of P. FIG. 7 shows the evaluation amount V(k) of the formula (2) when the relative displacement k is changed within a range of $-N/2 \leqq k \leqq N/2$. As described above, V(k) and V(k+1) which meet $V(k) \cdot V(k+1) < 0$ are linearly interporated to detect the deviation P. FIG. 8 shows a relationship between the image signals A(i) and B(i) when the evaluation amount V(k) is calculated while the relative displacement k changes in a range of $-3 \leqq k \leqq 3$. Hatched areas show the photo-electric conversion elements which are subject of the correlation.

Because the operation of the evaluation amount V(k) is done by correlation, the number of steps of operation increases as a function of N^2, where N is the number of photo-electric conversion elements. As a result, as the number N increases, the correlation operation time increases and the focus state detection time increases.

SUMMARY OF THE INVENTION

It is an object of the present invention to reduce a processing time so that a focusing state detection time is significantly shortened.

It is another object of the present invention to determine a first correlation amount for each relative displacement by utilizing a second correlation amount previously determined for other relative displacement so that common portions of correlation processing may be omitted.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 shows a block diagram of one embodiment of a focusing state detection apparatus of a camera in accordance with the present invention,

FIG. 2 shows a flow chart of an embodiment of the present invention,

FIG. 3 illustrates a processing method,

FIG. 4 shows an arrangement of an optical system of a conventional secondary focusing type focusing state detection apparatus,

FIGS. 5A, 5B and 5C show relationships between a focusing state in the secondary focusing system and an image deviation,

FIG. 6 shows image signals produced by two sensor arrays in the secondary focusing system,

FIG. 7 shows a change of evaluation amount in the secondary focusing system, and

FIG. 8 shows a relationship between two images in focusing state detection processing in the secondary focusing system.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

In a process of calculating $V(k)=V_1(k)-V_2(k)$ for each relative displacement k, the processing of $V_1(k)$, for example, may utilize $V_2(k-2)$ which has been processed for the relative displacement $(k-2)$ in order to shorten the processing time for the evaluation amount V(k). This is explained with reference to FIG. 8. The correlation processing of $V_1(-1)$ for determining the evaluation amount $V(-1)$ is almost identical to the correlation processing of $V_2(-3)$ for determining the evaluation amount $V(-3)$, and the correlation processing of $V_1(1)$ for determining the evaluation amount V(1) is identical to the correlation processing of $V_2(-1)$ for determining the evaluation amount $V(-1)$. In this manner, the processing of $V_1(k)$ is identical or almost identical to the correlation processing of $V_2(k-2)$ which has been done two pixel displacements before. Thus, the identical portions are not processed again but the previous results are utilized. This is more fully explained with reference to FIG. 3. As shown,

$$V_2(-3) = \sum_{i=0}^{11} A(i+1)\square B(i+3)$$
$$= A(1)\square B(3) + A(2)\square B(4) + \ldots + A(12)\square B(14)$$

Because $V(-1) = V_1(-1) - V_2(-1)$,

then

-continued

$$V_1(-1) = \sum_{i=0}^{13} A(i)\square B(i+2)$$
$$= A(0)\square B(2) + A(1)\square B(1) + \ldots + A(13)\square B(15)$$
$$= A(0)\square B(2) + V_2(-3) + A(13)\square B(15)$$

Accordingly, the correlation amount $V_1(-1)$ is a sum of the correlation amount $V_2(-3)$ and A(0)□B(2) and A(13)□B(15). Thus, the processing of the correlation amount $V_1(k)$ is attained by adding only two terms to the correlation amount $V_2(k-2)$, and the processing of the evaluation amount V(k) can be carried out almost in a time necessary to calculate the correlation amount $V_2(k)$. When the evaluation amount V(k) is to be calculated for k which is within a range of $k_1 \leqq k \leqq k_2$, the correlation amounts $V_2(k_1-2)$ and $V_2(k_1-1)$ for the relative displacements (k_1-2) and (k_1-1) are previously processed. Thus, the evaluation amount V(k) can be calculated in essentially one half the number of steps.

The above processing is equivalent to calculating and storing $V_1(k)$ for k which is within the range of $k_1 \leqq k \leqq k_2$, but the latter is disadvantageous in cost and circuit configuration. In the former method, it is necessary to store only V_2 which is two pixel displacements before and hence no large capacity memory is required to attain the shortening of the processing time.

A method for detecting a deviation of two images by using the above processing method is explained with reference to a flow chart of FIG. 2.

In a step 1, the correlation amounts V_2 for the relative displacements (k_1-2) and (k_1-1) are calculated. Loop calculation is carried out in a block over the relative displacement (k_1-2) to (k_1-1).

(Step 1-1) Determine the number M of pixels to be processed (corresponding to the hatched area in FIG. 8) based on the relative displacement k.

(Step 1-2) Check a sign of the relative displacement k.

(Step 1-3) If $k<0$, set $iA=0$, $iB=|k|$, where iA and iB are processing start addresses for images A and B, as shown in the formula (1). Namely, the image B is displaced.

(Step 1-4) If $k \geqq 0$, set $iA=|k|$, $iB=0$. In this case, the image A is displaced.

(Step 1-5) Set a process variable VB to "0".

(Step 1-6) For a processing relative address J which is within a range of 0 to (M−1), execute

$$VB \leftarrow VB + A(iA+J+1)\square B(iB+J)$$

(Step 1-7) At this point, the processing variable VB is equal to $V_2(k)$. A content of a work area BB which contains the process result before one pixel displacement is transferred to a work area BA which contains the process result before two pixel displacement, and the processing variable VB is transferred to the work area BB.

At the end of the step 1, the work area BA contains the correlation amount $V_2(k_1-2)$ and the work area BB contains the correlation amount $V_2(k_1-1)$.

In a step 2, the evaluation amount V(k) is calculated for the relative displacement k $(k_1 \leqq k \leqq k_2)$.

(Step 2-1) to (Step 2-4) Same as the Step 1-1 to Step 1-2.

(Step 2-5) The pre-processed content of the work area BA is transferred to the processing variable V_1.

The correlation amount V_2 for the relative displacement (k−2) has been stored in the work area BA.

(Step 2-6) Check the relative displacement k. If k=1, it means that the correlation amount V_1 has already been determined.

(Step 2-7) If k≦0, add A(iA)□B(iB+1) and A(iA+M−1)□B(iB+M) to the processing variable V1 to determine the correlation amount $V_1(k)$ for the relative displacement k.

(Step 2-8) If k≧2, subtract A(iA−1)□B(iB) and A(iA+M)□B(iB+M+1) from the processing variable V1, as opposed to the step 2-7, to determine the correlation amount $V_1(k)$ for the relative displacement k.

(Step 2-10) For the processing relative address J (0≦J≦M−1), execute

V2←V2+A(iA+J+1)□B(iB+J)

(Step 2-11) At this point, the processing variable V2 is equal to $V_2(k)$. The content of the work area BB is transferred to the work area BA, and the processing variable V2 is transferred to the work area BB. Thus, the work area BA contains the correlation amount $V_2(k-2)$ and the work area BB contains the correlation amount $V_2(k-1)$, for the next relative displacement k.

In this manner, the processing time can be reduced to substantially one half of the processing time required when the formula (1) is processed for each relative displacement k. The deviation P of the two images can be determined based on the evaluation amount V(k).

FIG. 1 shows a block diagram of an embodiment of a focusing state detection apparatus for a camera in accordance with the present invention. PRS denotes a control circuit of the camera which proceeds the correlation processing in accordance with the procedure shown in FIG. 2 to detect the deviation P of a pair of light intensity distributions of object images, that is, the focusing state in order to control the focusing of the imaging lens. It may be a one-chip microcomputer which contains CPU, RAM, ROM, EEPROM (electrically erasable programmable ROM) and input/output ports. The ROM and EEPROM store a series of controlling softwares and parameters including those for AF control. DBUS denotes a data bus, SHT denotes a shutter control circuit which accepts data supplied from the data bus DBUS while a control signal CSHT is supplied thereto from the control circuit PRS and controls the drive of a shutter leading curtain and trailing curtain in accordance with the input data. APR denotes a diaphragm control circuit which accepts data supplied from the data bus DBUS while the control signal CAPR is applied thereto and controls a diaphragm mechanism (not shown) in accordance with the input data. DSP denotes a display circuit which accepts data supplied from the data bus DBUS while the control signal CDSP is applied thereto and displays imaging information based on the input data. SWS denotes a group of switches such as release switch, continuous photographing mode switch and information setting switches.

SPC denotes a light intensity measurement circuit. An analog light intensity signal SSPC from the circuit SPC is supplied to the control circuit PRS where it is A/D converted for use as light intensity data to control the shutter control circuit SHT and the diaphragm control circuit APR. LCOM denotes a lens communication circuit which accepts data supplied from the data bus DBUS while the control signal CLCOM is applied thereto and serially communicates with a lens unit to be described later in accordance with the input data. It transmits data DCL for driving the lens in synchronism with a clock signal LCK to an in-lens control circuit to be described later and serially receives from the in-lens control circuit, lens information DLC such as current position of the imaging lens. BSY denotes a signal to inform to the camera that the imaging lens is moving. When this signal is present, the serial communication is not undertaken.

LNSU denotes the lens unit, and LPRS denotes the in-lens control circuit for driving a motor MTR in accordance with the serial input data DCL to move the imaging lens LNF. It includes a ROM which stores a focal distance of the imaging lens LNF and an open F value. ENC denotes an encoder which detects a pulse signal generated as a lens body tube which holds the imaging lens LNF is moved and supplies to the in-lens control circuit LPRS a current position signal of the imaging lens LNF. SDR denotes a sensor drive circuit for controlling a line sensor SNS such as DDC sensor having two sensor lines SAA and SAB in accordance with the input signals from the control circuit PRS. The sensor lines SAS and SAB may be two sections of one sensor line.

The operation is now described. Since the operation of the shutter control circuit SHT, diaphragm control circuit APR, display circuit DSP and light intensity measurement circuit SPC is not directly related to the present invention, the explanation thereof is omitted.

The control circuit PRS checks the state of the release switch of the switch group SWS and if it detects that the release switch has been actuated, it starts a series of focusing operations. It first supplies a start of storage signal STR and drives the photo-electric converter SNS through the sensor drive circuit SDR to produce image signals A(i) and B(i) for the light intensity distributions of the two images. The operation of the control circuit PRS, sensor drive circuit SDR and line sensor SNS is briefly explained below. When the control circuit PRS generates the start of storage signal STR, the sensor drive circuit SDR supplies a clear signal CL to the line sensor SNS to clear charges of the photo-electric converters of the sensor lines SA and SAB. Then, the line sensor SNS starts photo-electric conversion of light images formed on the sensor lines SAA and SAB by the secondary focusing lenses (which are not shown in FIG. 1 but are arranged as shown in FIG. 4) and to store the charges. After a predetermined time period since the start of the above operation, the sensor drive circuit SDR supplies a transfer signal SH to the line sensor SNS to transfer the charges stored in the photo-electric converter to the CCD. The sensor drive circuit SDR also supplies an end of storage signal END to the control circuit PRS and waits for a CCD drive clock CK to be supplied from the control circuit PRS. When the CCD drive clock CK is supplied, the sensor drive circuit SDR generates CCD drive signals $\phi 1$ and $\phi 2$ and supplies them to the line sensors SNS. The line sensor SNS, when it receives those signals, supplies the analog image signal SSNS to the control circuit PRS. Thus, the control circuit PRS A/D converts the analog image signal SSNS in synchronism with the CCD drive clock CK and stores the converted image signals A(i) and B(i) of the light intensity distributions of the two images in predetermined addresses in the RAM.

After the image signals A(i) and B(i) of the light intensity distributions of the two images have been stored, the control circuit PRS carries out the focusing

state detection processing to detect the focusing state of the imaging lens LNF. This information is sent to the lens communication circuit LCOM by the control signal CLCOM through the data bus DBUS. If a signal BSY is not supplied, the lens communication circuit LCOM determines that the imaging lens LNF is now in a stopped condition and supplies the focusing state information sent from the control circuit PRS to the in-lens control circuit LPRS, that is, supplies the data DCL in synchronism with the clock signal LCK. It also receives the lens information DLC from the in-lens control circuit LPRS. This information includes parameters such as conditions of the imaging lens LNF and is used for the imaging operation of the camera. On the other hand, the in-lens control circuit LPRS drives the motor MTR in accordance with data supplied from the camera to move the imaging lens LNF to a position corresponding to the data, that is, until the number of encoder pulses EPL supplied from the encoder ENC reaches the number specified by the data. While the motor MTR is driven, the signal BSY is supplied to the camera.

In this manner, the series of focusing state detection operation is completed.

The processing method of the present invention is not limited to the correlation processing shown by the formulas (2)–(5) but it may be applicable to broad correlation processing between two signals.

In accordance with the present invention, the first correlation amount to be determined for each relative displacement is determined by utilizing the second correlation amount previously determined for other relative displacement so that the correlation processing which is same as that previously done is omitted. As a result, the processing time is shortened and the focusing state detection time is significantly shortened.

What I claim is:

1. An apparatus for detecting a focusing state of an objective lens comprising:

optical means for receiving light fluxes transmitted through an objective lens and forming light intensity distributions based on an object whose relative position varies with a focusing state of the objective lens,

sense means having a plurality of photo-sensors for sensing the light intensity distributions to produce first and second signals for the respective light intensity distributions; and

processing means for manipulating the first and second signals to sequentially and relatively displace the first and second signals under a first relationship to determine a first correlation amount $V_1(k)$, manipulating the first and second signals to sequentially and relatively displace the first and second signals under a second relationship to determine a second correlation amount $V_2(k)$, subtracting the second correlation amount from the first correlation amount to determine an evaluation amount V(k), calculating the evaluation amount for each relative displacement, and calculating the relative position of the light intensity distributions based on the evaluation amounts to produce a signal indicating the focusing state of the objective lens;

said processing means calculating one of the first and second correlation amounts by utilizing another correlation amount previously calculated for another relative displacement.

2. An apparatus for detecting a focusing state of an objective lens according to claim 1, wherein said processing means calculates the first correlation amount for each relative displacement by utilizing the second correlation amount previously calculated for other relative displacement.

3. An apparatus for detecting a focusing state of an objective lens according to claim 1, wherein the evaluation amount V(k), first correlation amount $V_1(k)$ and second correlation amount $V_2(k)$ meet the following relationship:

$$\begin{aligned} V(k) &= V_1(k) - V_2(k) \\ &= \sum_{i=0}^{M-1} A(i) \square B(i + |k| + 1) - \sum_{i=0}^{M-1} A(i+1) \\ &\quad \square B(i + |k|) \qquad (k < 0) \\ &= \sum_{i=0}^{M-1} A(i + k) \square B(i+1) - \sum_{i=0}^{M-1} A(i + k + 1) \\ &\quad \square B(i) \qquad (k \geqq 0) \end{aligned}$$

where $M = N - |k| - 1$ is the number of pixels processed, N is the number of photo-sensors used to sense one of the light intensity distributions, A(i) is the first signal, B(i) is the second signal, and $i = 0, \ldots N-1$.

4. An apparatus for detecting a focusing state of an objective lens according to claim 1, wherein said optical means includes secondary focusing lenses having parallel optical axes.

5. A method for detecting a focusing state of an objective lens comprising the steps of:

forming light intensity distributions based on an object whose relative position varies with a focusing state of the objective lens, based on light fluxes transmitted through the objective lens;

sensing the light intensity distributions by sensing means having a plurality of photo-sensors to form first and second signals for the respective light intensity distributions; and

manipulating the first and second signals to relatively displace the first and second signals under a first relationship and to relatively displace the first and second signals under a second relationship different from the first relationship to produce a signal for indicating the focusing state of the objective lens based on the relative displacement of the light intensity distributions;

the calculation for one relative displacement utilizing a calculation result previously obtained for an identical or essentially identical portion under another relationship.

[57] **ABSTRACT**

The shutter blades of a scanning blade shutter and the movable element of an adjustable focus lens in a single lens reflex camera are actuated by a single or common drive. The scanning blade shutter is coupled to the common drive by a rotatably mounted beam member. The movable lens element is also coupled to the common drive through a drive link assembly and the same beam member. Actuation of the beam member by the common drive simultaneously moves the shutter blades in the single lens reflex camera toward their closed positions and moves the lens element coupled thereto by a drive link assembly toward a rangefinder-determined lens focal position. A solenoid coupled to a drive link in the drive link assembly and responsive to rangefinder-derived object distance signals actuates the drive link to uncouple the movable lens element from the beam member when the movable lens element has been moved to a particular focal position determined by the rangefinder. The common drive then moves the shutter blades to their full closed positions after the movable lens element has been uncoupled. The drive link connection between the beam member and the movable lens element is re-established subsequent to film exposure to thereby enable the common drive to return the movable lens element to its initial focal position while moving the shutter of the single lens reflex camera to its full open position.

FIG 6

COMMON DRIVE FOR SHUTTER BLADES AND OBJECTIVE LENS ASSEMBLY

BACKGROUND OF THE INVENTION

The present invention relates to a common shutter blade and lens focusing system drive for a photographic camera, in general, and to such a drive for a single lens reflex camera employing a scanning blade type shutter, in particular.

Photographic apparatus employing shutter blade mechanisms, in general, and scanning blade shutters, in particular, as well as a lens mechanism that may be automatically focused in accordance with a rangefinder-determined camera-to-subject distance are well known in the art. A camera employing a scanning blade shutter and a lens mechanism responsive to a rangefinder-determined subject distance signal is described in, for example, U.S. Pat. No. 4,192,587, entitled "Proportioned Fill Flash", by A. G. La Rocque, et al, issued Mar. 11, 1980, in common assignment herewith. For convenience, the disclosure in said LaRocque et al patent is specifically incorporated herein by reference.

Scanning shutter blade mechanisms are normally driven from a scene light blocking position toward a maximum aperture defining position and thereafter returned to their initial scene light blocking position during an exposure interval. Such scanning blade shutter mechanisms generally comprise a pair of scanning blade shutter elements each having a primary aperture therethrough. The shutter blade elements overlap for reciprocal movement with respect to each other. This movement drives the primary aperture into overlapping relationship with each other so as to define a progressively increasing and then decreasing effective primary aperture. The shutter blade mechanisms are normally driven by a spring and solenoid arrangement as shown in La Rocque et al, supra, or by a microcomputer controlled stepper motor incorporating a digitally encoded scanning blade position sensor as shown, for example, in U.S. Pat. No. 4,325,614, entitled "Exposure Control System With Shutter Operation Controlled by a Microcomputer", by D. L. Grimes, issued Apr. 20, 1982, in common assignment herewith.

Autofocus cameras of the aforementioned type generally embody a motor driven objective lens mechanism which must be stopped at an appropriate focal position corresponding to a previously determined camera-to-subject distance. In such cameras, it is desirable to provide a lens position encoder system to identify the instantaneous focal position of a lens element driven by said lens mechanism as it is moved through its plurality of different focal positions in order to precisely position the lens element at a previously determined object-distance-related focal position as shown, for example, in La Rocque et al, supra.

In prior adjustable focus lens cameras employing scanning shutter blades, the objective lens and shutter blade mechanisms are driven by a common drive either that sequentially drives the objective lens and the shutter blades or are driven by separate shutter blade and lens drive means. U.S. Pat. No. 4,278,340 to Toyama et al is an example of such a sequential lens and shutter blade drive and U.S. Pat. No. 4,199,244 to Shenk is an example of a camera employing separate shutter blade and lens drives. In addition, if an encoder system were to be employed in such cameras to determine the instantaneous focal position of the movable lens element as in, for example, La Rocque et al, supra, and the instantaneous blade position of the scanning shutter blades as in, for example, Grimes, supra, the prior art teaches the use of separate encoders for each such position sensing function. The use of duplicate drive means and encoders in an autofocus camera necessarily increases camera cost, size and complexity.

It is a primary object of the present invention, therefore, to provide a single or common drive for a photographic camera that is capable of driving the movable element of an adjustable focus lens to a previously determined lens focal position and of driving a scanning blade type shutter mechanism during an exposure interval.

It is another object of the present invention to provide a rangefinder-derived signal-responsive common drive that is capable of simultaneously driving both the shutter and focusing mechanisms in a single lens reflex camera.

It is a further object of the present invention to provide a single position-encoder that is capable of determining both the instantaneous blade position of a shutter blade mechanism and the instantaneous focal position of the movable lens element in an adjustable focus lens camera.

Other objects and/or advantages of our invention will be made readily apparent by referring to the preferred embodiment thereof described in detail below.

SUMMARY OF THE INVENTION

In accordance with the present invention, a single or common drive is provided that is capable of actuating both the objective lens and shutter and/or aperture mechanisms in an adjustable focus lens camera to a lens focal position corresponding to a previously determined camera-to-subject distance or other desired focal position and through an exposure interval, respectively. The shutter is directly coupled to the common drive and the objective lens mechanism is coupled to the common drive through a drive link assembly. Actuation of the common drive moves the initially open shutter mechanism towards its closed or light-blocking position and moves the objective lens mechanism coupled thereto by said drive link assembly toward a previously determined lens focal position. Means coupled to the drive link assembly and responsive to a signal representative of said previously determined camera-to-subject distance actuates said drive link assembly to uncouple the objective lens mechanism from the common drive when said lens mechanism has been moved to a focal position corresponding to said previously determined camera-to-subject distance. The common drive subsequently moves the shutter mechanism to its full closed position prior to the initiation of a film exposure interval. The drive link assembly connection between the common drive and said objective lens mechanism is re-established subsequent to a film exposure interval to thereby enable the common drive to return the objective lens mechanism to its initial focal position while moving the shutter to its initial open position.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a block diagram showing a photographic camera embodying the combination lens and shutter drive of the prevent invention.

FIG 2 is a front elevational view of the scanning shutter blades and associated drive mechanism of the present invention.

FIG. 3 is a sectional view taken on the line 3—3 in drawing FIG. 2.

FIG. 4 is a diagrammatic perspective view of the lens and associated lens drive mechanism of the present invention showing portions thereof removed to reveal otherwise hidden structure.

FIGS. 5A, 5B and 5C are sectional views taken on the line 5—5 in drawing FIG. 4 sequentially showing the lens-to-drive coupling means in an uncoupled, a transitional and coupled state, respectively.

FIG. 6 is a timeline showing a typical operational sequence of various lens and shutter drive related elements in the camera of FIGS. 1–5.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

Referring now to FIG. 1 of the drawings, there is shown at 10 a block diagram of a photographic camera incorporating a preferred embodiment of the combination lens and shutter drive mechanism of the present invention. Camera 10 is of the single lens reflex type and said camera includes housing 12 within which film is supported at focal plane 14 opposite hub 16. Lens assembly or lens mount 18 is positioned within hub 16 and is displaceable in axial direction 20 to form an in-focus image of subject 22 at said plane 14 when shutter mechanism 24 is actuated to generate an exposure interval after mirror 26 has been moved from its vertical or viewing position to its horizontal or film exposure position (shown in phantom) as functionally illustrated in said drawing FIG. 1. Exemplary of a single lens reflex camera of the type described above is U.S. Pat. No. 3,714,879 to Land et al and of the above-described displaceable or adjustable focus lens camera is the U.S. Patent to Shenk, supra.

Shutter mechanism 24 is driven by shutter/lens drive 30 through path 32 in response to drive signals from exposure and focus control 34 in a closed loop system that includes shutter blade position sensor 36, under the control of microcomputer 37. Lens mount 18 is also driven by said shutter/lens drive 30 through coupling means 38. Coupling means 38 is actuated between its coupled and uncoupled states by coupling operator 40 in response to coupling means control signals from exposure and focus control 34. Similarly, mirror 26 is actuated between its viewing and film exposure positions by mirror operator 42 and strobe flash 44 is fired, in response to mirror position control signals and flash fire signals, respectively, from said exposure and focus control 34. The coupling operator 40, the mirror operator 42 control signals and the flash fire signals from exposure and focus control 34 are also under the control of said microcomputer 37.

Microcomputer 37 is, in turn, responsive to a plurality of inputs. These include manual start input 46 provided in response to an operator manually actuating an exposure cycle start button and automatically provided inputs such as pre-exposure and exposure interval scene brightness conditions, designated 48, and a camera-to-scene distance input, designated 50, which is preferably provided by a sonar ranging system of the type disclosed in commonly assigned U.S. Pat. No. 4,081,626 to Muggli et al. Microcomputer 37 stores a plurality of selectable blade trajectory programs in a manner similar to that described in U.S. Pat. No. 4,427,276 to Feinerman et al and the implementation of any one particular trajectory program is automatically determined, in part, by such microcomputer 37 inputs as rangefinder determined subject distance and scene brightness conditions.

Shutter mechanism 24 functionally illustrated in drawing FIG. 1, is of the scanning shutter blade type, and is shown in much greater detail in drawing FIG. 2. FIG. 2 is a front elevational view of the scanning blade shutter forming said shutter mechanism 24. With respect to FIG. 2, shutter mechanism 24 comprises two overlapping shutter blade elements 52, 54 disposed for reciprocal sliding movement with respect to one another on baseblock 56. Shutter blade elements 52, 54 are respectively provided with scene light admitting primary apertures 58 and 60 to collectively define a progressive variation of effective aperture opening 62 in accordance with the simultaneous longitudinal and lateral displacement of one blade element with respect to the other blade element in a manner as is fully described in U.S. Pat. No. 3,942,183, entitled "Camera With Pivoting Blades" by George D. Whiteside, issued Mar. 2, 1976, in common assignment herewith and now specifically incorporated herein by reference. Effective aperture 62 may be varied between a light blocking and an infinite number of light unblocking positions and is shown in FIG. 2 in its fully open, light unblocking position. The primary apertures 8, 60 are selectively shaped and positioned so as to overlap and form a light entry exposure aperture 62 in baseblock 56 to thereby define said effective aperture 62, of varying size, as a function of the position of blade elements 52, 54.

Projecting from the baseblock 56 at a location spaced laterally apart from light entry exposure aperture 62 in drawing FIG. 2 is pivot pin or stud 64 which pivotally and translatably engages slots 66 and 68 respectively formed near one end of shutter blade elements 52, 54. Pin 64 may be integrally formed with the baseblock 56 and blade elements 52, 54 may be retained in engaging relation with respect to the pin 64 by any suitable retaining means. The opposite ends of blade elements 52, 54 include extended portions 70 and 72, respectively, which pivotally connect to opposite ends of walking beam member 74. Walking beam 74, in turn, is integrally formed with and is located at one end of rotor 78 of galvanometer actuator 80 and said actuator 80 is mounted in a fixed position with respect to said baseblock 56. In the preferred embodiment, walking beam 74 is pivotally connected at its distal ends to the shutter blade elements 52, 54 by coupling pins 82, 84, respectively.

Galvanometer actuator 80 provides the drive force required to displace scanning shutter blades 52, 54 with respect to each other and with respect to baseblock 56 over their complete aperture-forming operational range. Galvanometer actuator 80 is, in effect, a combination d'Arsonval galvanometer and a DC electric motor. Galvanometer actuator 80 includes cylindrically shaped permanent magnet 86 formed of magnetic segments, supported in cylindrically shaped soft iron support structure, that is mounted in a fixed position with respect to camera housing 12 (FIG. 1). The rotor 78, having multiple turn coil 88 wound thereon is mounted for rotation within cylindrically shaped magnet 86 and within the magnetic field of said permanent magnet 86. A rotational force is generated by multiple turn coil 88 and rotor 78 on which said coil 88 is wound in either a clockwise or counterclockwise direction when a DC current having a particular magnitude and direction is

passed through said coil **88** by exposure and focus control **34** (FIG. **1**) under the control of microcomputer **37** (FIG. **1**). Galvanometer actuator **80** has some of the characteristics of an electric motor in that it utilizes the forces produced by a magnetic field on a current-carrying conductor and some of the characteristics of a galvanometer in that the rotor rotates less than one complete revolution when actuated to drive shutter blade elements **52, 54** between their scene light blocking and unblocking positions.

Shutter blade mechanism **24** is provided with analog-type, blade displacement sensing encoder system **36** for continuously monitoring the position of shutter blade elements **52, 54** during the course of an exposure interval. As shown in FIG. **2**, encoder system **36** preferably includes laterally extending rectangular and triangular shaped secondary apertures **92, 94** respectively formed in scanning blades **52, 54** for movement therewith. However, other aperture shapes could be employed to form said secondary apertures. Apertures **92, 94** collectively define a progressive variation of effective secondary aperture opening **96** in accordance with the simultaneous lateral displacement of blade element **52** with respect to blade element **54**.

As is more clearly shown in drawing FIG. **3**, which is a sectional view taken on the line **3—3** in FIG. **2**, encoder system **36** additionally includes light emitting diode **98** and light sensing diode **100** mounted on opposite sides of the combination of shutter blades **52, 54** and lens mounting plate **108** (FIG. **4**). In this particular arrangement, light emitted by light emitting diode **98** is directed to light sensing diode **100** through effective secondary aperture opening **96** by reflecting mirror **102** and lens **104**. Light emitting diode **98** is energized prior to the initiation of a film exposure cycle actuating shutter blade mechanism **24**. Actuation of shutter blades **52, 54** of said shutter mechanism **24** by galvanometer actuator **80** causes a change in the size of effective secondary aperture opening **96** which, in turn, causes a progressive change in the amount of light sensed by the photosensitive surface of light sensing diode **100** through aperture opening **96**. An electrical signal representative of the instantaneous position of shutter blade elements **52, 54** in the form of an electrical current is generated by light sensing diode **100** in correspondence with the amount of light sensed by said diode **100**. This shutter blade position signal is subsequently transmitted by shutter blade position sensing encoder **36** to exposure and focus control **34** (FIG. **1**) through path **106**.

As shown in FIG. **4** of the drawings, lens mounting plate **108** is mounted in a fixed position with respect to camera housing **12** (FIG. **1**), immediately in front of galvanometer actuator **80**, walking beam **74** and shutter blades **52, 54**. Adjustable focus lens assembly **110** is mounted in a fixed position on said lens plate **108**. Lens assembly **110** includes front lens element **112** that is translatable along optical axis **114** by a conventional cam ring where it serves to focus images of subjects positioned in various locations within a range of subject distances at image plane **14** (FIG. **1**) of said single lens reflex camera **10**.

Drive link **116** is attached to lens mounting plate **108** by pins **118A** and **118B** projecting from said drive link **116** and through laterally extending elongated slots **120A** and **120B**, respectively, for reciprocating movement with respect to said mounting plate **108**. A portion of the lower edge of drive link **116** is formed with a gear rack **122** that is meshed with smaller gear **124** of compound gear **126** rotatably mounted on said lens mounting plate **108**. Larger gear **128** of said compound gear **126** is, in turn, in mesh with gear **130** formed in the periphery of conventional lens element translating cam ring **131** of lens assembly **110**. Latch **132** is attached to that end of drive link **116** remote from gear rack **122**, for rotation about latch axis **134**. Latch **132** is provided with bifurcation or open slot **136** at one end and lever arm **138** at the other. A spring (not shown) is provided to resist (i.e., to provide a biasing force against) the rotation of latch **132** about latch axis **134** in direction **140**.

Pin **142** projecting from the upper end of walking beam member **74** extends through arcuate clearance slot **144** in mounting plate **108** for limited arcuate movement therein. Pin **142** engages open slot **136** in latch **132** for pivotal movement therein when walking beam member **74** is actuated to drive link **116** through said latch **132**. If latch **132** is rotated in direction **140**, open slot **136** will move out of engagement with walking beam pin **142**. Subsequent rotational movement of walking beam member **74** after slot **136** has been so disengaged, will not be transmitted to drive link **116** nor to front lens element **112** of lens assembly **110** coupled thereto. Also, if walking beam member **74** is uncoupled from latch **132** and is subsequently moved relative to said latch **132**, pin **142** will move out of alignment with said slot **136**. FIG. **5A**, which is a sectional view taken on the line **5—5** in drawing FIG. **4** illustrates such movement. As shown in said FIG. **5A**, pin **142** projecting from walking beam **74** has moved laterally away from latch slot **136** under the influence of galvanometer actuator **80** coupled thereto and then latch **132**, now in its unlatch state, has biased back to its initial rotational position or the rotational position it assumes when in its walking beam **74** to drive link **116** latch state. The mechanical link between said latch **132** and walking beam **74** is re-established in the following manner as additionally illustrated in drawing FIGS. **5B** and **5C**.

Like FIG. **5A**, FIGS. **5B** and **5C** are also sectional views taken on the line **5—5** in drawing FIG. **4**. In FIG. **5B**, galvanometer actuator **80** (FIG. **4**) initially drives pin **142** projecting from walking beam member **74** toward latch **132**. Pin **142** is subsequently driven into cam surface **146** of latch **132**, thereby causing the slot **136** portion of latch **132** to cam outward in direction **148** away from mounting plate **108**. As pin **142** continues to move toward latch **132**, it ultimately becomes aligned with slot portion **136** thereof, as shown in drawing FIG. **5C**, thereby enabling slot **136** to pivot inward in direction **150** under the force of the above-noted force bias spring (not shown) of latch **132** to thereby mechanically couple said walking beam member **74** to drive link **116**.

As shown in drawing FIG. **4**, electrically actuated solenoid **152** is attached, in a fixed position, to lens mounting plate **108** and pivot link **154** is rotatably attached to said plate **108** by pin **156**. In addition, L-shaped slide link **158** is attached to mounting plate **108** by pins **160A** and **160B** projecting from said plate **108** through vertically extending, elongated slide link slots **162A** and **162B**, respectively, for reciprocating vertical movement with respect to said mounting plate **108**. Pin **164** projecting from one end of pivot link **154** engages slot **166** in solenoid armature **168** for pivotal movement therein and the other end of said pivot link **154** is, in turn, pivotally attached to the lower end of said slide link **158** by pin **169**. Arm **170** of slide link **158** at the upper end of said link **158** is in sliding contact with the

bottom surface of the lever arm **138** portion of latch **132**. The function of link arm **170** is to maintain contact between slide link **158** and latch arm **138** whenever drive link **116** moves in slots **120A** and **120B** relative to said slide link **158**. When electrical solenoid **152** is energized, armature portion **168** is electromagnetically attracted downward, causing pivot link **154** to rotate about pin **156** and thereby cause link **158** to slide upward on support pins **160A**, **160B**. This upward motion of slide link **158** is transferred to lever arm **138** through link arm **170**, causing latch **132** to rotate in direction **140** and thereby uncouple drive link **116** from walking beam member **74**.

DISCUSSION

A typical combined lens and shutter drive operational sequence will now be described in detail with respect to the above-described drawing FIGS. **1-5** and with respect to drawing FIG. **6**, which is a time line showing the sequence of operation of various lens and shutter drive related elements of single lens reflex camera **10**. Prior to the initiation of a typical exposure sequence employing the combined lens and shutter drive of the present invention, it should be noted that shutter mechanism **24** is in its full open position, walking beam member **74** is mechanically coupled to drive link **116** through latch **132** and mirror **26** is in its viewing or blocking position precluding any and all scene light from reaching image plane **14**.

A lens focusing and film exposure sequence is initiated by an operator actuation of manual start **46**. The actuation of manual start **46** causes initial scene brightness conditions to be determined by light sensing means (not shown) within scene brightness condition determining means **48** and causes rangefinder **50** to ultrasonically produce an electrical signal representative of subject distance. As shown in the time line of FIG. **6**, at t_1 which occurs subsequent to the determination of initial scene brightness conditions and subject distance, exposure and focus control **34** under the control of microcomputer **37** generates a forward shutter/lens drive signal causing galvanometer actuator **80** to translate front lens element **112**, through drive link **116**, to the focus position determined by rangefinder **50**. The focus position of lens element **112** is sensed by shutter blade encoder system **36** in that blades **52**, **54** are directly coupled to said lens element **112** through walking beam member **74** and drive link **116**.

When lens element **112** of lens assembly **110** has been driven to the desired focal position just prior to t_2 by galvanometer actuator **80**, solenoid **152** is energized at t_2 by exposure and focus control **34**, causing the downward movement of solenoid armature **168** to rotate pivot link **154** about pin **156** and slide link **158** to move vertically upward on pins **160A** and **160B**. The upward movement of slide link **158** is transferred to arm **138** of latch **132** by arm **170** of slide link **158** to thereby rotate latch **132** out of engagement with walking beam **74** as said latch **132** is rotated in direction **140** by such slide link **158** movement. After latch **132** has been disengaged from drive link **116**, galvanometer actuator **80**, moving in the same direction, drives shutter mechanism **24** to its full closed position at t_3. It should be noted that the forward drive signal to galvactuator **80** is interrupted just prior to t_2 or when lens element **112** has reached the desired focal position, and during the period of time that walking beam **74** is being uncoupled from drive link **116**.

Mirror **26** is actuated to its unblocking position between times t_3 and t_4 by mirror operator **42** and microcomputer controlled exposure and focus control **34**. A shutter mechanism **24** actuating exposure interval is initiated at t_5 and terminated at t_6 by exposure and focus control **34** in correspondence with the blade aperture size versus time trajectory program stored within microcomputer **37** that, if the sensed lighting conditions deem it necessary, includes the firing of scene illuminating strobe flash **44**. Mirror **26** is then returned to its scene light blocking position between t_7 and t_8 and coupling operator **40** is enabled by de-energizing solenoid **152** at said time t_8. In addition, at t_8, a reverse shutter/lens drive signal is also generated by microcomputer controlled exposure and focus control **34** causing galvanometer actuator **80** to drive shutter blades **52**, **54** in shutter mechanism **24** toward their open or light unblocking positions.

As galvanometer actuator **80** continues to move shutter mechanism **24** toward its full scene light unblocking position, pin **142** projecting from galvactuator coupled walking beam **74** engages cam surface **146** (FIG. **5B**) of latch **132**, causing slot **136** formed therein to pivot outward in direction **148** away from lens mounting plate **108**. At time t_9 with pin **142** moving in the same direction, said pin **142** becomes aligned or is moved into registration with latch slot **136**. When this occurs, the said slotted end of latch **136** is pivoted inward in direction **150** (FIG. **5C**) under the .force of the latch **132** bias spring (not shown) as said pin **142** enters said slot **136**. At this time, drive link **116** and movable lens element **112** once again become mechanically coupled to galvanometer actuator **80** through latch **132**. Galvanometer actuator **80** continues to drive shutter mechanism **24** to its full open position while simultaneously driving the now-coupled movable lens element **112** toward its initial focus position. At time t_{10}, shutter mechanism **24** has been moved to its full open position, movable lens element **112** has been moved to its initial focus position, and the shutter/lens drive signal from microcomputer controlled exposure and focus control **34** has been terminated.

As hereinabove described, a single actuator (galvanometer actuator **80**) has been employed to simultaneously drive the blade elements of a shutter mechanism while at the same time driving the movable element of an adjustable focus lens to a desired focus position during at least a portion of the shutter blade actuation cycle. In addition, it should be noted that, with the exception of pin **142** projecting from walking beam **74**, movable element **112** of lens assembly **110** and all of the means coupling said lens element to walking beam **74** are uncoupled from said walking beam **74** prior to the initiation of an image forming exposure interval. By uncoupling lens element **112** from walking beam **74** in this manner, inertial loading of galvanometer actuator **80** that might otherwise alter a programmed aperture size versus time scanning blade trajectory, is thereby precluded.

It will be apparent to those skilled in the art from the foregoing description of our invention that various improvements and modifications can be made in it without departing from its true scope. The embodiments described herein are merely illustrative and should not be viewed as the only embodiments that might encompas our invention.

What is claimed is:

1. A photographic camera, comprising:

means for defining a focal plane;

an adjustable focus lens for directing scene light along a given path to said focal plane, said lens having a movable element mounted for displacement over a given operational range for adjustment of said lens to focus images of subjects positioned in various locations within a range of subject distance at said focal plane;

a blade mechanism;

means for mounting said blade mechanism for displacement between a blocking arrangement precluding transmission of scene light along said given path to said focal plane and an unblocking arrangement, said blade mechanism including at least one blade portion displaceable during displacement of said blade mechanism;

means for detecting each progressive position of said one blade portion and for deriving an electrical signal representative of each such progressive blade position;

means for producing a subject distance signal representative of the distance between said camera and a particular subject within said focusing range;

drive means actuatable for displacing said blade mechanism between its said blocking and unblocking arrangements;

a light blocking member actuatable between light blocking and unblocking positions for independently controlling scene light transmission along said given path from said lens to said focal plane;

a drive link assembly for coupling said movable lens element to said blade mechanism, said assembly being actuatable between a first arrangement where said lens element is uncoupled from said blade mechanism and a second arrangement where said lens element becomes coupled to said blade mechanism; and

energizeable control means for actuating said drive means to initially displace said blade mechanism toward its said blocking arrangement in preparation for exposure while simultaneously displacing said movable lens element coupled thereto from an initial toward a particular focus position, to then displace said blade mechanism toward its said unblocking arrangement and back again so as to define an exposure interval during which scene light is transmitted to the focal plane and for finally actuating said light blocking member for its said light unblocking position to its said light blocking position subsequent to said exposure interval, said control means including means responsive to said subject distance signal and said blade position signal for actuating said drive link assembly to its said first arrangement during initial displacement of said blade mechanism to uncouple said lens element from said blade mechanism when said lens element has been positioned to a particular subject distance related focus position, and responsive to a signal indicating the end of an exposure interval for actuating said light blocking member to its said light blocking position, for actuating said drive means to displace said blade mechanism toward its said unblocking arrangement, and for actuating said drive link assembly to its said second arrangement to couple said lens element to said blade mechanism so as to simultaneously return said movable lens element and said blade mechanism to their respective initial position.

2. The invention of claim 1 wherein said blade mechanism includes a pair of scanning blade shutter elements mounted in an overlapping relationship for reciprocal movement with respect to one another, with each element having a primary aperture therethrough and with said reciprocal movement defining a progressively increasing and then decreasing effective primary aperture to thereby provide an exposure interval.

3. The invention of claim 1, wherein said control means includes means for generating an electromagnetic force inducing electrical current corresponding to a desired blade mechanism aperture size versus time trajectory curve and said drive means comprises:

a pair of permanent magnets of opposite polarity mounted in a spaced relation, said magnets having a magnetic field of predetermined intensity established therebetween; and

a rotor coupled to said blade mechanism, said rotor including a coil of electrical wire coupled to said control means and supported for limited rotation within said magnetic field in response to said electrical current.

4. The invention of claim 1, wherein said means for detecting each progressive position of said one blade comprises:

said one blade includes an encoder aperture disposed for displacement along a predetermined path in correspondence with the displacement of said one blade; and

a light emitting device and a light sensing device mounted in a spaced relation on opposite sides of the said encoder aperture displacement path for providing an output signal indicative of the progressive position of said one blade when the light emitted by said light emitting device is transmitted to said light sensing device by way of said encoder aperture as said encoder aperture moves along said predetermined path.

5. The invention of claim 4, wherein said blade mechanism includes a pair of shutter blades with each such blade incorporating an encoder aperture disposed for displacement along a predetermined path, in an overlapping relationship, between said light emitting and light sensing devices, in correspondence with its associated shutter blade, for progressively varying the amount of light transmitted therebetween to thereby provide an output signal indicative of the position of said shutter blades relative to one another.

6. The invention of claim 1, wherein said means for producing a subject distance signal representative of subject distance is an ultrasonic rangefinder.

7. The invention of claim 1, wherein said light blocking member is a mirror actuatable between said light blocking position where it reflects an image of a scene to be photographed for scene framing and focusing purposes and a reflex position where it permits scene light transmission between said lens and said focal plane.

8. The invention of claim 1, wherein said control means comprises:

means for deriving an electrical signal representative of scene lighting conditions;

means for storing a plurality of different trajectory signal programs defining corresponding blade trajectory curves that are appropriate for different photographic conditions;

means responsive to a program of trajectory signals for actuating said blade mechanism drive means in

a manner whereby the operation of said blade mechanism coupled thereto is characterized by an aperture size versus time trajectory curve defined by said program of trajectory signals; and

means responsive to said scene lighting conditions signal for selecting the appropriate trajectory signal program from said storage means and feeding a correlated program of trajectory signals to said blade mechanism driving means.

9. The invention of claim **1**, wherein said drive link assembly comprises:

a rotatably mounted compound gear having large and small diameter gear portions;

an elongated member mounted for reciprocating movement having an edge portion in the form of a rack gear with its gear teeth in mesh with the small diameter gear portion of said compound gear;

a lens mount for supporting and translatably focusing said movable lens element, said lens mount having gear teeth formed at its periphery with said gear teeth being in mesh with the teeth of said large diameter gear portion wherein reciprocating movement of said elongated member is coupled to said lens element for lens element focusing movement;

a latch assembly for coupling said drive means to said elongated member comprising a pin member coupled to said drive member and a latch member pivotally attached to an end portion of said elongated member having a recess therein for receiving said pin member; and

an electrical solenoid responsive to said blade position and subject distance signals and coupled to said latch member, actuatable between an uncoupled condition where said pin member is precluded from entering said latch member recess and a coupled condition where said pin member is permitted to enter said latch member recess to thereby couple said drive means to said elongated member.

10. The invention of claim **1**, wherein said photographic camera is a single lens reflex camera.

11. A photographic camera comprising:

means defining a focal plane;

an adjustable lens for directing scene light along a given path to said focal plane, said lens including a movable element displaceable over a given operational range for adjustment of said lens to focus an image at said focal plane of a subject at a location determined in accordance with a subject distance signal;

an exposure control mechanism including at least one blade member displaceable over a select path to facilitate control of the passage of scene light to said focal plane;

drive means actuatable for displacing said blade member along its select path;

coupling means operable, responsive to a first signal, for coupling said movable lens element to said blade member for displacement therewith and, responsive to a second signal for decoupling said lens element from said blade member;

means for producing said first signal for coupling said lens element to said blade member, and for actuating said drive means for displacement of said blade member along its said select path for movement of said lens element therewith; and

means responsive to said subject distance signal for producing said second signal to decouple said lens element from said blade member when said lens element is displaced to a suitable location for focusing an image of a subject located at a distance represented by said subject distance signal.

12. The invention of claim **11** including means for detecting the progressive displacement of said blade element and for deriving a blade position signal in accordance therewith, and wherein said means responsive to said subject distance signal includes means responsive to said blade position signal for producing said second signal to decouple said lens element when said blade position signal represents a blade displacement sufficient to displace said lens element to its said suitable location in accordance with said distance subject signal.

13. The invention of claim **12** wherein said subject distance signal defines the displacement of said blade element necessary to displace said lens element to a suitable location in accordance with subject distance, and said means responsive to said subject distance signal incudes means responsive to a blade position signal selected in accordance with said subject distance signal for producing said second signal to decouple said lens element from said blade element.

14. The invention of claim **13** wherein said blade member is actuatable for displacing said blade member from an initial position toward a terminal position and subsequently back to its said initial position, and said first signal is provided prior to displacement of said blade member from its initial position so as to displace said lens element from an initial position upon displacement of said blade member, said second signal is provided during displacement of said blade member toward its said terminal position so as to release said lens element at a focus position, and said first signal is subsequently provided during a displacement of said blade member back to its initial position so as to carry said lens element back to its said initial position.

15. A photographic method for use with photographic apparatus having an exposure mechanism including a blade member displaceable over the camera exposure path from an initial position towards a terminal position and back toward its initial position, and an adjustable focus lens including a lens element displaceably mounted for adjustment of said lens to focus images of subjects positioned at various distances from the camera on the camera focal plane, said method comprising the steps of:

coupling said lens element to said blade member so that said lens element is in an initial position when said blade element is in its initial position;

moving said blade member toward its said terminal position;

decoupling said lens element from said blade member during its movement in accordance with the distance of a subject from the camera so as to position said lens element at a location for focusing said subject at the focal plane of said camera; and

recoupling said lens element to said blade member as said blade member is returned to its said initial position so as to return said lens element to its said initial position in anticipation of subsequent movement of said blade element.

16. The method of claim **15** wherein said camera is an SLR camera and includes a displaceable reflex member for varying said camera between a viewing mode in which said reflex member blocks the taking path and an exposure mode in which said reflex member is in unblocking relation to the exposure path, and said initial

position of said blade member is a full open position of said exposure mechanism which is utilized for viewing in the viewing mode of said camera, and said recoupling step includes the coupling of said lens element to said blade member as said blade member is moved toward its initial position for viewing purposes and said decoupling step includes decoupling said lens element from said blade member as said blade member is moved toward its terminal position prior to varying of said camera to said exposure mode.

[57] **ABSTRACT**

An apparatus for detecting a focusing state of an objective lens comprises optical means for forming light intensity distributions of object images whose relative positional relationship changes with the focusing state of the objective lens, sensing means having a plurality of sensors for sensing the light intensity distributions to produce first and second signals relating to the light intensity distributions, signal processing means for relatively displacing the first and second signals by determining correlation information and producing a signal for adjusting the focusing state of the objective lens in accordance with the correlation information, and altering means for altering a displacement range within which the first and second signals are relatively displaced.

APPARATUS FOR DETECTING FOCUSING STATE OF OBJECTIVE LENS

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to an improvement in a focusing state detection apparatus which detects a focusing state by a relative positional relationship of light intensity distribution of two images of an object.

2. Related Background Art

In a prior art focus state detection apparatus for a camera, an exit pupil of an imaging lens is divided into two pupil areas and relative positional displacement of two light intensity distributions of two images formed by light fluxes transmitted through the pupil areas are observed to determine an in-focus state. For example, Japanese Patent Application Laid-Open Nos. 118019/1980 and 155331/1980 disclose a secondary focusing system in which a spatial image formed on a predetermined focus plane (corresponding to a film plane) by two secondary focusing optical systems is guided to two sensor planes so that relative positional displacement of the two images is detected.

The secondary focusing type focusing state detection apparatus is shown in FIG. 3. A field lens **3** is arranged coaxially with an optical axis **2** of an imaging lens **1** whose focusing state is to be detected. Two secondary focusing lenses **4***a* and **4***b* are arranged behind the field lens **3** symmetrically with respect to the optical axis **2**. Sensor arrays (Photo-electric conversion element arrays) **5***a* and **5***b* are arranged behind the lenses **4***a* and **4***b*. Diaphragms **6***a* and **6***b* are arranged in the vicinity of the secondary focusing lenses **4***a* and **4***b*. The field lens **3** essentially focuses an exit pupil of the imaging lens **1** onto pupil planes of the two secondary focusing lenses **4***a* and **4***b*. As a result, light fluxes applied to the secondary focusing lenses **4***a* and **4***b* correspond to those light fluxes which are emitted from non-overlapping equispace areas on the exit pupil plane of the imaging lens **1**, corresponding to the secondary focusing lenses **4***a* and **4***b*. When a spatial image formed in a vicinity of the field lens **3** is refocused on the planes of the arrays **5***a* and **5***b* by the secondary focusing lenses **4***a* and **4***b*, the positions of the two light intensity distributions of the two images on the sensor arrays **5***a* and **5***b* change in accordance with the displacement of the spatial image along the optical axis. FIG. **5** shows it. In FIG. **4**A which shows an in-focus state, the two light intensity distributions are positioned at the centers of the sensor arrays **5***a* and **5***b*, in FIG. **4**B which shows a near-focus state, the two light intensity distributions are moved away from the optical axis **2**, and in FIG. **4**C which shows a far-focus state, the two light intensity distributions are moved toward the optical axis **2**. These light intensity distributions are photo-electrically converted and the converted electrical signal is processed to detect a relative positional deviation of the two light intensity distributions. In this manner, the focusing state of the imaging lens **1** can be detected.

Methods for processing the photo-electrical converted signal from the sensor arrays **5***a* and **5***b* are disclosed in Japanese Patent application Laid-Open No. 142306/1983 and U.S. Pat. No. 4,333,007. Specifically, the following formula is operated for $k_1 \leqq k \leqq k_2$.

$$\begin{aligned} V(k) &= \sum_{i=0}^{M-1} A(i)\square B(i+|k|+1) - \sum_{i=0}^{M-1} A(i+1)\square B(i+|k|)\ (k<0) \\ &= \sum_{i=0}^{M-1} A(i+k)\square B(i+1) - \sum_{i=0}^{M-1} A(i+k+1)\square B(i)\ (k \geqq 0) \\ &= V_1(k) - V_2(k) \end{aligned} \tag{1}$$

where N is the number of sensors of the sensor array **5***a* or **5***b*, A(i) and B(i) are image signals from the i-th elements of the sensor arrays **5***a* and **5***b*, and M is the number of pixels processed ($M=N-k|-1$) $A(i)\square B(j)$ is an operator for A(i) and B(j). For example,

$$A(i)\square B(j) = |A(i)-B(j)\uparrow \tag{2}$$

$$A(i)\square B(j) = |A(i)-B(j)\uparrow^n \tag{3}$$

$$A(i)\square B(j) = \max|A(i), B(j)\uparrow \tag{4}$$

$$A(i)\square B(j) = \min|A(i)\ B(j)\uparrow \tag{5}$$

The formula (2) represents an absolute value of a difference between A(i) and B(i), the formula (3) represents accumulated product, the formula (4) represents a larger one of A(i) and B(j), and the formula (5) represents a smaller one. By the above definition, $V_1(k)$ and $V_2(k)$ can be considered as correlation amounts in a broad sense from the formula (1), $V_1(k)$ represents the correlation amount at a displacement $(k-1)$, and $V_2(k)$ represents the correlation amount at a displacement $(k+1)$. Accordingly, an evaluation amount V(k) which is the difference between $V_1(k)$ and $V_2(k)$ represents a change of correlation amount of the image signals A(i) and B(i) at a relative displacement k. Since a change is zero at the peak of the correlation amount, it is assumed that the peak of the correlation amount exists in a section [k, k+1] represented by

$$V(k)\cdot V(k+1) < 0 \tag{6}$$

and V(k) and V(k+1) are interpolated to detect the deviations of the image signals A(i) and B(i). FIG. **6** shows the light intensity distribution signals A(i) and B(i) for the two images formed when the number of sensors is 16 (N=16). There is a deviation of P. FIG. **7** shows the evaluation amount V(k) of the formula (2) when the relative displacement k is changed within a range of $-N/2 \leqq k \leqq N/2$. As described above, V(k) and V(k+1) which meet $V(k)\cdot V(k+1)<0$ are linearly interporated to detect the deviation P. FIG. **7** shows a relationship between the image signals A(i) and B(i) when the evaluation amount V(k) is calculated while the relative displacement k changes in a range of $-3 \leqq k \leqq 3$. Hatched areas show the sensors which are subject of the correlation.

The processing time of the evaluation amount V(k) significantly varies with a range of processing of the relative displacement k. Accordingly, it is preferable to limit the processing range to a narrow one. However, if the range is too narrow, the deviation of the two images when the imaging lens is in a large defocus state may depart from the processing range of the relative displacement k so that exact focusing state is not detected. Accordingly, a lower limit $k_1$and an upper limit k_2 of

the processing range are frequently set to $k_1 = -N/2$ and $k_2 = N/2$, where N is the number of sensors of the sensor array. However, where the processing range for the relative displacement k is preset, the processing may be done over unnecessary range if an imaging lens has a small defocusing state like a wide angle lens. In other words, excess processing is performed and unnecessary processing time is spent for the focusing state detection.

When the deviation P is calculated, contrasts of the two images are usably calculated. If the contrast is lower than a predetermined level, it is determined that the reliability of the resulting deviation P is low and the foucsing state detection is disabled. The disabling operation includes a so-called searching operation, in which the imaging lens is driven by a predetermined distance or continuously while expecting the increase of the contrast necessary for the focusing state detection. However, in the imaging lens having a relatively small maximum defocus amount such as a wide angle lens, the increase of the contrast by the searching operation is not expected because the defocus amount is inherently small.

On the other hand, if the imaging lens has a large maximum defocus amount such as a telescopic lens and the lens is in a large defocus state, a probability that the deviation P of the two images departs from the relative displacement k is high and the focusing state may not be detected.

In the prior art apparatus, since the focusing state detection operation takes a long processing time, high speed photographing cannot be attained particularly in a continuous photographing mode.

SUMMARY OF THE INVENTION

It is an object of the present invention to provide a focusing state detection apparatus which can reduce excess processing to detect the focusing state with a high response.

It is another object of the present invention to provide a focusing state detection apparatus which can exactly detect the focusing state for an exchange lens of an angle.

It is another object of the present invention to provide a focusing state detection apparatus which can exactly detect the focusing state, reduce waste processing and shorten focusing state detection time for an exchange lens of any angle.

It is another object of the present invention to provide a focusing state detection apparatus which can detect the focusing state to allow high speed continuous photographing.

In order to achieve the above objects, in an embodiment of the present invention, the processing range within which first and second signals are relatively displaced is varied with a maximum defocus amount inherent to an objective lens so that the smaller the maximum defocus amount of the objective lens is, the narrower is the processing range. When the focusing state detection is disabled, the maximum defocus amount of the objective lens is compared with a predetermined value, and if the former is smaller, the searching is inhibited so that the waste operation is prevented when the probability that the focusing state detection is enabled by searching is very low.

The processing range is varied in accordance with position information of a focusing component along an optical axis so that the processing range fully covers the movable range of the focusing component along the optical axis.

The processing range is varied in accordance with the maximum defocus amount of the objective lens and the position information of the focusing component along the optical axis so that the smaller the maximum defocus amount of the objective lens is, the narrower is the processing range, and the processing range always corresponds to the movable range of the focusing component along hhe optical axis.

In the continuous photographing mode, the processing range is narrower, compared to than a normal processing range after at least two frames of the continuous photographing mode so that the focusing state detection time is shortened.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** shows a block diagram of an embodiment of a focusing state detection apparatus of a camera in accordance with the present invention,

FIG. **2** shows a flow chart thereof,

FIG. **3** shows an arrangement of an optical system of a conventional secondary focusing type focusing state detection apparatus,

FIG. **4** shows a relationship between a focusing state and an image deviation in the secondary focusing system,

FIG. **5** shows image signals produced by two sensors in the secondary focusing system,

FIG. **6** shows a change of evaluation amount in the secondary focusing system,

FIG. **7** shows a relationship between two images in the focusing state detection in the secondary focusing system,

FIG. **8** shows a flow chart of another embodiment,

FIG. **9** shows a processing range for a relative displacement when position information of an imaging lens is used,

FIG. **10** shows a flow chart of another embodiment,

FIG. **11** shows a processing range for a relative displacement when position information of an imaging lens is used, and

FIG. **12** shows a flow chart of another embodiment.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

The preferred embodiments of the present invention will now be described.

FIG. **1** shows a block diagram of an embodiment of a focusing state detection apparatus for a camera in accordance with the present invention. CB denotes a camera body. PRS denotes a control circuit of the camera which may be a one-chip microcomputer which contains CPU, RAM, ROM, EEPROM (electrically erasable programmable ROM) and input/output ports. The ROM and EEPROM store a series of controlling software and parameters including those for AF control, DBUS denotes a data bus, SHT denotes a shutter control circuit which accepts data supplied from the data bus DBUS while a control signal CSHT is supplied thereto from the control circuit PRS and controls the drive of a shutter leading curtain and trailing curtain in accordance with the input data. APR denotes a diaphragm control circuit which accepts data supplied from the data bus DBUS while the control signal CAPR is applied thereto and controls a diaphragm mechanism (not shown) in accordance with the input data. DSP denotes a display circuit which accepts data

supplied from the data bus DBUS while the control signal CDSP is applied thereto and displays imaging information based on the input data. SWS denotes a group of switches such as release switch, continuous photographing mode switch and information setting switches.

SPC denotes a light intensity measurement circuit. An analog light intensity signal SSPC from the circuit SPC is supplied to the control circuit PRS where it is A/D converted for use as light intensity data to control the shutter control circuit SHT and the diaphragm control circuit APR. LCOM denotes a lens communication circuit which accepts data supplied from the data bus DBUS while the control signal CLCOM is applied thereto and serially communicates with a lens unit to be described later in accordance with the input data. It transmits data DCL for driving the lens in synchronism with a clock signal LCK to an in-lens control circuit to be described later and serially receives from the in-lens control circuit, lens information DLC such as current position of the imaging lens. BSY denotes a signal to inform the camera that the imaging lens is moving. When this signal is present the serial communication is not undertaken.

LNSU denotes the lens unit, and LPRS denotes the in-lens control circuit for driving a motor MTR in accordance with the serial input data DCL to move the imaging lens LNF. It includes a ROM which stores the maximum defocus amount, a focal distance and an open F value of the imaging lens LNF. ENC denotes an encoder which detects a pulse signal generated as a lens bodytube (which holds the imaging lens LNF) is moved and supplies to the in-lens control circuit LPRS current axial position information DV of the imaging lens LNF, that is, current focusing state information. SDR denotes a sensor drive circuit for controlling a line sensor SNS such as CCD sensor having two sensor arrays SAA and SAB in accordance with the input signals from the control circuit PRS. The sensor arrays SAS and SAB may be two sections of one sensor array.

The operation is now explained with reference to a flow chart of FIG. 2. Because the operations of the shutter control circuit SHT, diaphragm control circuit APR, display circuit DSP and light intensity measurement circuit SPC are not directly related to the present invention, the explanation thereof is omitted.

(Step 1) The line sensor SNS is driven through the sensor drive circuit SDR to produce image signals A(i) and B(i) of the two images. The operations of the control circuit PRS, sensor drive circuit SDR and line sensor SNS are briefly explained. When a start of storage signal STR is generated in the control circuit PRS, the sensor drive circuit SDR supplies a clear signal CL to the line sensor SNS to clear charges of the photo-electric converters of the sensor arrays SAA and SAB. Then, the line sensor SNS starts the photo-electric conversion and charge storage of the optical images formed on the sensor arrays SAA and SAB by the secondary focusing lens (not shown in FIG. 1 but arrayed as shown in FIG. 3). After a predetermined time period since the above operation has been started, the sensor drive circuit SDR supplies a transfer signal SH to the line sensor SNS to transfer the charges stored in the photo-electric converters to the CCD. The sensor drive circuit SDR also senss an end of storage signal END to the control circuit PRS and waits for a CCD drive clock CK to be supplied from the control circuit PRS. When the CCD drive clock CK is supplied, the sensor drive circuit SDR generates CCD drive signals ϕ_1 and ϕ_2, which are supplied to the line sensor SNS. When the CCD drive signals ϕ_1 and ϕ_2 are supplied, the line sensor SNS supplies an analog image signal SSNS to the control circuit PRS. Thus, the control circuit PRS A/D converts the analog image signal SSNS in synchronism with the CCD drive clock CK and stores the image signals A(i) and B(i) of the two images at predetermined addresses in the RAM.

(Step 2) The state of the continuous photographing mode switch of the switch group SWS is checked, and if it is in the continuous photographing mode, the process proceeds to a step 13, and if not, the process proceeds to a step 3.

(Step 3) Communication is made with the lens unit LNSU through the lens communication circuit LCOM to obtain the maximum defocus amount MD of the imaging lens LNS currently mounted from the lens information DLC. The relative displacement k is then set in the processing range of $-MD \leqq k \leqq MD$, that is, $k_1 = -MD$ and $k_2 = MD$.

(Step 4) The correlation processing shown in the formulas (2)–(5) is performed to obtain the focusing state detection information or the deviation P of the two images.

(Step 5) If the contrast of the signal is too low to assure the reliability of the result even if the deviation P is detected, the focusing state cannot be detected. Thus, the process proceeds to a step 10. Otherwise, the process proceeds to a step 6.

(Step 6) The absolute value of the deviation P is compared with a predetermined value, and if the former is smaller, that is, in an in-focus state, the process proceeds to a step 9, and otherwise the process proceeds to a step 7.

(Step 7) A sign (plus or minus) of the deviation P is checked to determine near-focus or far-focus. The data thereof is sent to the display circuit DSP to display the focusing state.

(Step 8) The movement of the imaging lens LNF is calculated in accordance with the deviation P determined in the step 4 and the data thereof is sent to the in-lens control circuit LPRS through the lens communication circuit LCOM. The in-lens control circuit LPRS drives the motor MTR to move the imaging data to the position corresponding to the data, that is, until the number of encoder pulse signals EPL supplied from the encoder ENC reaches the number designated by the data.

(Step 9) Data indicating the in-focus state is sent to the display circuit DSP to display the in-focus state.

(Step 10) The maximum defocus amount MD obtained in the step 3 is compared with a fixed defocus amount MS, and if $MD > MS$, the process proceeds to a step 12, and and if $MD \leqq MS$, the process proceeds to a step 11.

(Step 11) If $MD \leqq MS$, it means that the maximum defocus value of the imaging lens LNF currently mounted is relatively small. In this case, even if the imaging lens LNF is driven by a predetermined distance, that is, searched to retry the focusing state detection, the increase of the contrast is not expected because the maximum defocus amount is inherently small and hence a probability that the focusing state detection is enabled is low. Accordingly, in such a case, the searching is not carried out and the data indicating that the focusing state detection is disable is supplied to the

display circuit DSP and displayed thereby. Then, the process returns to the step 1.

(Step 12) If MD>MS, a probability that the focusing state detection is enabled by the searching is high, as opposed to the case where MD≦MS. Thus, the searching is carried out.

(Step 13) In the continuous photographing mode, the focusing state must be detected in a shorter time than the single photographing mode. During the continuous photographing mode, it is expected that the change of defocus amount of the object is small. Accordingly, a relative displacement k_c in a relatively narrow processing range is set, that is, $k_1=-k_c$ and $k_2=k_c$ to speed up the processing.

(Step 14) The correlation processing is performed in the processing range set in the step 13 to obtain the focusing state detection information.

(Step 15) Whether the focusing state detection is enabled or not is determined like in the step 5. If the focusing state detection is disabled, the searching in the continuous photographing mode is not desirable in view of high speed photographing. Accordingly, the process proceeds to the step 11 to display the disabling. If the focusing state detection is enabled, the process proceeds to the step 6 to determine whether in-focus state is attained or not. Then, the process proceeds to the step 9 or steps 7 and 8.

In the present embodiment, the maximum defocus amount MD of the lens currently mounted is obtained from the ROM in the in-lens control circuit LPRS, the processing range for the correlation processing is set in accordance with the maximum defocus amount MD, that is, the range of the relative displacement k is set widely if a lens having a large maximum defocus amount such as a telescopic lens is mounted and the range of the relative displacement k is set narrowly if a lens having a small maximum defocus amount MD such as a wide angle lens is mounted. Accordingly, in the former case, the disabling of the focusing state detection due to loss of common intensity distribution when the defocus amount is large is prevented, and in the latter case, a excess processing time is omitted and the focusing state detection time is shortened.

In the present embodiment, the maximum defocus amount MD of the lens mounted is obtained from the lens unit LNSU. The present invenion is also applicable to a case where such information is manually set. A zoom lens having a selectable focal distance may be used.

In the present embodiment, the maximum defocus amount MD of the lens currently mounted is obtained from the ROM of the in-lens control circuit LPRS and whether the searching is to be carried out or not is determined in accordance with MD. Namely, if the imaging lens (such as a wide angle lens which does not bring an expected effect even if the searching is carried when the focusing state detection is disabled) is mounted, the searching is not carried out. Accordingly, the focusing state detection time is shortened and waste power consumption is prevented.

In the present embodiment, the maximum defocus amount of the imaging lens is compared with the fixed defocus amount MS. An intensity may be added to the fixed defocus amount. That is, if the intensity is low, the fixed defocus amount MS may be somewhat lowered to broaden the range of the searching.

An operation of another embodiment is explained with reference to FIGS. **8** and **9**.

(Step 21) This step is identical to the step **1** of FIG. **2**.

(Step 22) The state of the continuous photographing mode switch of the switch group SWS is checked. If it is the continuous photographing mode, the process proceeds to a step **31**, and if not, the process proceeds to a process **23**.

(Step 23) Communication is established with the lens unit LNSU through the lens communication circuit LCOM to obtain the position information DV of the imaging lens LNF from the lens information DLC, and the processing range for the relative displacement k is set to $-N/2+DV\leqq k\leqq N/2+DV$, that is, $k_1=-N/2+DV$, $k_2=N/2+DV$, in accordance with the position information DV.

The position information DV is zero when the imaging lens LNF is at the center of the movable range, negative when it moves toward a near position. and positive when it moves toward an infinite position Accordingly, the imaging lens LNF is displaced in a direction at which all of the above described processing range can be covered, keeping the relative displacement k in the processing range constant.

That is explained in further detail with reference to FIG. **3**.

For example, in view of that the number of pixels in a sensor arrays SAA and SAB is 24 (N=24), the processing range of the displacement k is set to be $-12\leqq k\leqq 12$. Let us assume, in view of the above state, that the movable range of the imaging lens LNF is 20 mm, and the displacement of one pixel of the sensor corresponding to 1 mm in the movable range of the imaging lens LNF. When the imaging lens LNS is at an arrow position a (infinite position), the position information DV is (+10) and the processing range is

$$k_1=-12+10=-2$$

$$k_2=12+10=22$$

In the above case, where the processing range of the relative displacement k is constant, the displacement in the processing range becomes large, as shown in FIG. **3**.

In the prior art system the processing range for the relative displacement k is that shown by broken lines and hense the focusing state detection is disabled when the defocus amount is large. By the use of the positional information DV, the area which could not heretofore been covered can be included in the processing range and the disabling of the focusing state detection is prevented. On the other hand, when the imaging lens LNF is at an arrow position c (very near position), the position information DV is −10 and the processing range is

$$k_1=-12+(-10)=-22$$

$$k_2=12+(-10)=2$$

In that case, the displacement in a indifinite direction to be covered with the process becomes larger. When the imaging lens LNF is at an arrow position b (center of the movable range), the operation is the same as that in the prior art.

(Step 24) The correlation processing shown in the formula (1) is carried out to obtain the focusing state detection information or the deviation P of the two images.

(Steps 25 to 28) These steps are identical to the steps 5 to 8.

(Step 30) The imaging lens LNF is driven by a predetermined distance for searching.

(Step 31) In the continuous photographing mode, the focusing state must be detected in a shorter time than the single photographing mode, and the change of the defocus amount of the object is small. Thus, the relative displacement k_c is set to a relatively narrow processing range, that is, $k_1 = -k_c$ and $k_2 = k_c$ to speed up the processing.

(Step 32) The correlation processing is carried out to obtain the focusing state detection information in the processing range set in the step 31.

(Step 33) Whether the focusing state detection is enabled or not is detected as is done in the step 25. If the focusing state detection is disabled, the process proceeds to a process **34**, and if it is enabled, the process proceeds to a step 26 to determine if the in-focus state is attained. Then, the process proceeds to the step 29 or the steps 27 and 28.

(Step 34) Since it is not desirable to carry out the searching during the continuous photographing mode in view of speed, data indicating that the focusing state detection is disabled is sent to the display circuit DSP for displaying it.

In the embodiment shown in FIGS. **8** and **9**, the range of the relative displacement k is set in accordance with the position information DV of the imaging lens LNF at the start of the focusing state detection. Accordingly, the focusing state detection is assured even if an imaging lens LNF having the defocus amount of as large as N/2 is mounted.

The operation where the position information DV and the maximum defocus amount MD of the imaging lens LNF are used is explained with reference to FIGS. **10** and **11**.

(Step 41) The line sensor SNS is driven through the sensor drive circuit SDR to obtain the image signals A(i) and B(i) of the two images.

(Step 42) The state of the continuous photographing mode switch of the switch group SWS is checked. If it is the continuous photographing mode, the process proceeds to a step 53, and if not, the process proceed to a step 43.

(Step 43) Communication is established with the lens unit LNSU through the lens communication circuit LCOM to obtain the maximum defocus amount MD' of the imaging lens LNF currently mounted (for example, one half of the maximum defocus amount MD of the actual imaging lens LNF) and the position information DV of the imaging lens LNF from the lens information DLC, and the relative displacement k is set in the range of $-MD'+DV \leqq k \leqq MD'+DV$, that is, $k_1 = -MD'+DV$, $k_2 = ML'+DV$, in accordance with the above information. As described above, the position information DV is zero when the imaging lens LNF is at the center of the movable range, negative when it moves toward a near position, and positive when it moves toward an infinite position. Accordingly, when the processing range for the relative displacement k is determined, the maximum defocus amount MD' which is, for example, one half of the maximum defocus amount MD of the actual imaging lens LNF is used. Thus, this value is used as the maximum defocus amount of the imaging lens LNF.

This is explained in further detail with reference to FIG. **11**. Let us assume that the maximum defocus amount MD' of the imaging lens LNF is 10 mm (actual maximum defocus amount MD is 20 mm) and the movable range of the imaging lens LNS is 20 mm. When the imaging lens LNS is at an arrow position a (infinite position), the position information DV is 10 and the processing range is

$$k_1 = -10+10=0$$

$$k_2 = 10+10=20$$

Thus, as shown in FIG. **11**, the processing range coincides with the movable range of the imaging lens LNS, and the disabling of the focusing state detection is prevented and no waste processing is carried out. In the prior art system (which the number of pixels is 24 (N=24)), the processing range for the relative displacement k is that shown by broken lines and hence a long time is required for the focusing state detection (this is remarkable for a wide angle lens) and the focusing state detection is disabled when the defocus amount is large. By the use of the maximum defocus amount MD', the processing range coincides with the movable range of the imaging lens LNF. By the use of the position information DV, the portion which could not heretofore been covered can be included in the processing range. Accordingly, the focusing state detection time can be shortened and the disabling of the focusing state detection is prevented. When the imaging lens is at an arrow position C (very near position), the positional information DV is -10 and the processing range is

$$k_1 = -10+(-10)=-20$$

$$k_2 = 10+(-10)=0$$

when the imaging lens LNF is at an arrow position b (center of the movable range), the position information DV is 0 and the processing range is

$$k_1 = -10+0=-10$$

ti $k_2 = 10+0=10$

[Step 44] The correlation processing shown in the formula (1) is carried out to obtain the focusing state detection information or the deviation P of the two images.

[Step 45]If the reliability of the result is low because the contrast of the signal is low even if the deviation P can be detected, the focusing state detection is disabled. In this case, the process proceeds to a step 50, and if the focusing state detection is enabled, the process proceeds to a step 46.

[Step 46] The absolute value of the deviation P is compared with a predetermined value, and if the former is smaller, that is, if the displacement is such that the focusing state can be regarded as in-focus state, the process proceeds to a step 49, and if the former is larger, the process proceeds to a step 47.

[Step 47] Whether the focusing state is near-focus or far-focus is determined by the sign (plus or minus) of the deviation P, and the detected data is sent to the display circuit DSP to display the focusing state.

[Step 48] The distance of drive of the imaging lens LNF is calculated based on the deviation P obtained in the step 44, and the calculated data is sent to the in-lens control circuit LPRS through the lens communication circuit LCON. The operation of the lens unit LNSU is briefly explained. The in-lens control circuit LPRS drives the motor MTR to drive the imaging lens LNS to the position corresponding to the above data, that is, to

drive the imaging lens LNS until the number of encoder pulse signals EPL supplied from the encoder ENC searches the value specified by the data.

[Step 49] The data indicating the in-focus state is sent to the display circuit DSP to display it.

[Step 50] The maximum defocus amount MD obtained in the step 43 and determined to disable the focusing state detection in the step 45 is compared with the fixed defocus amount MS, and if MD>MS, the process proceeds to a step 52, and if MD≦MS, the process proceeds to a step 51.

[Step 51] If MD≦MS, it means that the maximum defocus amount of the imaging lens LNF currently mounted is relatively small. In this case, even if the imaging lens LNF is moved by a predetermined distance, that is, searching is carried out to detect the focusing state, the increase of the contrast is not expected because the defocus amount is inherently small. Thus, a probability that the focusing state detection is enabled is low. Accordingly, in such a case, the searching is not carried out and the data indicating that the focusing state detection is disabled is supplied to the display circuit DSP to display it. Then, the process returns to the step 41.

[Step 52] If MD>MS, a probability that the focusing state detection is enabled by the searching is high a opposed to the case where MD≦MS. Thus, the searching is carried out.

[Step 53] This is identical to the step 31 of FIG. **8**.

[Step 54] This is identical to the step 32 of FIG. **8**.

[Step 55] Like in the step 45, whether the focusing state detection is enabled or not is determined, and if the focusing state detection is disabled, the searching during the continuous photographing mode is not preferable from the standpoint of speed. Thus, the process proceeds to the step 51 to display the disabling. If the focusing state detection is enabled, the process proceeds to the step 46 where whether the in-focus state is attained or not is checked. Then, the process proceeds to the step 49 or the steps 47 and 48.

In the embodiment of FIG. **10**, the maximum defocus amount MD of the lens currently mounted is obtained from the ROM in the in-lens control circuit LPRS, and the processing range for the relative displacement k is set in accordance with the maximum defocus amount MD. That is, when a lens having a large maximum defocus amount such as a telescopic lens is mounted, the processing range is set widely, and if a lens having a small maximum defocus amount MD such as a wide angle lens is mounted, the processing range is set narrowly. The position information DV of the imaging lens LNF at the start of the focusing state detection is obtained and the relative displacement k is displaced in an effective direciton to determine the processing range. Accordingly, the processing range coincides with the movable range of the imaging lens LNF and whatever focusing lens is mounted the focusing state detection is assured and excess processing time can be saved so that the focusing state detection time can be shortened.

FIG. **12** shows a flow chart of another embodiment. Most portions of this flow chart correspond to the flow chart of FIG. **2** and a step 60 is newly added.

[Step 60] Whether a frame is the first one in the continuous photographing mode or not is checked. If it is, the process proceeds to the step 3, and if not, the process proceeds to the step 14.

In the present embodiment, during the continuous photographing mode, the range of correlation processing, that is, the processing range is narrowed. Accordingly, the focusing state detection time is shortened and the focusing state detection compatible to the high speed continuous photographing can be carried out. At a second frame in the continuous photographing mode, the operation is the same as that of the normal photographing mode (single photographing mode). The range of displacement is set to the relative displacement kc in or after the second frame. Accordingly, a probability that the focusing state detection is disabled is lowered.

In the present embodiment, the operation in the first frame of the continuous photographing mode is the same as that of the normal photographing mode. Alternatively, in the continuous photographing mode, the process may immediately proceed to the step 14, that is, the processing range may be set to the relative displacement kc. As a result, a probability that the focusing state detection is enabled is lowered but photographing suitable to the continuous photographing mode is attained.

We claim:

1. An apparatus for detecting a focusing state of an objective lens, comprising:

light intensity forming optical means for forming light intensity distributions concerning images whose relative positional relationship changes with the focusing state of the objective lens;

sensing means having a plurality of sensors for sensing said light intensity distributions to produce first and second signals relating to the light intensity distributions;

signal processing means for relatively shifting the first and second signals by determining correlation information and producing a focusing signal for the objective lens in accordance with the correlation information; and

altering means for altering a displacement range within which the first and second signals are relatively displaced.

2. An appartus for detecting a focusing state of an objective lens according to claim **1** wherein said altering means alters the displacement in accordance with a maximum defocus amount inherent to the objective lens.

3. An apparatus for detecting a focusing state of an objective lens according to claim **1** wherein said altering means alters a displacement in accordance with a current focus setting of the objective lens.

4. An apparatus for detecting a focusing state of an objective lens according to claim **1** wherein said altering means alters a displacement in accordance with a maximum defocus amount inherent to the objetive lens and a position of a focusing area of the objective lens on a optical axis.

5. An apparatus for detecting a focusing state of an objective lens according to claim **1** wherein said altering means alters a displacement smaller than a normal displacement in and after a second frame in a continuous photographing mode.

6. A camera system comprising: an imaging lens assembly removably mounted on a camera body and having a focusing lens unit including focusing lens means for forming an object image and information storage means for storing defocus information on a maximum defocus amount;

said camera body including light intensity distribution forming means for forming light intensity distributions concerning images whose relative posi-

tional relationship changes in accordance with a focusing state of the focusing lens means, sensing means having a plurality of sensors for sensing the light intensity distributions to produce first and second signals relating to the light distributions, signal processing means for relatively displacing the first and second signals by determining correlation information and producing a signal for adjusting the focusing state of said focusing lens means in accordance with said correlation information, and altering means for altering a displacement range within which said first and second signals are relatively displaced in accordance with defocus information stored in said information storage means.

7. A camera system according to claim **6** wherein said camera body further includes position detection means for detecting a position of said focusing lens unit on an optical axis to produce position information, and said altering means alters the diplacement range in accordance with said position information.

8. A camera system according to claim **6** wherein said camera body further includes mode selection means for (1) selecting a continuous photographing mode or a single photographing mode, and (2) producing continuous photographing mode information indicating at least a second frame in the continuous photographing mode, and wherein said altering means narrows the displacement range in accordance with the continuous photographing mode information.

9. A camera system according to claim **6** wherein said signal processing means causes said camera system to operate in a non-standard manner if a focusing state of said focusing lens means cannot be detected, and said camera body further includes inhibit means for inhibiting the non-standard operation when said defocus information is smaller than a predetermined value.

10. An apparatus for detecting a focusing state of an objective lens, comprising:

light intensity distribution forming means for forming light intensity distributions concerning images whose relative positional relationship changes with the focusing state of the objective lens;

sensing means having a plurality of sensors for sensing the light intensity distributions to produce first and second signals relating to the light intensity distributions;

signal processing means for (1) relatively shifting said first and second signals by determining correlation information and producing a signal for adjustng the focusing state of the objective lens in accordance with said correlation information, and (2) producing a search signal for causing the objective lens to search when the focusing state detection is disabled; and

search inhibit means for inhibiting the searching when a maximum defocus amount of the objective lens is smaller than a predetermined value.

[57] **ABSTRACT**

In a triplet type objective for a compact lens shutter camera with a diaphragm arranged behind the lens system, the first lens element is formed of glass and the second and third lens elements are formed of plastic, so that it is advantageous in manufacturing cost and weight. Furthermore, sufficient marginal light rays and flatness of the image field can be obtained.

TRIPLET TYPE OBJECTIVE WITH A DIAPHRAGM ARRANGED BEHIND THE LENS SYSTEM

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to an objective for compact lens-shutter cameras whose diaphragm is arranged behind the whole optical system, and more particularly to a compact wide angle objective with a simple construction for cameras for a spread use.

2. Description of the Prior Art

With a compact lens-shutter camera for cameras for a spread use, a wide angle objective with a diaphragm arranged behind the whole lens system is advantageous for accommodation in the camera, for compactization of the camera or the objective itself and for realization of precise focusing. As this kind of objective, triplet type objectives with $F_{No.}$ of 4–2.8 and a total angular field coverage of 60°–64° have been proposed. With a wide angle triplet type objective, since an astigmatic difference tends to become large at a marginal angular field, it was conventional to construct this type of objective by the use of lens elements formed of a glass with a high refractive index. For example, in Japanese patent application laid-open No. Sho. 59-34510, all lens elements, one or two of which have an aspherical surface, are formed of glass with a high refractive index to construct an objective with a total angular field coverage of 64°, and $F_{No.}$ of 3.5. In Japanese patent application laid-open No. Sho. 57-2012, an objective with $F_{No.}$ of 4 and a total angular field of 64° has been realized with the use of a glass with a high refractive index. But forming a lens element of glass of a high refractive index incurs an increase in the manufacturing cost.

Besides, with a triplet type objective with a diaphragm arranged behind the whole lens system, a problem exists in that the amount of marginal light rays tends to become insufficient and this promblem has not been solved.

SUMMARY OF THE INVENTION

An object of the present invention is to provide a triplet type wide angle objective with a compact size and light weight, which can secure a sufficient amount of marginal light rays, whose manufacturing cost is low, whose construction is advantageous in manufacturing of lens elements and whose aberrations are corrected well.

To achieve these objects a triplet type objective according to the present invention, as shown in FIG. 1, comprises a lens system and a diaphragm (S) arranged behind the lens system. The lens system consists of, from the object side, a first positive meniscus lens element (L_1) having a positive refractive power on the object side surface, a second biconcave lens element (L_2) and a third biconvex lens element (L_3). The first lens element (L_1) is formed of glass and the second (L_2) and third lens (L_3) elements are formed of plastic. Further, the lens systems fulfills the following conditions:

$$0.25f<\Sigma d+b<0.45f \quad (1)$$

$$0.15<N_1-N_3<0.4 \quad (2)$$

wherein,

f represents the focal length of the lens system;

Σd represents the axial distance from the first surface (r_1) to the last surface (r_6) of the lens system, b represents the axial distance from the last surface (r_6) of the lens system to the diaphragm (S), N_1 represents the refractive index of the first lens element (L_1), and N_3 represents the refractive index of the third lens element (L_3).

Condition (1) is to increase the amount of marginal light rays which, otherwise would tend to be insufficient with a wide angle triplet type objective having a diaphragm arranged behind the whole lens system. If the upper limit of the condition (1) is violated, it becomes difficult to secure a sufficient amount of marginal light rays and the objective becomes bulky in size. On the other hand, if the lower limit of condition (1) is violated, the curvature of the field deteriorates, and further, the thickness of the peripheral portion of the positive lens elements decreases so much that manufacturing of the lens elements becomes difficult.

According to the present invention, the second negative lens element (L_2) and the third positive lens element (L_3) are made of plastic, so that the change of back focus caused by a change of the temperature is cancelled, and both the weight of the objective and the cost for manufacturing of the lens elements can decrease. Although the third plastic lens element (L_3) has a week refractive index, the first lens element (L_1) made of glass with a stronger refractive index prevents the petzval sum from becoming great, so that the astigmatic difference is corrected well. Thus, the present invention is characterized in that the refractive index of the first lens element (L_1) is much greater than that of the third lens element (L_3) as represented by the condition (2). When the condition (2) is satisfied, an image field of the objective can be ketp substatially flat over an angular field of 65°. If the lower limit of the condition (2) is violated, the petzval sum cannot be made small and the astigmatic difference at a large angular field becomes great. On the other hand, the upper limit of the condition (2) shows the highest limit of the refractive index of the glass which is normally available as the first lens element (L_1).

Furthermore, according to the present invention, it is desirable to fulfill the following conditions:

$$1.1/f<\phi_1<1.9/f \quad (3)$$

$$-0.75/f<\phi_{23}<0.02/f \quad (4)$$

$$0.8f<-r_3<3.0f \quad (5)$$

$$0.38f<r_5<0.76f \quad (6)$$

$$0.35f<-r_6<0.64f \quad (7)$$

wherein, ϕ_1 represents the refractive power of the first lens element (L_1), ϕ_{23} represents the composite refractive power of the second and the third lens elements (L_2) and (L_3), r_3 represents the radius of curvature of the object side surface of the second lens element (L_2), r_5 represents the radius of curvature of the object side surface of the third lens element (L_3) and r_6 represents the radius of curvature of the image side surface of the third lens element (L_3).

Condition (3) is desirable for compactization of the objective and for security for the marginal light rays.

When the condition (3) is satisfied, the objective can be constructed compactly and the marginal light rays required for providing an object image being bright

even at marginal portions can be secured. If the lower limit of condition (3) is violated, marginal light rays are cut off, so that vignetting at a large angular portion of the field increases. In contrast thereto, if the upper limit of the condition (3) is violated, the petzval sum increases so much that it becomes difficult to correct the curvature of field and the positive distortion is caused remarkably, while the marginal light rays can be secured to more of a extent and the objective can be constructed more compactly.

Condition (4) is desirable for decreasing the change of the back focus depending on the change of temperature which is caused by use of plastic lenses. As the composite refractive power of the second and the third lens elements (L_2) and (L_3) becomes small, the change of the back focus can be well cancelled. But, if the composite refractive power (ϕ_{23}) becomes small beyond the lower limit of condition (4), the refractive power of the first lens element should be so great that the curvature of field cannot be corrected well. On the contrary, if the upper limit of condition (4) is violated, the change of back focus depending on the change of temperature becomes great, so that a means for mechanically changing the back focus should be accommodated in a lens barrel.

Conditions (5), (6) and (7) are for correcting spherical aberration, curvature of field and the coma well. The radius of curvature (r_3) of the object side surface of the second lens element (L_2) is effective for correcting the coma caused by the lower marginal ray in the intermediate and marginal area, whereas the radius of curvature (r_6) of the image side surface of the third lens element (L_3) is effective for correcting the coma caused by the upper marginal ray.

If the upper limit of condition (5) is violated, spherical aberration and curvature of field undergo over-correction. On the contrary, if the lower limit of condition (5) is violated, spherical aberration is in an undercorrection state and the coma towards the outward direction is produced at the intermediate area of the picture format.

If the upper limit of condition (6) is violated, spherical aberration and curvature of field are in an over-correction state and if the lower limit of condition (6) is violated, spherical aberration and curvature of field are in an undercorrection.

If the upper limit of condition (7) is violated, spherical aberration is in overcorrection state and the coma towards the inward direction is produced in the marginal area. In contrast thereto the lower limit of condition (7) is violated, spherical aberration and curvature of field are not corrected well.

For still better correction of aberrations, it is desirable that conditions (5), (6) and (7) have the following range:

$$0.9f < -r_3 < 1.3f \quad (5)'$$

$$0.38f < r_5 < 0.65f \quad (6)'$$

$$0.35f < -r_6 < 0.62f \quad (7)'$$

When a plastic lens element is used, it becomes easier to employ an aspherical surface. According to this invention it is desirable to employ an aspherical surface for one of the surfaces of the second and third lens elements (L_2) and (L_3), so that spherical aberration, distortion, curvature of field and coma which are not so satisfactory corrected in case of an objective consisting of only spherical lens elements can be corrected almost completely. Furthermore, it is better to employ one more aspherical surface for another surface of the second and third lens elements (L_2) (L_3) in order to correct aberrations in high degrees.

Another triplet type objective of the present invention comprises a lens system and a diaphragm (S) arranged behind the lens system. The lens system consists of, from the object side, a first positive meniscus lens element (L_1) having a positive refractive power on the object side surface, a second biconcave lens element (L_2) and a third biconvex lens element (L_3). The first lens element (L_1) is formed of glass and the second and third lens elements (L_2, L_3) are formed of plastic. Further, the lens system fulfills following conditions:

$$0.15 < N_1 - N_3 < 0.4 \quad (8)$$

$$1.4 < N_2 < 1.65 \quad (9)$$

$$1.4 < N_3 < 1.65 \quad (10)$$

wherein

N_2 represents the refractive index of the second lens element.

Condition (8) is the same as condition (2) and has the same meaning.

The upper limit of conditions (9) and (10) is set in consideration of the refractive index of plastics which are normally available for a lens. If the lower limit of condition (9) is violated, the curvature of field is in an overcorrection state and the coma to the inward direction becomes difficult to be corrected. On the other hand, if the lower limit of condition (10) is violated, the spherical aberration is in an undercorrection state.

The features of the present invention which are believed to be novel are set forth with particularity in the appended claimed. The present invention, both as to its organization and manner of operator, together with further objects and advantages thereof, may best be understood by reference to the following description, taken in conjunction with the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a cross sectional view of an objective according to the respective embodiments of the present invention;

FIGS. **2A** to **2C** represent the aberration curves of the embodiment **1** respectively;

FIGS. **3A** to **3C** represent the aberration curves of the embodiment **2** respectively;

FIGS. **4A** to **4C** represent the aberration curves of the embodiment **3** respectively;

FIGS. **5A** to **5C** represent the aberration curves of the embodiment **4** respectively;

FIGS. **6A** to **6C** represent the aberration curves of the embodiment **5** respectively;

FIGS. **7A** to **7C** represent the aberration curves of the embodiment **6** respectively;

FIGS. **8A** to **8C** represent the aberration curves of the embodiment **7** respectively;

FIGS. **9A** to **9C** represent the aberration curves of the embodiment **8** respectively;

FIGS. **10A** to **10C** represent the aberration curves of the embodiment **9** respectively;

FIGS. **11A** to **11C** represent the aberration curves of the embodiment **10** respectively;

FIGS. 12A to 12C represent the aberration curves of the embodiment 11 respectively;

FIGS. 13A to 13C represent the aberration curves of the embodiment 12 respectively;

FIGS. 14A to 14C represent the aberration curves of the embodiment 13 respectively;

FIGS. 15A to 15C represent the aberration curves of the embodiment 14 respectively.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

The following description is provided to enable any person skilled in the optical and camera field to make and use the invention and sets forth the best modes contemplated by the inventors for carrying out their invention. Various modifications, however, will remain readily apparent to those skilled in the art, since the generic principles of the present invention have been defined herein specifically to provide a relatively economical and easily manufactured triplet type objective. The derivation of the formulas and the relation of the powers set forth herein can be accomplished with the assistance of a computer. The present invention represents the parameters of a compromise balance of acceptable aberrations which can be relatively easily manufactured to provide a low cost lens system for utilization with a compact lens shutter camera.

In the drawings, FIG. 1 shows the position of the lens elements. Values of radii of curvature and axial distances for each lens element and air spaces in the respective embodiments are provided in the accompanying tables set forth herein, and the schematic cross sectional view of FIG. 1 follows the normal conventions of an object at the left-hand side of the drawing and the image plane at the right-hand side. The lens system of all embodiments fulfill the following conditions:

$$1.7<N_1<1.9,\ 35<\nu_1<50 \quad (11)$$

$$1.4<N_2<1.65,\ 27<\nu_2<50 \quad (12)$$

$$1.4<N_3<1.65,\ 35<\nu_3<65 \quad (13)$$

wherein, N_2 represents the refractive index of the second lens element (L_2), ν_1 represents abbe number of the first lens element (L_1), ν_2 represents abbe number of the second lens element (L_2) and ν_3 represents abbe number of the third lens element.

The following tables 1 to 14 disclose, respectively design parameters of embodiments 1 to 14 of the present invention. In the embodiments L_1, L_2, L_3 are the lens elements from the object side, r_1, r_2, r_3... is respectively the radius of curvature from the object side, and the d_1, d_2, d_3 . . . is respectively the axial thickness including both air spaces and the actual thickness of a lens element. Nd_1, Nd_2, Nd_3 is respectively the refractive index of the first through third lens element and νd_1, νd_2, νd_3 is respectively the abbe number of the first (L_1) through third lens element (L_3). A surface with the mark * represents an aspherical surface, whose configuration is defined as follows:

$$X = \frac{Y^2}{ri + ri\sqrt{1-\left(\frac{Y}{ri}\right)^2}} + AY^2 + BY^4 + CY^6 + DY^8 + EY^{10} + FY^{12} + \ldots$$

wherein, X represents the coordinate along the optical axis measured from an imaginary plane tangent to the aspherical surface perpendicularly to the optical axis, Y represents the coordinate perpendicular to the optical axis from the optical axis, ri represents a paraxial radius of curvature, and A, B, C, D, . . . is aspherical coefficient.

What is claimed is:

1. A triplet type objective lens system with a diaphragm arranged behind the lens system, comprising from the object side:
   - a first positive meniscus lens element made of a glass material and having a positive refractive power on the object side surface;
   - a second biconcave lens element made of a plastic material;
   - a third biconvex lens element made of a plastic material, and
   - a diaphragm, wherein the lens system fulfills the following conditions:

$$0.25f<\Sigma d+b<0.45f$$

$$0.18<N_1-N_3<0.4$$

wherein:
   - f represents a focal length of the whole lens system;
   - Σd represents an axial distance from the object side surface of the first lens element to the image side surface of the third lens element;
   - b represents an axial distance from the image side surface of the third lens element to the diaphragm;
   - N_1 represents a refractive index of the first lens element, and
   - N_3 represents a refractive index of the third lens element.

2. A triplet type objective lens system as claimed in claim 1, wherein the triplet type objective lens system fulfills the following conditions:

$$0.8f<-r_3<3.0f$$

$$0.38f<r_5<0.76f$$

$$0.35f<-r_6<0.64f$$

wherein
   - r_3 represents the radius of curvature of the object side surface of the second lens element;
   - r_5 represents the radius of carvature of the object side surface of the third lens element and
   - r_6 represents the radius of curvature of the image side surface of the third lens element.

3. A triplet type objective lens system as claimed in claim 1, wherein one of the surfaces of the second and the third lens elements is an aspherical surface.

4. A triplet type objective lens system as claimed in claim 1, wherein two surfaces of the second and the third lens elements are aspherical surfaces.

5. A triplet type objective lens system as claimed in claim 1, wherein the lens system further fulfills the following conditions:

$$1.1/f<\phi_1<1.9/f$$

$$-0.75/f<\phi_{23}<0.02/f$$

$$0.9f<-r_3<1.3f$$

$$0.38f<r_5<0.65f$$

$$0.35f<-r_6<0.62f$$

wherein:
   - ϕ_1 represents the refractive power of the first lens element;
   - ϕ_{23} represents the compound refractive power of the second and third lens elements;
   - r_3 represents the radius of curvature of the object side surface of the second lens element;
   - r_5 represents the radius of curvature of the object side surface of the third lens element, and
   - r_6 represents the radius of curvature of the image side surface of the third lens element.

6. A triplet type objective comprising,
   - (a) a lens system which comprises from the object side;
     - a first positive meniscus lens element having a positive refractive power on the object side surface,
     - a second biconcave lens element,
     - a third biconvex lens element,
     - wherein, the first lens element is formed of glass and the second and third lens elements are formed of plastic, and
   - (b) a diaphragm arranged behind the lens system,
   - (c) wherein the lens system fulfills the following conditions:

$$0.18<N_1-N_3<0.4$$

$$1.4<N_2<1.65$$

$$1.4<N_3<1.65$$

wherein
   - N_1 represents the refractive index of the first lens element;
   - N_2 represents the refractive index of the second lens element; and
   - N_3 represents the refractive index of the third lens element.

7. A triplet type objective as claimed in claim 6, wherein the triplet type objective fulfills the following condition:

$$-0.75/f<\phi_{23}<0.02/f$$

wherein:
   - ϕ_{23} represents the composite refractive power of the second and third lens elements; and
   - f represents the focal length of the lens system.

8. A triplet type objective, wherein the triplet type objective having the following values.

	radius of curvature		axial distance		refractive index		Abbe number
		f = 100 2ω = 64° $F_{No.}$ 3.5					
r_1	32.638						
		d_1	12.57	Nd_1	1.78850	νd_1	45.68
r_2	75.166						
		d_2	2.71				
r_3	−126.741						
		d_3	3.71	Nd_2	1.58400	νd_2	31.0
r_4	27.191						
		d_4	6.00				
r_5	54.404						
		d_5	6.57	Nd_3	1.49140	νd_3	57.8
r_6	−51.527						
		b	3.71				
r_7	∞						

9. A triplet type objective lens system with a diaphragm arranged behind the lens system, comprising from the object side:

a first positive meniscus lens element made of a glass material and having a positive refractive power on the object side surface;

a second biconcave lens element made of a plastic material;

a third biconvex lens element made of a plastic material, and

a diaphragm, wherein the lens system fulfills the following conditions:

$$1.1/f < \phi_1 < 1.9/f$$

$$-0.75./f < \phi_{23} < 0.02/f$$

$$0.8f < -r_3 < 3.0f$$

$$0.38f < r_5 < 0.76f$$

$$0.35f < -4_6 < 0.64f$$

wherein:

ϕ_1 represents the refractive power of the first lens element;

ϕ_{23} represents the compound refractive power of the second and third lens elements;

r_3 represents the radius of curvature of the object side surface of the second lens element;

r_5 represents the radius of curvature of the object side surface of the third lens element, and

r_6 represents the radius of curvature of the image side surface of the third lens element.

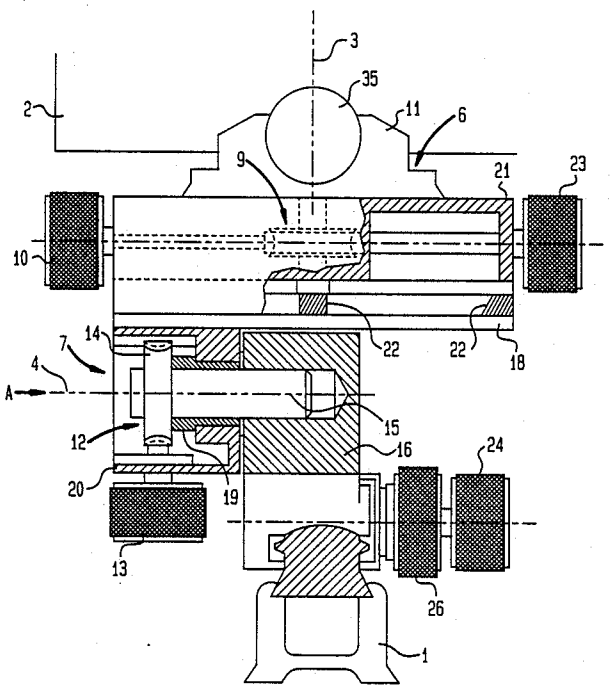

FIG. 1

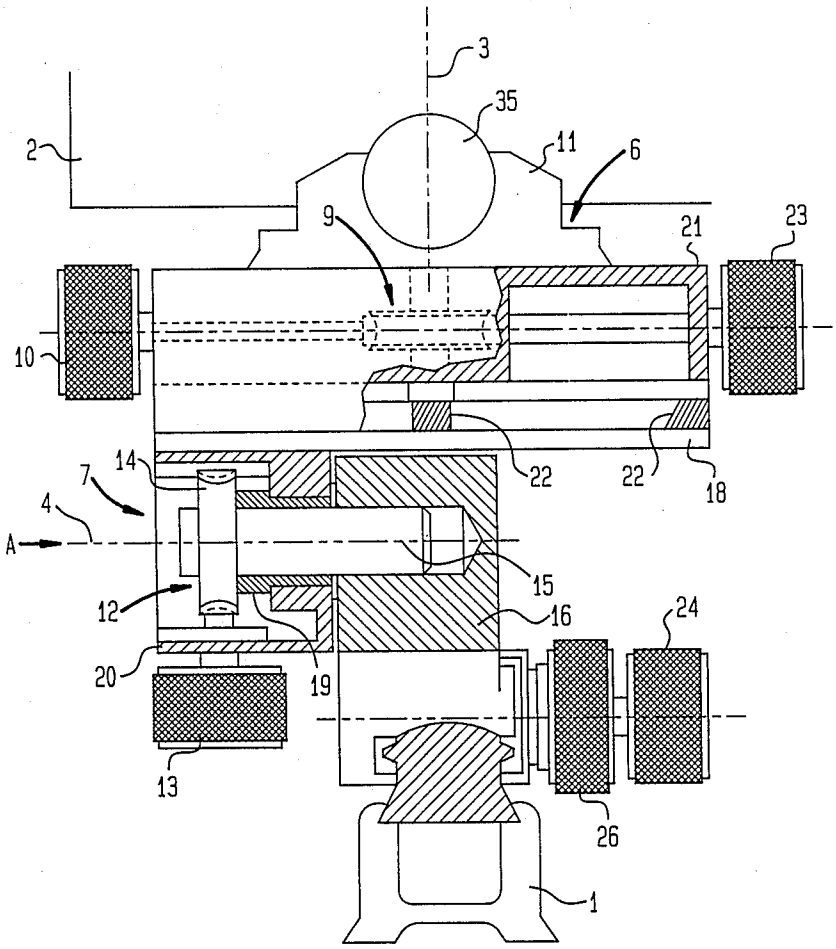

FIG. 2

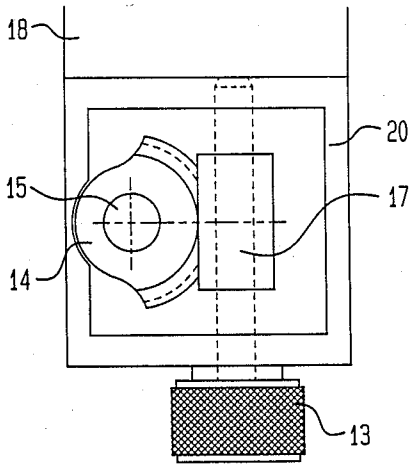

FIG. 3

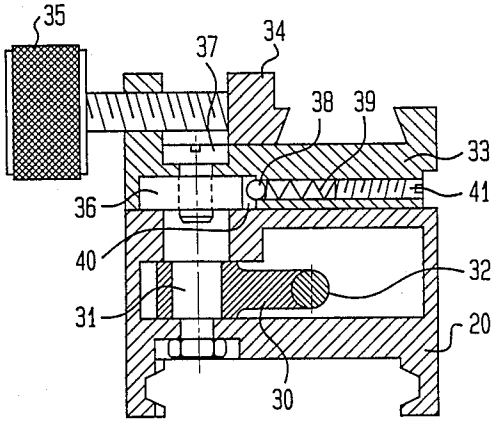

FIG. 4

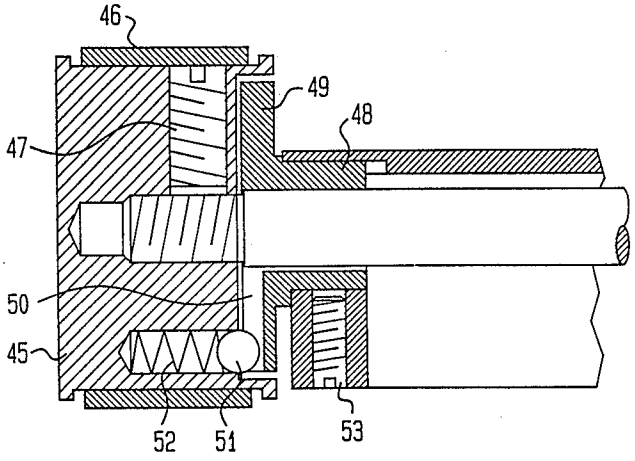

HOLDING APPARATUS FOR AN IMAGE FRAME OR OBJECTIVE FRAME OF A PROFESSIONAL CAMERA

The present invention is concerned with a holding apparatus for an image frame or objective frame of a professional camera and for attachment to the base of the latter which holding apparatus has at least a first and second device and is turnable with respect to a camera base about at least two swivelling axes intersecting each other at a right angle wherein the first device which defines a swivelling axis such that it extends vertically through or parallel to the focal plane or the principal plane of the objective and which includes a swivelling device with an actuating mechanism for turning the image frame or objective frame is arranged above the second device which defines a second swivelling axis such that it extends transversely to the camera base and to the first swivelling axis and which is adjustably mounted on the camera base by means of a focussing device with an actuating mechanism.

Such cameras, with which two or three object points located at various distances from the camera are sharply projected simultaneously and/or compensation of perspective distortions is possible are known.

The rotation of the image frame or objective frame is obtained in a manner known per se by arranging the device defining the vertical swivelling axis above the device defining the horizontal swivelling axis. This manner of proceedings is justified in the technical world so as to prevent the so-called wobble movement of the image frame or objective frame. To prevent these wobble movements, in a manner known per se, the turning about the horizontal swivelling axis must occur prior to the swivelling about the vertical swivelling axis.

In known designs of professional cameras, the image carrier or objective carrier is connected to the camera base via a holder in such a manner that it is merely shiftable on the camera base, or is additionally turnable with respect to the camera base. This turning is obtained only when the swivelling range of the device respectively provided at the top is not sufficient and when adjusting the approximate inclination of the image carrier or objective carrier.

The invention is based on the object to create an apparatus of the above-mentioned kind whose swivelling range is not limited and which is accurately and easily adjustable over the entire swivelling range.

This object is solved according to the invention by the characterizing features of patent claim **1**.

The advantage of the invention resides primarily in the formation of a precise compact unit of the holding apparatus with small dimensions.

In the following, the invention is described with reference to the accompanying drawings.

It shows:

FIG. **1** a partly broken up view of an embodiment of a holding apparatus according to the invention,

FIG. **2** a view in direction "A" in FIG. **1**,

FIG. **3** a section through the first device, and

FIG. **4** a section through an actuating unit.

FIG. **1** shows an embodiment of a holding apparatus adjustably mounted on a camera base **1** and on top of which the image frame or objective frame **2** is detachably affixed. The image frame or objective frame **2** is turnable with the holding apparatus according to FIG. **1** with respect to the camera base **1** through the known base rotation about two swivelling axes **3**, **4** intersecting each other at right angle. The first swivelling axis **3** extends through or closely parallel to the focal plane or principal frame of the objective, and the second swivelling axis **4** extends in vicinity of the camera base **1** transversely to the latter and to the first swivelling axis **3**.

The holding apparatus illustrated in FIG. **1** includes a first device **6** which defines the first swivelling axis **3**, and a second device **7** which defines the second swivelling axis **4**. The first device **6** is mounted above the second device **7**.

The first device **6** includes a worm gear with an actuating mechanism **10**, a holder **11** for the image frame orobjective frame **2** and a locking clutch which is arranged between holder and worm gear in order to limit the torque acting on the worm.

The second device includes a worm gear **12** with an actuating mechanism **13**. The worm wheel **14** of the worm gear is mounted in non-rotational manner on a worm wheel axle **15** which defines the second swivelling axis **4** and is mounted in non-rotational manner in a bottom part **16** which is slidable on the camera base **16**. The worm **17** is rotatably mounted in a top part **18** and connected with the actuating mechanism **13** (FIG. **2**). Top part **18** is pivoted on the worm wheel axis **15** by means of a bearing **19**. Top part **18** includes a housing **20** which embraces the worm gear **12** and is pivoted on the worm wheel axis **15**, and an adjusting device **21** which has a fine motion **22** with actuating mechanism **23** and in which the first device **6** is mounted for adjusting the image frame or objective frame **2** transversely to the camera base **1**. Bottom part **16** is provided with a focussing device **24** to shift the holding apparatus in longitudinal direction of the camera base **1**.

The holding apparatus can further include a second adjusting device which is provided with an actuating mechanism and **26** arranged between bottom part **16** and the to adjust the image frame or objective frame **2** vertical to the camera base **1**.

FIG. **3** shows a section through the first device **6** mounted in the first adjusting device **21**. As already mentioned, the first device **6** includes a worm gear whose worm wheel **30** is mounted in non-rotational manner on a worm wheel axle **31**, and whose worm **32** is connected with the actuating mechanism **10**. Worm wheel **30** and the worm **32** are supported in the first adjusting device. Holder **11** includes a plate **33** mounted on the worm wheel axle **32**, a clamping element **34** with a screw for clamping the image frame or objective frame **2** or a third device for turning about its horizontal center axis. The worm wheel axle **31** has a collar **36** on which the plate **33** is arranged. Plate **33** is fixed to the worm wheel axle by means of a screw **37**. As already mentioned, the first device **6** includes a locking clutch. As shown in FIG. **3**, the locking clutch includes a sphere **38**, a spring **39** which forces the sphere in a V-shaped notch **40** within the collar **36** of the worm wheel axle **31**, and a screw **41** by which the pressure force acting on the sphere **38** is adjustable.

It follows from the above-stated description that the holding apparatus includes several actuating mechanisms which can be classified into two groups, that is a first group of at least the actuating mechanisms **23** and **24** and **26** which cause a displacement i.e. a vertical adjustment, a cross motion and a focussing, and a second group of at least the actuating mechanisms **10**, **13** which cause a turning. As can be seen from FIG. **1**, the holding apparatus is designed in such a manner that the

actuating mechanisms of the first group are located with respect to the camera base **1** at the one side and the actuating mechanisms of the second group are located at the other side of the camera base **1**. Through this arrangement, the adjustment on a professional camera is simplified.

In order to further simplify the adjustment, the actuating mechanisms **10** and **13** of the second group are provided with a locking clutch. FIG. **4** shows such an actuating mechanism. The actuating mechanism includes a turning knob **45** which is provided with a gripping surface at the circumference. The turning knob **45** is screwed to the worm shaft **17** or **32** and secured by a locking screw **47**. The locking mechanism includes a bushing **48** with a flange **49** which has a recess **50** at the upper side, a sphere **51** movably arranged within the turning knob **45**, and a compression spring **52** which is arranged within the turning knob **45** and pushes the sphere **51** against the flange **49**. Bushing **48** is retained by a locking pin **53**. During rotation of the actuating mechanism, per revolution the sphere **51** is forced once into the recess **50**. Through the design of the respectively actuated mechanism, upon each engaging of the sphere **51** into the recess by means of the locking device, an information is delivered about the angle about which the respective device is swivelled.

Instead of the actuating mechanisms or in addition thereto, also driving motors can be provided controlled by an electric unit.

I claim:

1. In a professional camera having a camera base, an objective frame and image frame, and a holding device arranged on the camera base for adjusting independently the objective frame and the image frame about a first and a second swivelling axis intersecting each other at a right angle; said holding device comprising:

a top part and a bottom part shiftable on the camera base;

first swivelling means accommodated in said top part and provided with a first actuating mechanism for adjustment about said first swivelling axis; and

second swivelling means arranged below said first swivelling means for adjustment about said second swivelling axis which extends perpendicular to and in vicinity of said camera base, said second swivelling means including a worm gear with a worm wheel axle mounted in said bottom part in non-rotational manner and rotatably supporting said top part, said worm wheel axle defining said second swivelling axis, a worm wheel fixedly arranged on said worm wheel axle, and a worm mounted in said top part and meshing with said worm wheel for providing adjustment about said second swivelling axis.

2. The camera as defined in claim **1** wherein said first swivelling means includes

a holder in which the image frame and objective frame are respectively insertable and clamped, and

a locking clutch to limit the torque acting on said first swivelling means during adjustment about said first swivelling axis.

3. The camera as defined in claim **2** wherein said first swivelling means includes a worm gear having a worm wheel axle provided with a recess, said locking clutch being a spring-loaded sphere which engages in said recess in said worm wheel axle of said first swivelling means.

4. The camera as defined in claim **1**, and further comprising focusing means for adjusting said holding device along the camera base in a longitudinal direction thereof, said focusing means being arranged in said bottom part.

5. The camera as defined in claim **1**, and further comprising a second actuating mechanism connected to said worm for adjusting the camera about said second swivelling axis, said worm being rotatably arranged in said top part.

6. The camera as defined in claim **1**, and further comprising:

first adjusting means connected to said top part and including a fine motion with a further actuating mechanism for moving the camera transversely with respect to the camera base, said first swivelling means being mounted in said first adjusting means.

7. The camera as defined in claim **4**, and further comprising:

second adjusting means including a fine motion with a further actuating mechanism for moving the camera vertically with respect to the camera base, said second adjusting means being arranged between said bottom part and said focusing means.

8. The camera as defined in claim **5** wherein each of said first and second actuating mechanisms includes a turning knob and locking means associated to said turning knob to deliver an information about the angle by which said first and second swivelling means are adjusted.

9. The camera as defined in claim **8** wherein said turning knob is screwed to said worm wheel axle, said locking means including

a bushing surrounding said worm wheel axle and including a flange extending at a distance to said turning knob and provided with a recess,

a sphere accommodated in said turning knob, and

a compression spring arranged within said turning knob and acting on said sphere in direction of said flange, said sphere being pushed into said recess by said spring once per revolution of said turning knob.

10. The camera as defined in claim **5**, and further comprising:

first adjusting means including a third actuating mechanism for moving the camera transversely with respect to the camera base, and

second adjusting means including a fourth actuating mechanism for moving the camera vertically with respect to the camera base, said first and second actuating mechanisms which cause an adjustment of the camera about said first and second swivelling axes and said third and fourth actuating mechanisms which cause a displacement of the camera are arranged on opposite sides of a vertical plane extending along the camera base.

11. The camera as defined in claim **10** wherein at least one of said actuating mechanisms being a servo mechanism actuated by an electric unit.

[57] **ABSTRACT**

An objective lens system having a pair of plano-convex lenses disposed adjacent each other with the convex surfaces facing each other and aligned along common optical axis. A plurality of optical fibers surround the plan-convex lenses to convey light and illuminate an object to be viewed by the objective lens assembly. Adjustably positioned adjacent the second plano-convex lens is a field lens system including an elongate rod lens for conducting the intermediate image from the plano-convex lenses and to relay it to an ocular lens system for viewing by the user.

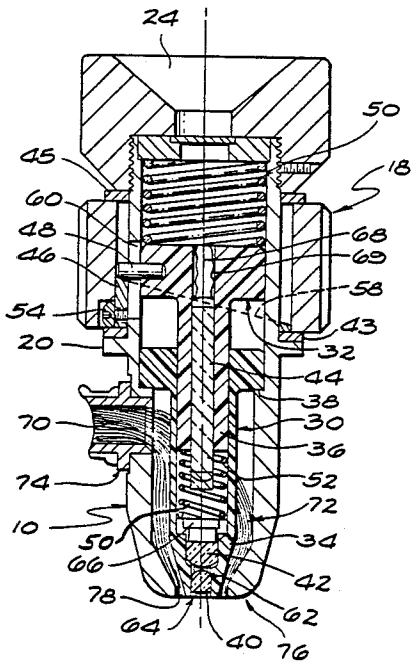

FIG. 1

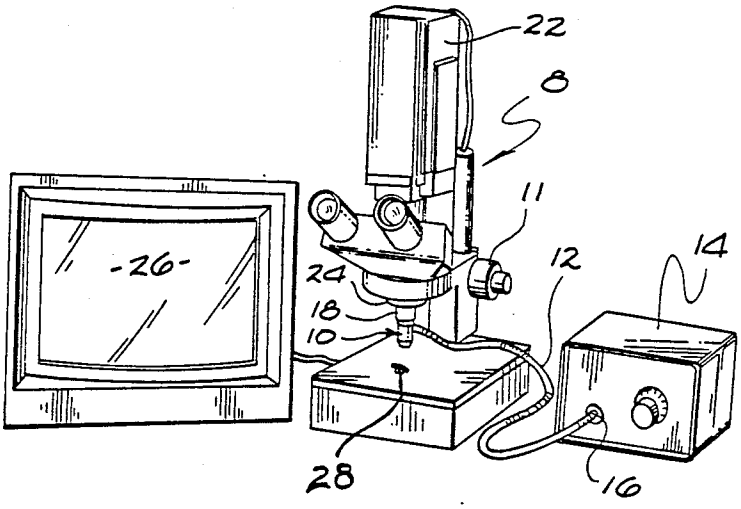

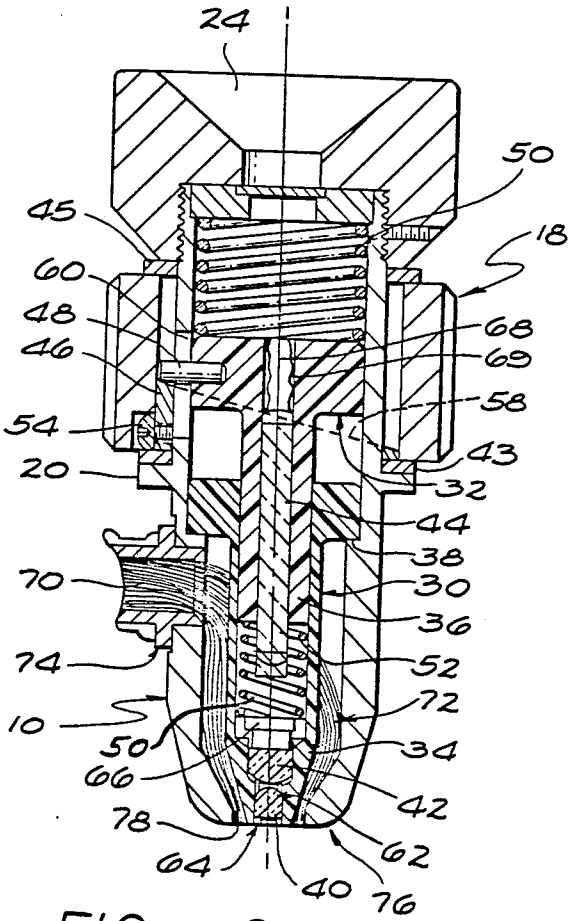

FIG. 2

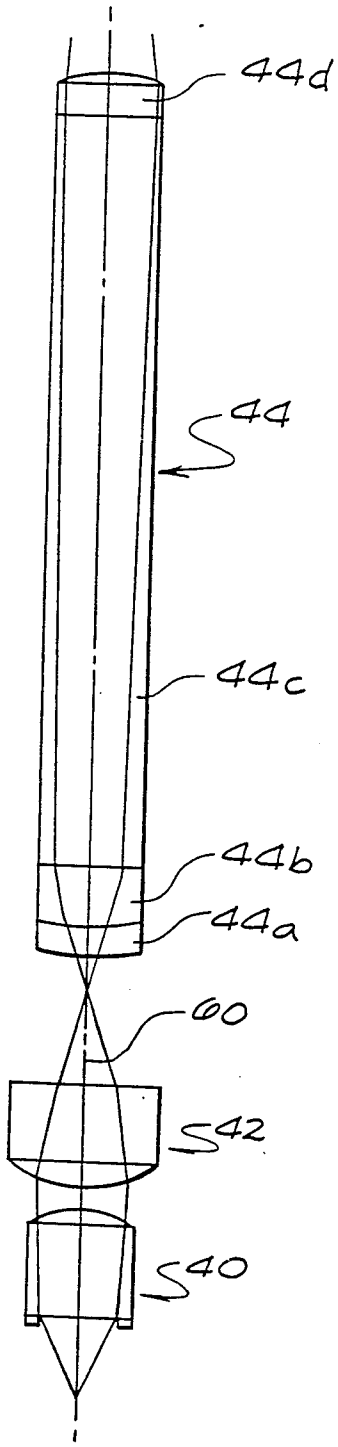

FIG. 3

OBJECTIVE LENS ASSEMBLY

BACKGROUND OF THE INVENTION

The present invention relates to microscope devices and more particularly to objective lens assemblies for use in visually inspecting small-sized parts.

It is frequently desirable to visually inspect small-sized articles of manufacture having parts with substantial depth dimensions such as small diameter bore holes. Traditionally, microscopes having conventional lens systems adapted for viewing slides of specimens have been used to inspect parts which are too small to be clearly viewed by the naked eye. However, such microscopes generally have a very shallow fields at the object plane. Consequently, if the part to be inspected has any significant depth dimensions associated with its features the microscope must be repeatedly refocused in order for the user to be able to examine the entire part. Refocusing takes time and is tiring on the eyes of the user. Further, these microscopes generally do not provide for adequate surface illumination of the part being inspected which makes the inspection of contoured and recessed surfaces even more difficult.

The present invention provides an objective lens assembly which features substantial depth of field at the object plane so that parts can be easily viewed with clarity throughout their depth with a minimum amount of refocusing. Further, the present invention provides a lens assembly which efficiently furnishes illumination to the object being inspected and which is compact in design and is adaptable to be fitted on most conventional microscope bodies.

SUMMARY OF THE INVENTION

The present invention comprises an objective lens assembly for use in inspecting small-sized parts. The present invention includes a pair of adjacent plano-convex lenses, a field lens system and a mechanism for illuminating the part being inspected. The plano-convex lenses are positioned with their convex surfaces facing each other and are aligned along a common optical axis with the field lens system.

In the preferred embodiment, the plano-convex lenses have short radii of curvature of about one-eighth of an inch and form a comparably small aperture opening. The field lens system includes an elongate rod lens and is positionally adjustable for accomplishing any focusing that may be required. The illumination mechanism includes a set of light conducting fibers coaxially mounted in a ring around the plano-convex lenses.

In operation, the pair of plano-convex lenses receives light from the object being inspected and focuses that light into an image characterized by substantial depth of field. The field lens system receives light from that image, processes the light and relays it to an ocular lens system for viewing by the user. The illumination mechanism directs light onto the object being inspected so that it can be clearly viewed by the user.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** shows a perspective view of the objective lens assembly of the present invention mounted for use on a binocular microscope.

FIG. **2** shows a cross-section of the objective lens assembly of the present invention.

FIG. **3** shows a schematic light ray diagram for the lens components of the objective lens assembly.

DESCRIPTION OF THE PREFERRED EMBODIMENT

Referring now to FIG. **1**, a perspective view of the objective lens assembly which constitutes the present invention is shown as mounted for use on an otherwise conventional binocular microscope **8**. The assembly includes a circular body **10** which is tapered toward its lower end and a light fiber containing cable **12** attached to one side of the body **10**. The cable **12** is also attached to a high intensity light source **14** through a connector **16** at the far end of the cable opposite the body **10**. The middle part of the body **10** is concentrically surrounded by a rotatable focusing ring **18** which is used to provide a manually operated focusing capability. The upper part of the body **10** is secured to a mounting piece **24**. The mounting piece **24** is detachable from the body **10** and can be replaced by way of a variety of couplers suitable for connecting the objective lens assembly to any of a number of microscopes. The microscope **8** also includes a video camera **22** for recording the image produced by the objective assembly which is connected to a video monitor **26** for providing a video display.

Referring now to FIG. **2**, a cross-section of the objective lens assembly is shown. The objective assembly includes an objective housing **30** and a field lens housing **32** which are secured within the interior of the body **10** and function to hold the lenses **40**, **42** and **44** in position. The housings **30** and **32** are both circular in construction and fit concentrically within the body **10** so that their positions are horizontally fixed. Further, both housings **30** and **32** have cylindrically shaped elements **34** and **36** which extend downward toward the object being viewed **28** and provide the actual mounting locations for the optical lenses **40**, **42** and **44**. The objective housing **30** is secured to the shoulder **38** of the body **10** so that its position is also vertically fixed. However, the position of the field lens housing **32** is vertically adjustable through rotation of the focusing ring **18**, the action of the cam sleeve **46**, the drive pin **48** and the springs **50** and **52**. The spring **50** bears on the upper axial end of the housing **32** while the spring **52** bears on the lower axial end of the housing **32**. Together the two springs preload the housing so that the position of the housing **32** with respect to the body **10** can be smoothly adjusted. The focusing ring **18** is mounted between the retaining ledge **20** and a washer **43** and the mounting piece **24** and a washer **45** so that its movements are vertically constrained. The cam sleeve **46** is positioned between the focusing ring **18** and the body **10**. The cam sleeve **46** is rotationally secured to the focusing ring **18** by the stop bolt **54** and its upper surface **58** is in sliding contact with the drive pin **48**. The cam sleeve **46** is sloped around its circumference on its upper surface as shown by the dashed line **58**. The drive pin **48** is attached to the housing **32** but is vertically movable in the slot **60** in the body **10** in response to the position of the cam sleeve **46** and the focusing ring **18**. The structural elements of the lens asssembly such as the body **10**, housings **30** and **32**, focusing ring **18** and cam sleeve **46** may be manufactured of conventional metals such as brass using traditional metal working machines and techniques such as lathes and milling machines.

The lens **40** and **42** are mounted immediately adjacent to one another within circular cavities in the lower end of the housing **30**. The lenses **40** and **42** are separated by

a small spacer **62** which is of much lesser width than the radii of curvature of the lenses. The lens **40** and **42** are held in position by the washer **64** and the objective retainer **66** which is loaded by the spring **50**. The lens **44** is mounted in the circular passage **68** in the housing **32**. The lens **44** is cemented into the passage **68** along with a convoluted spacer **69** having a black matt finish for absorbing any stray light.

The cable **14** contains a bundle **70** of light conducting fibers. The cable **14** connects to the inlet fixture **74** of the body **10**. The bundle **70** is split into groups **72** of separate fibers which extend coaxially around the housing **30** and the lenses **40** and **42** in the annular spaces between the body **10** and housing **30**. The lower tips **76** of the fibers are cemented into a ring **78** concentric with the lens **40**. The ends of the fibers which form the ring are cut flush the body **10** and polished to allow them to efficiently emit light toward the object **28** being viewed.

Referring now to FIG. **3**, an enlarged view of the lens system without its supporting structure is illustrated. The lenses **40, 42** and **44** are aligned in the order given along a common optical axis **60**. The lens **40** is a thick plano-convex lens having a very small radius of curvature which will preferably range between 0.05 and 0.3 inch and a comparably small aperture which will preferably range between 0.04 to 0.25 inch. The lens **42** is also a thick plano-convex lens having the same radius of curvature as the lens **40**. The lens **42** is wider than the lens **40** to allow it to be more easily mounted within the housing **30**. The lenses **40** and **42** are mounted in close proximity so that they are separated by a distance which is much less the radii of the curvature of the lenses and are mounted in opposed fashion so that their convex surfaces face one another. The lenses **40** and **42** act to receive light from the object being inspected and transmit an image of that object characterized by a substantial depth of field to the field lens **44**. The lens **44** actually includes four separate lens parts, **44*a***, **44*b***, **44*c*** and **44*d***. The lens parts **44*a*** and **44*b*** form an achromatic lens pair for magnifying the image and for correcting the image for chromatic aberrations. The lens part **44*c*** is a rod lens with a ground surface around its cylindrical circumference for transmitting an image with a minimum of divergence, diffusion and reflective losses. The lens part **44*d*** is a focusing lens for helping to properly relay the image to an ocular lens system. The exact characteristics of a set of suitable lenses for an objective lens assembly as shown in FIG. **2** and **3** are given in Table I below.

TABLE I

	Lens 40	Lens 42	Lenses 44a, 44b, 44c, 44d
Radius of Curvature	.123"	.123"	.530/.290", .290", 0", .545"
Diameter	.106"	.152"	.183", .183", .183", .183"
Thickness	.105"	.105"	.040", .080", 1.25", .070"
Index of Refraction	1.51680	1.51680	1.78831, 1.72000, 1.62041, 1.720
Dispersion	64.17	64.17	47.7, 50.2, 60.3, 50.2

The lenses described above may be manufactured using conventional lens grinding techniques. The lenses described in Table I would provide an assembly adapted for inspecting efficiently parts having dimensions typically in the range of 1 to 100 thousandths of an inch in size and depth dimensions of up to 1 to 3 inches.

Referring now again to FIG. **1**, in operation the objective lens assembly may be attached to a conventional microscope **8**. The cable **12** is connected to a high intensity light source **14**. The object to be viewed **28** is then placed under the objective lens assembly and the light source **14** turned on. The height of the objective assembly is adjusted to the appropriate range for the magnification desired using the microscope positioning controls **11**. If necessary, the focusing ring **18** is then rotated to adjust the position of the field lens system **44** (see FIG. **2**) and bring the object into proper focus. The object may then be visually examined through the microscope **8**. The light fibers and ring **72** provide the required illumination. The lenses **40** and **42** (see FIGS. **2** and **3**) cooperate to provide an image characterized by substantial depth of field and only minor aberrations. The lens system **44** helps to correct any aberrations in the image and relays it (directly or indirectly) up to the ocular lens system for the microscope with a limited amount of divergence and light loss.

While the system of this invention has been described in conjunction with particular embodiments, it should be apparent that certain changes could be made without departing from the principles of the invention. Consequently, the embodiments provided are intended to be illustrative only and are not meant to limit the scope of the following claims.

We claim:

1. An objective lens assembly for use in visually inspecting small sized parts microscope applications for viewing an object, comprising:

a pair of plano-convex lenses for receiving light from an object and forming an optical image of the same, said lenses having equal radii of curvature of from 0.05 to 0.3 inch and said lenses mounted so that they are maintained in close proximity to one another and the convex surfaces of the lenses face one another; means for illuminating said object with high intensity light;

means for receiving light from image formed by said pair of plano-convex lens and relaying said image to an ocular lens system comprising a field lens system including an achromatic lens pair for correcting for chromatic abberations, an elongate rod lens for transmitting the image with reduced divergence and a relay lens for focusing the image for further transmission.

2. The objective lens assembly of claim **1**, wherein said means for illuminating comprises a ring of light conducting fibers coaxial with said pair of plano-convex lenses.

3. An objective lens assembly for use in microscope applications for viewing an object, comprising:

a pair of plano-convex lenses for receiving light from an object and forming an optical image of the same, said lenses having equal radii of the curvature of from 0.05 to 0.3 inch and said lenses mounted so that they are maintained in close proximity to one another and the convex surfaces of the lenses face one another;

a plurality of light conducting fibers mounted in a ring coaxial with said pair of plano-convex lenses for illuminating said object;

a field lens system including an achromatic lens pair of plano-convex lenses, processing the image and relaying it to an ocular lens system.

4. The objective lens assembly of claim **1**, further including focusing means for adjusting the position of said field lens system relative to said pair of plano-convex lenses, said focusing means including a drive pin attached to said lens system, a cam sleeve in slidable

contact with said drive pin and a rotatable focusing ring attached to said cam sleeve.

5. The objective lens assembly of claim 4 which further includes a housing for receiving said field lens system; and spring means disposed at opposite ends of said housing to support said housing for smooth focusing adjustment of said field lens system.

COMPACT WIDE-ANGLE OBJECTIVE

FIELD OF THE INVENTION

My present invention relates to a photographic wide-angle objective and, more particularly, to a comparatively short wide-angle objective whose field of view is comparatively wide both at small apertures and with larger apertures.

BACKGROUND OF THE INVENTION

Wide angle objectives are, of course, known in the art. Typical of such objectives are those designed in accordance with L. Bertele, which generally provide a symmetrical arrangement of the individual lenses and cemented-lens components or elements.

A disadvantage of such earlier lens systems is that they have a relatively long construction, are comparatively large and bulky and require front and rear lens diameters which are so large that difficulties are encountered in building them into cameras. They also limit the adjustment capabilities of so-called large-format cameras.

OBJECTS OF THE INVENTION

It is, therefore, the principal object of the present invention to provide an improved wide-angle objective, which can be used highly effectively for large-format cameras, in which these drawbacks are eliminated or reduced.

Another object of the invention is to provide an alternative to conventional objectives and which will yield a wide field of view in a compact construction and with good correction for all lens apertures. It is another object of this invention to provide a compact wide-angle objective which can be used as an alternative to a normal objective and compact construction and excellent correction for all apertures as well as an alternative for bulky wide-angle objectives which are dimensionally sensitive and can guarantee sharpness only with stepped-down apertures, the improved objective being of comparatively short construction, using comparatively small lens diameters and nevertheless having excellent sharpness over the full range of apertures and at various distances with an image angle of at least 70° in the fully open state of the lens and of at least 80° with a stepped-down aperture.

SUMMARY OF THE INVENTION

These objects and others which will become apparent hereinafter are attained, in accordance with the present invention in a six-element eight-lens wide angle objective which consists essentially of, from the object side to the image side of the objective:

a first element constituted by a convex negative meniscus first lens **L1** with radii r_1 and r_2 and a thickness along the axis of d_1 and a refractive index of n_1;

a second positive-meniscus element **L2** separated from the first element by a spacing d_2 measured along the axis and constituted by a second lens **L2***a* cemented to a third lens **L3**, the second lens **L2** being of refractive index n_2 and having radii r_3 and r_4 and a thickness along the axis of d_3, the third lens **L2***b* being of refractive index n_3 and having radii r_4 and r_5 and a thickness along the axis of d_4;

a third element **L3** separated from the second element by a spacing d_5 along the axis and constituted by a positive meniscus fourth lens having radii r_6 and r_7, a refractive index n_4, and a thickness along the axis of d_6;

a fourth positive element **L4** spaced from the third element along the axis by a spacing d_6 and constituted of a fifth lens **L4***a* cemented to a sixth lens **L4***b*, the fifth lens **L4***a* having radii r_8 and r_9 and being of a thickness d_8 along the axis and of a refractive index n_5, the sixth lens **L4***b* having radii r_9 and r_{10} and being a lens with a refractive index n_6 and a thickness along the axis of d_9;

a fifth positive meniscus element **L5** spaced along the axis by a spacing d_{10} from the fourth element and consisting of a seventh lens with a refractive index n_7, radii r_{11} and r_{12} and a thickness d_{11} along the axis; and

a sixth negative element **L6** in the form of an eighth lens of biconcave configuration, separated by a spacing d_{12} along the axis from the fifth element and having a refractive index n_8, radii r_{13} and r_{14} and a thickness d_{13} along the axis, and wherein:

the radius r_{14} is greater than the radius r_{13} of the eight lens and is turned toward an image side of the objective, and the following conditions are also satisfied:

$$(d_2+d_{12})<(d_8+d_9)/2, \text{ and}$$

$$(d_7+d_8+d_9+d_{10}+d_{11}+d_{12}+d_{13})>0.48D$$

where D is the sum of all of the thicknesses and spacings.

The essential features of the new angle objective of the invention is thus that the first lens element is a negative meniscus convex toward the image side and the six-lens element **L6** is biconcave with its larger radius r_{14} turned toward the image side, the objective satisfying the conditions given above. Throughout this description, whenever the summation sign is used, it will be understood to represent D, the total of the lens thicknesses and of the air spacings d_1–d_{13}.

According to a feature of the invention, the wide-angle objective further satisfies the conditions:

$$n_1<1.55$$

$$n_8<1.55$$

$$(n_2+n_3+n_4+n_5+n_6+n_7)/6>1.62.$$

Best results are obtained when the lenses or lens elements are characterized by the following parameters (where in practical terms the units are mm) for a focal length of 100 units the image distance is 81.9 units, the image angle is 70° for an aperture ratio of 1:5.6 and is 80° for an aperture ratio of 1:11.0, and said radii, thicknesses and spacings are given below in said units:

$r_1 = 39.152$			
	$d_1 = 2.517$	$n_1 = 1.4645$	$\nu_1 = 65.77$
$r_2 = 20.221$			
	$d_2 = 3.510$		
$r_3 = 29.616$			
	$d_3 = 6.623$	$n_2 = 1.7550$	$\nu_2 = 52.30$
$r_4 = 87.298$			
	$d_4 = 4.967$	$n_3 = 1.6254$	$\nu_3 = 35.56$
$r_5 = 29.998$			
	$d_5 = 7.000$		
$r_6 = 48.217$			
	$d_6 = 1.987$	$n_4 = 1.7725$	$\nu_4 = 49.60$
$r_7 = 55.911$			
	$d_7 = 3.312$		
$r_8 = 321.496$			
	$d_8 = 19.312$	$n_5 = 1.6204$	$\nu_5 = 60.33$
$r_9 = -19.009$			

-continued

	$d_9 = 1.987$	$n_6 = 1.6668$	$\nu_6 = 33.01$
$r_{10} = -27.981$			
	$d_{10} = 0.338$		
$r_{11} = -117.436$			
	$d_{11} = 5.841$	$n_7 = 1.6204$	$\nu_7 = 60.33$
$r_{12} = -44.848$			
	$d_{12} = 2.583$		
$r_{13} = -28.475$			
	$d_{13} = 2.517$	$n_8 = 1.4787$	$\nu_8 = 58.70$
$r_{14} = 131.465$			
	$\Sigma d = 62.494$		

wherein ν_1 to ν_8 are the Abbe numbers of the first, second, third, fourth, fifth, sixth, seventh and eight lenses, respectively, and Σd is the sum D of all of said thicknesses and spacings.

Alternatively the objective conforms to the parameters (also with the units being mm):

for a focal length of 100 units the image distance is 79.98 units, the image angle is 70° for an aperture ratio of 1:5.6 and is 80° for an aperture ratio of 1:11.0, and the radii, thicknesses and spacings are given below in the units:

$r_1 = 40.585$			
	$d_1 = 2.512$	$n_1 = 1.4645$	$\nu_1 = 65.77$
$r_2 = 20.329$			
	$d_2 = 2.942$		
$r_3 = 28.243$			
	$d_3 = 6.611$	$n_2 = 1.7550$	$\nu_2 = 52.30$
$r_4 = 78.065$			
	$d_4 = 4.958$	$n_3 = 1.6254$	$\nu_3 = 35.56$
$r_5 = 29.234$			
	$d_5 = 6.988$		
$r_6 = 48.279$			
	$d_6 = 1.983$	$n_4 = 1.7725$	$\nu_4 = 49.60$
$r_7 = 61.979$			
	$d_7 = 3.303$		
$r_8 = 735.997$			
	$d_8 = 19.278$	$n_5 = 1.6180$	$\nu_5 = 63.40$
$r_9 = -18.981$			
	$d_9 = 1.983$	$n_6 = 1.6668$	$\nu_6 = 33.01$
$r_{10} = -27.595$			
	$d_{10} = 0.337$		
$r_{11} = -100.513$			
	$d_{11} = 5.831$	$n_7 = 1.6180$	$\nu_7 = 63.40$
$r_{12} = -44.952$			
	$d_{12} = 2.578$		
$r_{13} = -27.416$			
	$d_{13} = 2.512$	$n_8 = 1.4645$	$\nu_8 = 65.77$
$r_{14} = 158.107$			
	$\Sigma d = 61.816$		

wherein ν_1 to ν_8 are the Abbe numbers of the first, second, third, fourth, fifth, sixth, seventh and eight lenses, respectively, and Σd is the sum D of all of the thicknesses and spacings.

The compact wide-angle objective has been found to be especially advantageous for large format cameras, i.e. those which expose a negative with an image format of 90 mm × 120 mm or some other large format camera.

The compact wide-angle objective of the invention is surprisingly short and compact by comparison with wide-angle lenses used heretofore. The combination of a highly compact construction with high image quality to the edge of the image angle of 80 combined with the fact that the wide angle characteristics are retained even at relatively high openings has proven to be of great advantage in large format photography with respect to the ease of working in this medium and the high image quality which is obtained at all distances.

BRIEF DESCRIPTION OF THE DRAWING

The above and other objects, features and advantages of the present invention will become more readily apparent from the following description, reference being made to the accompanying drawing in which:

FIG. 1 is a schematic axial section of a compact wide-angle lens according to the invention;

FIG. 2 is a graph showing the spherical aberration, the deviation from a sinosoidal characteristic of the astigmatism and the characteristics of a first embodiment of the invention; and

FIG. 3 is a graph similar to FIG. 2 of a second embodiment.

SPECIFIC DESCRIPTION

FIG. 1 shows a wide-angle compact objective having an optical axis OA along which are arranged from the object side OS to the image side IS six lens elements and a total of eight lenses.

These include a first lens element L1 of negative refractivity consisting of a single lens with radii of curvature r_1 and r_2 and a thickness d_1 as measured along the axis.

At a spacing d_2 from the first lens element L1 is a second lens element L2 consisting of two lenses L2*a* and L2*b* which are cemented together. The radii of curvature of these lenses are represented at r_3, r_4 and r_5 and the respective thicknesses are d_3 and d_4. Both lenses L2*a* and L2*b* are positive refracting lenses. At a spacing d_5 there follows a third lens element L3, also of positive refractivity and consisting of a single lens with radii r_6 and r_7 and a thickness of d_6.

The fourth positive lens element L4 is separated by a distance d_7 from the third element L3 and consists of two cemented positive lenses L4*a* and L4*b* with respective radii r_8, r_9 and r_{10} and thicknesses d_8 and d_9.

A spacing d_{10} can separate the fifth lens element L5 which is also of positive refractivity from the lens element L4.

The lens element L5 also consisting of a single lens has radii r_{11} and r_{12} and a thickness d_{11}.

A spacing d_{12} is provided between the sixth and final lens element L6 and the lens element L5. The lens element L6 is a negative lens with radii r_{13} and r_{14} and a thickness d_{13}. The refractive indices of the lenses L1, L2*a*, L2*b*, L3, L4*a*, L4*b*, L5 and L6 are represented at n_1–n_8, respectively.

According to the invention, these lenses fulfill the following criteria:

(1) $r_1 > r_2$

(2) $r_{13} < r_{14}$

(3) $n_1 < 1.55$ and $n_8 < 1.55$

(4) $(n_2+n_3+n_4+n_5+n_6+n_7)/6 > 1.62$.

(5) $(d_2+d_{12}) < (d_8+d_9)/2$

(6) $(d_7+d_8+d_9+d_{10}+d_{11}+d_{12}+d_{13}) > 0.48D$

Criteria (1) and (2) concern the first and sixth lens elements L1 and L6 of the system.

For correction of the image field curvature and a uniform image field illumination of a large format objective having an image angle of at least 70° or 80°, the first

lens L1 should have a negative refractivity. For correction purposes, a negative meniscus lens L1 is used with a convex curvature turned toward the object side.

For the correction of coma, distortion and transverse color correction over the total image field, a symmetrical refractive index sequencing of the individual lenses is selected for the sequence of individual lenses and lens elements (L1–L6) is not symmetrical itself, the last lens L6 nevertheless having a negative refractivity.

This lens is formed as a biconcave lens (contrast with lens L1) whose radius r_{14} turned toward the image plane is greater than its radius r_{13} turned away from the image plane. This relationship has been found to improve the correction of coma for all openings and for color correction and the correction of color coma over the total image field while the air spacing d_{13} is held to a minimum.

The use of glasses with low refractive index in the outermost negative lenses L1 and L6 (criterion 3) and of high refractivity glasses in all other lenses (criterion 4) has been found to be especially advantageous for the correction of the Petzval sum with simultaneous correction of chromatographic error and all other image defects and allows flattened lens structures or large radii structures in the lens elements L12–L5.

The use of large lens thicknesses for the inner lens elements L2–L5 has been found to be advantageous for correction of systems having large image angles. In conventional wide-angle objectives, this approach has been used close to the diaphragm. For a system of the present type with an image angle of at least 70° or 80°, it suffices to have as the largest thickness element the fourth element L4 (d_8+d_9) This provides an advantage of the present system over conventional systems in that the overall weight of the objective is less. Simultaneously it allows the air spaces d_2 and d_{13} to be very small (criterion 5) which is important for good correction of image field curvature, coma and chromatographic errors and chromatographic coma even with short object distances.

Known objectives of the wide Gauss type with large air spaces between the outermost negative meniscus lenses and the neighboring positive lens elements show, by comparison to the lenses of the invention, clearly poorer image quality as one moves into the short object-distance ranges.

The limitation of a single very thick lens in the region of the diaphragm and the minimalization of the air spaces d_2 and d_3 ensure a short axial length of the objective in conjunction with a small diameter of the objective based upon the small diameters of the first and last lens elements L1 and L6, thereby making the objective particularly suitable for large format cameras by comparison with earlier wide angle lenses.

For correction of all image defects, it has been found to be advantageous that the length of the first part of the system formed by the lenses L1–L3 should be similar to that of the second part of the system formed by the elements L4–L6. This is assured by the criterion 6.

FIGS. 2 and 3 show the image reproduction quality graphically. The first tubular example given herein corresponds to FIG. 2 while FIG. 3 corresponds to the second tabular example herein.

I claim:

1. A wide-angle objective consisting essentially of six elements and eight lenses aligned along an optical axis, said lenses consisting, in succession from an object side, of:

a first element constituted by a convex negative meniscus first lens L1 with radii r_1 and r_2 and a thickness along said axis of d_1 and a refractive index of n_1;

a second positive-meniscus element L2 separated from said first element by a spacing d_2 measured along said axis and constituted by a second lens L2*a* cemented to a third lens L3, said second lens L2 being of refractive index n_2 and having radii r_3 and r_4 and a thickness along said axis of d_3, said third lens L2*b* being of refractive index n_3 and having radii r_4 and r_5 and a thickness along said axis of d_4;

a third element L3 separated from said second element by a spacing d_5 along said axis and constituted by a positive meniscus fourth lens having radii r_6 and r_7, a refractive index n_4, and a thickness along said axis of d_6;

a fourth positive element L4 spaced from said third element along said axis by a spacing d_6 and constituted of a fifth lens L4*a* cemented to a sixth lens L6*a*, said fifth lens L4*a* having radii r_8 and r_9 and being of a thickness d_8 along said axis and of a refractive index n_5, said sixth lens L4*b* having radii r_9 and r_{10} and being a lens with a refractive index n_6 and a thickness along said axis of d_9;

a fifth positive meniscus element L5 spaced along said axis by a spacing d_{10} from said fourth element and consisting of a seventh lens with a refractive index n_7, radii r_{11} and r_{12} and a thickness d_{11} along said axis; and

a sixth negative element L6 in the form of an eighth lens of biconcave configuration, separated by a spacing d_{12} along said axis from said fifth element and having a refractive index n_8, radii r_{13} and r_{14} and a thickness d_{13} along said axis, and wherein:

said radius r_{14} is greater than the radius r_{13} of said eight lens and is turned toward an image side of the objective, and the following conditions are also satisfied:

$$(d_2+d_{12})<(d_8+d_9)/2, \text{ and}$$

$$(d_7+d_8+d_9+d_{10}+d_{11}+d_{12}+d_{13})>0.48D$$

where D is the sum of all of said thicknesses and spacings.

2. The wide-angle objective defined in claim 1, further satisfying the criteria:

$$n_1<1.55$$

$$n_8<1.55$$

$$(n_2+n_3+n_4+n_5+n_6+n_7)/6>1.62.$$

3. The wide-angle lens defined in claim 2 wherein, for a focal length of 100 units the image distance is 81.9 units, the image angle is 70° for an aperture ratio of 1:5.6 and is 80° for an aperture ratio of 1:11.0, and said radii, thicknesses and spacings are given below in said units:

$r_1 = 39.152$			
	$d_1 = 2.517$	$n_1 = 1.4645$	$\nu_1 = 65.77$
$r_2 = 20.221$			
	$d_2 = 3.510$		
$r_3 = 29.616$			
	$d_3 = 6.623$	$n_2 = 1.7550$	$\nu_2 = 52.30$
$r_4 = 87.298$			
	$d_4 = 4.967$	$n_3 = 1.6254$	$\nu_3 = 35.56$

-continued

$r_5 = 29.998$			
	$d_5 = 7.000$		
$r_6 = 48.217$			
	$d_6 = 1.987$	$n_4 = 1.7725$	$\nu_4 = 49.60$
$r_7 = 55.911$			
	$d_7 = 3.312$		
$r_8 = 321.496$			
	$d_8 = 19.312$	$n_5 = 1.6204$	$\nu_5 = 60.33$
$r_9 = -19.009$			
	$d_9 = 1.987$	$n_6 = 1.6668$	$\nu_6 = 33.01$
$r_{10} = -27.981$			
	$d_{10} = 0.338$		
$r_{11} = -117.436$			
	$d_{11} = 5.841$	$n_7 = 1.6204$	$\nu_7 = 60.33$
$r_{12} = -44.848$			
	$d_{12} = 2.583$		
$r_{13} = -28.475$			
	$d_{13} = 2.517$	$n_8 = 1.4787$	$\nu_8 = 58.70$
$r_{14} = 131.465$			
	$\Sigma d = 62.494$		

wherein ν_1 to ν_8 are the Abbe numbers of the first, second, third, fourth, fifth, sixth, seventh and eight lenses, respectively, and Σd is the sum D of all of said thicknesses and spacings.

4. The wide-angle lens defined in claim 2 wherein, for a focal length of 100 units the image distance is 79.98 units, the image angle is 70° for an aperture ratio of 1:5.6 and is 80° for an aperture ratio of 1:11.0, and said radii, thicknesses and spacings are given below in said units:

$r_1 = 40.585$			
	$d_1 = 2.512$	$n_1 = 1.4645$	$\nu_1 = 65.77$
$r_2 = 20.329$			
	$d_2 = 2.942$		
$r_3 = 28.243$			
	$d_3 = 6.611$	$n_2 = 1.7550$	$\nu_2 = 52.30$
$r_4 = 78.065$			
	$d_4 = 4.958$	$n_3 = 1.6254$	$\nu_3 = 35.56$
$r_5 = 29.234$			
	$d_5 = 6.988$		
$r_6 = 48.279$			
	$d_6 = 1.983$	$n_4 = 1.7725$	$\nu_4 = 49.60$
$r_7 = 61.979$			
	$d_7 = 3.303$		
$r_8 = 735.997$			
	$d_8 = 19.278$	$n_5 = 1.6180$	$\nu_5 = 63.40$
$r_9 = -18.981$			
	$d_9 = 1.983$	$n_6 = 1.6668$	$\nu_6 = 33.01$
$r_{10} = -27.595$			
	$d_{10} = 0.337$		
$r_{11} = -100.513$			
	$d_{11} = 5.831$	$n_7 = 1.6180$	$\nu_7 = 63.40$
$r_{12} = -44.952$			
	$d_{12} = 2.578$		
$r_{13} = -27.416$			
	$d_{13} = 2.512$	$n_8 = 1.4645$	$\nu_8 = 65.77$
$r_{14} = 158.107$			
	$\Sigma d = 61.816$		

wherein ν_1 to ν_8 are the Abbe numbers of the first, second, third, fourth, fifth, sixth, seventh and eight lenses, respectively, and Σd is the sum D of all of said thicknesses and spacings.

[57] **ABSTRACT**

The present invention provides an objective lens system for optical recording type disks, comprising from a light source side to a disk side; a first lens element having a positive refractive power, said first lens element having at least an aspherical surface; a second lens element having a positive refractive power; and wherein the objective lens system fulfills the following condition:

$$-\frac{1}{2}<\beta<-\frac{1}{8}$$

wherein β represents the magnification of the whole lens system.

OBJECTIVE LENS SYSTEM FOR OPTICAL RECORDING TYPE DISKS

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to an objective lens system for optical recording type disks, such as digitally recorded audio disks, video disks, etc. .

2. Description of the Prior Art

In such objective lens system, it is required to correct the aberrations to an extraordinarily high degree and to achieve a high resolving power, in order to form, on the disk, an extreme small spot image whose size is determined in accordance with the limit of the diffraction of light. Thus, a numerical aperture about 0.4~0.5 is necessary in type of lens system.

An objective lens system of this type has been proposed, for example, in Japanese Laid-Open Patent Application No. SHO No. 55-4068. However, a conventional optical recording type disk device is constructed as shown in FIG. 1. In FIG. 1, a light bundle emitted from a laser light source (2) is converted to a parallel light bundle by a collimating lens system (4). The parallel light bundle is incident on a beam splitter (6) from the light source side. The beam splitter (6) has a half mirror for dividing the light incident thereon by reflection and transmission. Thus, the parallel light bundle transmitted through the beam splitter (6) is concentrated into a spot on a rear surface of disk (10) by an objective lens system (8). The reflected light bundle from the disk (10) is incident on the beam splitter (6) from the disk side through the objective lens system (8). One part of such light bundle is reflected on the beam splitter (6) toward a lens system for focus detection (12), and another part thereof is transmitted through the beam splitter (6). The light bundle reflected toward the lens system (12) is incident on a light receiving device (14) through the lens system (12).

The lens system (12) is used for detecting the focusing condition of the objective lens system (8) on the rear surface of the disk (10). This lens system (12) includes a cylindrical lens element (12*a*) in order to generate a great amount of astigmatism in a predetermined direction perpendicular to the optical axis. The light receiving device includes plurality of light receiving cells which are arranged symmetrically with respect to the optical axis. Thus, the focusing condition of the objective lens system is detected in accordance with the output signals from such light receiving cells. A diffraction grating (16) is arranged so that the tracking condition of the light bundle incident on the disk (10) is detected a well-known three beam method.

FIG. 2 shows another arrangement of the prior art in which the collimating lens system (4) is arranged on the disk side of the beam splitter (6).

In the above arrangement, two methods for tracking of the light bundle incident on the disk (10) are known. One of the methods is to use a galvano mirror which is vibrated for changing the position of the light spot on the disk (10). However, in this method, it is necessary to correct various aberrations of the objective lens system with respect to the off-axial rays, since the light rays incident on the objective lens system would have some inclination angle to its optical axis. Thus, it causes to increase the number of the lens elements in the objective lens system, and to deteriorate the compactness of the objective lens system due to the extension of the focal length thereof.

Therefore, another method is often applied. This method is to shift the objective lens system perpendicularly to its optical axis for tracking of the light bundle. This method has an advantage in that it requires to correct the aberrations of the objective lens system only with respect to the paraxial rays, because the light rays incident on the objective lens system are always parallel to its optical axis. However, in this method, the construction of the objective lens system is required to be light in weight and to be simple, because the objective lens system itself is shifted for tracking.

Furthermore, it should be raised to make a pick-up device for disks more compact. Two methods would be considered for making the optical system in the pick-up device more compact. One of them is to shorten the focal length of the objective lens system for decrease the distance between the laser light source and the disk. However, the radius of curvature of any refractive surface in the objective lens system become small in proportion to the shortening of the focal length of the objective lens system. The sensitivity of the optical performance to a manufacturing error is undesirably increased in proportion to shortening of the focal length of the objective lens system. Thus, this method has a limit in minimizing the focal length of the objective lens system.

Another method is to increase the numerical aperture NA of the collimating lens system. However, this method requires the designer to increase the number of the lens elements in the collimating lens system. Thus, it causes and increase in the cost. Furthermore, in this method, the dispersion of the astigmatic difference in the laser light source becomes another problem.

SUMMARY OF THE INVENTION

An object of the present invention is to provide an objective lens system which is useful for making the pick-up device compact in construction.

Another object of the present invention is to provide an objective lens system which is suitable for tracking by shifting the objective lens system.

According to the present invention, an objective lens system for optical recording type disks, comprising from a light source side to a disk side;

a first lens element having a positive refractive power, said first lens element having at least an aspherical surface;

a second lens element having a positive refractive power; and

wherein the objective lens system fulfills the following condition:

$$-\frac{1}{2}<\beta<-\frac{1}{8}$$

wherein:

β represents the magnification of the whole lens system.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 represents a cross sectional view of the optical system for optical recording type disks according to the prior art;

FIG. 2 represents a cross sectional view of the optical system for optical recording type disks according to another prior art;

FIG. 3 represents a cross sectional view of the optical system for optical recording type disks according to the present invention:

FIG. 4 represents a cross sectional view of the objective lens system for optical recording type disks according to the embodiments 1, 2, 3, 4 and 7 of the present invention;

FIG. 5 represents a cross sectional view of the objective lens system according to the embodiments 8, 9, 11, 13, 15 of the present invention;

FIG. 6 represents a cross sectional view of the objective lens system according to the embodiments 6 and 14 of the present invention;

FIG. 7 represents a cross sectional view of the objective lens system according to the embodiments 5, 10 and 12 of the present invention;

FIG. 8 represents a cross sectional view of the objective lens system according to the embodiment 16 of the present invention;

FIG. 43 represents a cross sectional view of the objective lens system according to the embodiment 26 of the present invention;

FIGS. 44A to 44C represent the aberration curves of the embodiment 26;

FIG. 45 represents a cross sectional view of the objective lens system according to the embodiment 27 of the present invention;

FIGS. 46A to 46C represent the aberration curves of the embodiment 27;

FIG. 47 represents a cross sectional view of the objective lens system according to the embodiment 28 of the present invention;

FIGS. 48A to 48C represent the aberration curves of the embodiment 28;

FIG. 49 represents a cross sectional view of the objective lens system according to the embodiment 29 of the present invention;

FIGS. 50A to 50C represent the aberration curves of the embodiment 29;

FIG. 51 represents a cross sectional view of the objective lens system according to the embodiment 30 of the present invention;

FIGS. 52A to 52C represent the aberration curves of the embodiment 30;

FIG. 53 represents a cross sectional view of the objective lens system according to the embodiment 31 of the present invention;

FIGS. 54A to 54C represent the aberration curves of the embodiment 31;

FIG. 55 represents a cross sectional view of the objective lens system according to the embodiment 32 of the present invention;

FIGS. 56A to 56C represent the aberration curves of the embodiment 32;

FIG. 57 represents a cross sectional view of the objective lens system according to the embodiment 33 of the present invention;

FIGS. **58A** to **58C** represent the aberration curves of the embodiment **33**;

FIG. **59** represents a cross sectional view of the objective lens system according to the embodiment **34** of the present invention; and

FIGS. **60A** to **60C** represent the aberration curves of the embodiment **34**;

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

The following description is provided to enable any person skilled in the optical field to make and use the invention and sets forth the best modes contemplated by the inventors for carrying our invention. Various modifications, however, will remain readily apparent to those skilled in the art, since the generic principles of the present invention have been defined herein specifically to provide a relatively economical and easily manufactured objective lens system. The derivation of the formulas and the relation of the powers set forth herein can be accomplished with the assistance of a computer. The present invention represents the parameters of a compromise balance of acceptable aberrations which can be relatively easily manufactured to provide a low cost lens system.

In the drawings, schematic cross sectional views disclose the position of the lens elements. Due to the number of lens elements involved, it was not deemed appropriate to include individual designation of the radii of curvature and axial distances for each lens element and air space. These values, however, are provided in the accompanying tables set forth herein, and the schematic cross sectional views of the respective embodiments follow the normal conventions of the light source at the left-hand side of the drawing and the disk at the right-hand side.

The features of the present invention which are believed to be novel are set forth with particularity in the appended claims. The present invention, both as to its organization and manner of operation, together with further objects and advantages thereof, may best be understood by reference to the following description, taken in conjunction with the accompanying drawings.

As shown in FIG. **3**, the present invention provides the objective lens system (**18**) for optical recording type disks, comprising from the light source side to the disk side, a first lens element (L_1) having a positive refractive power, said first lens element (L_1) having at least an aspherical a second lens element (L_2) having a positive refractive power, and wherein the objective lens system (**18**) fulfills the following condition:

$$-\frac{1}{2}<\beta<-\frac{1}{8} \quad (1)$$

wherein, β represents the magnification of the whole lens system (**18**).

The objective lens system according to the present invention consist of only two lens elements (L_1) (L_2). If one of such two lens elements has a negative refracting power, a positive refracting power of another lens element must be too strong for obtaining a predetermined positive power of the whole lens system. Therefore, in the present invention, both of two lens elements have positive refracting powers, respectively.

In the present invention, the objective lens system (**18**) concentrate into a spot on the disk (**10**) the light emitted from the laser light source, without converting the light to a parallel light bundle by the conventional collimating lens system. Thus, the objective lens system according to the present invention must be corrected well in various aberrations with respect to a finite object. It is different from the conventional objective lens system which must be well corrected in various aberrations with respect to an infinite object, since the conventional objective lens system is located in a parallel light bundle formed by the collimating lens system. Thus, the magnification β of the conventional objective lens system is zero.

On the other hand, the magnification β of the objective lens system according to the present invention is limited as shown in the condition (1). If the upper limit of the condition (1) is violated, it is difficult to shorten the distance between the laser light source (**2**) and the disk (**10**). Contrary, if the lower limit of the condition (**1**) is violated, the following defects is present: At first, a space for locating the beam splitter or the diffraction grating is too decreased. Next, it becomes difficult to read the correct information memorized by the disk, since the information of high density memorized by the disk can not be magnified enough, and since the offaxial aberrations are generated. Therefore, the magnification β of the objective lens system according to the present invention is limited as shown in the condition (1).

Here, even if the conventional objective lens system used in the magnification $\beta=0$ is applied to the optical system relating to the present invention in which the objective lens system is used in the magnification β limited in the condition (1), it is impossible to achieve a high resolving power reaching to 1 μm because the numerical aperture NA is decreased. Namely, the following relationship is held:

$$NA\beta=NA\infty/(1-\beta)$$

wherein, $NA\beta$ represents the numerical aperture of the lens system when $\beta<0$, $NA\infty$ represents the numerical aperture thereof when $\beta=0$, and β represents the magnification thereof. Thus, if the objective lens system having a numerical aperture $NA\infty=0.45$ is used in the condition $\beta=-\frac{1}{4}$, the numerical aperture $NA\beta$ in such condition is 0.36. Therefore, it is impossible to achieve the resolving power of 1 μm. Here, if the diameter of the objective lens system is increased in order to increasing the numerical aperture thereof in such condition, it becomes difficult to correct the various aberrations well. Therefore, the conventional objective lens system used in the condition $\beta=0$ can not used in the magnification limited in the condition (1).

However, if the conventional objective lens system itself is shifted for tracking such lens system should be corrected in various aberrations with respect only to the paraxial rays, because the parallel light rays are always incident on such lens system. On the other hand, if the objective lens system according to the present invention is shifted for tracking, various aberrations must be also corrected well for the offaxial rays. Thus, the objective lens system according to the present invention must be corrected well in various aberrations not only for the paraxial rays but also for the offaxial rays.

In the present invention, an aspherical surface is introduced in order to correct the aberrations well. Here, it is not effective for improving the aberrations to introduce an aspherical surface to the second lens element (L_2). The reason is as follows: In the objective lens system according to the present invention, the light rays emitted from the light source (**2**) are incident on the

second lens element (L_2) after they has been refracted by the first lens element (L_1). Thus, a height of a light ray incident on the first lens element (L_1) is relatively larger than that on the second lens element (L_2). Therefore, if an aspherical surface is introduced to any surface of the second lens element (L_2) for correcting the spherical aberration, the large coma aberration is generated in the offaxial region and can not be corrected.

Therefore, in the present invention, an aspherical surface is introduced to either of the two surfaces of the first lens element (L_1). In the case when the light source side surface (r_1) of the first lens element (L_1), the positive spherical aberration is generated too much by the surface (r_1), and other three surfaces (r_2) (r_3) and (r_4) of the first and second lens elements (L_1) and (L_2) not only correct the coma aberration and the astigmatism well, but also generate the negative spherical aberration for cancelling the above positive spherical aberration. Thus, good correction of the aberrations is achieved in both of the paraxial and offaxial regions.

The light source side surface (r_1) of the first lens element (L_1), should meet the following conditions to be effective for correcting the aberrations and for securing a proper working distance.

$$0.70<f_1/f_2<1.50 \quad (2)$$

$$0.33<f_1/f<1.30 \quad (3)$$

$$-1.00<\frac{r_1+r_2}{r_1-r_2}<1.00 \quad (4)$$

wherein, f_1 represents the focal length of said first lens element (L_1), f_2 represents the focal length of the second lens element (L_2), d_1 represents the axial thickness (d_1) of the first lens element (L_1), f represents the focal length of the whole lens system, r_1 represents the paraxial radius of curvature of the light source side surface (r_1) of the first lens element (L_1), and r_2 represents the radius of curvature of the disk side surface (r_2) of the first lens element (L_1).

Condition (2) defines the ratio in refraction index between the first and second lens element (L_1) and (L_2). If the focal length f_1 of the first lens element (L_1) becomes short over the lower limit of the condition (2), the working distance of such lens system becomes too short. Therefore, such lens system is impractical since it is in danger to collide with the disk by the vibration. On the other hand, if the focal length f_1 of the first lens element (L_1) becomes long over the upper limit of the condition (2), since the refractive power of the second lens element (L_2) becomes great compared with that of the first lens element (L_1), it becomes difficult to correct the coma aberration and the astigmatism in the offaxial region well.

Condition (3) limits the axial thickness d_1 of the first lens element (L_1). The axial thickness d_1 mainly influences the working distance WD of the objective lens system and the correction of the astigmatism and the coma aberration in the offaxial region. If the lower limit of the condition (3) is violated, it becomes impossible to secure enough working distance, because the axial distance d_2 between the disk side surface (r_2) of the first lens element (L_1) and the light source side surface (r_3) of the second lens element (L_2) must become large for correcting the aberrations in the offaxial region. Furthermore, the aberrations in the offaxial region are deteriorated considerably compared with that in the paraxial region, because the inclination of the image plane of the objective lens becomes large. On the other hand, if the upper limit of the condition (3) is violated, although the working distance WD is secured enough, the compactness of the objective lens system is deteriorated and the weight thereof becomes too heavy, since the axial thickness (d_1) of the first lens element (L_1) becomes excessively large.

Condition (4) limits the shape of the first lens element (L_1). It means that the first lens element (L) is a bi-convey lens element. If the lower limit of the condition (4) is violated, the astigmatism is generated excessively. Here, although such astigmatism would be corrected well by means of the second lens element (L_2), it becomes difficult to correct the coma aberration. If the upper limit of the condition (4) is violated, it becomes difficult to correct the aberrations, since the refractive power of the first lens element (L_1) becomes too weak so that the height of the light rays incident on the second lens element (L_2) becomes too large.

In addition to the above conditions (1) to (4), the following conditions is effective for correcting the aberrations in both of the paraxial and offaxial region.

$$0.2<\phi_3<0.7 \quad (5)$$

$$0.6<\phi_2+\phi_3<1.0 \quad (6)$$

$$|\phi_2-\phi_3|<0.6 \quad (7)$$

provided by, $\phi_2=(1-N_1)\cdot f/r_2$, and $\phi_3=(N_2-1)\cdot f/r_3$, wherein, N_1 represents the refractive index of the first lens element (L_1), N_2 represents the refractive index of the second lens element (L_2) and r_3 represents the radius of curvature of the light source side surface (r_3) of the second lens element (L_2).

Condition (5) defines the refractive power of the light source side surface (r_3) of the second lens element (L_2). If the lower limit of the condition (5) is violated, it is necessary to increase the refractive power of the disk side surface (r_4) of the second lens element (L_2) for achieving a predetermined magnification, which causes to generate the coma aberration undesirably, and to increase undesirably the sensitivity of the optical performance to a manufacturing error, since the radius of curvature of the disk side surface (r_4) of the second lens element (L_2) becomes too small. On the other hand, if the upper limit of the condition (5) is violated, the optical performance in the offaxial region is excessively deteriorated since the astigmatism is considerably generated.

Conditions (6) and (7) relate to the balance in refractive power between the disk side surface (r_2) of the first lens element (L_1) and the light source side surface (r_3) of the second lens element (L_2). If the lower limit of the condition (6) is violated, the coma aberration is undesirably generated, since it is necessary to increase the refractive powers of the light source side surface (r_1) of the first lens element (L_1) and the disk side surface (r_4) of the second lens element (L_2) for achieving the predetermined magnification. Contrary, if the upper limit of the condition (6) is violated, the radii of curvature of the disk side surface (r_2) of the first lens element (L_1) and the light source side surface (r_3) of the second lens element (L_2) become considerably smaller since the refractive indices of such two surfaces (r_2) and (r_3) become too strong, and causes an increase in the sensitivity of the optical performance to manufacturing errors. If the upper or lower limit of the condition (7) is violated, the

proper balance between the refractive power of the disk side surface (r_2) of the first element (L_1) and that of the light source side surface (r_3) of the second lens element (L_2) can not be maintained, and results the correction of the aberrations in the offaxial region, especially the correction of the astigmatism therein, becomes difficult.

In the case when an aspherical surface is introduced on the disk side surface (r_2) of the first lens element (L_1), it is possible to correct not only the spherical aberration but also to correct the astigmatism and the coma aberration in the offaxial region. In this case, the following conditions are effective for correcting the aberrations;

$$0.47<d_1/f<1.25 \quad (8)$$

$$0<d_2/d_1<1.00 \quad (9)$$

wherein, f represents the focal length of the whole lens system, d_1 represents the axial thickness (d_1) of the first lens element (L_1), and d_2 represents the axial distance (d_2) between the disk side surface (r_2) of the first lens element (L_1) and the light source side surface (r_3) of the second lens element (L_2).

Condition (8) is effective for correcting the astigmatism. If the lower limit of the condition (8) is violated, it is difficult to correct the astigmatism, and to secure the proper edge thickness of the first lens element (L_1) since the axial thickness thereof becomes too small. If the upper limit of condition (8) is violated, it is difficult to correct the spherical aberration even though an aspherical surface is introduced to the lens system. Furthermore, the total weight of the objective lens system becomes too heavy for practical use since the thickness of the first lens element (L_1) becomes too thick.

On the other hand, if the upper limit of condition (9) is violated by increasing the axial distance (d_2), it becomes difficult to correct the spherical aberration since the refractive power of the disk side surface (r_2) of the first lens element (L_1) must be increased, even though an aspherical surface is introduced to such surface (r_2). Furthermore, if the upper limit of the condition (9) is violated by increasing the axial distance (d_2), it becomes difficult to correct the coma aberration. Namely, although the coma aberration, which is increased in proportion to an increase in the axial distance (d_2), may be corrected by increasing the axial thickness (d_1) of the first lens element (L_1), such correction is improper since the axial thickness (d_1) is limited in the condition (8).

In the case when an aspherical surface is introduced on the disk side surface (r_2) of the first lens element (L_1), the following conditions are further effective for correcting the coma aberration in addition to the above conditions (8) and (9):

$$0.80<f\cdot(\phi_1+\phi_4)<1.30 \quad (10)$$

$$0.10<f\cdot\phi_4<0.80 \quad (11)$$

provided by, $\phi_4=(1-N_2)/r_4$, $\phi_1=(N_1-1)/r_1$, wherein, N_1 represents the refractive index of the first lens component (L_1), N_2 represents the refractive index of the second lens component (L_2), r_1 represents the radius of curvature of the light source side surface (r_1) of the first lens element (L_1), and r_4 represents the radius of curvature of the disk side surface (r_4) of the second lens element (L_2).

In order to correct the coma aberration well, a proper balance between the refractive power of the light source side surface (r_1) of the first lens element (L_1) and that of the disk side surface (r_4) of the second lens element (L_2), is necessary. The condition (10) defines such balance. If the lower limit of the condition (10) is violated, spherical aberration is undesirably generated. Here, although such spherical aberration may be corrected by increasing the refractive power of the light source side surface (r_1) of the first lens element (L_1), such correction generates excessive coma aberration, since the above proper balance is not maintained. Such coma aberration can not be corrected by introducing an aspherical surface to the disk side surface (r_2) of the first lens element (L_1). On the other hand, if the upper limit of the condition (10) is violated, the coma aberration is generated excessively, which can not be corrected by introducing an aspherical surface.

The condition (11) defines the refractive power of the disk side surface (r_4) of the second lens element (L_2). If the lower limit of the condition (11) is violated, the refractive power of the light source side surface (r_1) of the first lens element (L_1) must become too strong, in order to achieving a predetermined refractive power of the objective lens system. This generates undesirable the coma aberration, which can not be corrected by introducing an aspherical surface. If the upper limit of the condition (11) is violated, the refractive power of the disk side surface (r_4) of the second element (L_2) becomes too strong. This results in the generation of coma aberration on such surface (r_4), which would not be corrected well.

In the present invention, a method for manufacturing a lens element having an aspherical surface is not limited at all. For example, such a lens element can be manufactured by a press, if it is constituted of a glass material. On the other hand, such a lens element can be manufactured by well-known molding method, if it is constituted of a plastic material. Furthermore, such a lens element can be manufactured by cementing a thin layer of a synthetic resin or a plastic material, which has an aspherical surface of desired shape, to a predetermined spherical surface of a lens element made of a glass material, the spherical surface having paraxial radius of curvature of the desired aspherical surface, as shown in the embodiments 16 and 29 indicated below.

The following Tables 1 to 34 disclose, respectively, the first through thirty-fourth embodiments of the present invention. In the Tables, f equals the focal length, r is the radius of curvature with respective sub numbers indicating the surfaces from the light source to disk side along the optical axis, d represents the axial distance and includes both the air spaces and the actual thickness of the lenses along the optical axis, and finally n equals the refractive index in the wavelength $\lambda=800$ nm and again, the sub numbers refer to the particular optical element from the light source to disk side. The asterisk (*) represents the aspheric surface defined as follows, and its coefficients are shown at the bottom of respective Tables:

$$X = 1 + \frac{Coh2}{\sqrt{1-\epsilon Co^2h^2}} + \Sigma Cih^{2i} \; (i = 1, 2, 3 \ldots)$$

wherein, X represents the coordinate along the optical axis measured from the top of the basic surface, h represents the coordinate perpendicular to the optical axis measured from the optical axis (height from the optical axis), Co represents the curvature (1/r) of the basic surface, Ci represent the aspherical surface coefficients,

and ϵ represents the quadric surface coefficient of the basic surface.

To all Tables, in addition to the objective lens system according to each embodiment, a glass block (G) is shown in the light source side of the objective lens system, which corresponds to the beam splitter (**6**), the diffraction grating (**16**) or a cover glass of the laser light source (**2**). The radii of curvature of the light source side surface (r_{g1}) of the glass block (G) and the disk side surface (r_{g2}) thereof are indicated as r_{g1} and r_{g2}, respectively, in the Tables. The axial thickness (d_{g1}) of the galss block (G) is indicated as d_{g1}, and the axial distance (d_{g2}) between the disk side surface (r_{g2}) of the glass block (G) and the light source side surface (r_1) of the first lens element (L_1). The refractive index of the glass block (G) in the wavelength of 800 nm is indicated as Ng. Furthermore, in all embodiments, a plate (P) is located on the disk side of the objective lens system, which corresponds to the disk (**10**). The radii of curvature of the plate (P) are indicated as r_{p1} and r_{p2} from the light source to the disk side, respectively. The axial distance between the disk side surface (r_4) of the second lens element (L_2) and the light source side surface (r_{p1}) of the plate (P) is indicated as d_4, and the axial thickness of the plate (P) is indicated as dp. The refractive index of the plate (P) in the wavelength of 800 nm is indicated as Np.

Furthermore, in all Tables, NA represents the numerical aperture of the objective lens system according to the embodiment of the disk side, f represents the focal length thereof, WD represent the working distance thereof, and β represents the magnification thereof.

$f \cdot \phi_4 = 0.44$

What is claimed is:

1. An objective lens system for optical recording type disks, comprising from a light source side to a disk side;

a first lens element of a positive refractive power; and

a second lens element of a positive refractive power,

wherein the light source side surface of the first lens element is aspherical while all of the other surfaces are spheric, and wherein the lens system fulfills the following conditions:

$$-\tfrac{1}{2} < \beta < -\tfrac{1}{8}$$

$$0.70 < f_1/f_2 < 1.50$$

$$0.47 < d_1/f < 1.25$$

wherein:

β represents the magnification of the whole lens system;

d_1 represents the axial thickness of the first lens element;

f_1 represents the focal length of the first lens element;

f_2 represents the focal length of the second lens element; and

f represents the focal length of the whole lens system.

2. An objective lens as claimed in claim **1**, wherein the lens system further fulfills the following condition:

$$-1.00 < (r_1+r_2)/(r_1-r_2) < 1.00$$

wherein:

r_1 represents the paraxial radius of curvature of the light source side surface of the first lens element; and

r_2 represents the radius of curvature of the disk side surface of the first lens element.

3. An objective lens system as claimed in claim **2**, wherein the lens system further fulfills the following conditions:

$$0.2 < \phi_3 < 0.7$$

$0.6<\phi_2+\phi_3<1.0$

$|\phi_2-\phi_3|<0.6$

provided by:

$\phi_2=(1-N_1)\cdot f/r_2$

$\phi_3=(N_2-1)\cdot f/r_3$

wherein:

N_1 represents the refractive index of the first lens element;

N_2 represents the refractive index of the second lens element; and

r_3 represents the radius of curvature of the light source side surface of the second lens element.

4. An objective lens system for optical recording type disks, comprising from a light source side to a disk side;

a first lens element of a positive refractive power; and

a second lens element of a positive refractive power, wherein the disk side surface of the first lens element is aspherical while all of the other surfaces are spheric, and wherein the lens system fulfills the following conditions:

$-\frac{1}{2}<\beta<-\frac{1}{8}$

$0.47<d_1/f<1.25$

$0<d_2/d_1<0.85$

wherein:

β represents the magnification of the whole lens system;

d_1 represents the axial thickness of the first lens element;

d_2 represents the axial distance from the disk side surface of the first lens element to the light source side surface of the second lens element; and

f represents the focal length of the whole lens system.

5. An objective lens system as claimed in claim **4**, wherein the lens system further fulfills the following conditions:

$0.80<f\cdot(\phi_1+\phi_4)<1.30$

$0.10<f\cdot\phi_4<0.80$

provided by:

$\phi_1=(N_1-1)/r_1$

$\phi_4=(1-N_2)/r_4$

wherein:

N_1 represents the refractive index of the first lens element;

N_2 represents the refractive index of the second lens element;

r_1 represents the radius of curvature of the light source side surface of the first lens element; and

r_4 represents the radius of curvature of the disk side surface of the second lens element.

[57] **ABSTRACT**

An objective lens system for use in a device for optically reading digital data on an optical disk is constituted by a single objective lens without use of a collimator lens element. A light source side aspherical surface of the objective lens element has a positive refractive power and a disk side surface thereof has a positive refractive power, too. The objective lens system is used with the projecting magnification β which falls within the range $-\frac{1}{2}<\beta<-\frac{1}{8}$.

The objective lens system fulfills the following condition:

$$0.9 \leqq (N_1-1)r_1/f \leqq 3.9$$

$$1.4 \leqq d_1 r_1/f^2 \leqq 4.0$$

$$1.4 \leqq d_1^2/f^2(N_1-1) \leqq 4.0$$

wherein,

f represents the focal length of the single lens element;

r_1 represents the paraxial radius of curvature of the light source side surface of the single lens component;

N_1 represents the refractive index of the single lens element; and

d_1 represents the axial thickness of the single lens element.

OBJECTIVE LENS SYSTEM FOR OPTICAL READING DEVICE

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to an objective lens system for a device for optically reading digitalized information on an optical disk such as DAD.

2. Description of the Prior Art

Conventional objective lens systems for use in a device for optically reading digitalized information need a collimator lens element (c) as shown in FIG. **6** when an objective lens is constituted by a single lens element or need an objective lens constituted by a plurality of lens elements as shown in FIG. **7** when no collimator lens element (c) is provided. In case of the former type, the collimator lens element (c) is always fixed while the objective lens element (L) is shifted, so that two lens-barrels are needed, resulting in difficulty of adjustment of the optical axis of the whole optical system.

As the objective lens systems of this type usually has an aspherical surface on the single objective lens element, optical performance is seriously deteriorated due to misalignment of the objective lens with the whole optical system and thus the adjustment of the optical axis of the single lens element to the whole optical system should be carried out very precisely. Also in case of the latter type, in which the objective lens element comprises a plurality of lens elements, it is necessary to arrange the lens barrel very precisely to maintain sufficient optical performance although an objective lens systems of this type need a larger space for the arrangement of the lens barrel as compared with those of the former type and distortion of the lens barrel due to the change of temperature causes misalignment of the lens elements, so that the optical performance tends to be deteriorated.

SUMMARY OF THE INVENTION

An object of the present invention is to provide an improved objective lens system for an optical reading device.

Another object of the present invention is to provide an objective lens system which does not have a collimator lens element but has an objective lens constituted by a single lens element adapted to receive directly light rays from a semiconductor laser and to converge the light rays on an optical disk.

Still another object of the present invention is to provide an objective lens system of the above mentioned type, in which the diameter of the single objective lens element can be finished with less precision so long as the centers of both sides of the lens element coincide with one another, and in which lens barrels can be manufactured with less precision, whereas the optical performance of the single objective lens element can be maintained when the lens barrel supporting the single objective lens element is provided with an adjusting mechanism which adjusts the inclination and deviation of the lens element relative to the optical axis of the whole optical system.

Further object of the present invention is to provide an objective lens system which can be used with definite magnification.

Still further object of the present invention is to provide an objective lens system of the above mentioned type, wherein aberrations are well corrected.

To achieve these objects, an objective lens system according to the present invention has an objective lens constituted by a single lens element; having a light source side aspherical surface with a positive refractive power and a disk side surface with a positive refractive power. The objective lens system is used with the projecting magnification β which falls within the range, $-\frac{1}{2}<\beta<-\frac{1}{8}$, wherein the objective lens system fulfills the following conditions:

$$0.9 \leqq (N_1-1)r_1/f \leqq 3.9$$

$$1.4 \leqq d_1 r_1/f^2 \leqq 4.0$$

$$1.4 \leqq d_1^2/f^2(N_1-1) \leqq 4.0$$

wherein f represents the focal length of the single lens element, r_1 represents the paraxial radius of curvature of the light source side surface of the single lens element, N_1 represents the refractive power of the single lens element and d_1 represents the axial thickness of the single lens element.

The objects and features of the present invention which are believed to be novel are set forth with particularly in the appended claims. The present invention, both as to its orgainzation and manner of operation, together with further objects and advantages thereof, may best be understood by reference to the following description, taken in connection with the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWING

FIG. **1** is a cross sectional view of the objective lens system according to embodiments 1, 3, 4, 5, 7, 8, 9, 10, 11, 12 of the present invention;

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

The following description is provided to enable any person skilled in the optical field to make and use the invention and sets forth the best modes contemplated by the inventor for carrying out my invention. Various modifications, however, will remain readily apparent to those skilled in the art, since the generic principles of the present invention have been defined herein specifically to provide a relatively economical and easily manufactured objective lens system. The derivation of the formulas and the relation of the powers set forth herein can be accomplished with the assistance of a computer. The present invention represents the parameters of a compromise balance of acceptable aberrations which can be relatively easily manufactured to provide a low cost lens system.

In the drawings, schematic cross sectional views disclose the position of the lens element. Values of the radii of curvature and axial distances for each lens element and air space are provided in the accompanying tables set forth herein. The schematic cross sectional views of the respective embodiments follow the normal conventions of the light source at the left-hand side of the drawing and the disk at the right hand side.

As shown in FIGS. **1** and **2**, the present invention provides an objective lens system for a device for optically reading digital data on an optical disk with a single lens element (L) whose light source side aspherical surface (r_1) has a positive refractive power, and whose disk side surface (r_2) has a positive refractive index, and the objective lens system is used with the projecting magnification β which falls within the range,

$$-\frac{1}{2}<\beta<-\frac{1}{8}. \quad (2)$$

With no collimator lens arranged in front of the single objective lens element (L), incident light rays come into the single lens element (L) from an oblique direction inclined to the optical axis, so that the objective lens system according to this invention is used with a definite projecting magnification. The range of the magnification is limited in condition (1). If the magnification β becomes greater beyond the upper limit of condition (1), the distance between the light source and the disk cannot be shortened to the extent leading to satisfactory compactization of the objective lens system.

On the other hand, if the magnification β becomes smaller beyond the lower limit of condition (1), a space for arrangement of a beam splitter and so on cannot be assured and the image height required for correcting aberrations well cannot be provided in case that the objective lens element (L) is arranged inclined.

Assume here that a conventional objective lens element whose aberrations are corrected well at the magnification $\beta=0$ is used with the magnification 8 remaining in the range $-\frac{1}{2}<\beta<-\frac{1}{8}$ as an objective lens of an objective lens system not necessitating a collimator lens. In this case, the numerical aperture decreases, so that sufficient resolving power of 1 μm, cannot be achieved. This can be understood from the following equation

$$NA\beta=NA\infty/(1-\beta)$$

in which $NA\infty$ is the numerical aperture of the disk side surface at the magnification $\beta=0$ and $NA\beta$ is the numerical aperture of the disk side surface of the objective lens element at the magnification $\beta<0$. If the objective lens element with $NA\infty=0.45$ is used and at the magnification $\beta=-\frac{1}{4}$, the $NA\beta$ becomes 0.36. The resolving power becomes poorer as the numerical aperture $NA\beta$assumes a smaller value. Therefore at the magnification $\beta=-\frac{1}{4}$ with $NA\beta=0.36$ resolving power of 1 μm, cannot be achieved. If the aperture of the objective lens element (L) is increased in order to make $NA\beta$ great, spherical aberration in the on-axial region, and the coma aberration in the off-axial region, are caused considerably. To correct these aberrations the objective lens system according to the present invention fullfills the following conditions:

$$0.9\leqq(N_1-1)r_1/f\leqq3.9 \quad (2)$$

$$1.4\leqq d_1r_1/f^2\leqq4.0 \quad (3)$$

$$1.4\leqq d_1^2/f^2(N_1-1)\leqq4.0 \quad (4)$$

wherein, f represents the focal length of the single lens element, r_1 represents the paraxial radius of curvature of the light source side surface of the single lens element, N_1 represents the refractive index of the single lens element and d_1 represents the axial thickness of the single lens element.

If the radius of curvature of the light source side surface (r_1) becomes small beyond the lower limit of the condition (2), the coma is generated, which is hard to be corrected. If the refractive power of the single lens element (L) becomes small beyond the lower limit of the condition (2), the absolute value of the radius of curvature of the light source side surface or the disk side surface of the lens element should be small in order to keep the predetermined focal length, but in either case the coma is generated, which is hard to be corrected. On the other hand, if the radius of curvature of the light source side surface (r_1) increases, considerable coma flare is generated near the pupil of the single lens element. This coma flare can be corrected by forming the lens element of a glass with high refractive power, but the refractive power of the lens element becomes great beyond the upper limit of the condition (2), resulting in generation of the astigmatism and failure to keep the optical performance in off-axial region well.

If the axial thickness (d_1) or the radius of curvature (r_1) of the light source side surface of the single lens element (L) becomes small beyond the lower limit of the condition (3), the absolute value of the radius of curvature of the disk side surface (r_2) should be made greater in order to keep the predetermined focal length so that the astigmatism becomes difficult to be corrected. In contrast thereto, if the axial thickness (d_1) or the radius of curvature (r_1) of the light source side surface of the single lens element (L) becomes great beyond the upper limit of the condition (3), the absolute value of the radius of curvature of the disk side surface (r_2) should be made small, so that even with the effect of the aspherical surface the coma is generated, which is difficult to be corrected.

If the axial thickness (d_1) becomes small or the positive refractive power of the single lens element (L) becomes great beyond the lower limit of the condition (4), the absolute value of the radius of curvature of the light source side surface (r_1) or the disk side surface (r_2) should be made great. If, here, the absolute value of the radius of curvature of the disk side surface (r_2) becomes great, the astigmatism becomes difficult to be corrected, and if that of the light source side surface (r_1) becomes great, the coma flare is generated, which is difficult to be corrected even with the effect of the aspherical surface. On the other hand, if the axial thickness (d_1) becomes great or the positive refractive power becomes small beyond the upper limit of the condition (4), the absolute value of the radius of curvature of either side surface should be made small, so that the coma is generated, which cannot be corrected well even with the effect of the aspherical surface.

It is desired that the disk side surface is aspherical for better correction of the comma.

Additionally the following condition is effective in combination with the conditions (2), (3), (4) in order to correct the coma much btter:

$$0 \leqq f(N_1^2 - N_1 - 1)/|r_2| \leqq 1.2 \quad (5)$$

wherein, r_2 represents the radius of curvature of the disk side surface of the single lens.

If the refractive power of the single lens element (L) becomes small beyond the lower limit of the condition (5), the absolute value of the radius of curvature of the light source side surface (r_1) or the disk side surface (r_2) should be small, so that the coma cannot be corrected well. Furthermore, in case the disk side surface is aspherical, the absolute value of radius (r_2) of this surface becomes small, causing the radius of curvature of the disk side surface (r_2) assume a small value so that the distance from the aspherical surface to the imaging plane tangent to the top point of the aspherical surface becomes great, much precision is needed to manufacture a cast and to form the aspherical surface by molding. On the other hand, if the absolute value of the radius of curvature of the disk side surface (r_2) becomes small beyond the upper limit of the condition (5), the coma becomes hard to be corrected.

According to the present invention, the following conditions are effective instead of the above conditions, (2), (3), and (4):

$$1.4 \leqq (N_1 - 1)r_1/f \leqq 3.9 \quad (6)$$

$$1.6 \leqq d_1 r_1/f^2 \leqq 4.0 \quad (7)$$

wherein, f represents the focal length of the single lens element, r_1 represents the paraxial radius of curvature of the light source side surface of the single lens element, N_1 represents the refractive index of the single lens element, and d_1 represents the axial thickness of the single lens element.

This example of the invention is shown in FIGS. **1** and **2**.

In the case where the light source side surface is aspherical and the disk side surface is spherical, it is desired to form the single lens element of a glass with a higher refractive power in order to correct the coma better. To this end it is desired to fulfill conditions (6) and (7). These conditions have the same meanings respectively as the conditions (2) and (3) and if the lower and upper limits are violated, the same aberrations as in the case of violations of the conditions (2) and (3) are generated.

Additionally, the following condition is effective in combination with the conditions (6) and (7) in order to correct the coma much better:

$$0 \leqq f(N_1^2 - N_1 - 1)/|r_2| \leqq 1.2 \quad (8)$$

wherein, r_2 represents the radius of curvature of the disk side surface of the single lens element.

This condition is the same as condition (5) and if the lower and upper limits are violated, the same aberrations are generated.

Furthermore, according to the present invention, the following conditions are effective instead of the above conditions (1), (2), (3) and (4):

$$0.9 \leqq (N_1 - 1)r_1/f \leqq 3.9 \quad (9)$$

$$1.2 \leqq d_1 r_1/f^2 \leqq 4.0 \quad (10)$$

$$0.7 \leqq r_1(N_1 - 1)(1 + |\beta|)/-r_2 \leqq 3.0 \quad (11)$$

wherein,

f represents the focal length of the single lens element,

r_1 represents the paraxial radius of curvature of the light source side surface of the single lens element,

N_1 represents the refractive index of the single lens element,

d_1 represents the axial thickness of the single lens element,

r_2 represents the radius of curvature of the disk side surface of the single lens element and

β represents the magnification of the single lens element.

This example of the invention is shown in FIGS. **3**, **4** and **5**.

The conditions (9) and (10) have the same meanings respectively as conditions (2) and (3) and the same aberrations as in the case of violation of the conditions (2) and (3) are generated if the upper or lower limits are violated.

Condition (11) shows the relation between the shape of the single lens element (L) and the magnification. If the magnification becomes greater beyond the upper limit of the condition (11), aberrations in the off-axial region, especially the coma become difficult to be corrected. And if the absolute value of the radius of curvature of the light source side surface (r_1) becomes greater as compared with that of the disk side surface (r_2) beyond the upper limit of condition (11), aberrations in the off-axial region, especially coma cannot be corrected

well. On the other hand, if the absolute value of the radius of curvature of the light source side surface (r_1) becomes smaller as compared with that of the disk side surface (r_2) beyond the lower limit of condition (11), coma flare is generated at the marginal ray, and it cannot be corrected well.

The disk side surface is desired to be aspherical so that the coma may be corrected well.

It is desired that conditions (9) and (10) have the following ranges respectively in order to correct abberations better.

$$1.4 \leqq (N_1-1)r_1/f \leqq 3.9 \quad (12)$$

$$1.6 \leqq d_1 r_1/f_2 \leqq 4.0 \quad (13)$$

According to the present invention the following conditions are effective instead of the above conditions (2), (3) and (4):

$$0.9 < (N_1-1)r_1/f < 3.9 \quad (14)$$

$$0.6 < r_1/r_2 \cdot (N_1-1) < 1.7 \quad (15)$$

$$0.5 < \epsilon < 1.5 \quad (16)$$

wherein, f represents the focal length of the single lens element, r_1 represents the paraxial radius of curvature of the light source side surface of the single lens element, N_1 represents the refractive index of the single lens element, r_2 represents the radius of curvature of the disk side surface of the single lens element, and ϵ represents the conic constant.

This example of the invention is shown in FIGS. 1 and 2.

Condition (14) is the same as condition (2) and has the same meaning.

Condition (15) is the condition for correcting aberrations in the off-axial region. If the refractive power of the single lens element at the predetermined focal length becomes greater than the upper limit of the condition (15), the absolute value of the radius of curvature of the disk side surface (r_2) is increased, so that the astigmatism is generated. If the ratio of the radius of curvature of the light source side surface (r_1) to that of the disk side surface (r_2) becomes greater than the upper limit of condition (15), the absolute value of the radius of curvature of the disk side surface (r_2) becomes excessively small, so that the coma is generated, which cannot be corrected well. On the other hand, if the refractive power of the single lens element becomes smaller than the lower limit of condition (15), the absolute value of the radius of curvature of the disk side surface is decreased, so that the coma is generated. And if the ratio of the radius of curvature of the light source side surface (r_1) to that of the disk side surface (r_2) decreases beyond the lower limit of condition (15), the absolute value of the radius of curvature of the disk side surface (r_2) becomes excessively great, so that the astigmatism is generated and a satisfactorily good optical performance at the desired image height cannot be obtained.

Condition (16) is the condition for correcting aberrations in off-axial region. If the conic constant becomes great beyond the upper limit of condition (16), spherical aberration undergoes under-correction especially at the marginal ray. On the other hand, if the conic constant becomes small over the lower limit of condition (16), spherical aberration undergoes over-correction, which is difficult to be corrected.

The aspherical surface of the single lens element (L) can be provided by forming an aspherical layer of grease on the spherical glass.

The following tables 1 to 18 disclose, respectively, design parameters of the first through 18th embodiments of the present invention. In the tables, f equals the focal length of the whole lens system, rg_1 and rg_2 is the radius of curvature of the light source side and disk side surface of the cover glass (G) of the semiconductor laser, r_1 and r_2 are the radii of curvature respectively of the light source side surface and the disk side surface, rp_1 and rp_2 are the radius of curvature of the light source side and disk side surface of the cover glass (P) of the disk, dg_1, dg_2, (d_0), d_1, d_2 and dp represent the axial distance including both air spaces and the actual thickness of the lens element, cover glass of the semiconductor and the disk and finally Ng, N_1, and Np represent respectively the refractive index of the cover glass of the semiconductor (G), the single lens element (L), and the cover glass of the disk (P) at the wavelength λ=800 nm. The asterisk (*) represents the aspherical surface defined as follows, and values for coefficients appearing in the formula are shown at the bottom of respective tables:

$$x = \frac{Coh^2}{1+\sqrt{1-\epsilon Coh^2}} + \Sigma c_i h^{2i} \; (i = 1,2,3,\ldots m)$$

wherein, x represents the coordinate along the optical axis measured from an imaginary plane tangent to the aspherical surface perpendicularly to the optical axis, h represents the coordinate perpendicular to the optical axis measured from the optical axis, Co represents paraxial curvature ($1/r_1$) of the light source side surface of the lens (L), ϵ represents the conic constant and c_i represent the aspherical surface coefficients. Furthermore, NA represents the numerical aperture of the objective lens system, and β represents the magnification.

Among the following embodiments, it should be noted that the paraxial curvature ($Co=1/r_1$) of the aspherical surface is zero in the first to third embodiments. This is favorable to a test or measurement of the formed shape of the aspherical surface in manufacturing, since the paraxial curvature can be left out of consideration.

What is claimed is:

1. An objective lens system with a single lens element for use in a device for optically reading digital data on an optical disk, said single lens element including:

a light source side aspherical surface having a positive refractive power; and

a disk side surface having a positive refractive power; and wherein

said objective lens system is used with the projecting magnification β, $-\frac{1}{2} < \beta < -\frac{1}{8}$ and the objective lens system fulfills the following conditions:

$$0.9 \leqq (N_1 - 1)r_1/f \leqq 3.9$$

$$1.4 \leqq d_1r_1/f^2 \leqq 4.0$$

$$1.4 \leqq d_1^2/f^2(N_1 - 1) \leqq 4.0$$

wherein:

f represents the focal length of the single lens element;

r_1 represents the paraxial radius of curvature of the light source side surface of the single lens element;

N_1 represents the refractive index of the single lens element; and

d_1 represents the axial thickness of the single lens element.

2. An objective lens system as claimed in claim 1, wherein said disk side surface is an aspherical surface.

3. An objective lens system as claimed in claim 2, wherein the objective lens system further fulfills the following condition:

$$0 \leqq f(N_1^2 - N_1 - 1)/|r_2| \leqq 1.2$$

wherein:

r_2 represents the radius of curvature of the disk side surface of the single lens element.

4. An objective lens system with a single lens element for use in a device for optically reading digital data on an optical disk;

said single lens element including:

a light source side aspherical surface having a positive refractive power; and

a disk side surface having a positive refractive power; and wherein

said objective lens system is used with the projecting magnification β, $-\frac{1}{2} < \beta < -\frac{1}{8}$ and the objective lens system fulfills the following conditions:

$$1.4 \leqq (N_1 - 1)r_1/f \leqq 3.9$$

$$1.6 \leqq d_1 r_1/f^2 \leqq 4.0$$

wherein:

f represents the focal length of the single lens element;

r_1 represents the paraxial radius of curvature of the light source side surface of the single lens element;

N_1 represents the refractive index of the single lens element; and

d_1 represents the axial thickness of the single lens element.

5. An objective lens system as claimed in claim 4, wherein the objective lens system further fulfills the following condition:

$$0 \leqq f(N_1^2 - N_1 - 1)/|r_2| \leqq 1.2$$

wherein:

r_2 represents the radius of curvature of the disk side surface of the single lens element.

6. An objective lens system with a single lens element for use in a device for optically reading digital data on an optical disk, said single lens element including:

a light source side aspherical surface having a positive refractive power; and

a disk side surface having a positive refractive power; and wherein the objective lens system fulfills the following conditions:

$$0.9 \leqq (N_1 - 1)r_1/f \leqq 3.9$$

$$1.2 \leqq d_1 r_1/f^2 \leqq 4.0$$

$$0.7 \leqq r_1(N_1 - 1)(1 + |\beta|)/-r_2 = 3.0$$

wherein:

f represents the focal length of the single lens element;

r_1 represents the paraxial radius of curvature of the light source side surface of the single lens element;

N_1 represents the refractive index of the single lens element;

d_1 represents the axial thickness of the single lens element;

r_2 represents the radius of curvature of the disk side surface of the single lens component; and

β represents the magnification of the single lens element.

7. An objective lens system as claimed in claim 6, wherein said disk side surface is an aspherical surface.

8. An objective lens system as claimed in claim 6, herein the objective lens system further fulfills the following conditions:

$$1.4 \leqq (N_1 - 1)r_1/f \leqq 3.9$$

$$1.6 \leqq d_1 r_1/f^2 \leqq 4.0.$$

9. An objective lens system with a single lens element for use in a device for optically reading digital data on an optical disk, said single lens element including:

a light source side aspherical surface having a positive refractive power; and

a disk side surface having a positive refractive power; and wherein

said objective lens system is used with the projecting magnification β, $-\frac{1}{2} < \beta < -\frac{1}{8}$ and wherein the objective lens system fulfills the following conditions:

$$0.9 < (N_1 - 1)r_1/f < 3.9$$

$$0.6 < r_1/-r_2 \cdot (N_1 - 1) < 1.7$$

$$0.5 < \epsilon < 1.5$$

wherein:

f represents the focal length of the single lens element;

r_1 represents the paraxial radius of curvature of the light source side surface of the single lens element;

N_1 represents the refractive index of the single lens element;

r_2 represents the radius of curvature of the disk side surface of the single lens element; and

ϵ represents the conic constant.

10. An objective lens system with a single lens element for a device for optically reading digital data on an optical disk, comprising the following design parameters:

NA = 0.47 f = 1.0 β = −0.17

radius of curvature		axial distance		refractive index	
rg_1	∞				
		dg_1	0.067	Ng	1.49000

RETROFOCUS-TYPE OBJECTIVE FOR AN ENDOSCOPE

This is a continuation of application Ser. No. 743,356, filed June 10, 1985.

BACKGROUND OF THE INVENTION

(a) Field of the Invention

The present invention relates to a retrofocus-type objective for an endoscope and, more particularly, to a retrofocus-type objective for an endoscope of which aberrations are corrected favourably in all of the states that said objective is focused, i.e., the state focused on an object at a short distance, state focused on an object at a long distance, and respective states of focusing on objects at intermediate distance.

(b) Description of the Prior Art

An endoscope should have such overall structure that liquid will not enter the inside thereof. Therefore, an object for an endoscope is so arranged that the front lens thereof serves also as a cover glass. This means that, for an object for an endoscope, it is impossible to adopt the focusing method to advance the lens system as a whole or focusing method to advance the front lens through those focusing methods are widely adopted for lens systems in general. As a method devised in order to solve the above-mentioned problem, there is a known focusing method to keep the front lens group fixed and to move the rear lens group.

An objective for an endoscope disclosed in U.S. Pat. No. 4,059,344 is known as an objective for which the above-mentioned focusing method is adopted. Said known objective is designed as a retrofocus-type objective which comprises a front lens group comprising a diverging lens L_1, and a rear lens group comprising converging lenses L_2, L_3 and L_4, and which is arranged to be focused by moving the lens L_2 along the optical axis, said known objective being suitable for the use with a device which constructed so that liquid will not enter the inside.

However, said known objective has disadvantages as explained below. That is, though aberrations thereof are corrected favourably when said known objective is focused on an object at a long distance, it is difficult to say that aberrations when focused on an object at a short distance are corrected satisfactorily favourably, i.e., astigmatism is undercorrected. Therefore, the resolving power in the marginal portion is not satisfactory.

Besides, in recent years, it is strongly desired to observe an object by enlarging it as far as possible at the time of observation by an endoscope. Therefore, also in the field of objectives for endoscopes, there is an increasing demand for a lens system which can be focused on an object at the infinite distance up to an object at an extremely short distance that corresponds to the object distance at the time of photographing by a camera using a macro lens. From the above-mentioned view point, the known objective according to the afore-mentioned patent has a disadvantage that it cannot be focused on an object at an extremely short distance at which the object can be observed with a satisfactorily high magnification.

SUMMARY OF THE INVENTION

It is, therefore, a primary object of the present invention to provide a retrofocus type objective for an endoscope of which aberrations are corrected favourably in well balanced state for both cases that the objective is focused on an object at a long distance and that the objective is focused on an object at an extremely short distance, and which makes it possible to obtain a satisfactorily high magnification for observation.

The objective according to the present invention has a lens configuration as shown in FIG. **1**. That is, the objective according to the present invention comprises, in the order from the object side, a first lens component comprising a negative lens, a stop, a second lens component comprising a positive meniscus lens which is concave toward the object side, a third lens component comprising a positive lens, a fourth lens component comprising a positive lens and a negative lens, and a fifth lens component comprising a positive lens. Besides, the objective according to the present invention is arranged to be focused by advancing the third and fourth lens components and, moreover, arranged to fulfill the conditions (1) and (2) shown below:

$$-0.9 < f_1/f_a \tag{1}$$

$$1.0 < f_2/f_a < 1.3 \tag{2}$$

where, reference symbol f_1 represents the focal length of the first lens component, reference symbol f_2 represents the total focal length of the second through the fifth lens components, and reference symbol f_a represents the focal length of the lens system as a whole when focused on an object at a short distance.

Generally, retrofocus-type objectives have such tendency that astigmatism becomes considerably undercorrected as the object point approaches the lens system and, as a result, the image surface inclines toward the "minus" side. Therefore, when it is desired to focus the lens system on an object at a short distance, it is important to correct the above-mentioned inclination of image surface. Especially in case of objectives for endoscopes, correction of image surface is difficult because the field angle is generally large.

On the other hand, to arrange that a satisfactorily high magnification can be obtained when the lens system is focused on an object at a short distance, the distance l from the front focal point of the lens system as a whole to the object should be made satisfactorily small compared with the focal length f_a of the lens system as a whole.

Besides, as an objective for an endoscope is to be arranged in a distal end of an endoscope with a small diameter, lens diameters whould be made small. Therefore, balance of heights of rays which pass through respective lens groups should be also taken into consideration.

Out of the above-mentioned requirements, the problem to prevent the image surface from inclining toward the "minus" side is extremely important in order to arrange that the marginal portion of image can be observed favourably. For this purpose, in case of the objective for an endoscope according to the present invention, Petzval's sum is corrected by controlling the power of the rear lens group thereof comprising the second through the fifth lens components and having positive refractive power.

The condition (2) is established for the above-mentioned purpose. If f_2/f_a is made smaller than 1.0, Petzval's sum will be overcorrected. If, on the contrary, f_2/f_a is made larger than 1.3, Petzval's sum will be un-

dercorrected. In either case, it is impossible to obtain favourable quality of image. Besides, if f_2/f_a is made smaller than 1.0 and power of the rear lens group becomes considerably strong, the heights of offaxial rays become high in the front lens groups thereof comprising the first lens component whihc is arranged as a negative lens. As a result, the diameter of the front lens becomes large, and this is not desirable.

To obtain a high magnification when the objective is focused on an objective at a short distance in the state that the focal length f_2 is selected in the range defined by the condition (2), it is necessary to fulfill the condition (1).

If f_1/f_a is made smaller than the lower limit of the condition (1) and power of the front lens group becomes weak, the airspace between the front and rear lens groups should be made large in order to obtain the desired value of field angle. As a result, the distance between the object and front focal point of the lens system as a whole becomes long when the lens system is focused on an object at a short distance and, consequently, it is impossible to made the magnification high.

The objective which fulfills the conditions (1) and (2) shown in the above is capable of accomplishing the object of the present invention. However, when said objective is arranged that the airspace D between the first and second lens components fulfills the condition (3) shown below, it is possible to make the available focusing range satisfactorily wide when the objective is focused by means of the rear lens group, which is a positive lens group, and it is possible to make the magnification satisfactorily high when the objective is focused on an object at a short distance.

$$D/f_a<0.7 \quad (3)$$

That is, when D/f_a is made smaller than 0.7, the length of a system comprising the first lens component and the second lens component becomes short, and the heights of rays which go out from the second lens component become low. As a result, the space available for moving a focusing group, which comprises the third lens component and the fourth lens component, can be made large and it is possible to arrange that the objective can be focused up to an object at an extremely short distance. Moreover, as the heights of rays which enter the above-mentioned focusing group do not become so high, it is also possible to correct aberrations favourably and to make the variation of aberrations small.

By limiting the values of f_1 and f_2 in relation to the focal length of the lens system as a whole as described so far, it is possible to obtain an objective of which the enlarging magnification when observing an object at a short distance is satisfactorily high. Furthermore, by limiting the airspace D between the first and second lens components as described in the above, it is possible to obtain an objective with a satisfactorily wide focusing range.

Besides, to obtain favourable quality of image in both cases of observation, i.e., at the time of ordinary observation of an object at a long distance and at the time of observation of an object at a short distance by magnifying the object, it is preferable to arrange that the objective according to the present invention further fulfills the conditions (4), (5) and (6) shown below:

$$1.0 < r_1/fa < 4.0 \quad (4)$$

$$-1.5 < r_4/fa < -1.0 \quad (5)$$

-continued

$$1.3 < R < 4.0 \quad (6)$$

$$1/R = 1/r_6 + 1/r_{10}$$

where, reference symbol r_1 represents the radius of curvature of the surface of the object side of the first lens component, reference symbol r_4 represents the radius of curvature of the surface on the object side of the second lens component, reference symbol r_6 represents the radius of curvature of the surface on the object side of the third lens component, and reference symbol r_{10} represents the radius of curvature of the surface on the image side of the fourth lens component.

Generally, regarding the retrofocus-type lens systems which are arranged to be focused by advancing the positive lens group arranged as the rear lens group, it is known that, when aberrations to be caused at the time of ordinary observation of an object at a long distance are corrected favourably, aberrations at the time of observation of an object at a short distance comes to the state that astigmatism becomes a "minus" value with a large absolute value and, consequently, the resolving power decreases considerably. Besides, it is known that astigmatism is defined by the difference between the converging point of sagittal rays and converging point of meridional rays and that astigmatism to be caused becomes smaller when the shapes of respective surface of lenses becomes closer to the shapes concentric with the stop. The conditions (4) and (5) shown in the above are established by taking the above-mentioned point into consideration.

If, in the conditions (4) and (5), r_1/f_1 and/or r_4/f_a is made smaller than the lower limit thereof, astigmatic difference will be overcorrected. If r_1/f_a and/or r_4/f_a is made larger than the upper limit thereof, astigmatic difference will be undercorrected.

The objective according to the present invention is arranged that the third lens component and the fourth lens component are movable. Therefore, when it is considered that the third and fourth lens components constitute a movable lens group, it is possible to correct astigmatic difference by limiting the radius of curvature r_6 of the foremost surface of said movable lens group and the radius of curvature r_{10} of the rearmost surface of said movable lens group as defined by the condition (6).

If, in the condition (6), the value of R becomes smaller than the lower limit, i.e., 1.3, astigmatic difference will be undercorrected. If the value of R becomes larger than the upper limit, i.e., 4.0, astigmatic difference will be overcorrected.

As described so far, the objective according to the present invention is arranged that the absolute value of astigmatic difference, which is generally caused in the retrofocus-type objectives, is made small by means of the surface r_1 and surface r_4 in the front lens group by arranging that said surfaces fulfill the conditions (4) and (5). Besides, by limiting the values of r_6 and r_{10} as defined by the condition (6), it is possible to correct astigmatic difference in well balanced state also in case that the objective is arranged to be focused by moving the lens components in the rear lens group.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 shows a sectional view of the retrofocus-type objective for an endoscope according to the present invention;

FIGS. **2** and **3** respectively show graphs illustrating aberration curves of Embodiment 1 of the present invention when the object distance is 14.2450 and 1.5385 respectively;

FIGS. **4** and **5** respectively show graphs illustrating aberration curves of Embodiment 2 of the present invention when the object distance is 14.2045 and 1.53609 respectively;

FIGS. **6** and **7** respectively show graphs illustrating aberration curves of Embodiment 3 of the present invention when the object distance is 14.2045 and 1.53409 respectively;

FIGS. **8** and **9** respectively show graphs illustrating aberration curves of Embodiment 4 of the present invention when the object distance is 14.27755 and 1.54198 respectively;

FIG. **10** shows a sectional view of a known objective for an endoscope; and

FIGS. **11**, **12** and **13** respectively show graphs illustrating aberration curves of said known objective for an endoscope when the object distance is 10.5965, 1.56986 and 1.2755 respectively.

In respective embodiments shown in the above, reference symbols r_1 through r_{12} respectively represent radii of curvature of respective lens surfaces, reference symbols d_1 through d_{11} respectively represent thicknesses of respective lenses and airspaces between respective lenses, reference symbols n_1 through n_6 respectively represent refractive indices of respective lenses, and reference symbols ν_1 through ν_6 respectively represent Abbe's numbers of respective lenses.

All of embodiments shown in the above are arranged to integrally advange the third and fourth lens components so as to make it possible to observe an object at a short distance by enlarging the object. In other words, respective embodiments are arranged that both of ordinary observation of an object at a long distance and observation of an object at a short distance by enlarging the object are performed by varying the airspaces d_5 and d_{10} as shown in the numerical data of respective embodiments.

For the purpose of comparison, the numerical data of the objective for an endoscope disclosed in Japanese published examined patent application No. 15005/80 (U.S. Pat. No. 4,059,344) are shown below.

$r_1 = 2.7033$		
$d_1 = 0.2747$	$n_1 = 1.51633$	$\nu_1 = 64.15$
$r_2 = 0.5675$

$d_9 = 0.2747$	$n_5 = 1.78472$	$\nu_5 = 25.71$
$r_{10} = 16.9937$		
$d_{10} = 1.7760$	(variable)	
$r_{11} = \infty$	(image surface)	

object distance	magnification	d_5	d_{10}
10.5965	−0.087	0.5616	1.3827
1.56986	−0.475	0.1682	1.7760
1.2755	−0.563	0.0770	1.8673

In the numerical data shown in the above, the values for the object distance 1.2755 are reference values obtained by converting the numerical data of said known objective into the case of magnification −0.563 which is aimed at by the present invention. The actual numerical data of said known objective are given on the basis of object distances 10.5965 and 1.56986.

Besides, in case of said known objective having the numerical data shown in the above, the values which correspond to respective conditions of the present invention are as shown below.

$f_a = 1$, image height $= 0.58281$
$f_1/f_a = -1.442$, $f_2/f_a = 1.3482$
$D/f_a = 1.144$, $r_1/f_a = 2.6802$
$r_4/f_a = -2.7323$, R $= 5.31$

Said known objective does not satisfy any of the conditions given in the present invention except the condition (4).

As described in datail in the above and as it will be evident from respective embodiments, the retrofocus-type objective for an endoscope according to the present invention is arranged that the magnification at the time of observation of an object at a short distance is higher compared with known objectives for endoscopes and, at the same time, arranged that the resolving power when observing an object at a short distance is favourable and is well balanced with the resolving power at the time of observation of an object at a long distance so that favourable quality of image is obtained in both of the above-mentioned cases of observation.

I claim:

1. A retrofocus-type objective for an endoscope comprising a first lens component comprising a negative lens, a stop, a second lens component comprising a positive meniscus lens arranged to be concave toward the object side, a third lens component comprising a positive lens, a fourth lens component comprising a cemented doublet consisting of a positive lens and a negative lens, and a fifth lens component comprising a positive lens in the order from the object side, said retrofocus-type objective being arranged to be focused by advancing said third lens component and said fourth lens component and, moreover, to fulfill the conditions (1) and (2) shown below:

$$-0.9 < f_1/f_a \quad (1)$$

$$1.0 < f_2/f_a < 1.3 \quad (2)$$

where reference symbol f_1 represents the focal length of the first lens component, reference symbol f_2 represents the total focal length of the second through the fifth lens components, and reference symbol f_a represents the focal length of the lens system as a whole when focused on an object at a short distance,

said objective further satisfying the following conditions:

$$D/f_a < 0.7 \quad (3)$$

where reference symbol D represents the airspace between the first and second lens components,

and further fulfilling the conditions (4), (5) and (6) shown below:

$$1.0 < r_1/f_a < 4.0 \quad (4)$$

$$-1.5 < r_4/f_a < -1.0 \quad (5)$$

$$1.3 < R < 4.0 \quad (6)$$

$$1/R = 1/r_6 + 1/r_{10}$$

where reference symbol r_1 represents the radius of curvature of the surface on the object side of the first lens component, reference symbol r_4 represents the radius of curvature of the surface on the object side of the second lens component, reference symbol r_6 represents the radius of curvature of the surface of the object side of the third lens component, and reference symbol r_{10} represents the radius of curvature of the surface on the image side of the fourth lens component.

2. A retrofocus-type objective for an endoscope according to claim 1 having the following numerical data:

$r_1 = 2.6667$		
$d_1 = 0.1994$	$n_1 = 1.51633$	$\nu_1 = 64.15$

[57] **ABSTRACT**

A temperature compensating method an automatic diaphragm control amplifier used with an objective lens for a CCTV camera lowers or raises an adjusted level of video signal as an ambient temperature rises of lowers, respectively. The temperature compensating means compensates for a temperature-dependent variations in the DC component of the video signal coming from the camera and thereby to prevents the level of video signal from lowering as the ambient temperature rises or lowers.

TEMPERATURE COMPENSATING METHOD IN AUTOMATIC DIAPHRAGM CONTROL AMPLIFIER USED WITH OBJECTIVE FOR CCTV CAMERA

BACKGROUND OF THE INVENTION

Industrial Field of Application

The present invention relates to an automatic diaphragm control amplifier used with an objective for a closed circuit television (CCTV) camera.

Prior Art

In the prior art there has been no means provided for temperature compensation of a video signal level and, even if the level of a video signal actually varied due to a temperature variation, this video signal was usually processed by the built-in circuit arrangement of the camera as if the signal included no such level variation.

Problems to be Solved by Invention

In the camera employing pickup means other than a pickup tube such as a vidicon tube which is able to vary its sensitivity by changing its target voltage, this variation is often used in order to obtain optimal performance of said pickup tube or pickup element, so that a high quality picture of good S/N ratio is obtained for a bright scene and a high sensitivity takes preference over S/N ratio for a dark scene so that the function of the video gain control circuit incorporated in the camera is based on a brightness of the scene. This prior art camera has been inconvenient to use as an adequately bright scene would often result in a low quality picture of inferior S/N, since a level value set by changing the gain of the video amplifier is variable regardless of the brightness. For example, the video signal level may be lowered for the bright scene due to a temperature rise during shooting of this scene, and this signal level may function to increase the video amplifier gain of the camera as if the scene was darkened.

Furthermore, the pickup tube or the solid state pickup element is likely to be accompanied with increased dark current as a temperature rise resulting in that a portion of the picture which should be dark becomes bright. In addition to this tendency, lowering of the signal level due to the temperature rise may affect the function of the automatic diaphragm control amplifier to such an extent that an effective portion of the video signal is reduced and, in an extreme case, there will be no recognizable picture.

SUMMARY OF THE INVENTION

Measures to Solve Problems

Such a circuit arrangement having no means for temperature compensation and exhibiting such a characteristic that a level of video signal is alternated with increasing temperature is indicated by a solid line A in FIG. 4. In this Figure, the characteristic corresponding to a situation in which a scene has been darkened may result, as a temperature rises, even when the scene really remains bright. Such an influence of temperature can be overcome by a compensating element applying a compensation amount, which is more than a variation amount which would occur in the circuit arrangement having no means for temperature compensation, within a range of temperature higher than the normal temperature. This compensation amount may be less than a variation amount which would occur in the circuit arrangement having no means for temperature compensation, within a range of temperature lower than the normal temperature, as indicated by a broken line B in FIG. 4.

Thus, the present invention broadly resides in a temperature compensating method in an automatic diaphragm control amplifier used with an objective lens for CCTV camera, in which an adjusted level of video signal lowers or rises as an ambient temperature rises or lowers, respectively, characterized in that there in provided temperature compensating means adapted to compensate a temperature dependent variation in the DC component of the video signal coming from the camera and thereby to prevent the level of video signal from becoming lower than a value adjusted at the normal temperature as the ambient temperature rises or lowers. More specifically, the present invention resides in a temperature compensating method in an automatic diaphragm control amplifier used with an objective lens for a CCTV camera wherein the automatic diaphragm control amplifier is energized from a single source or double source and when a mid-point voltage (0 or Vcc/2) is stable, between a ground and a negative source voltage or between the mid-point voltage and ground, a bleeder resistance is provided. The bleeder resistance includes a fixed resistance and thermistor, a resistance value of said fixed resistance being selected to be infinitely small relative to a resistance value of said thermistor, and a voltage thus obtained from said bleeder resistance being applied to an operational amplifier in parallel with the video signal coming from the camera in order to achieve a desired temperature compensation. In an alternative embodiment, the present invention further resides in a temperature compensating method in an automatic diaphragm control amplifier used with an objective lens for a CCTV camera wherein the automatic diaphragm control amplifier is energized from a double source or a single source and when a mid-point voltage (0 or Vcc/2) is unstable, a bleeder resistance is provided consisting of two fixed resistances of same value connected between the source and a ground, and a thermistor connected between the mid-point voltage and the ground in parallel with the one of said two fixed resistances which is connected to the ground. A voltage thus obtained from said bleeder resistance is applied to an operational amplifier in parallel with the video signal coming from the camera in order to achieve a desired temperature compensation.

Operation

With the automatic diaphragm control amplifier having the characteristic as indicated by the solid line A in FIG. 4, the level of video signal lowers as a temprature rises above the normal temperature, resulting in an exposure as if a scene (i.e., an object to be shot) is darkened and resulting in a corresponding rise in a gain of the pickup tube and the solid state pickup element, so that the lens aperture is enlarged and a picture of inferior S/N ratio is produced. In contrast therewith, according to the temperature compensating method of this invention, the video signal is compensated by an amount smaller than a variation amount occurring at the normal temperature when the ambient temperature is lower than the normal temperature but by an amount larger than a variation amount occurring at the normal temperature when the ambient temperature is higher than the normal temperature. In this manner, the video signal can be compensated so that its level is always maintained higher than a level at the normal temperature and, as a consequence, the automatic diaphragm

control amplifier is free from any influence of the temperature.

BRIEF DESCRIPTION OF DRAWING

FIG. **1** is a circuit diagram illustrating an important part of an embodiment of the method according to the present invention;

FIG. **2** is a circuit diagram similar to FIG. **1** but concerning another embodiment;

FIG. **3** is a graphic diagram illustrating a characteristic of a compensated signal; and

FIG. **4** is a graphic diagram illustrating compensating characteristic curves of the automatic diaphragm control amplifier with respect to the video signal level.

EMBODIMENTS

In an embodiment as illustrated by FIG. **1**, the circuit is energized from a double source (+V, −V) or single source (Vcc) and a mid-point voltage (0 or Vcc/2) thereof is stable. A video signal **V1** coming from the camera is coupled through a resistance **R1** to an inverting terminal (−) of an operational amplifier A while the mid-point voltage is input through a resistance **R3** to a non-inverting terminal (+). The inverting terminal (−) is connected through a feedback resistance **R4** to an output terminal and an output signal Vout is amplified to (**R4/R1**) **V1**. The inverting terminal (−) and the non-inverting terminal (+) are in a state of imaginary short-circuit and both of them are at a voltage equal to the mid-point voltage (Vcc/2).

When the ambient temperature rises above the normal temperature and, as a result, the video signal level of the automatic diaphragm control amplifier including the operational amplifier A lowers as indicated by the solid line A in FIG. **4**, a rectified portion **V1** of the video signal increases in proportion to the temperature rise and the lens aperture is correspondingly reduced with respect to the aperture at the normal temperature so that the gain of the solid state pickup element or like increases.

In view of this, the present invention provides an arrangement such that a fixed resistance **R5** is serially connected to a thermistor nR between the mid-point voltage (0 or Vcc/2) and the negative source (−V) or the ground (**0**), and a signal **V2** obtained from a bleeder resistance consisting of said fixed resistance and said thermistor is coupled through a resistance **R2** to the inverting terminal (−) of the operational amplifier A in parallel with the video signal **V1**. A resistance value of said fixed resistance **R5** is selected to be infinitely smaller than the resistance value of the thermistor nR.

With such arrangement, it will be obvious from FIG. **3** that the signal **V2** lowers below the mid-point voltage (Vcc/2) as the ambient temperature rises above the normal temperature and the resistance value of the thermistor nR correspondingly decreases. Thus, the video signal **V1** in parallel with said signal **V2** is compensated so as to be correspondingly reduced. The signal **V2** infinitely approches the mid-point voltage (Vcc/2) as the ambient temperature lowers below the normal temperature and the resistance value of the thermistor nR correspondingly increases. As a consequence, the video signal level based on the output signal Vout is kept above the level at the normal temperature, as indicated by the broken line in FIG. **4**.

A secondary embodiment is given for the case in which the circuit arrangement is energized from double source (+V, −V) or single source (Vcc) and the mid-point voltage is unstable.

Referring to FIG. **2** illustrating the case of a single source voltage, the non-inverting terminal (+) of the operational amplifier A is applied via the resistance **R3** with a mid-point voltage (Vcc/2) across two fixed resistance **R7**, **R8** of same resistance value connected between the source Vcc and the ground **0**. This mid-point voltage is unstable and the inverting terminal (−) in synchronization therewith is also unstable. Thus, these terminals are in imaginary short-circuit state. Concerning the signal **V2** for temperature compensation, two fixed resistances **R5**, **R6** of same resistance value are connected between the source Vcc and the ground **0** while the thermistor nR is connected in parallel with said fixed resistance **R6** on the ground side between the mid-point voltage (Vcc/2) and the ground **0** so that the signal **V2** is input from the bleeder resistance consisting of said thermistor nR and said fixed resistance **R5** to the inverting terminal (−) of the operational amplifier A via the resistance **R3**, in parallel with the video signal **V1** coming from the camera.

In such a case, the signal **V2** for temperature compensation maintains the same relationship with the mid-point voltage (Vcc/2) as the relationship indicated by FIG. **3** as the ambient temperature varies, even though the mid-point voltage is unstable. Thus, there is provided the output signal Vout derived from the video signal which has supplied from the camera and then appropriately compensated.

Effect

With the temperature compensating method according to the present invention, as has been described hereinabove, there is provided the temperature compensating means for the automatic diaphragm control in which the adjusted level of video signal lowers or rises as the ambinent temperature rises or lowers, respectively, so that said temperature compensating means compensates for a temperature-dependent variation in DC component of the video signal coming from the camera and thereby prevents the level of video signal from becoming lower than the value adjusted at the normal temperature as the ambient temperature rises or lowers. Accordingly, when the temperature compensating method of the present invention may be employed in the camera utilizing a high sensitivity pickup tube and the solid state pickup element so devised, in order to obtain the optimal performance of said pickup tube or said pickup element, so that a high quality picture of good S/N ratio is obtained for a bright scene and a high sensitivity takes preference over S/N ratio for a dark scene, i.e., the video gain control circuit incorporated in the camera is activated as the scene is darkened, the level of video signal coming from the camera is appropriately compensated so as to prevent this level from lowering and thereby the desired performance of the automatic diaphragm control amplifier is maintained regardless of the temperature variation, even if the level value set to change the gain of the video amplifier is variable independently of the brightness, for example, the video signal level lowers for the bright scene due to the temperature rise during shooting of this scene.

What is claimed is:

1. A method of compensating for variations in video signal gain caused by variations in ambient temperature in an automatic diaphragm control of a video camera comprising:

receiving said video signal;

varying a DC component of said video signal in response to variations in ambient temperature to thereby compensate for temperature-dependent variations in said DC component of said video signal.

2. The method of compensating as set forth in claim 1 wherein said step of varying a D.C. component attenuates said video signal.

3. A method of compensating for variations in video signal gain caused by variations in ambient temperature in an automatic diaphragm control of a video camera comprising:

receiving said video signal;

variably attenuating at least a component of said video signal in response to variations in ambient temperature to thereby compensate for temperature-dependent variations in said video signal.

4. A temperature compensating circuit for an automatic diaphragm control amplifier of a video camera wherein said video signal has a level which varies with variations in ambient temperature comprising:

means for amplifying said video signal; and

temperature compensation means, operatively connected to said means for amplifying, for varying the level of said video signal supplied to said means for amplifying.

5. The temperature compensating circuit of claim 2 further comprising:

a voltage source having first and second source voltages and a stable midpoint voltage level therebetween;

said temperature compensation means including,

a voltage divider including first and second resistances connected between said midpoint voltage and the lower of said first and second source voltage levels, and

a bleeder resistance connected between said means for amplifying and said voltage divider,

said second resistance having a resistance value which varies in relation to ambient temperature to control the amount of attenuation of said video signal occurring through said bleeder resistance.

6. The temperature compensating circuit of claim 5 wherein increased ambient temperature reduces the resistance of said second resistance to increase the attenuation of said video signal.

7. The temperature compensating circuit of claim 4 further comprising:

a voltage source having first and second source voltages and a floating midpoint voltage level therebetween; said temperature compensator means including,

a voltage divider including first and second resistances connected across said first and second source voltages to establish a midpoint voltage,

a bleeder resistance connected between said means for amplifying and said voltage divider,

a third resistance, connected in parallel to said second resistance, having a resistance value which varies in relation to ambient temperature to control the amount of said video signal occurring through said bleeder resistance.

8. The temperature compensating circuit of claim 7 wherein increased ambient temperature reduces the resistance of said third resistance to increase the attenuation of said video signal.

[57] **ABSTRACT**

A mounting for a sun shade, a filter or both for the usual bulky lens of a professional video camera can be moved forward or backward parallel to the lens axis on two parallel guide rails (**3, 4**), the rear ends of which are fixed on a frame (**18**) supported forward of the lens mounting support (**9**) by rods (**25, 26**) and a structure (**9**) which supports the lens. On the guide rails extending foward from the frame (**18**) there is mounted a back-and-forth shiftable articulation device (**10, 13, 14**) which permits swinging of its outer member (**14**), only in the forward position of the device, about the articulation joint (**13**). Movement of the accessory towards and away from the lens is driven by an eccentric arm (**19**) which is linked to a swinging member (**22**) for transmitting linear motion. A manipulation member **21** serves to move the eccentric arm **19**. When the articulation device is in its forward position, the free ends (**7, 8**) of the guide rails (**3, 4**) come out of the holes (**15, 16**) in the front member (**14**) of the shiftable articulation device and thus release the locking of the articulation joint (**13**), so that the sun shade, etc., and its bellows (**27**) can be swung out of the field of view of the lens.

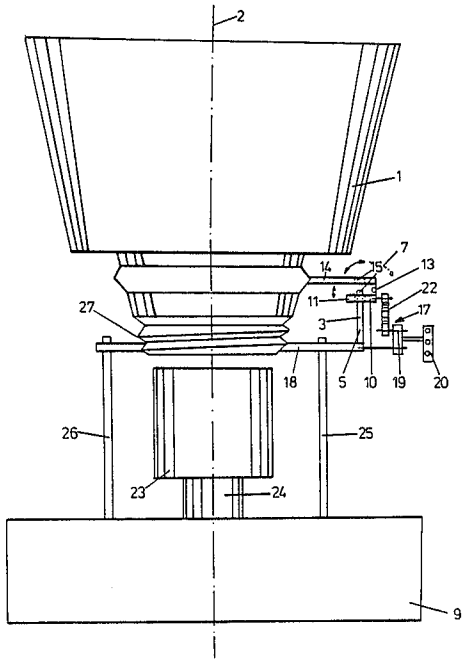

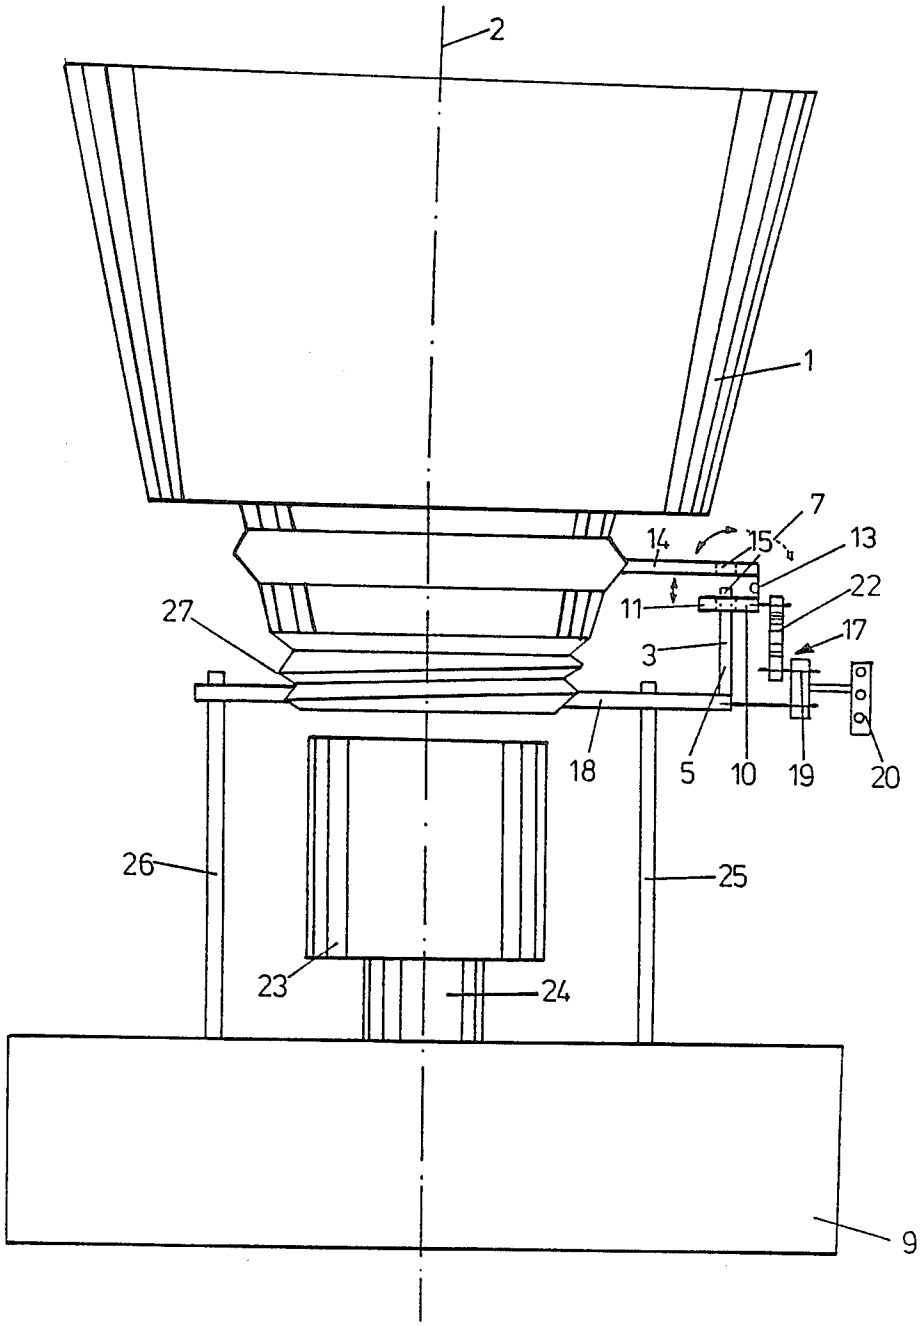

FIG. 1

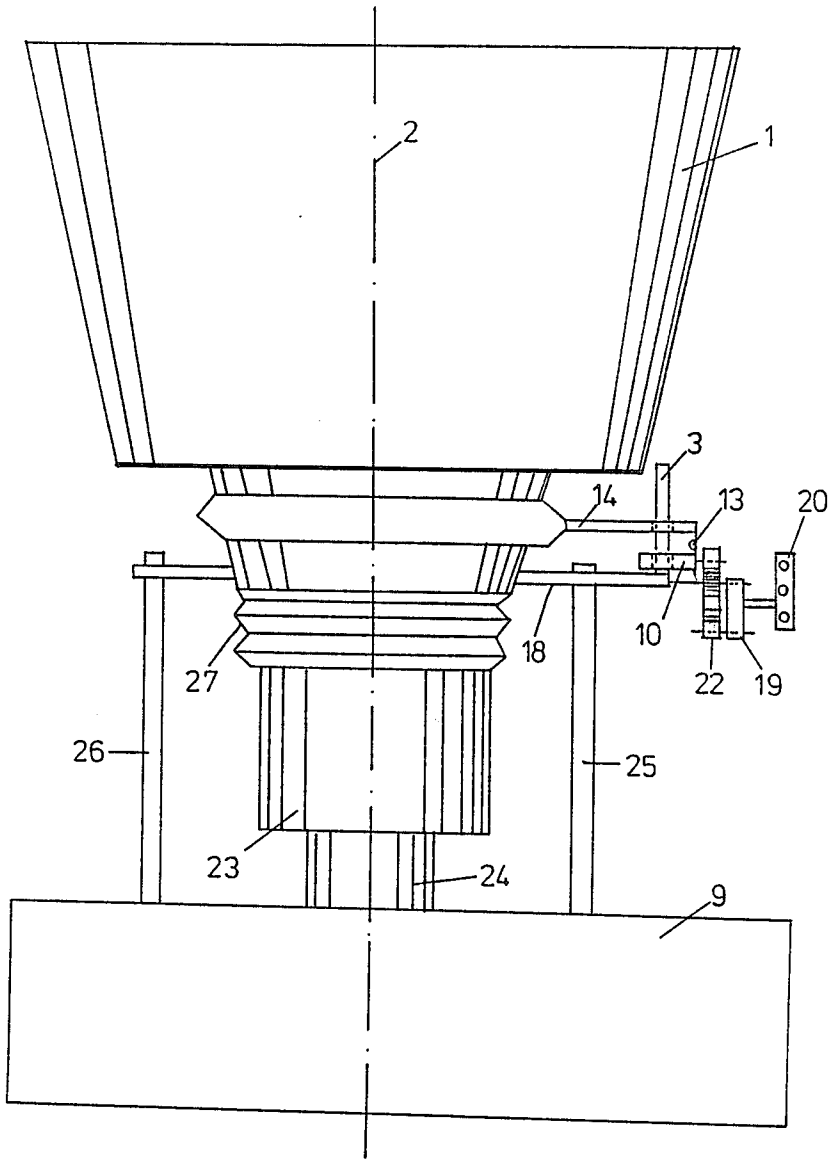

FIG. 2

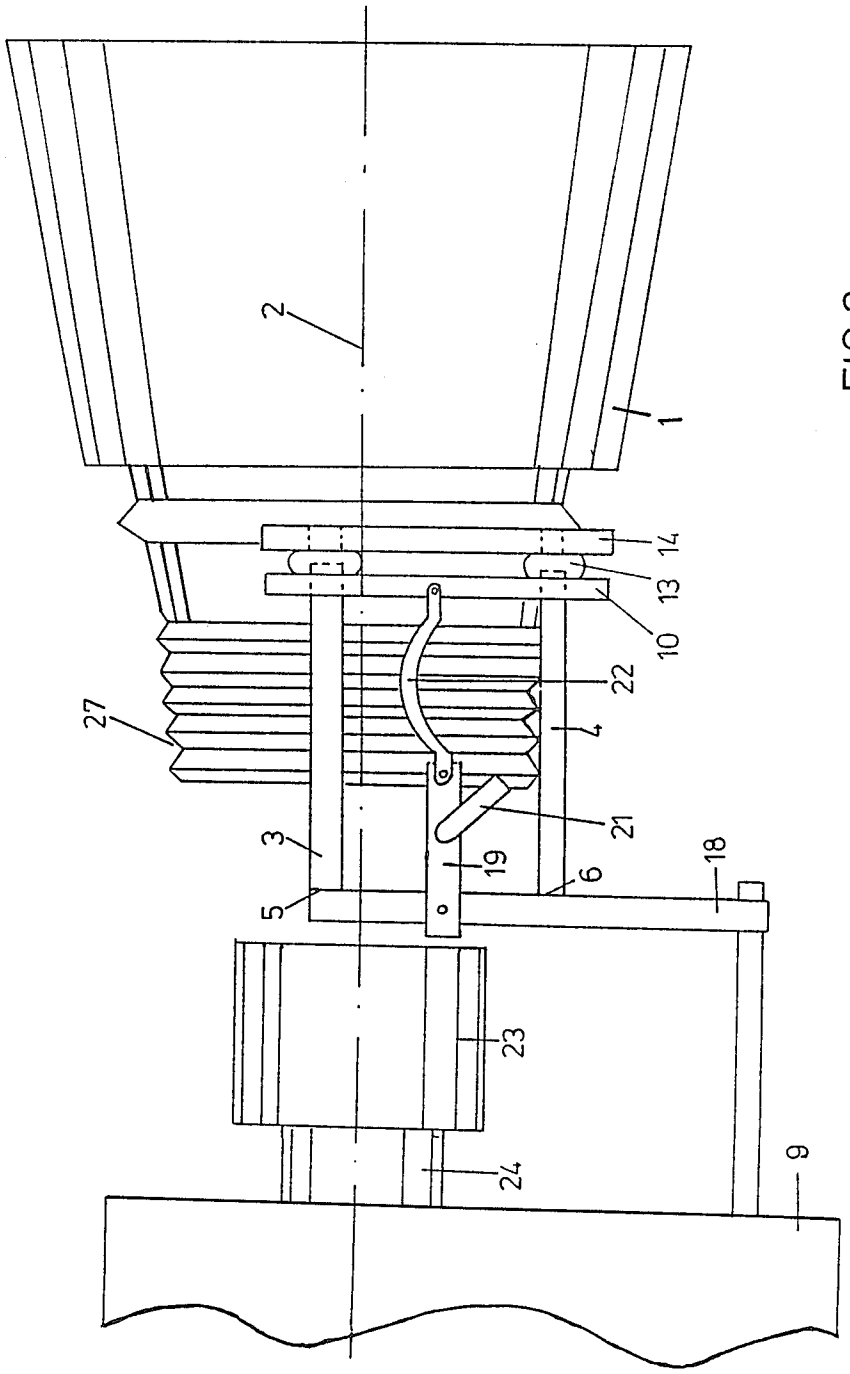

FIG.3

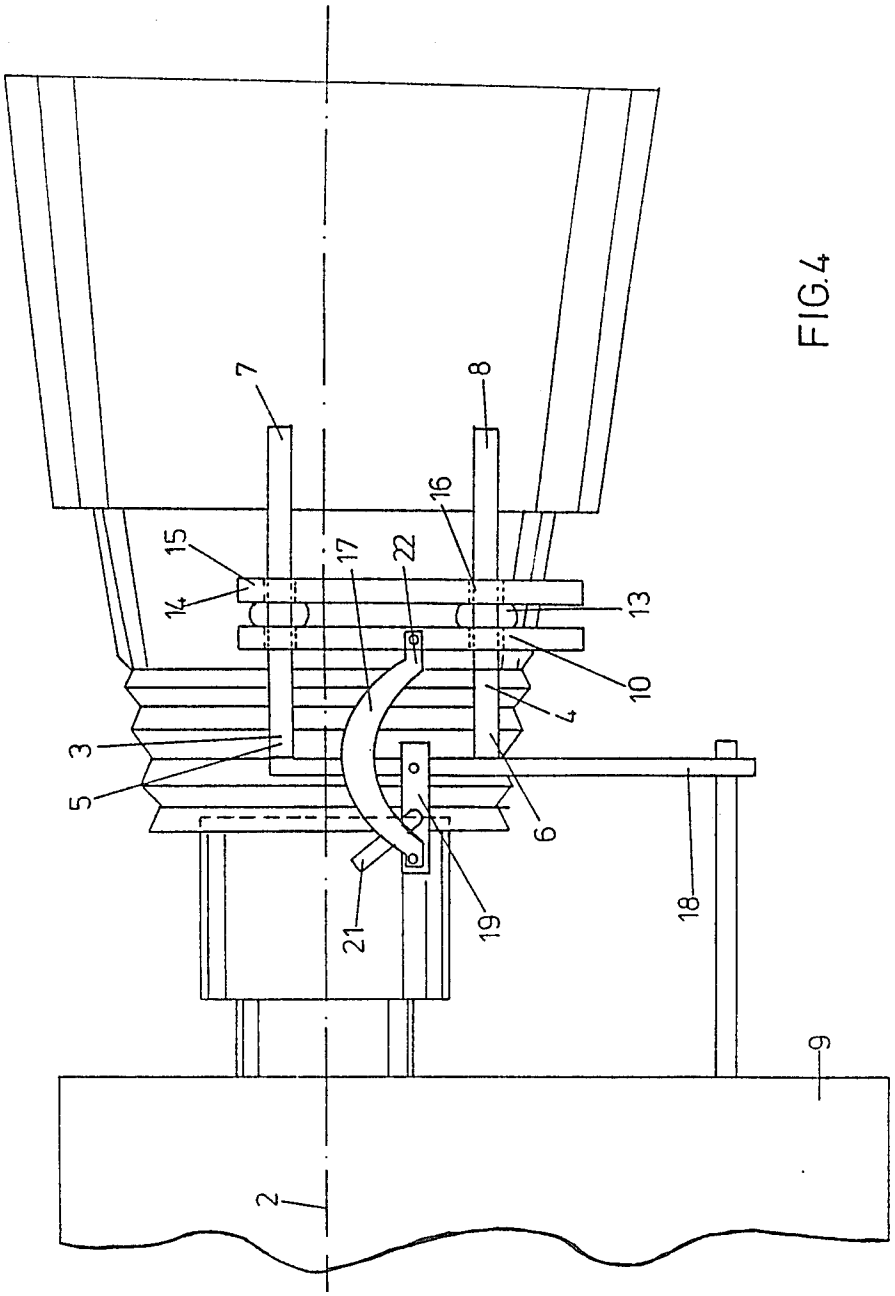

FIG.4

SWINGABLE HOLDER FOR ANTERIOR ACCESSORIES OF AN OBJECTIVE LENS

This invention concerns a holder for front-of-lens accessories for the objective lens of an optical system such as a photographic or television camera such that an accessory can be swung away from the optical path in use and swung back so that it fits over the front end of the objective lens. Such holders are particularly important for large objective lenses such as are used in professional motion picture and television cameras. In such cases, the objective lens mounting of the camera itself is integrated with the camera mount or holder, so that it is, as a rule, movably mounted on a stable stationary structure.

Such objective lenses in many cases have a relatively large diameter. The same holds also for the accessories to be mounted in front of it (hereinafter referred to as anterior accessories) such as sunshades, which are sometimes called "mattboxes", filter holders or combinations of sunshade and filter holders. These anterior accessories must fit closely over the lens in order to exclude stray light to a great extent, as a result of which the connection usually involves the provision of a flexible bellows. The anterior accessory must have a sufficiently large opening in order not to cut off any part of the field of wide angle objectives. In general, for certain sizes of wide angle objectives, only particular anterior accessories designed for such wide angle service can be used. The anterior accessories are so bulky and heavy that removing them by unscrewing or the like, as is done in the case bf cameras for amateur use, no longer makes sense. For these reasons, such anterior accessories are connected with the objective lens support by a displacement mechanism in order to shift the entire anterior accessory forward, thereby also making possible removal of the bellows which surrounds the objective lens at its free front end to keep out stray light when the accessory is in working position. Furthermore, in addition to the displacement mechanism, the holder for anterior accessories of the kind above discussed also has a mechanism for swinging the accessories out of the optical path. This has form of a two-part articulation which makes it possible, after the forward displacement of the accessory holder, to swing the entire anterior accessory to one side, or up, or down, away from the objective lens.

In the known holders above described for anterior accessories suitable for large lenses, the mount for the anterior accessories must first be brought forward with effort and some difficulty, then a positioning catch for the swing mechanism must be released and finally, the anterior accessory must be swung outside of the picture angle of the lens in order to carry out various necessary operations, such as removal of the lens for checking it and possibly cleaning of the film plate, or replacing the lens with another objective lens. After any of these operations for checking or replacing the lens, all of the described stages must be carried out in reverse sequence to put the anterior accessory back in working position.

Displacing the anterior accessory holder away from the lens requires much effort and the releasing of the positioning catch or lock is troublesome, all of which, in situations requiring a quick change of lens, can have the result that certain scenes cannot be correctly recorded on tape or film or correctly given live television reproduction.

SUMMARY OF THE INVENTION

It is an object of the present invention to provide a mounting for anterior accessories for objective lenses in such a form that the release of the swinging mechanism is simplified.

Briefly, a guide rail, and preferably two of them, are disposed parallel to the axis of the lens having one end fixed in place on the lens support, which may be the camera body or similar structure. The guide rail has free ends at which an articulation structure is provided having an inner member mounted shiftably on the guide rails and an outer member articulated to the inner member by a swing joint and connectable also to an anterior accessory for the lens, the inner and outer members being, in working position, essentially parallel to each other and at right angles to the guide rails. The easy release of positioning for permitting swinging is made possible by providing apertures in the outer member directed towards the guide rails for locking the articulation of outer member in working position.

An important concept involved in the invention is to couple the positioning of the swinging mechanism with the linear displacement mechanism of the anterior accessory holder in such a way that the positioning is automatically released when the forward displacement of the anterior accessory is complete and that after the swinging of the anterior accessory onto the lens axis and pushing it back towards the lens, the positioning lock snaps in place automatically. This is provided in such a way that, in the swingable outer member of the articulation, positioning holes are provided which are directed to and face guide rail ends when the accessory holder is in its forward position. When the anterior accessory is pushed onto the lens, the guide rails catch in these positioning holes and when the anterior accessory is shifted fully forwards, the free ends of the guide rails come out of the positioning apertures so that the swinging mechanism is automatically set free.

In a preferred embodiment, a drive is provided between the attachment frame for the fixed ends of the guide rails and the inner member of the articulation which can displace the anterior accessory forward and back over a predetermined distance. The most varied kinds of means can be used for such a drive, for example, an electric motor, a rack rod engaging a rotatable gear or a spring mechanism.

The drive preferably consists of an eccentric device, of the over-center lever type. An eccentric arm has a forward position in which its length is additive to that of a swinging lever actuated by it and a rearward position where its length is subtracted from that of the swinging lever, in determining the distance of the articulation from the mounting frame for the fixed ends of the guide rails. A manipulation lever is linked or fastened to the eccentric lever to supply torque to the eccentric movement. The length of the guide rails, the size relations and the dimensional ratios of eccentric arm and swinging lever can be so determined that by rotation of the eccentric arm in a first direction by 180° a defined positioning of the anterior accessory at or against the lens can be obtained and by rotation about 180° in the opposite direction a shifting away of the anterior accessory from the lens by a defined distance results as well as a simultaneous clearing of the positioning openings. It is particularly useful for the middle section of the swinging member to be arcuately shaped to facilitate handling and also the development of the

necessary torque for the actuation of the eccentric drive.

With such a drive, an anterior accessory at a working position at or against the front of the objective lens can be shifted forward with a single lever movement by a precisely defined amount and with a small use of force up to a final stop position and the rotary mechanism will thus be immediately freed and the anterior accessory can then be swung out of the field of view of the lens for a lens change or other necessary operation. When that operation is completed, the anterior accessory can be swung back to the optic axis of the lens after which a single lever movement of 180° in the opposite direction can lock the accessory in position and perform the exact return of the bellows of the accessory onto the lens. Furthermore, on account of the frictional conditions present intermediate positioning of the eccentric arm by its manipulating lever is possible to a certain degree. That can produce a somewhat modified spacing of the anterior objective from the lens for the same lens focal length, or adapt an anterior accessory for a somewhat larger range of lens focal lengths. Changing the spacing modifies the angle of incidence conditions at the accessory.

Another possible use of the intermediate positioning of the advance and retraction lever is to accommodate to a certain extent the use of lenses of different physical (barrel) length. In this case, an intermediate positioning of the displacement lever can provide a precise placing of the bellows on the end of the lens for different lens barrel lengths.

The accessory mounting of the present invention makes single-handed manipulation possible with minimum amount of applied force, whereas heretofore displacement required effort with the use of both hands and a danger of putting the overall camera support out of adjustment.

BRIEF DESCRIPTION OF THE DRAWINGS

The invention is further described by way of illustrative example with reference to the annexed drawings, in which

FIG. 1 is a top view of a laterally disposed anterior accessory holder with the anterior accessory shifted into its forward (non-working) position;

FIG. 2 is a top view like FIG. 1 with the anterior accessory in its working position on the lens;

FIG. 3 is a side view corresponding to the top view shown in FIG. 1, and

FIG. 4 is a side view corresponding to the top view in FIG. 2.

DESCRIPTION OF THE ILLUSTRATED EMBODIMENT

In the several figures of the drawings, the same parts are designated with the same reference numerals.

FIG. 1 shows the accessory 1 in a location centered on the optic axis 2 of the lens 23. The lens 23 is mounted on the objective lens support 9 by means of an intermediate member 24. For reasons of simplification of the drawings, the remaining components are not shown, especially those in the light transmission path from the lens 23 to the camera (not shown) located behind the end support 9 which may be a front surface of the camera. The stationary structure to which the end support 9 and the rest of the camera are fixed is likewise not shown.

Beneath the lens 23 two rods 25 and 26, parallel to the optic axis of the lens are provided on which a sliding frame 18 can be shifted in forward and back adjustment to serve, in fixed position, as a mounting frame. At one side of the frame 18, a guide rail 3 is provided which is again parallel to the optic axis 2 and has a fixed end 5 connected rigidly to the frame 18. Parallel to the mounting frame 18 there is in FIG. 1 an outer member 14 of an articulation device which is connected by an articulation joint 13 with the inner member which runs parallel to the outer member 14. The inner member 10 of the articulation device has a guiding feature, such as an aperture, collar or sleeve, which runs along the guide rail 3 and as can be seen in the side views of FIGS. 3 and 4, it also has a similar guiding feature 12 on a second guide rail 4 running parallel to the guide rail 3. Thus, as the inner articulation member 10 slides back and forth on the guide rails 3 and 4, the outer member 14 of the articulation and the complete accessory 1 connected to the outer member 14 likewise run back and forth on the guide rails 3 and 4.

FIG. 1 also shows a mechanical drive 17 which consists essentially of an eccentric arm 19, a swinging eccentric drive member 22 and a manipulating lever 20. The front section of the swinging member 22 is mounted so as to pivot on the inner member 10 of.the articulation device. The free rear end of the swinging member 22 is connected to rotate with the free end of the eccentric arm 19, whereas the other end of the eccentric arm 19 is mounted so as to rotate about a pin on the mounting frame 18. In the neighborhood of the bearing pin on which the eccentric 19 turns, an actuating lever, already mentioned, is provided which has openings in which, if needed, there can be fastened a rod for more easily actuating the lever 20 and the eccentric arm 19.

FIG. 2 clearly shows the same arrangement as FIG. 1, except that the accessory 1 is in this case placed at the front end of the lens 23. Such placing of the accessory is produced by means of a mechanical drive by rotating the actuating lever 20 and the arm 19 by 180°. In contrast with FIG. 1, FIG. 2 shows the free end 7 of the guide rail 3 projecting through the positioning aperture 15 of the outer member 14 of the articulation device, so that in this case, the accessory 1 is fixed against swinging movements. The bellows 27 at the rear end of the accessory 1 surrounds the free front end of the lens 23. It can further be seen from FIG. 2 that the eccentric 19 is turned by 180° to the rear and likewise the actuating lever 20 connected to it, as compared with FIG. 1. The rotation of the lever 20 by 180° to the rear produces a corresponding rotation of the eccentric 19 on which the lever is fixed and which is mounted to rotate on the free end of the swinging member 22. In that way, the articulation device 10, 13, 14 connected with the swinging member 22 and the accessory 1 fastened thereto are rearwardly displaced towards the front of the lens 23.

FIG. 3 shows a side view of the accessory holder of the invention in its position shown in top view in FIG. 1, i.e., with the accessory 1 shifted forwards. It is particularly evident from FIG. 3 that there are two guide rails 3 and 4 which are parallel to each other and parallel to the optic axis 2 of the lens and that their respective rear ends are fixed in place on the mounting frame 18 which is mounted from below and from the rear and is itself connected with a rod 25 (and a rod 26 as shown in FIG. 1), preferably in a swingable but also fixable manner, the

rods 25 and 26 being connected to the lens support structure 9.

The shift lever 21 is in this case (FIG. 3), unlike the shift lever of 20 of FIGS. 1 and 2, shown in an oblique position extending downward and forward although it preferably lies in the same plane as the eccentric arm 19. It is so shown for reasons of making it more readily seen. For simplifying handling and manipulation, and to some extent for increasing the available torque, the middle section of the swinging member 22 is arched or bowed, preferably upwards. The articulation structure with its inner member 10, outer member 14 and the articulation joint 13 inbetween, is also visible in FIG. 3. The inner member 10 has guideways 11 and 12 respectively for the upper guide rail 3 and the lower guide rail 4. The outer member 14 has positioning (locking) holes 15 and 16 which are located and directed to receive the free ends 7 and 8 of the guide rails 3 and 4.

FIG. 4 is a side view of the subject matter shown in top view in FIG. 2, namely the accessory 1 in place, in its holder, on the lens 23. In contrast with FIG. 3, it is here noticeable that the accessory 1 is displaced rearwardly, to the left in the drawing, so that the free ends 7 and 8 of the respective guide rails 3 and 4 pass through the positioning or locking apertures 15 and 16 FIG. 4 furthermore shows an altered position of the eccentric 19 and of the actuating lever 21, rotated by 180° counterclockwise compared to FIG. 3. It can be seen that in FIG. 3 the eccentric arm effectively adds its length to that of the swinging link member 22, and in FIG. 4 subtracts its length therefrom in determining the spacing of the member 13 from the frame 18.

Although the invention has been described with reference to a particular illustrative embodiment, it will be understood that variations and modifications are possible within the inventive concept. For example, a single guide rail of suitable profile, perhaps of cross-shaped cross-section, might be used instead of the two guide rails 3 and 4, or, on the other hand, three or four guide rails could be used instead of two, in each case modifying the aperture pattern in the outer articulation member 14 and, if necessary, the shape and dimensions of the latter to fit the new guide rail pattern.

I claim:

1. Accessory holder for holding accessories in front of an objective lens of an optical system, said lens having an optic axis and being mounted on a supporting structure located rearwardly thereof, comprising:

at least one guide rail (3, 4) disposed parallel to said optic axis (2) of said lens (23), said at least one guide rail having one end (5, 6) fixed in place on said supporting structure (9) of said lens and having another end (7, 8) which is a free end;

articulation structure comprising inner (10) and outer (14) members held together by an articulation joint (13) having an axis, for permitting swinging of said outer member (14) relative to said inner member (10) about said joint axis, said inner member (10) being mounted for movement along said at least one guide rail in a manner maintaining said articulation axis perpendicular to said at least one guide rail and said outer member (14) having a locked position relative to said inner member wherein at least one aperture of said outer member are penetrated by said at least one guide rail thereby locking said outer member (14) in an orientation perpendicular to said optic axis, and;

means for mounting, on said outer member (14) of said articulation structure, at least one accessory for said lens having an optic axis so that in said locked position of said outer member (14) said optic axis of said accessory substantially coincides with said optic axis of said lens, and

said inner member (10) of said articulation structure being displaceable along said at least one guide rail from a first position in which said accessory is in a working position at the front end of said lens to a second position in which said inner member (10) is located on said at least one guide rail near its said free end while said outer member (14) of said articulation structure is beyond said free end of said at least one guide rail, and back from said second position to said first position,

said outer member being provided with at least one said aperture corresponding to the location of said at least one guide rail for locking said outer member against swinging about said articulation axis when said articulation structure occupies its said first position and during its approach to and travel away from its said first position.

2. Accessory holder for holding accessories in front of an objective lens of an optical system, said lens having an optic axis and being mounted on a supporting structure located rearwardly thereof, comprising:

a plurality of guide rails (3, 4) disposed parallel to said optic axis (2) of said lens (23), said guide rails each having one end (5, 6) fixed in place on said supporting structure (9) and each having another end (7, 8) which is a free end;

an articulation structure comprising inner (10) and outer (14) members held together by an articulation joint (13) having an axis, for permitting swinging of said outer member (14) relative to said inner member (10) about said joint axis, said inner member (10) being mounted for movement along said guide rails (3, 4) in a manner maintaining said articulation axis perpendicular to said guide rails (3, 4) and said outer member (14) having a locked position relative to said inner member wherein apertures of said outer member (14) are respectively penetrated by said guide rails, thereby locking said outer member (14), in an orientation perpendicular to said optic axis; and

means for mounting, on said outer member (14) of said articulation structure, at least one accessory for said lens having an optic axis so that in said locked position of said outer member (14) said optic axis of said accessory substantially coincides with said optic axis of said lens,

said inner member (10) of said articulation structure being displaceable along said guide rails (3, 4) from a first position in which said accessory mounted on said outer member is in a working position at the front end of said lens (23) to a second position in which said inner member (10) is located on said guide rails (3, 4) near their respective free ends (7, 8) while said outer member (14) of said articulation structure is beyond said free ends (7, 8) of said guide rails,

said apertures (15, 16) of said outer member (14) having a size and shape corresponding to the respective sizes and shapes of the cross-sections of said respective guide rails and a disposition corresponding to the disposition of said guide rails with respect to each other, for locking said outer member

against swinging about said articulation axis when said articulation structure occupies its said first position and during its approach to and travel away from its said first position.

3. The accessory holder of claim 2 including also a frame (18) mounted on said supporting structure (9) of said lens, on which said frame said fixed ends (5, 6) of said guide rails (3, 4) are fastened, and means (17) for facilitating and controlling the shifting of said inner member (10) of said articulation structure back and forth on said guide rails for displacing a said accessory mounted on said outer member (14) back and forth over a predetermined path length.

4. The accessory holder of claim 3, wherein said means for facilitating and controlling displacement comprise:

an eccentric member (19) having a first pivot about which it is rotatable and an eccentric pivot spaced therefrom;

a link member (22) pivotally linked at one end to said eccentric member at said eccentric pivot thereof and having a pivot at its other end defining one working end of said means for facilitating and controlling the displacement of said inner member, the other working end thereof being said first pivot of said eccentric member, said two working ends of said means for facilitating and controlling displacement of said inner member being respectively fixed on said inner member (10) and on said frame (18), and

an appendage (20, 21) extending from said eccentric member for manually applying force thereto and capable of rotating said eccentric member (19) at least 180° about its said first pivot.

5. The accessory holder of claim 4, wherein said first pivot of said eccentric member (19) is disposed for permitting said eccentric member to rotate about a fixed location on said frame (18) and said pivot of said link member at its end remote from said eccentric pivot of said eccentric member is located to permit to said link member (22) to swing about a fixed location on said inner member (10) of said articulation structure, the length of said guide rails and the dimensional ratios of the distances between the pivots of said eccentric member and between the pivots of said link member are such that 180° rotation of said eccentric member in one direction produces an accurate apposition of a said accessory mounted on said outer member (14) at the front of said lens (23) and a rotation by 180° of said eccentric member in the opposite direction provides a displacement of said accessory away from said lens for a predetermined distance to a location where said apertures (15, 16) of said outer member (14) of said articulation structure are cleared and said outer member (14) is thereby released for swinging about said articulation axis.

6. The accessory holder of claim 5, wherein the mid portion of said link member (22) is bowed so as to assure clearance between said link member and said first pivot of said eccentric member when said accessory is held close to said lens by said accessory holder.

7. The accessory holder of claim 5, wherein said outer member (14) of said articulation structure holds a sun shade, a filter, or both a sun shade and a filter.

[57] **ABSTRACT**

An objective observation optical material comprises a sheet material composed of a plurality of spot-like transparent portions and an opaque portion and each of the spot-like transparent portions is formed into a circular shape having preferably a diameter of 0.7 to 2.0 mm or substantially a polygonal shape (including one whose sides are curved arcuately) inscribing or circumscribing such circle. The spot-like transparent portions are arranged to scatter in uniformly arranged positions so as to form connected regular triangles or squares whose sides are for example in the range from 2.0 to 5.5 mm.

OBJECTIVE OBSERVATION OPTICAL MATERIAL

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to an objective oberservation optical material capable of screening ultraviolet rays and correcting such defects of vision as nearsightedness, farsightedness, astigmatism and presbyopia.

2. Description of the Prior Art

In the past, generally the incidence of ultraviolet rays to the eyes has been prevented by the use of glasses made by providing parallel-surface glasses or plastic pieces with suitable light screening properties and/or absorbing properties with respect to specific wavelengths by adding a light screening or absorbing substance during their raw material stage, coloring the transparent glasses or applying a coating to the surface of the glasses, i.e., so-called sunglasses and in the case of the wearer having nearsightedness, farsightedness, astigmatism or presbyopia the glasses have consisted of lenses or other glasses have been worn on the sunglasses for correcting the defect of vision.

However, such sunglasses are expensive and often they are not used habitually thus requiring the provision of a case for carrying or accommodating the glasses. Also, in everyday life or when going out, particulary or for protection from the intense sunshine in the summer, the sunshine on a snowy day or the reflected light of such sunshine, it is necessary to use a more powerful ultraviolet screening substitute for glasses in place of the sunglasses and the same applies to any person having nearsightedness farsightedness, astigmatism or presbyopia.

SUMMARY OF THE INVENTION

It is the primary object of the present invention to provide an objective observation optical material which is so designed that where such a situation occurs in a moment and sunglasses and correction glasses are not on hand but a person is required to look at a thing, it is possible to use the material for providing in place of such glasses any of those things kept at one's side or carried on the person, e.g., a stationery such as an underlaying sheet or ruler, a book cover, a bookmarker, a corner of a book cover, a cash card, credit card or member's card, a watch band, a shoulder belt for bags or a tag.

In other words, in accordance with the invention the objective observation optical material comprises an opaque sheet formed with a large number of uniformly scattered spot-like transparent portions and each of the spot-like transparent portions is formed into a circular shape having a diameter in the range of 0.7 to 2.0 mm or substantially a polygonal shape inscribing or circumscribing this circle (including one whose sides are each curved arcuately). The transparent portions should preferably be scattered uniformly in a staggered manner, for example, so that their center distance becomes 2.0 to 5.5 mm. Suitable materials for the above-constructed optical material of this invention must be substances having a suitable strength, physical properties, elegance and durability required for use as the materials for the previously mentioned articles as well as the capacity for maintaining the transparency of the transparent portions for a comparatively long period of time and these substances include for example plastics such as soft or hard polyvinyl chloride, polyacrylic, methacrylic acid, polyurethane, polyolefin and polyester plastics. It is to be noted that the transparent portions may take the form of holes made through the material and the material may be an opaque material such as a metal sheet. There is no particular need to limit the material to the above-mentioned plastics.

On the other hand, means for forming the spot-like transparent portions and the opaque portion separately from each other may be a method in which an opaque portion is printed by photogravure on the surface of a transparent sheet of such plastic material so as to leave spot-like blank portions and then a transparent film is applied onto the printed surface or it may be a method of printing an opaque layer over the whole surface of a transparent film and forming transparent portions or holes by such means as etching or punching. Also, any of various other methods may be used.

The thus constructed objective observation optical material of this invention is used daily in conformity with the purpose for which the article is primarily intended so that when a need occurs in a moment to confirm an object in a place where ultraviolet rays are abundant irrespective of indoor or outdoor, the optical material is held in front of the eyes to face and look at the object or view a field. In such a case, the amount of the incident light to the eyes through the spot-like transparent portions is restricted considerably by the opaque portion and one may gaze or stare at the object with open eyes. As a result, the eyes unconsciously make movements to distinguish the object in sight so that the ciliary body or the structure for adjusting the curvature of the crystalline lens in front of the eyeball of each eye functions naturally in such a manner that the curvature is decreased if the person is nearsighted and the curvature is increased if the person is farsighted thereby permitting detailed observation of the object.

Thus, not only a person of the normal vision but also a person having nearsightedness, farsightedness, astigmatism or presbyopia can comparatively accurately look at an object through the optical material according to the invention.

This principle is similar to that of a pinhole camera which takes a picture through a minute aperture so that even if there are variations in the relative distance of an object corresponding to the object to be photographed in the case of a camera, the focal point is not varied much owing to the long depth of focus and therefore the object can be seen clearly through the optical material.

The above and other objects as well as advantageous features of the invention will become more clear from the following description taken in conjunction with the drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a partial plan view showing in enlarged form an embodiment of an optical material according to the invention.

FIGS. **2A**, **2B** and **2C** show some exemplary geometrical shapes of the spot-like transparent portions.

FIG. **3** is a graph showing the relation between the hole diameter and the eyesight (directional eyesight or the definition of an object viewed through the holes formed in the optical material of FIG. **1**.

FIG. **4** is a plan view of a watch band made of the optical material shown in FIG. **1**.

FIG. 5 is a plan view of a book cover incorporating in corner thereof the optical material shown in FIG. 1.

FIG. 6 is a plan view of a bookmarker incorporating in a part thereof the optical material shown in FIG. 1

FIG. 7 shows an example in which the optical material of FIG. 1 is incorporated in a cash card.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

Referring to FIGS. 1, 2A, 2B and 2C, numeral 1 designates an optical material according to the invention, and 2 a plurality of spot-like transparent portions formed into a polygonal shape such as one whose sides circumscribe a circle of a diameter r and are arcuately curved as shown in FIG. 2A, a circular shape of a diameter r as shown in FIG. 2B or a polygonal shape inscribing a circle of a diameter r as shown in FIG. 2C. A plurality of such spot-like transparent portions 2 are each arranged at the apex of each of a plurality of contiguous regular triangles whose sides have a length of 2.0 to 5.5 mm as shown at l in FIG. 1 and thus the transparent portions 2 are arranged in a staggered manner. Numeral 3 designates an opaque portion. FIGS. 2A and 2C show the hexagonal transparent portions and in FIG. 2A the sides of the hexagonal shape are curved inwardly.

Referring to FIG. 3, there is illustrated a graph showing the relation between the diameter r of the spot-like transparent portions 2 and the eyesight (directional eyesight) when looking at an object by using the optical material according to the embodiment of FIG. 1. From this Figure it will be seen that an essential requirement of the invention resides in that the diameter r of the plurality of spot-like transparent portions is selected between 0.7 and 2.0 mm and preferably between 1.0 and 1.2 mm.

It is to be noted that the spot-like transparent portions may take the form of spot-like holes formed through the material and it has been confirmed that from the standpoint of reducing the interference in the field of view it is preferable to arrange the transparent portions 2 uniformly at such positions that their center distance becomes 3.0 and 5.0 mm, that is, they are arranged to scatter in a staggered manner so as to form regular triangles or squares whose sides are between 2.0 and 5.5 mm.

While it is more desirable to use a plastic material for forming the optical material 1 in the light of physical properties, working properties in manufacture, cost and elegancy as mentioned previously, the invention is not necessarily limited to such plastic materials and the use of materials having the same effects is of course within the scope of the invention. Also, while a description has been made of suitable means for forming the holes or transparent portions 2 and the opaque portion 3, the invention is not limited to these means and a metal sputtering employing a mask and the like may also be used as effective means for the purpose.

From the foregoing description it will be seen that in addition to an essential application of an article made by using as its material the optical material of the invention, e.g., an underlaying sheet, ruler, book cover, corner of a book cover, part of a bookmarker, cash card, member's card, commutation ticket holder, watch band, shoulder belt for bags or tag, the optical material of this invention is not only effective for use as an objective observation optical material in place of sunglasses when its use is required to protect the user from the glare of ultraviolet rays such as the intense sunlight or the reflection from deep snows but also effective to correct such defect of vision as the nearsightedness, farsightedness, astigmatism or presbyopia. These effects are attained by the fact that the shape and size (area) of the plurality of spot-like transparent portions 2 as well as their positions in the opaque portion 3 are specified such that the adjacent transparent portions overlap in the field of view and there is no break in the field of view thereby providing the continuous field of view. On the other hand, a greater part of the ultraviolet rays to the field of view is blocked by the opaque portion 3 and also the field of view is continuous as mentioned previously. Thus, there is no obstruction from the vision point of view thus permitting to accurately look at an object in the intense ultraviolet rays.

FIG. 4 shows by way of example a watch band made of the optical material 1 shown in FIG. 1. In the Figure, numeral 4 designates the watch proper and 5 the band made of the optical material.

FIG. 5 shows an exemplary application in which the optical material 1 of FIG. 1 is incorporated in a portion 7 of a cover of a book cover 6 and the portion 7 is cut off the cover to read the book through it in place of glasses for far vision.

FIG. 6 also shows an exemplary application in which the optical material 1 of FIG. 1 is incorporated in a bookmarker 8 and a portion 9 of the bookmarker 8 is made of the optical material 1.

FIG. 7 shows another exemplary application in which the optical material of the invention is incorporated in a bank cash card. In the Figure, numeral 10 designates a card, 11 a magnetic recording zone, 12 a bank name stamping portion, 13 a registration number stamping portion, 14 a depositor's name stamping portion, and 15 scattering arranged spot-like transparent portions arranged in a centralized area of the card.

We claim:

1. An optical objective sheet material which is capable of permitting sufficient light transmission therethrough to support human vision, at least a part of the sheet being generally opaque but with a large number of spot-like transparent portions distributed uniformly thereover, each spot-like transparent portion being formed of substantially hexagonal shape inscribing a circle having a diameter in the range of 0.7 to 2.0 mm, the sides of the hexagonal shape being arcuately concaved and the transparent portions arranged in a staggered manner such that lines connecting their adjacent central points form regular triangles.

2. An optical material as claimed in claim 1 wherein the centers of adjacent transparent portions are spaced at distances in the range from 2 to 5.5 mm.

3. An optical material as claimed in claim 1 wherein the centers of adjacent transparent portions are uniformly spaced from one another at a distance in the range of 3 to 5 mm.

4. An optical material as claimed in claim 1, wherein each spot-like transparent portion comprises a hole formed through the sheet material.

5. A dual function assembly device comprising a readily portable and/or accessible object having, as a part of it, or associated with it, another object having a primary function, and also as a part of it, or associated with it, a piece of sheet material at least a portion of which has a secondary function of forming an optical objective which is capable of permitting sufficient light transmission therethrough to support human vision, at

least a part of the sheet being generally opaque but with a large number of spot-like transparent portions distributed uniformly thereover, each spot-like transparent portion being formed of substantially hexagonal shape inscribing a circle having a diameter in the range of 0.7 to 2.0 mm, the sides of the hexagonal shape being arcuately concaved and the transparent portions arranged in a staggered manner such that lines connecting their adjacent central points form regular triangles.

6. A device according to claim **5** wherein said device is a wrist watch band comprising said sheet material.

7. A device according to claim **5** wherein said sheet material forms a part of a book cover.

8. A device according to claim **2** wherein said spot-like transparent portions of said sheet material are confined to one corner of a book cover.

9. A device according to claim **5** wherein said sheet material comprises a bookmark.

10. A device according to claim **9** wherein said spot-like transparent portions are confined to an area no more than half the area of the bookmark.

11. A device according to claim **5** wherein said sheet material comprises a credit card or cash card.

12. A device according to claim **11** wherein said spot-like transparent portions are confined to a centralized area of said card.

13. A dual function device according to claim **5** wherein the centers of adjacent transparent portions are uniformly spaced from one another at a distance in the range of from 2 to 5 mm.

[57] **ABSTRACT**

The present invention provides an objective lens system specifically designed for optically recording and reading digital data on an optical disc. The lens system includes three lenses, with one of the lenses having an aspherical surface. The first lens element can have a positive power with a spherical surface on its light source side. The second lens element can have a positive refractive power while a third lens element can also have a positive refractive power. The lens system can fulfill the following conditions.

$$-0.3 < f/r_1 < 0.25$$

$$|r_4/r_3| < 0.5$$

wherein:

f represents the focal length of the whole lens system;

r_1 represents the paraxial radius of curvature of the light source side aspherical surface of the first lens element;

r_3 represents the radius of curvature of the light source side surface of the second lens element; and

r_4 represents the radius of curvature of the disk side surface of the second lens element.

OBJECTIVE LENS SYSTEM FOR OPTICAL RECORDING AND READING DEVICE

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to an objective lens system for a device for optically recording and reading digitalized information on an optical disk which is utilized as a document file or the like.

2. Description of the Prior Art

In case of recording the information on the disk, a more intensive light energy is required than the case of reading the information. Therefore, not only the numerical aperture, NA on the disk side but also that the numerical aperture NA' on the light source side should be increased in comparison with the case of an objective lens for exclusive use of reading the information. An increase of the magnification, $\beta(=NA'/NA)$ of the objective lens system may suit the above purpose. As magnification becomes greater, however, an angle of incidence becomes so greater as to cause both spherical aberration and coma which are difficult to be corrected well. An attempt to correct such aberrations with a combination of only spherical lens elements would necessitate a greater number of lens elements forming the objective lens system with its size and weight inevitably increased.

Japanese patent applications laid open Nos. 58-211729, 57-154213 and 59-157607 are cited to show prior art objective lens systems in this field of art.

SUMMARY OF THE INVENTION

An object of the present invention is to provide an improved objective lens system for an optical recording and reading device.

Another object of the present invention is to provide an objective lens system that is available for both recording and reading the information.

Still another object of the present invention is to provide such an objective lens system with one aspherical lens element and two spherical lens elements.

Further object of the present invention is to provide an objective lens system of the above mentioned type which has a great numerical aperture with the aberrations well corrected over its full image height (such as $y'=0.2$), for all its increased magnification (such as $|\beta| \geqq 0.37$)

Still further object of the present invention is to provide the objective lens system with a compact size and a light weight.

According to the present invention, an objective lens system for optical recording and reading device, comprises from a light source side to a disk side, a first lens element having a positive refractive power, said first lens element having an aspherical surface on the light source side, a second lens element having a positive refractive power, and a third lens element having a positive refractive power, wherein the objective lens system fulfills the following conditions:

$$-0.3 < f/r_1 < 0.25$$

$$|r_4/r_3| < 0.5$$

wherein f represents the focal length of the whole lens system; r_1 represents the paraxial radius of curvature of the light source side aspherical surface of the first lens element; r_3 represents the radius of curvature of the light source side surface of the second lens element and r_4 represents the radius of curvature of the disk side surface of the second lens element.

The objects and features of the present invention which are believed to be novel are set forth with particularity in the appended claims. The present invention, both as to its organization and manner of operation, together with further objects and advantages thereof, may best be understood by reference to the following description, taken in connection with the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWING

FIG. **1** represents a cross sectional view of the objective lens system according to embodiment 1 of the present invention;

FIG. **2** represents a cross sectional view of the objective lens system according to embodiments 2, 3, 4, 8, 10 of the present invention;

FIG. **3** represents a cross sectional view of the objective lens system according to embodiments 5, 6, 7, 9, 11, 12, 13, 14, 15 of the present invention;

FIGS. **4A** to **4C** represent the aberration curves of the embodiment 1;

FIGS. **5A** to **5C** represent the aberration curves of the embodiment 2;

FIGS. **6A** to **6C** represent the aberration curves of the embodiment 3;

FIGS. **7A** to **7C** represent the aberration curves of the embodiment 4;

FIGS. **8A** to **8C** represent the aberration curves of the embodiment 5;

FIGS. **9A** to **9C** represent the aberration curves of the embodiment 6;

FIGS. **10A** to **10C** represent the aberration curves of the embodiment 7;

FIGS. **11A** to **11C** represent the aberration curves of the embodiment 8;

FIGS. **12A** to **12C** represent the aberration curves of the embodiment 9;

FIGS. **13A** to **13C** represent the aberration curves of the embodiment 10;

FIGS. **14A** to **14C** represent the aberration curves of the embodiment 11;

FIGS. **15A** to **15C** represent the aberration curves of the embodiment 12;

FIGS. **16A** to **16C** represent the aberration curves of the embodiment 13;

FIGS. **17A** to **17C** represent the aberration curves of the embodiment 14; and

FIGS. **18A** to **18C** represent the aberration curves of the embodiment 15;

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

The following description is provided to enable any person skilled in the optical field to make and use the invention and sets forth the best modes contemplated by the inventor for carrying out my invention. Various modifications, however, will remain readily apparent to those skilled in the art, since the generic principles of the present invention have been defined herein specifically to provide a relatively economical and easily manufactured objective lens system. The derivation of the formulas and the relation of the powers set forth herein can be accomplished with the assistance of a computer. The present invention represents the parameters of a

compromise balance of acceptable aberrations which can be relatively easily manufactured to provide a low cost lens system.

In the drawings, schematic cross sectional views disclose the position of the lens elements. Values of the radii of curvature and axial distances for each lens element and air space are provided in the accompanying tables set forth herein. The schematic cross sectional views of the respective embodiments follow the normal conventions of the light source at the left-hand side of the drawing and the disk at the right hand side.

As shown in FIGS. **1**, **2**, **3**, which show the objective lens system according to the present invention along with the cover glass(**1**) of the semiconductor laser and the cover glass(P) of the laser disk, the present invention provides the objective lens system available for optically recording and reading information on an optically disk, comprising from the light source side to the disk side, a first lens element (L_1) having a positive refractive power, said first lens element(L_1) having a aspherical surface on the light source side, a second lens element(L_2) having a positive refractive power, and a third lens element(L_3) having a positive refractive power, in which the objective lens system fulfills the following conditions:

$$-0.3<f/r_1<0.25 \quad (1)$$

$$|r_4/r_3|<0.5 \quad (2)$$

wherein, f represents the focal length of the whole lens system, r_1 represents the paraxial radius of curvature of the light source side aspherical surface of the first lens element, r_3 represents the radius of curvature of the light source side surface of the second lens element and r_4 represents the radius of curvature of the disk side surface of the second lens element.

As is already explained, the magnification (=NA'/NA) of the objective lens system should become greater in order to increase the numerical aperture NA' on the light source side. This makes the angle of ray incidence to the objective lens system too large, which causes spheric aberration and coma. Although the spherical aberration may be corrected by means of an aspherical surface, the coma cannot be corrected well even with other spherical surfaces when the absolute value of the paraxial radius (r_1) of curvature of the light source side of the first lens element(L_1) is made excessively small. In order to correct the coma the condition (1) limits the paraxial radius (r_1) of curvature of the light source side of the first lens (L_1). If the absolute value of the paraxial radius(r_1) of curvature of the light source side of the first lens (L_1) becomes small to an extent violating the lower or upper limit of the condition (1), the coma cannot be corrected well, so that sufficient optical performance can be achieved only at a small image height.

The condition(2) defines the shape of the second lens element(L_2) with positive power. If the absolute value of the radius of the curvature of the light source side surface (r_3) compared with that of the disk side surface (r_4) becomes smaller in the second lens element (L_2), the astigmatism is increasing and the working distance is decreasing. Although such an astigmatism may be theoretically corrected by both increasing the thickness (d_1) of the first lens element and widening the air space (d_2) between the first and the second lens elements, this approach would fail to maintain the necessary working distance.

In addition to the above conditions, it is recommended to fulfill the following conditions:

$$1.5<f_3/f<4.0 \quad (3)$$

$$-0.41\leqq f_1/r_1\leqq 0.41 \quad (4)$$

wherein, f_3 represents the focal length of the third lens element(L_3) and f_1 represents the focal length of the first lens element(L_1).

The condition (3) defines the positive refractive power of the third lens element(L_3). If the positive refractive power of the third lens element (L_3) becomes great beyond the lower limit of the condition (3), the working distance becomes too short. On the other hand, if the positive refractive power becomes weak beyond the upper limit of the condition (3), the positive refractive power of the first lens element(L_1) and the second lens element (L_2) have to become too strong for the coma to be satisfactorily corrected.

Furthermore, the condition(4) is to prevent the absolute value of the power for the light source side surface (r_1) from excessively increasing in comparison with the power for the first lens element(L_1). If the power of the light source side of the first lens element(L_1) becomes great and positive beyond the upper limit of condition (4), the coma is generated, which is not corrected easily. On the other hand, if the power of the light source side of the first lens element (L_1) becomes great and negative beyond the lower limit of the condition (4), the first lens element (L_1) becomes a meniscus lens element with a small radius of curvature, and the astigmatism is generated, which cannot be corrected well. The following tables 1 to 15 disclose, respectively, design parameters of the first through fifteenth embodiments of the present invention. In the tables, f equals the focal length of the whole lens system, r is the radius of curvature with respective sub numbers indicating the surface of the lens elements from the light source side along the optical axis, r_{p1} and r_{p2} are the radius of curvature of the light source side and disk side of the cover glass(P) of the disk, d_1 to d_5 represent the axial distance including both air spaces and the actual thickness of the lenses, d_p represents the thickness of the cover glass(P) of the disk, and finally N_1, N_2, N_3, and N_p represent respectively the refractive index of the first lens element(L_1), the second lens element(L_2), the third lens element(L_3) and the cover glass(P) at the wavelength $\lambda=870$ nm. The asterisk(*) represents the aspherical surface defined as follows, and values for coefficients appearing in the formula are shown at the bottom of respective tables:

$$x=\frac{Coh^2}{1+\sqrt{1-\epsilon Coh^2}}+\Sigma C_i h^{2i}\ (i=1,2,3,\ldots m) \quad .$$

wherein, x represents the coordinate along the optical axis measured from an imaginary plane tangent to the aspherical surface perpendicularly to the optical axis, h represents the coordinate perpendicular to the optical axis measured from the optical axis, Co represents paraxial curvature ($1/r_1$) of the light source side surface of the first lens(L_1), ϵ represents the quadratic surface coefficient and C_i represent the aspherical surface coefficients. Furthermore, NA represents the numerical

aperture of the objective lens system, and β represents the magnification.

Among the following embodiments, it should be noted that the paraxial curvature ($Co=1/r_1$) of the aspherical surface is zero in the first to third embodiments. This is favorable to a test or measurement of the formed shape of the aspherical surface in manufacturing, since the paraxial curvature can be left out of consideration.

$f_1/r_1 = 0.18$

What is claimed is:

1. An objective lens system for a device for optically recording and reading digital data on an optical disk, comprising from a light source side to a disk side,

a first lens element having a positive refractive power, said first lens element having an aspherical surface on the light source side;

a second lens element having a positive refractive power; and

a third lens element having a positive refractive power, wherein the objective lens system fulfills the following conditions:

$$-0.3 < f/r_1 < 0.25$$

$$|r_4/r_3| < 0.5$$

wherein:

f represents the focal length of the whole lens system;

r_1 represents the paraxial radius of curvature of the light source side aspherical surface of the first lens element,

r_3 represents the radius of curvature of the light source side surface of the second lens element and

r_4 represents the radius of curvature of the disk side surface of the second lens element.

2. An objective lens system as claimed in claim 1, wherein the objective lens system further fulfills the following conditions:

$$1.5 < f_3/f < 4.0$$

$$-0.41 \leqq f_1/r_1 \leqq 0.41$$

wherein:

f_3 represents the focal length of the third lens element(L_3) and

f_1 represents the focal length of the first lens element(L_1).

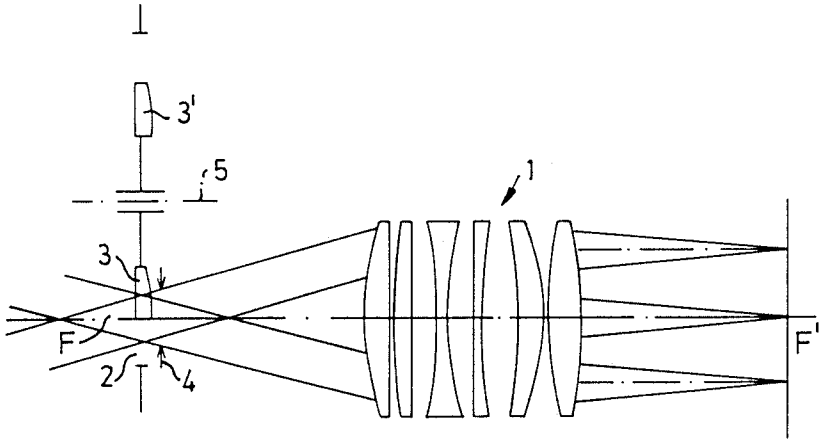
[57] **ABSTRACT**

The present invention relates to an image-forming objective which is capable of forming sharp images of objects at at least two different distances from the objective, there being arranged at one focal plane of the objective a corrective element divided into at least two fields in which the refractive power differs between them.

8 Claims, 1 Drawing Sheet



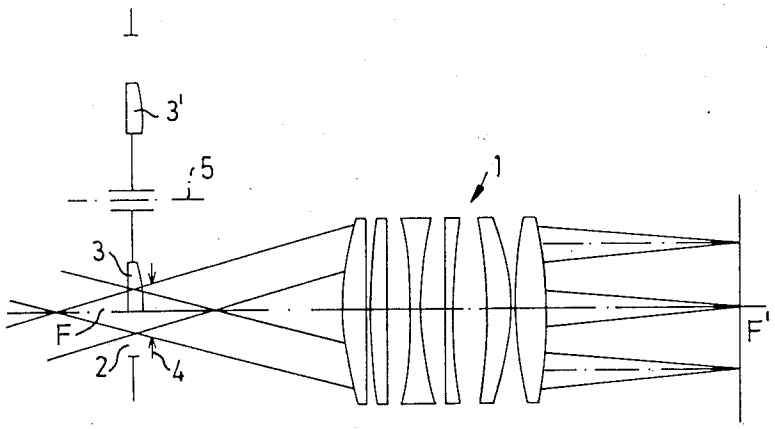


FIG. 1

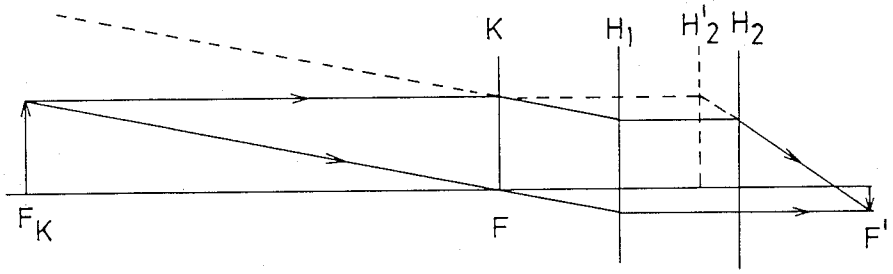

FIG. 2

MULTIFOCAL OBJECTIVE

DESCRIPTION OF THE PRIOR ART

An objective with these properties is known from U.S. Pat. No. 3,588,227 and is designed to serve as a microscope objective. Two objects in front of the objective are imaged sharply in the focal plane and with the same magnification. According to the principle of the known design, at the image-side focus of the objective, an optical element is arranged which in one half of this focal plane functions as a positive lens, acting to focus the closest object on the focal plane, and in the other half thereof functions as a plane-parallel disc without any net refraction (thus only the refractive power of the objective itself acts on beams in this half) so that the beams from the more distant object are not refracted as much and, because of a choice of suitable dimensions, are focused in the very same focal plane.

SUMMARY OF THE INVENTION

One object of the present invention is to produce a photographic objective, which is of particular use in moving picture and TV-cameras, making it possible in a single scene to provide sharp images of two objects at different distances, i.e., each with its own depth of field. The image thus combined should have a natural appearance, and if two different optical systems are used, it is particularly important that the unsharp image of one object made by the system which makes a sharp image of the other object, disrupt the sharp image of the other system as little as possible. Otherwise, the unsharp image could create a visible ghost image. If, however, the fuzzy image is of the same size as and is superimposed on a sharp image, the image will be perceived as sharp.

It is previously known to achieve this purpose by using two different objectives and mirror devices. Major mechanical stability problems are encountered in this case, however. Furthermore, it is difficult to make two images coincide exactly, one with a sharp object A and an unsharp object B and the other with an unsharp object A and a sharp object B. The two images of A, one sharp and one unsharp, must be superimposed on each other even if they do not lie in the center of the image surface, which means that the objective must provide the same magnification. One purpose of the invention is to achieve such a consolidation of images, and to do this with a single objective, suited to photography, cinematography, TV, etc.

The objective revealed by the above-mentioned patent specification does not constitute a solution to the problem according to the invention. Two objects A and B at different distances will each be sharply imaged in individual halves by the known objective and be of the same size, but at the same time the unsharp images will be of different sizes, and therefore an unsharp and different-sized image of A, for example, will be superimposed on the sharp image of A. This will have a very disturbing effect in a cinematographic picture, for example.

In other designs, relating to photographic objectives, lenses divided into zones are used, similar to Fresnel lenses, for instance, and are revealed in, for example, No. GB-A-335 696 and U.S. Pat. Nos. 2,546,996 and 2,651,237. While the zones do provide sharp images of objects at different distances, the problem of the unequal magnifications of the unsharp ghost images of the different objects has not been addressed and therefore the purpose of the present invention has not been achieved. It is true that U.S. Pat. No. 2,651,238 discusses this problem, but the solution there indicated was that the ghost images be so greatly out of focus that they do not disturb the sharp images, which can be difficult to achieve except with very small individual depths of field and with a large aperture.

The above-mentioned purpose and other purposes and advantages are achieved according to the invention, which has an image-forming objective of the type described by way of introduction, in which the corrective element is arranged in the objective focal plane closest to the object. The unsharp image of an object, which is also giving a sharp image, will be of the same size as the sharp image. It is true that the contrast of the composite image will be poorer than the contrast in a normal image, but the effect thereof will not be disturbing and can even provide an artistically pleasing soft focus, which is otherwise achieved with special diffusion discs. This effect can be enhanced further by providing one or even both of the fields in the corrective element with a diffusion disc or the like.

The different fields in the corrective element can, if required, be placed anywhere in the front focal plane of the objective. It is particularly advantageous, however, to arrange the fields symmetrically in relation to the optical axis. In a bifocal design, for example, it is advisable to have the boundary between the fields be a diameter which intersects the optical axis. For more than two objects and fields, the fields can be made in the form of circular sectors with the points on the optical axis. This has the advantage that a diaphragm placed closely thereto will stop down all of the images the same amount. Otherwise, other field distributions can provide a number of special effects. For example, with an annular zone the associated image can be made soft and diffused by stopping down, in many cases to interesting effects. It can be worth mentioning that one of the fields in the corrective element can suitably be open, and in a simple and practical embodiment of a bifocal objective, the corrective element can consist of a thin lens system which is semicircular, and can be considered to be a half fore-lens.

Several such corrective systems can be mounted on an arrangement in front of the objective, so that they can be easily interchanged, e.g., in a revolver mounting. If "half fore-lenses" are used, the focusing for one image will be done in the usual manner (as a rule by moving the objective relative to the film plane), while the focus of the other image is obtained by suitable selection of the fore-lens. Instead of a simple thin system, it is also possible to set in a system with variable refraction, more or less along the lines of a zoom lens. The objective behind it can of course also be a zoom lens, and this may require a certain calculated effort, which does, however, lie within the capacity of the optical designer.

BRIEF DESCRIPTION OF THE DRAWINGS

The invention is clearly revealed in the drawings,

FIG. 1 of which shows schematically an objective according to the invention, while FIG. 2 shows a schematic beam path.

DESCRIPTION OF THE PREFERRED EMBODIMENT

The composite objective shown in FIG. **1** comprises a cinematographic objective **1** with a focal length of 50 mm represented in approximately natural size. The foci are located at F and F′ and a film plane has been drawn in at the rear focal plane. In the front focal plane there is a "half" lens **3** which extends as far as the optical axis, and an iris **4**.

Since it is well known how objectives are designed (see for example Conrady, Applied Optics and Optical Design, parts I and II, New York 1957, Dover), it is unnecessary to describe the seven-lens objective shown. As regards the element **3**, it is drawn as a single, thin lens, and such a design is usually satisfactory, especially if the diopter number does not need to be high. An achromatization may be advisable, although this should be determined in relation to the actual lack of sharpness already there due to the unsharp image superimposed on the sharp image.

With a setting for one of the objects, as in the figure, at infinity, the focal length for the lens element **3** should be equal to the distance to the other object, with the lens **3** forming a virtual image at infinity.

The functioning of the system may be clearer by applying Gullstrand's formula for refractive power in two combined lens systems:

$$D=D_1+D_2-\delta\cdot D_1\cdot D_2$$

where D_1 and D_2 are the diopter number (m^{-1}) of the systems and δ is the distance between the systems (or their principal-facing planes in Gauss' approximation). If, as here, the lens element **3** (diopter number D_2) is at the focus of the composite objective (diopter number D_1), the result will be $D=D_1$.

Thus the corrective element does not effect the focal length of the system. FIG. **2** shows a schematic optical path, the main objective being represented by the focal points F and F′ and the principal planes H_1 and H_2. The corrective element K is shown as a thin lens with focal point F_K. Two rays are shown for an object at F_K, and it can be seen therefrom that the front principal plane of the system coincides with that of the main objective, while the rear principal plane of the system will be displaced towards the object just enough so that the object at F_K will be in focus at F′.

When using a thin lens **3** in the form of a half lens, its edge should be well blackened to avoid light scattering. Experience has shown that the corrective element must also be well centered in relation to the optical axis. Otherwise the sharp and the unsharp image will not coincide but will be somewhat laterally displaced (net wedge effect). In a cinematographic objective with a movable or interchangeable corrective element, for purely practical reasons there must be a reproducible and exact centering, of the order of a few hundredths of a millimeter (for 50 mm focal length).

In order to avoid difficult vignetting problems, an objective should be used which is computed so that its entrance pupil is located at the forward focus (socalled telecentric objective). The diaphragm **4** will then also be at the actual entrance pupil of the objective.

FIG. **1** also shows schèmatically a revolver mechanism with an axis of rotation **5** and two corrective elements **3** and **3′**. Several different corrective elements can suitably be mounted in holes in the revolver disc, leaving one hole empty, so that the objective **1** can also be used as an ordinary objective. As already pointed out, this revolver mechanism should be made with high precision and the corrective elements be well centered; this does not present any insurmountable technical problems, but should be kept in mind during its design.

The invention provides a photographic objective which solves the problem of imaging sharply in a single scene objects located at different distances from the camera, each of the objects having its own depth of field. To date, such imaging, has in practice had to be done by stopping way down. As an example of what can be achieved with an objective with F=50 mm, it is possible with a stop-number of 4 (with a resolution requirement of 0.03 mm) to obtain the two depths of field 1.8–2.2 m and 6.7–19 m (settings 2 m and 10 m). If one stops down to f-stop **14**, the combined depth of field will then be 1.5 m−∞. A comparable depth of field achieved with conventional stopping-down would require f-stop 28.

In addition to the great increase in usable depth of field, one should also mention the previously unknown, purely artistic unique effects which can be obtained through the invention, whereby the focus can be concentrated to selected dramatic areas of a filmed scene. In still-photography as well, the invention can provide a new means for achieving new artistic effects free of the limitations previously, considered unavoidable and dictated by the technology. Ideally, pictures should be true to nature, and the lack of deep focus, which the human eye unconsciously compensates for by continually changing focus, must create an unnatural impression, which can be largely eliminated by the invention.

We claim:

1. A lens system having an image-forming objective which is capable of forming sharp images of objects at at least two different distances from said objective, a corrective element (3) divided into at least two fields of differing refractive power being arranged at one focal plane (F) of the objective, said corrective element (3) being arranged in the objective focal plane (F) which is located closest to a said object, and an entrance pupil of said objective being located at its forward focus in the direction of said object.

2. A lens system objective according to claim **1**, wherein said fields are symmetrically arranged in relation to an optical axis of said objective.

3. A lens system objective according to claim **1** or **2**, including an aperture device at the forward, object-directed focus of said objective.

4. A lens system according to claim **1** or **2**, wherein said corrective element consists of a single or composite lens, which is halved along a diameter, which intersects said optical axis of said objective.

5. A lens system according to claim **3**, wherein said corrective element has a variable focal length.

6. A lens system according to claim **1**, wherein said corrective element is removably mounted.

7. A lens system according to claim **6**, comprising a plurality of corrective elements with different focal lengths mounted in openings in a revolver mechanism.

8. A lens system according to claim **1**, wherein one of said fields is provided with a means for reducing sharpness to achieve a so-called soft focus effect.

AUTOMATIC DIAPHRAGM CONTROL DEVICE FOR TV CAMERA OBJECTIVE

BACKGROUND OF THE INVENTION

1. Industrial field of application

The present invention relates to an automatic diaphragm control device for TV camera objective.

2. Prior art

As an automatic diaphragm control device for TV camera objective, a so-called one-way spring driven type has already been well known but has rarely been adopted in practice in view of its inconveniently limited range of useful driving voltage and poor reliability. A control device adapted for controllably driving the diaphragm in both directions, i.e., so as to open and close the diaphragm, respectively, has also been known and has been commonly employed, because the latter type provides a higher reliability and permits the consumed current to be effectively reduced.

However, demand for a more compact TV camera has recently increased and it has been found that the conventional control device of the bidirectional driving type cannot satisfactorily serve the objective of such a compact TV camra, since the conventional control device is too complicated in its structure to be correspondingly made compact.

3. Problems to be solved by the invention

A principal object of the present invention is, in view of the above-mentioned inconveniences, to provide an improved diaphragm control device of high reliability for a TV camera objective which includes a drive mechanism simplified and made compact by adopting the conventional one-way spring driven type while overcoming its inherent drawbacks, permitting both drive and control of the diaphragm to be achieved with a single power source, and leads to a reduction in current consumption.

SUMMARY OF THE INVENTION

Measures to solve the problems

To achieve the object as set forth above, the present invention provides an automatic diaphragm control device for a TV camera objective utilizing video signals from a TV camera, said automatic diaphragm control device comprising: first means primarily for adjustment of the video signals during a low contrast; second means primarily for adjustment of the video signals during a high contrast and also adapted to keep video output signals previously adjusted and set by the first means during the low contrast from any substantial variation; third means for stabilization of a source voltage in order to inhibit a possible variation of the video output signals preset by said first and second means or a possible increase of current; fourth means by which a braking can be effected on the basis of amplification of rectified signals provided by said first and second means and on the basis of a feedback signal from a detecting coil of a diaphragm driving servomotor, and, to drive the servomotor, for supplying the servomotor with a stabilized driving voltage substantially amplified in a one-way drive circuit having a voltage gain according to an obtained control signal; and fifth means to activate operational amplifiers respectively used in said first, second and fourth means with a single power source, and thereby realizing a highly reliable automatic diaphragm control device for TV camera objective having a variable photometric function, which is operable with a reduced current consumption and a compact structure.

Operation

It is well known that a video signal from a TV camera has an amplitude varying within a wide range depending upon a total brightness of an object to be shot and also upon a type of the TV camera used. According to the present invention, the first means adjusts the video output signals from the TV camera first on the basis of the overall brightness or the average brightness of the bright area and the dark area of the object during low contrast. More specifically, a level of the video output signal from the TV camera is greatly amplified when the level is low and slightly amplified when the level is high so that a constant output variation may be obtained. The second means is adapted to obtain a video signal based on the low contrast area by cutting the video signal portion corresponding to the bright area when the bright area and the dark area exhibit a high contrast in the object to be shot. Accordingly, even when the second means cuts the video signal portion corresponding to the bright area with respect to the object having a low contrast, the video signal previously adjusted and set by the first means during the low contrast is never varied by the second means because the video signal portion corresponding to the bright area has a relatively low level when the object is of a low contrast and cutting of this signal portion will not affect the overall video signal. Subsequently, the third means functions to stabilize the source voltage. In view of the fact that the video signal obtained by the first and second means, the diaphragm control signal obtained from this video signal and a diaphragm driving voltage depending upon said diaphragm control signal are all based on the source voltage, the source voltage serving the electric circuit of the device is kept by this third means at a constant level and thereby becomes highly reliable. The fourth means is adapted to effect a desired control on the basis of amplification of a rectified signal provided by said first and second means and on the basis of a feedback signal from a detecting coil of a diaphragm driving servomotor, and to drive the servomotor by supplying the servomotor with a stabilized driving voltage substantially amplified in a one-way drive circuit having a voltage gain according to an obtained control signal. Finally, the fifth means is adapted to provide a reference voltage in the first, second and fourth means as a mid-range voltage of the source voltage and thereby to activate said respective means with a single source voltage.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a circuit diagram illustrating one embodiment of the device according to the present invention;

FIG. **2** is a functional diagram of the first means thereof;

FIG. **3** is a functional diagram of the second means thereof;

FIG. **4** is a diagram illustrating a relationship between the object to be shot and the corresponding video signal;

FIG. **5** is a schematic diagram illustrating an input waveform before controlled by the means according to the present invention; and

FIGS. **6** and **7** are schematic diagrams illustrating the control waveforms provided by the means according to the present invention.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

The present invention will be now described more in detail with respect to embodiments as illustrated by the accompanying drawings. Referring to FIG. **1**, reference numeral **1** designates an input terminal adapted to input a video signal Vin from a TV camera and connected to an inverted amplifier/rectifier I. In this circuit I, the input terminal **1** is connected through a resistor R2 to a ground side **4** and through a capacitor C2 and a resistor R3 to an inverted input terminal **11** of an operational amplifier A1 associated with the first and second means according to the present invention. A non-inverted input terminal **12** of the operational amplifier A1 is connected through a resistor R4 to a mid-range voltage terminal **2** described hereafter in detail and there is provided a variable resistor VR1 serving as a feedback resistor between the inverted input terminal **11** and an output terminal **13**. Such circuit I is adapted to remove the DC component of the video signal Vin by said capacitor C2 and provides at the output terminal **13** an inversely amplified signal Vac, wherein said variable resistor VR1 may be adjusted for continuously changing a gain (amplification factor) of the operational amplifier A1. Thus, this circuit I constitutes the first means according to the present invention. Specifically, the gain increases as a resistance value of the variable resistor VR1 is increased and conversely decreases as said resistance value is reduced. This is illustrated by FIG. **2** in which an input variation γ becomes large when an optimal video signal level for the camera is relatively high and the input video signal Vin is also high. In such a situation, the resistance value may be adjusted to a lower level so as to reduce the gain. For a small input variation γ of the video signal Vin, on the contrary, the resistance value may be adjusted to a higher level to increase the gain and thereby obtain an inversely amplified signal Vac of a constant level. During this process, the input video signal Vin should be adjusted to have an amplitude in accordance with the overall brightness of the object to be shot, namely, the function of circuit I is principally to adjust the video output signal for objects of low contrast.

Reference numeral II designates a limiter circuit adapted for continuous limitation of a negative side output (video signal output portion corresponding to a bright area in the overall object) of the video signal inversely amplified by said operational amplifier A1 and constitutes the second means according to the present invention. The limiter circuit II is provided in parallel to said variable resistor VR1 and comprises a diode D2 and a variable resistor VR2 adapted to control current flowing through said diode D2, in which the inverted input terminal **11** of the operational amplifier A1 is connected to an anode of the diode D2 while a cathode of the diode D2 is connected through the variable resistor VR2 to the output terminal **13**. As shown by solid line(**2**) in FIG. **3**, this limiter circuit II is adapted to obtain an input/output characteristic such that a negative side of the output voltage from the operational amplifier A1 is forcibly suppressed by the diode D1. Referring to FIG. **3**, the abscissa indicates an input voltage V11 apearing at the inverted input terminal **11** of the operational amplifier A1 and the ordinate indicates an output voltage **13** appearing at the output terminal **13**. As shown, the output voltage V13 is limited to a constant level of β as the input voltage V11 exceeds a level of α. It should be noted here that a broken line (**1**) corresponds to a characteristic which would be exhibited without any limitation.

The inverted signal Vac obtained in said inverted amplifier is then rectified by a voltage multiplying rectifier which is provided immediately subsequent to said inverter amplifier. In this voltage multiplying rectifier, a voltage multiplying capacitor C3 is connected to said output terminal **13**, an output terminal **14** of said capacitor C3 is connected through a diode D3 to the midrange voltage terminal **2** to produce a voltage multiplied signal V14 corresponding to the inverted signal Vac containing both a positive side and a negative side, and a diode D4 is forwardly connected to said output terminal **14** so as to provide a rectified signal Vdc. There are provided a capacitor C and a resistor R5 between the voltage multiplying rectifier and ground for the purpose of smoothing said rectified signal Vdc.

Said rectified signal Vdc is coupled through a resistor R6 to an inverted input terminal **21** of an operational amplifier A2 constituting the fourth means according to the present invention adapted to provide a control signal for an automatic diaphragm controlling servomotor. There is provided between the inverted input terminal **21** and an output terminal **23** of the operational amplifier A2 a resistor R7 serving as a feedback resistor adapted to determine an amplification degree or factor in conjunction with said resistor R6. Reference C5 designates an integrating capacitor provided in parallel with the resistor R5. The input terminal **21** is also connected through a resistor R9 to an output terminal of a detecting coil **5** adapted to detect operation of the servomotor M for diaphragm control so that a feedback signal with which the servomotor M is stopped may be obtained. Another output terminal of said detecting coil **5** is connected to the mid-range voltage terminal. Additionally, a non-inverted input terminal **22** is connected through a resistor R8 to the mid-range voltage terminal **2** so that said rectified signal Vdc and the braking signal provided from the detecting coil **5** are compared with a mid-range voltage Vo as a reference voltage. As a result of such comparison, a difference relative to the mid-range voltage Vo appearing at the non-inverted input terminal **22** is relatively low and, in consequence, a control signal Vout appearing at the output terminal **23** is low when the signal appearing at the inverted input terminal **21** is relatively high while a difference relative to the mid-range voltage Vo appearing at the non-inverted input terminal **22** is relatively high and, in consequence, the control signal appearing at the output terminal **23** is high when the signal appearing at the inverted input terminal **21** is relatively low.

Said control signal is applied to an immediately subsequent one-way drive circuit having a voltage gain and thereby said diaphragm control servomotor M is driven with a substantially amplified driving voltage. A resistor R10 is inserted between the output terminal **23** of said operational amplifier A2 and the ground **4**, and said output terminal **23** is also connected through a resistor R11 to the base of a transistor TR2. The collector of said transistor TR2 is connected through a resistor R12 to the positive terminal **3** of the source, and is also connected to the base of a transistor TR3 which is provided with said transistor TR2 as a pair. The emitter terminal of the transistor TR2 is connected through a resistor R14 to the ground **4**, and it also connected through a feedback resistor **13** to the collector terminal of said transistor TR3. The emitter terminal of the transistor

TR3 is connected to the positive terminal 3 of the source. Reference numeral 6 designates a driving coil of the one-way drive circuit associated with the servomotor M and this coil 6 is connected at one terminal with the collector of said transistor TR3 and at the other terminal connected to the ground 4 of the source circuit. Transistors TR2 and TR3 form a Darlington connection by which a voltage having an extremely high amplification factor is applied to the driving coil 6 in proportion to the control signal Vout applied to the base of the transistor TR2.

The diagphragm driving servomotor M is, in the embodiment shown, normally biased under action of a spring 7 to be rotated in the diaphragm closing direction while the driving coil 6 drives the servomotor M against said spring 7 in the diaphragm opening direction so that diaphragm control may be performed under a balance with the spring 7.

Reference numeral III designates a power supply circuit constituting the third means adapted to stabilize the source voltage for the device according to the present invention at a constant level. In this power supply circuit, the collector of a transistor TR1 is connected to a positive terminal 8 of the source and serially connected through a resistor R1 and a capacitor C1 to the ground terminal 4, a junction of said resistor R1 and said capacitor C1 is connected to the base of the transistor TR1 and said base is connected through a Zener diode D1 to the ground terminal 4 so that the base voltage may be kept constant independently of a voltage variation at the positive terminal 8 to supply the positive terminal 3 of the source corresponding to the emitter terminal of the transistor TR1 with constant voltage and current.

Reference numeral V designates a mid-range voltage supply circuit constituting the fifth means according to the present invention connected to said power supply circuit III. This circuit V is adapted to output an intermediate (preferably $\frac{1}{2}$) of the stabilized source voltage to the mid-range voltage terminal 2. In the specific embodiment as shown, a smoothing capacitor C7 and serial resistors R15, R16 having the same resistance value are provided in parallel across the positive terminal 3 and the ground 4, and a junction point 51 of said resistors R15, R16 is connected to the mid-range voltage terminal 2 so that a voltage equal to $\frac{1}{2}$ of the source voltage is output to the mid-range voltage terminal 2. Reference C6 designates a smoothing capacitor connected between the mid-range voltage terminal 2 and the ground 4.

The manner in which the device according to the present invention operates will now be considered in reference to the embodiment of the above-mentioned arrangement. Assuming that the video signal Vin is input to the input terminal 1 with a waveform (b) as illustrated in the test chart (a) of FIG. 4, this waveform will have a positive rectangular area corresponding to the bright area of the scene of a video level Vd, a synchro level Vs and an amplitude Vp-p. Such a video signal Vin has its DC component removed by the capacitor C2 and, in consequence, the positive side area and the negative side area are biased with respect to the reference voltage Vo, as seen in FIG. 5. This signal is then inversely amplified by the operational amplifier A1, as seen in FIG. 6 (*a*), on the basis of the mid-ranged voltage Vo applied from the mid-range voltage terminal 2 and appears at the output terminal 13 as Vac. The gain of this operational amplifier A1, namely, the amplification factor, depends on a ratio of the resistance value of the variable resistor VR1 to that of the resistor R3, so that it is possible to increase or decrease the gain and, therefore, the amplitude of the inverted signal Vac by regulation of the resistance value of said variable resistor VR1. Thus, the first means according to the present invention is implemented for appropriate adjustment of the video signal during the low contrast.

Now in the limiter circuit II, the variable resistor VR2 may be regulated to limit the portion of the video signal corresponding to the bright area and thereby obtaining an object to be shot principally adjusted on the basis of the dark area during the high contrast. More specifically, the variable resistor VR2 may be first regulated so as to have an infinite resistance value to obtain the inverted signal Vac having a waveform similar to one illustrated in FIG. 6. When this inverted signal Vac is applied to the capacitor C3 of the voltage multiplying/rectifying circuit, the diode D3 becomes conductive with the negative side signal and thereupon the capacitor C3 is charged. The immediately following positive side signal is applied thereto and the multiplied voltage is DC rectified with its amplitude remaining unchanged, as illustrated in FIG. 7 (*b*), providing a control signal suitable for detection of the video level Vd of FIG. 4 (*b*) in order to adjust the object on the basis of the bright area therein. When the resistance value of the variable resistor VR2 is adjusted to 0, the diode D2 becomes conductive and the the limitation is effected as seen in FIG. 3 (2), so that the bright portion of the video signal Vin is cut as seen in FIG. 7 (*a*), resulting in the inverted signal Vac free form the portion indicated by broken line. This inverted signal Vac is rectified by the multiplied voltage signal and DC-regenerated as illustrated in FIG. 7 (*b*), as in the previous case. Here is provided the control signal suitable to adjust the object on the basis of the dark area therein corresponding to the video signal Vin with its bright portion having been cut. During the low contrast, the video output signal preset by the first means will be hardly affected by the limiter circuit even when the latter is activated, since the bright portion of the video signal Vin has a relatively small amplitude during this low contrast.

The rectified signal Vdc is applied to the inverted input terminal 21 of the operational amplifier A2 and compared with the mid-range voltage appearing at the non-inverted input terminal 22 to obtain the control signal Vout at the output terminal 23. Simultaneously the feedback signal also is applied from the detecting coil 5 of the servomotor M to the inverted input terminal 21 and, therefore, the control signal Vout contains also the braking signal for the servomotor M.

The control signal Vout is input to the one-way drive circuit having the voltage gain of the Darlington connection consisting of two transistors TR2, TR3 and it is thus possible to supply the driving coil 6 of the servomotor M with an extremely high driving voltage even when the control signal is of a relatively low level. More specifically, in proportion to a variation in the control signal Vout applied to the base of the transistor TR2, the voltage applied from the source terminal 3 to the collector of the transistor TR3 is amplified over a wide range. For example, assuming that the control signal Vout derived from the optimal video signal for a given object causes the driving coil 6 to maintain the diaphragm at a predetermined opening angle relative to the normal biasing of servomotor M in the diaphragm

closing direction by force of the spring 7, there occurs no variation in the control signal Vout and the driving coil 6 continues to be supplied with a constant voltage from the source, so long as there occurs no change in the object condition. Upon occurrence of a change in the object condition, e.g., the object becomes brighter, the rectified signal Vdc increases, the above-mentioned comparison with the mid-range voltage in the operational amplifier A2 provides a lower voltage (control signal Vout) at the output terminal 23, the base voltage of the transistor TR2 in the one-way drive circuit decreases, the voltage applied to the driving coil 6 is reduced and the diaphragm is driven by the spring 7 in the closing direction, then the diaphragm is held at the subsequent condition of the optimal video signal. When the object becomes darker, reversely, the rectified signal Vdc decreases, the output signal (i.e. control signal) from the operational amplifier A2 increases, the voltage supplied to the driving coil 6 increases and the servomotor M is driven in the diaphragm opening direction against the action of the spring 7, then the diaphragm is held at the subsequent condition of the optimal video signal.

The source stabilizer circuit III serving as the third means according to the present invention now maintains the base voltage of the transistor TR1 by the resistor R1, the capacitor C1 and the Zener diode D1 so that the voltage applied from the power supply terminal 8 to the collector thereof may be constant at the emitter side of the source 3, the mid-range voltage of said first and second means according to the present invention may be kept constant, the source voltage of the Fourth means also may be kept constant, and thus the reliability thereof may be improved.

Finally, the mid-range voltage supply circuit serving as the fifth means according to the present invention supplies the mid-range voltage intermediate of said stabilized source voltage to the operational amplifiers A1, A2 associated with said first, second and fourth means so that the control voltage Vout based on such mid-range voltage may be obtained with a single source and the diaphragm controlling servomotor may be driven by amplifying this control voltage.

Effect

As obviously understood from the foregoing description, there is provided, in accordance with the present invention, an automatic diaphragm control device for a TV camera objective utilizing a video signal from a TV camera, said automatic diaphragm control device comprising the first means primarily for adjustment of the video signals during the the low contrast, the second means primarily for adjustment of the video signal during high contrast and also adapted to keep the video output signal previously adjusted and set by the first means during the low contrast against any substantial variation, the third means for stabilization of the source voltage in order to inhibit a possible variation of the video output signal preset by said first and second means or a possible increase of current, the fourth means by which braking of the servomotor can be effected on the basis of amplification of the rectified signal provided by said first and second means and on the basis of the feedback signal from the detecting coil of the diaphragm driving servomotor, and in order to drive the servomotor, supplying the servomotor with the stabilized voltage substantially amplified in the one-way drive circuit having a voltage gain according to the obtained control signal, and the fifth means to activate the operational amplifiers respectively used in said first, second and fourth means with a single power source. With such arrangement, a variable photometric function is provided, for example, it is possible to regulate the video signal coming from the TV camera on the basis of the overall brightness of the object to be shot and, during high contrast, the optimal video signal can be obtained by cutting the signal portion corresponding to the particularly bright area. Moreover, by stabilizing the source voltage and deriving the control signal based on the mid-range voltage intermediate of this stabilized source voltage, both driving and control of the diaphragm can be achieved with a single source. Furthermore, the source voltage can be amplified over an extremely wide range based on the control signal and then supplied via the one-way drive circuit to the servomotor in order to drive the diaphragm. Thus a highly reliable automatic control device of a TV camera objective is provided which can be easily made compact.

What is claimed is:

1. An automatic diaphragm control device for a TV camera objective comprising:
   - first adjustment means for adjusting a low contrast video signal from said TV camera;
   - second adjustment means for adjusting a high contrast video signal from said TV camera and for preventing a video signal adjusted by said first adjustment means from being substantially varied;
   - voltage stabilization means for stabilizing a source voltage used as a power supply for said device, to prevent variations in the video signals adjusted by said first and second adjustment means;
   - a servomotor for driving a diaphragm of said TV camera objective including a driving coil and a detecting coil;
   - control means for halting the operation of said servomotor in response to said adjusted video signals and a feedback signal from said detecting coil, and for driving said servomotor by applying a stabilized voltage to said driving coil; and
   - means for providing a voltage supply to said first and second adjustment means and said control means, which voltage supply is of a predetermined value that is less than said source voltage.

2. An automatic diaphragm control device for a TV camera objective according to claim 1, wherein said first adjustment means comprises an operational amplifier adapted to inversely amplify a DC component of the low contrast video signal in a gain-variable manner.

3. An automatic diaphragm control device for a TV camera objective according to claim 1, wherein said first adjustment means comprises an operational amplifier adapted to inversely amplify a DC component of the low contrast video signal in a gain-variable manner and said second adjustment means comprises a diode adapted to suppress a negative signal portion of an output signal from the operational amplifier serving as the first adjustment means.

4. An automatic diaphragm control device for a TV camera objective according to claim 1, wherein said voltage stabilization means comprises a transistor having a base voltage held at a constant level under action of a resistor, a capacitor and a Zener diode and outputs at its emitter a voltage supplied from a power supply terminal to its collector which is stabilized at a constant level;

wherein said constant voltage outputted at the emitter is supplied to the first and second adjustment means and the control means.

5. An automatic diaphragm control device for a TV camera objective according to claim 1, wherein the control means comprises an operational amplifier for amplifying a multiplied and rectified signal based on adjusted signals from the first and second adjustment means and said feedback signal from said detecting coil in order to provide a control signal, and a Darlington transistor connection consisting of two transistors for supplying said control signal to said driving coil as an extremely high driving voltage.

6. An automatic diaphragm control device for a TV camera objective according to claim 1, wherein the voltage supply means functions to supply operational amplifiers respectively used in the first and second adjustment means and control means with a mid-range voltage intermediate of said source voltage stabilized by the voltage stabilization means as a reference voltage so that both diaphragm driving and diaphragm control can be achieved with a single source.

AUTOMATIC DIAPHRAGM CONTROL DEVICE OF VARIABLE PHOTOMETRY TYPE USED IN OBJECTIVE FOR TELEVISION CAMERA

BACKGROUND OF THE INVENTION

Industrial field of application

The present invention relates to an automatic diaphragm control device of variable photometry type where its objective is for television cameras that are adapted for automatically controlling the objective diaphragm utilizing a video signal supplied from the television camera.

Prior art

As has already been disclosed, for example, in the specifications of U.S. Pat. No. 4,451,851 and U.S. Pat. No. 4,472,743, the conventional television camera utilizing the video signal for automatic diaphragm control is provided with the control circuit having the photometric mode converting function and the sensitivity adjusting function so as to adapt to various shooting environments.

To obtain the optimum picture, in addition to the proper sensitivity adjustment depending on the absolute luminance of an object to be shot, the luminance ratio of bright and dark areas, i.e., the range of contrast is one of the important factors. The range of contrast in the natural world is as high as an order of 10:1 even under clouded sky and often an order of 100:1 under bright sky while the range of contrast which can be represented on the television-reproduced picture is as low as 30 to 40:1. Accordingly, for the picture simultaneously including a bright area and a dark area, it is impossible for a viewer to see both of these areas simultaneously and it must be determined whether the bright area should be selected as the main object to be shot or the dark area should be selected as the main object to be shot.

Theoretically, so-called average photometry mode is suitable for the case in which the dark area is selected as the main object to be shot while so-called peak photometry mode is preferable for the case in which the bright area is selected as the main object to be shot. As the video photometric method of prior art utilizing the video signal coming from the television camera for diaphragm control, any one of the abovementioned types. However, use of such photometric method in a fixed manner has caused various inconveniences. Specifically, for the picture simultaneously including the bright area and the dark area, the average photometry mode has often resulted in the bright area being solidly white or gradientless while the peak photometry mode has often made the dark area, which should be adequately visible in view of the camera sensitivity, almost invisible. With both the peak photometry mode and the average photometry mode, it is required to determine whether the bright area should be selected as the main object to be shot or the dark area should be selected as the main object to be shot, for the scene simultaneously including these bright and dark areas. It is preferred, therefore, that when the object to be shot has no extremely dark area, namely it is in a low contrast condition, the video signal of a same level is obtained even after the photometry mode has been variable adjusted.

Referring to FIG. 12, for example, with a photometric adjuster circuit having its characteristic change from the curve (1) to the curve (2), which provides a steeper gradient of the video signal level, as the photometric mode is variably adjusted from the average photometry mode to the peak photometric mode for a low constrast object, it is assumed that an area ratio of the bright zone to the overall scene is A, a video signal level a covered by the optimum range (shaded zone) has obtained by selecting the characteristic (1). If the area ratio is changed by zooming from A to B, the video signal level would be substantially in excess of said optimum level range and result in an over-luminance. Certainly, the photometry mode may be variably adjusted to the characteristic (2) at this time point to obtain a video signal level b covered also by said optimum range again. However, when the area ratio A is restored by zooming, there occurs an under-luminance a'. To restore the optimum level range a, the photometric mode must be adjusted again to the characteristic (1) or the characteristic (2) must have a sensitivity adjustment to obtain the characteristic (2)'. According to the characteristic curve (2)', an over-luminance b' appears at the area ratio B. Thus, with the photometry adjuster circuit presenting the steeper gradient of the video signal level in the low contrast condition, the selective adjustment between the sensitivity adjustment and the photometric mode adjustment is so difficult that the adjustment may often be disturbed.

To avoid such disturbance, it is desirable that the characteristic video signal level exhibits no substantial variation in the low contrast condition whether the average photometry mode or the peak photometry mode is selected and, therefore, adjustment of the video signal level can be achieved only by the sensitivity adjustment in the low contrast condition while variable adjustment of the photometry mode is effective only in the high contrast condition.

SUMMARY OF INVENTION

Problems to be solved by invention

FIG. 2 illustrates characteristic curves exhibited by photometric adjuster means of variable peak photometry type which will be described in detail later, in which (1) represents a characteristic curve of the average photometry mode and (2) represents a characteristic curve of the peak photometry mode. The photometry adjuster means of this type maintains the video signal level constant until the area ratio of the bright zone to the scene overall decreases to a certain value S (1) or S (2), respectively, and cannot maintain the peak value as said area ratio is further reduced, since there occurs then an over-luminance. Accordingly, during variation in the area of the bright zone, particularly during variation of the focal distance by zooming, an abrupt change of the video signal level at the certain point S (1) or S (2) sometimes gives a viewer an unnatural impression. Nevertheless, such photometry adjuster means is suitable for a case in which the main object to be shot is limited to the bright zone of the scene and only this bright zone is continuously regarded.

FIG. 4 illustrates characteristic curves exhibited by photometry adjuster means of variable average photometry type which will be mentioned more in detail later, in which a curve (1) represents a characteristic obtained when the average photometry mode is selected and a curve (2) represents a characteristic obtained when the peak photometry mode is selected. The photometry adjuster means of this type is characterized in that the video signal level gradually varies as the area of the bright zone varies and such gradual variation

occurs also when the area ratio of the bright zone is changed by zooming. With the consequence, unnatural impression encountered by the photometry adjuster means of the previously mentioned type can be eliminated by the photometry adjuster means of this type but the latter is not suitable for the case in which only the bright zone is concentratively regarded.

As will be obvious from the foregoing description, all of these photometric adjustments are adapted to adjust a variation of the video signal level according to the area ratio of the bright zone to the overall scene, when the latter is of a relatively high contrast, and the over-luminance occurs as said area ratio of the bright zone is further reduced not only when the variable average photometry mode is selected but also when the variable peak photometry mode is selected, although such over-luminance is remarkable particularly when the variable average mode is selected. To solve this problem of the over-luminance, it will be advantageous that the photometry adjuster means can selectively have a drastic peak characteristic as represented by a curve (3) in FIGS. 2 and 4.

However, incorporation of the two photometric circuits into the objective as diaphragm control circuits which may be changed over to each other as desired will be extremely difficult, because a space for these photometric circuits is restricted in view of a serious demand for a compact objective.

A first and principal object of the present invention is to provide a device including a fixed photometric circuit of a drastic peak characteristic in a part of a variable photometric circuit so as to be readily switched by switching means to perform a drastic peak photometric adjustment, in addition to an ordinary variable photometry adjustment.

A second object of the present invention is to provide an automatic diaphragm control device of variable photometry type used in a television camera in which the variable photometric circuit is also arranged so as to be switched between the variable peak mode and the variable average mode so that a simple operation of changing over on one and the same circuit permits the variable photometry of both types to be selectively performed in order to obtain not only said drastic peak characteristic but also versatile photometric characteristics optimum for various requirements.

Measures to solve problems

These objects are achieved, according to the present invention, by providing an automatic diaphragm control device of variable photometry type used in the objective of a television camera including the variable photometry adjuster means as illustrated by FIG. 2 or 4 and the photometric means having drastic peak characteristic and utilizing a video signal coming from the television camera to effect the diaphragm control, said automatic diaphragm control device comprising: first means consisting of sensitivity adjusting means principally to adjust a video output signal in a low contrast condition; second means consisting of variable photometry adjusting means principally to adjust a video output signal in a high contrast condition; third means for photometric adjustment of a video output signal in a drastic peak mode independently of the photometric adjustment by said second means; and means permitting said second and third means to be selectively used as desired by switching therebetween. As another solution, the present invention provides an automatic diaphragm control device of variable photometry type used in the objective of television camera having said variable peak photometric characteristic as illustrated in FIG. 2 and said variable average photometric characteristic as illustrated in FIG. 4 incorporated into one and the same circuit so as to be readily changed over therebetween for selective use thereof and utilizing a video signal coming from the television camera to effect the diaphragm control, said automatic diaphragm control device comprising: first means consisting of sensitivity adjusting means principally to adjust a video output signal in a low contrast condition; second means consisting of variable photometry adjusting means principally to adjust a video output signal in a high contrast condition; third means for photometric adjustment of a video output signal in a drastic peak mode independently of the photometric adjustment by said second means; means permitting said second means to be selectively used as means for the variable photometry in an extreme peak mode and means for the variable photometry in an extreme average mode as desired by switching therebetween; and means permitting said third means to be selectively used as desired by switching. As a further solution, the present invention provides an automatic diaphragm control device of variable photometry type used in the objective for television camera, said automatic diaphragm control device comprising: first means consisting of an inverted amplifier adapted for inverted amplification of a video signal output from the television camera with a variable amplification ratio relative to a reference voltage; second means adapted to be selectively used as desired, by switching, as means for peak photometric adjustment consisting of a voltage doubling rectifier including a capacitor of which the charging voltage can be adjusted by voltage doubling and rectifying the video signal inversionally amplified in said inverted amplifier and means for an average photometric adjustment consisting of a limiter circuit adapted to adjustably limit a negative component of the video signal inversionally amplified in said inverted amplifier; third means for photometric adjustment of the video output signal in an extreme peak mode independently of the variable photometric adjustment performed by said second means; and means permitting said second and third means to be selectively used as desired by switching therebetween.

Functions

A first function of the device constructed according to the present invention is based on a feature such that a fixed photometric circuit of a drastic peak characteristic is a part of a variable photometric circuit so to be readily switched as by switching means to perform a drastic peak photometric adjustment, in addition to an ordinary variable photometric adjustment. A second function of the device according to the present invention is based on a feature such that the variable photometric circuit is also arranged so as to be switched between the variable peak mode and the variable average mode so that a simple operation of changing over on one and the same circuit permits the variable photometry of both types to be selectively performed in order to obtain not only said drastic peak characteristic but also versatile photometric characteristics optimum for various requirements.

BRIEF DESCRIPTION OF DRAWING

FIG. 1 is a circuit diagram illustrating an important part in an embodiment of the device constructed according to the present invention;

FIG. 2 is a diagram schematically showing a variation in characteristics of the device depending on a photometric adjustment;

FIG. 3 is a circuit diagram similar to FIG. 1 but concerning another embodiment;

FIG. 4 is a diagram similar to FIG. 2 but concerning the embodiment of FIG. 3;

FIG. 5 is a circuit diagram similar to FIGS. 1 and 3 but concerning still another embodiment;

FIG. 6 is a diagram similar to FIGS. 2 and 4 but concerning the embodiment of FIG. 5;

FIG. 7 is a diagram illustrating an object to be shot and waveforms of the video signal in the respective circuit stages:

FIG. 8 is a circuit diagram illustrating a basic circuit in the third means;

FIG. 9 is a diagram illustrating waveforms of the video signal depending on the characteristics;

FIG. 10 is a diagram illustrating characteristics exhibited by another embodiment of the limiter circuit in the second means;

FIG. 11 is a diagram illustrating waveforms of the video signal depending on characteristics; and

FIG. 12 is a diagram illustrating the characteristics involving various problems in the prior art.

EMBODIMENTS

The present invention will be described more in detail with reference to preferred embodiments as illustrated by the accompanying drawing.

Referring to a circuit diagram illustrated by FIG. 1, reference numeral 1 designates a video signal input terminal adapted to input a video signal coming from the television camera to the device according to the present invention, and this terminal is connected through a capacitor 2 to first means I consisting of an inverted amplifier including components such as a resistor 4, a variable resistor 7 and an operational amplifier 3.

In the inverted amplifier, an inverted input terminal 31 of the operational amplifier 3 is connected through the resistor 4 to said capacitor 2 while a non-inverted input terminal 32 is connected through a resistor 6 to a reference voltage terminal 5 regulated to a mid-point voltage corresponding to a half of a source voltage. The variable resistor 7 is disposed as a feedback resistor between the inverted input terminal 31 and an output terminal 33. The inverted amplifier is adapted to inversionally amplify the video signal having its DC component removed in said capacitor 2 and to adjust a resistance value of said variable resistor 7 relative to said resistor 4 in order to change an amplification ratio of the operational amplifier 3.

Reference numeral II designates second means consisting of a voltage doubling rectifier adapted for voltage doubling amplification of the video signal which has been inversionally amplified by said inverted amplifier, in which a voltage doubling capacitor 9 including a variable resistor 8 connected in parallel therewith is connected to the output terminal 33 of said operational amplifier 3, the reference voltage terminal 5 is connected through a diode 10 to an output terminal P2 of said capacitor 9 and a diode 11 is serially connected to said output terminal P2. The variable resistor 8 functions to change a charging voltage of the voltage doubling capacitor 9 and is so arranged that said charging voltage becomes zero when said variable resistor 8 has a resistance value of zero and increases as the resistance value increases. The diode 11 serves to DC rectify a signal appearing at the output terminal P2 of the capacitor 9. To smooth this rectified signal, there is provided a capacitor 12 and a resistor 13 between an output terminal of said diode 11 and the reference voltage terminal 5.

Reference numeral III designates the third means according to the present invention which is adapted to adjust the charging voltage of the capacitor 2 so as to convert the photometric characteristic to that of a drastic peak mode. In the embodiment illustrated, the output terminal of the capacitor 2 is connected through a switch 18 and a diode 19 to the reference voltage terminal 5.

A circuit characteristic of the third means III will be now considered in reference with a principle diagram of FIG. 8. A relationship between an input voltage Vin and an output voltage Vout is given by a following equation:

$$Vout = \left[\frac{R4}{R3 + R4} \left(1 + \frac{R5}{R1} + \frac{R5}{R2} \right) - \frac{R5}{R1} \right] Vin$$

In the equation above, Vout may take various values as a function of R3 and when R3=infinity

$$Vout = -(R5/R1) \cdot Vin,$$

and when R3=0

$$Vout = (1 + R5/R2) \cdot Vin.$$

Thus, the output voltage Vout has opposite polarities according to the values of R3, i.e., those of infinity and zero.

In the embodiment illustrated by FIG. 1, the resistor R3 comprises the switch 18, and a state of the switch OFF corresponds to R3=infinity while a state of switch ON corresponds to R3=0.

Assuming that a signal having a waveform Vin of FIG. 9(*a*) is applied as an input signal to the circuit of FIG. 8, an inverted output signal Vout as illustrated by FIG. 9(*b*) is provided when the variable resistor R3 is set to infinity (i.e., switch OFF) and a non-inverted output signal Vout as illustrated by FIG. 9(*c*) when the variable resistor R3 is set to zero. Both of these output signals contain no DC component and, therefore, are in a stabilized state in which positive and negative areas are equal to each other with respect to a base line 0—0.

In this way, the circuit functions as an average photometric circuit when R3=infinity (switch OFF). Specifically, the circuit is affected by a variation in the amplitude so long as a bright zone (central rectangular zone) is relatively large and such influence decreases as the bright zone becomes small. The circuit functions as a peak photometric circuit when R3=0 (switch ON) and can detect a variation of the amplitude even if the bright zone becomes small.

The diode 19 which is connected through the switch 18 to the reference voltage terminal 5 as illustrated by FIG. 1 is turned ON with the negative component of the input signal Vin when the switch 18 is in the state of ON and charges the capacitor 2, and turned OFF with the following positive signal component, a positive voltage results that is added to the previously charged negative voltage to achieve amplification. Thus, there is established a circuit having a drastic peak characteristic

which can detect the signal corresponding to a small bright zone even for a low contrast object to be shot.

In the circuit arrangement as mentioned above, it is assumed that a video signal Vin of a waveform as illustrated by FIG. 7(*b*) is applied to the video signal input terminal **1** with respect to a test chart of FIG. 7(*a*) when the switch **18** in the third means III is in the state of OFF. In this waveform a rectangular portion at the positive side corresponds to a bright zone of the picture, Vd represents a video level and Vs represents a synchro level. This video signal Vin is inversionally amplified in the inverted amplifier as illustrated by FIG. 7(*c*) and is output as an inverted signal V33 on the output terminal **33** of said inverted amplifier. This inverted signal V33 has its DC component already removed by the capacitor **2** and, in consequence, it is in a stabilized state in which the positive area and the negative area are equal to each other with respect to the base line (mid-point voltage line 0—0). Now the variable resistor **7** may be adjusted so as to increase its resistance value relative to the resistor **4** to increase an amplification ratio of the inverted amplifier proportionally and vice versa. Thus, the amplification ratio may be changed to adjust the amplitude Vp-p of the inverted signal V33 and thereby to achieve the sensitivity adjustment which is the function of the first means I according to the present invention.

The inverted signal V33 is then rectified in the voltage doubling rectifier. At this point, adjustment of the variable resistor **8** to the resistance value of 0 results in that the capacitor **9** does not function at all and a signal VP2 appearing at the output terminal P2 of said capacitor **9** becomes equal to the inverted signal V33 as seen in FIG. 7(*d*). Although the diode **10** is turned on with the negative component of the inverted signal V33, passage through the resistor **8** (R=0) prevents the capacitor **9** from being charged and the positive voltage V+ depends on an average value. Therefore, such photometric mode can be considered as the average photometric mode as indicated by the characteristic curve (**1**) in FIG. **2**, which is suitable for the case in which a dark zone is selected as the main object to be shot. When the variable resistor **8** is adjusted to the resistance value of infinity, on the other hand, the diode **10** is turned on with the negative component of the inverted signal V33 and the capacitor **9** is charged. A following positive signal is added to the previously charged voltage and the output signal VP2 is DC rectified as illustrated by FIG. 7(*e*), so that the amplitude of the video level Vd can be detected even when a width d of the bright zone is relatively small. Accordingly, such photometric mode with the variable resistor **8** being adjusted to the resistance value of infinity can be considered as the peak photometric mode as indicated by the characteristic curve (**2**) in FIG. **2**, which is suitable for the case in which the bright zone is selected as the main object to be shot. It should be understood that the variable resistor **8** may be adjusted to the intermediate resistance value to obtain the corresponding intermediate photometric mode which may be indicated by a curve having its rising portion within the shaded zone in FIG. **2**.

In the low contrast condition, an amplitude Vd corresponding to the bright zone is low relative to the full amplitude Vp-p of FIG. 7(*b*) and there is no variation in the amplitude V+ of FIGS. 7(*d*) and (**3**). As a result, the video signal level is not substantially affected by conversion of the photometric mode. Referring to FIG. **2** illustrating characteristics of the respective photometric modes, the curve (**1**) indicates the characteristic of the peak photometric mode and the curve (**2**) indicate the characteristic of the peak photometric mode. As will be obvious from FIG. **2**, in which the abscissa indicates the area ratio of the bright zone (with respect to the overall scene) and the ordinate indicates the video signal level, the video output signal level is substantially constant no matter whether the average photometric mode (**1**) is selected or the peak photometric mode (**2**) is selected so long as the area ratio is higher than S (**1**). This means that the video signal level is not affected by the photometric adjustment in the low constrast condition. Furthermore, even if said area ratio is varied by the operation of zooming, the video signal level is maintained substantially constant for the object to be shot, in which the area ratio of the bright zone is higher than S (**1**).

In this manner, the sensitivity adjusting means relying upon the variable resistor **7** of said inverted amplifier constitutes the first means principally serving to adjust the video output signal during the low contrast while the photometric adjusting means relying upon the variable resistor **8** of said voltage doubling rectifier constitutes the second means principally serving to adjust the video output signal during the high contrast, and the video output signal level once adjusted by the first means is free from any substantial variation even when said second means is adjustably activated during the low contrast.

When the switch **18** of the third means III according to the present invention is turned ON, a non-inverted amplified signal forming a drastic peak appears on the output terminal **33** of the operational amplifier **3**, as has previously been mentioned, and thus a photometric characteristic as indicated by the curve (**3**) in FIG. **2** is obtained at the circuit output terminal **20**, permitting a drastic peak photometry to be achieved with respect to a small spot in the bright zone.

In the circuit arrangement as illustrated in FIG. **3**, the basic construction of the voltage doubling rectifier and the third means III is identical to that of FIG. **1** and the circuit elements of similar functions are designated by the similar reference numerals. Specifically, the circuit arrangement corresponds to the circuit arrangement of FIG. **1** except that the variable resistor **8** for photometric adjustment is replaced by a limiter circuit for photometric adjustment as the second means II provided in the inverted amplifier. The limiter circuit functions to limit the negative output of the video signal inversionally amplified in the operational amplifier **3** and connected in parallel with the variable resistor **7** for sensitivity adjustment.

The limiter circuit comprises a diode **14** and a variable resistor **15** adapted to control the current flowing through said diode **14**. The anode of said diode **14** is connected to the inverted input terminal **31** of the operational amplifier **3** and the cathode thereof is connected through the variable resistor **15** to the output terminal **33**. The limiter circuit is so arranged that, as indicated by a solid line (**2**) in FIG. **10**, an input/output characteristic may be obtained, in accordance with the negative side of the operational amplifier **3** which is forcibly suppressed by the diode **14**. More specifically, referring to FIG. **10** in which the abscissa indicates an input voltage V31 on the input terminal **31** and the ordinate indicates an output voltage V33 on the output terminal **33**, the negative output voltage V33 would be represented by a broken line (**1**) in FIG. **10** as the input voltage V31 increases in excess of α, so as in accordance with the

normal input/output characteristic. However, said limiter circuit III is adapted to limit the output voltage V33 so as to be maintained at the level of β as indicated by a solid line (2), even when the input voltage increases beyond α. The variable resistor **15** of the limiter circuit may be properly adjusted to obtain the peak photometric mode, the average photometric mode or the intermediate photometric mode.

First, when the variable resistor **15** is adjusted to the resistance value of infinity, the limiter circuit is not activated and, as a consequence, the inverted signal V33 has a waveform as illustrated by FIG. 7(*c*). This inverted signal V33, when input to the voltage doubling capacitor **9** of the voltage doubling rectifier, is DC-regenerated by the diode **10** as V+ without any change of its amplitude Vp-p as seen in FIG. 7(*e*), thus providing the peak photometric mode in which the bright zone is selected as the main object to be shot. When the variable resistor **15** of the limiter circuit is adjusted to the resistance value of zero, the diode **14** is turned on and the operational amplifier **3** is output-limited, with a result that a peak portion beyond α in FIG. **10** is cut off from the signal Vd corresponding to the bright zone of FIG. 7(*b*) and the inverted signal V33 as indicated by a solid line in FIG. **11**. This inverted signal V33 is DC-rectified in the voltage doubling rectifier, as shown in FIG. 11(*b*), providing a voltage doubled signal VP2 which has no signal component of amplitude Vp-p corresponding to the bright zone and is substantially approximate to the average value. Thus, the average photometric mode is established, this mode being suitable for the case in which the dark zone is selected as the main object to be shot. Finally, adjustment of the variable resistor **15** to the intermediate resistance value may provide the photometric mode intermediate of the above-mentioned peak and average photometric modes. Moreover, in the low contrast condition, the amplitude Vd corresponding to the bright zone is low relative to the full amplitude Vp-p of FIG. 7(*b*), so there is no difference in the amplitude between the peak photometry waveform of FIG. 7(*e*) and the average photometry waveform of FIG. 11(*b*). Accordingly, conversion of the photometric mode has no significant influence upon the video signal level. Referring to FIG. **4** which illustrates characteristics of the respective photometric modes for the low contrast scene, a curve (1) corresponds to the average photometric mode and a curve (2) corresponds to the peak photometric mode. Also in FIG. **4**, the abscissa indicates the area ratio of the bright zone (with respect to the overall picture) and the ordinate indicates the video signal level. At the area ratio higher than S2, the video output signal level exhibits almost no variation no matter whether the average photometric mode (1) or the peak photometric mode (2) is selected, indicating that the video signal level is not affected by the photometric adjustment in the low contrast situation. In this case, the photometric adjustment of variable average type accompanied with a gradual variation of the video signal is effected as the area ratio is varied by operation of zooming, and the video signal level is maintained substantially constant for the object including the bright zone of which the area ratio is higher than S (1).

In this manner, the sensitivity adjusting means relying upon the variable resistor **7** of said inverted amplifier constitutes the first means principally serving to adjust the video output signal during the low contrast, the photometric adjusting means relying upon the variable resistor **15** of said limiter circuit constitutes the second means principally serving to adjust the video output signal during the high contrast, and, even when said second means is adjusted during the low contrast, the video output signal level once adjusted by said second means is not significantly affected thereby. Furthermore, turning on of the switch **18** of the third means III provides, as in the previous embodiment, the drastic peak photometric characteristic ((3) in FIG. **4**).

In the circuit diagram of FIG. **5**, the circuit elements having the similar functions to those in the circuit diagrams of FIGS. **1** and **3** are designated by the similar reference numerals. Referring to FIG. **5**, a variable resistor **16** and a switch SW provided between the terminal **33** and the point **P2**, in parallel with the the capacitor **9** of the voltage doubling rectifier constitutes the second adjust means of the variable peak photometric type, as shown in FIG. **1**, adapted to adjust the charging voltage of the capacitor **9**. The diode **14**, the switch SW and the variable resistor **16** which are provided in parallel with the variable resistor **7** of the inverted amplifier constitutes the limiter circuit serving as the second adjusting means of variable average photometric type as shown in FIG. **3**. In such a manner, the relatively peak-characteristic photometric adjuster circuit included in the second means II is selected by connecting the switch SW to one connection terminal A, the average photometric characteristic (1) is selected by adjusting the variable resistor **16** to the resistance value of zero, and the peak photometric characteristic (2) is selected by adjusting the variable resistor **16** to the resistance value of infinity. The relatively average-characteristic photometric adjuster circuit relying on the limiter circuit in the second means II is selected by connecting the switch SW to another connection terminal B, the average photometric characteristic (1) is selected by adjusting the variable resistor **16** to the resistance value of zero, and the peak photometric characteristic (2) is selected by adjusting said variable resistor **16** to the resistance value of infinity.

Thus, the user can select the photometric adjustment of variable peak photometric type or variable average photometric type merely by changing over the switch SW, carrying out the average photometric adjustment or adjusting the common variable resistor **16** of the peak photometric adjustment, and obtain the drastic peak-characteristic photometric means as indicated by the curve (3) by turning the switch **18** of the third means III on.

Effects

With the device constructed according to the present invention in the manner as has been described hereinabove, the sensitivity adjustment can be achieved by the first measure, for example, adjusting the resistor for varying the amplification ratio of the inverted amplifier, the photometric mode is selected by the second measure, for example, adjusting the variable resistor for photometric adjustment among the average photometric mode, the peak photometric mode and intermediate photometric mode so as to achieve an appropriate photometric adjustment, and the drastic peak photometric means can be activated by operating the switch as the third measure. Additionally, the video signal level is almost not affected by changing over the photometric mode for the object being in the low contrast condition, so the optimum video signal level can be obtained only by the sensitivity adjustment in such low contrast situation and the photometric adjusting can be selectively

performed only for the scene of the high contrast. In this way, the sensitivity adjustment and the photometric adjustment may be effected as separate adjusting measures to facilitate adjustment of the optimum video signal level. Furthermore, both the sensitivity adjustment and the photometric adjustment may be performed only once for the object of the low contrast and for the object of the high contrast, respectively, to obtain the optimum picture over a wide contrast range from the lowest contrast to the highest contrast. Finally, the second means also may be selected as desired between the variable peak photometric type and the variable average photometric type. Thus, there is provided the automatic diaphragm control device for the objective of television camera that is useful for various applications.

What is claimed is:

1. An automatic diaphragm control device for objective of television camera utilizing a video signal coming from the television camera to effect the diaphragm control, said automatic diaphragm control device comprising:

first means consisting of sensitivity adjusting means principally to adjust a video output signal in a low contrast condition;

second means consisting of variable photometric adjusting means principally to adjust a video output signal in a high contrast condition;

third means for photometric adjustment of a video output signal in a drastic peak mode independently of the photometric adjustment by said second means; and

means permitting said third means to be selectively used as desired by switching.

2. An automatic diaphragm control device for objective of television camera as defined by claim 1, wherein the second means permits the variable photometry to be automatically controlled in a peak mode, on one hand, and the video output signal during the high contrast to be continuously adjusted in accordance with an area ratio of a bright zone with respect to an overall object to be shot, on the other hand.

3. An automatic diaphragm control device for objective of television camera as defined by claim 1, wherein the second means permits the variable photometry to be automatically controlled in an average mode, on one hand, and the video output signal during the high contrast to be continuously adjusted in accordance with an area ratio of a bright zone with respect to an overall object to be shot, on the other hand.

4. An automatic diaphragm control device for objective of television camera utilizing a video signal coming from the television camera to effect the diaphragm control, said automatic diaphragm control device comprising:

first means consisting of sensitivity adjusting means principally to adjust a video output signal in a low contrast condition;

second means consisting of variable photometric adjusting means principally to adjust a video output signal in a high contrast condition;

third means for photometric adjustment of a video output signal in a drastic peak mode independently of the photometric adjustment by said second means;

means permitting said second means to be selectively used as means to perform the variable photometry in a peak mode and means to perform the variable photometry in an average mode as desired by switching therebetween; and

means permitting said second and third means to be selectively used as desired by switching therebetween.

5. An automatic diaphragm control device for objective of television camera, said automatic diaphragm control device comprising:

first means consisting of an inverted amplifier adapted for inverted amplification of a video signal from the television camera with a variable amplification ratio relative to a reference voltage;

second means adapted to be selectively used as desired, by switching, as means for peak photometric adjustment consisting of a voltage doubling rectifier including a capacitor of which the charging voltage can be adjusted by voltage doubling rectifying the video signal inversionally amplified in said inverted amplifier and means for average photometric adjustment consisting of a limiter circuit adapted to adjustably limit a negative component of the video signal inversionally amplified in said inverted amplifier; third means for photometric adjustment of the video output signal in an extreme peak mode independently of the variable photometric adjustment performed by said second means; and means permitting said second and third means to be selectively used as desired by switching therebetween.

[57] **ABSTRACT**

In the disclosed photographic objective, a focusing lens group is arranged on the image side of a stop. To focus, all or part of the lens group, or the stop and all or part of the lens group, are moved to maintain an exit pupil at a substantially constant position.

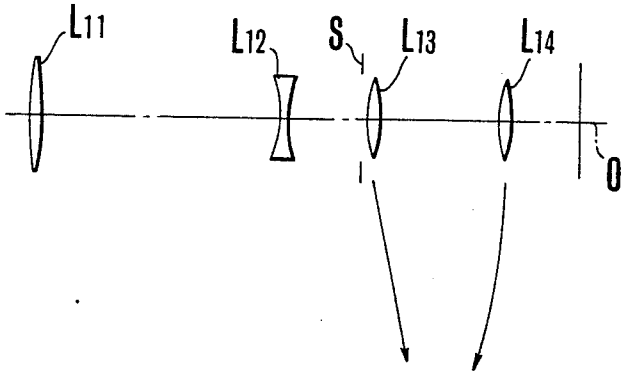

FIG.2

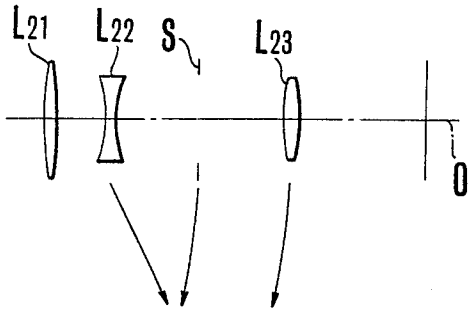

FIG.3

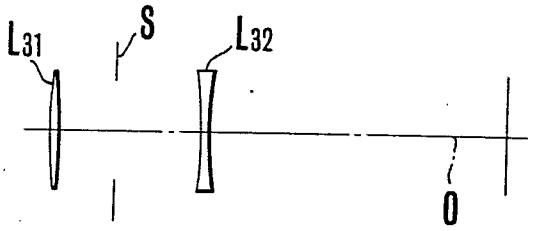

PHOTOGRAPHIC OBJECTIVE

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to photographic objectives and more particularly to photographic objectives of the rear focus type in which one or more lens components on the image side of a stop is or are movable for focusing the objective.

2. Description of the Prior Art

Color cameras having color separation prisms or other color separation optical systems such as stripe filters or mosaic filters should offer good color reproducing characteristics. To achieve this end it is generally recommended that their photographic objectives have an exit pupil at as long a distance as possible (preferably at least 200–300 mm, and ideally infinity) and that that distance be left unchanged. Even for an objective having a shortened exit pupil distance, as is sometimes necessary in actual practice, facilitating an electrical correction of the color reproduction makes it desirable that the exit pupil distance remain constant.

At the same time, the use of one of the constituent lens members which lies on the image side of the diaphragm for focusing purposes, or the employment of a so-called rear focus type of photographic objective, is advantageous for reducing the weight and the complexity of mechanical focus control signal transmission. This is so because the distance between the focusing member and the camera body is short. For this reason, a growing number of photographic objectives of this type have been developed in recent years.

As usual, the rear focus type of photographic objective is associated with a change of the position of the exit pupil resulting from the movement of the focusing member that lies behind the diaphragm. Therefore, application of this type of objective to color cameras with color separation optical systems poses a problem with respect to the color reproductivity.

This problem is also encountered when a zoom lens has its diaphragm in a space between the zoom components.

A proposal has been made to move the diaphragm of a zoom lens and one of the zoom components so as to maintain the position of the exit pupil constant. This appears in Japanese Patent Publication No. SHO 51-4135 (published Nov. 9, 1976).

SUMMARY OF THE INVENTION

It is an object of the invention to provide a photographic objective which focuses with a movable component or components on the image side of a diaphragm, i.e. an objective of the rear focus type, while still maintaining the position of an exit pupil constant.

To achieve this, one of the features of the invention is that at least two movable components for focusing are arranged on the image side of a diaphragm, and as these components are moved axially in different relation from each other, the paths of movement of the focusing components are so defined that in case the diaphragm is taken as an object point, the position of an image point is not caused to change by focusing while the diaphragm is made either stationary or movable with focusing. This makes it possible to maintain the position of the exit pupil.

BRIEF DESCRIPTION OF THE DRAWINGS

FIGS. **1**, **2** and **3** are schematic diagrams indicating different configurations of embodiments of photographic objectives according to the present invention respectively.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

FIG. **1** illustrates a first embodiment of a photographic objective of the rear focus type according to the present invention. The objective includes, from front to rear, positive first and negative second components **L11** and **L12** which remain stationary during focusing, a stop S and positive third and positive fourth components **L13** and **L14** which are movable for focusing.

Shown in the lower half of the figure are arrow-marked lines indicating the different relations of the components **L13** and **L14** as they are moved axially during focusing.

In the above-described configuration, the components **L13** and **L14** which lie on the image side of the stop S are made movable for focusing. The ratio of their axial movements is determined so that as the stop S is taken as an object for the components **L13** and **L14**, an image point (corresponding to the position of an exit pupil of the entire system) remains constant. This maintains the constant position of the exit pupil against focusing despite independent movement of the components which lie on the image side of the stop (in this instance, **L13** and **L14**).

In the following equations **f3** designates the focal length of the lens component **L13**, **f4** the focal length of the lens component **L14**, **e3** the axial distance between the stop S and the lens component **L13**, **e4** the axial distance between the lens component **L13** and the lens component **L14**, $\alpha 3$ an inclination angle of the light beam between the stop S and the lens component **L13** with respect to the optical axis **0**, $\alpha 4$ an inclination angle of the light beam between the lens component **L13** and the lens component **L14** with respect to the optical axis **0**, h the height of the light beam in the lens component **L13** from the optical axis **0**, and d the axial distance between the lens component **L13** and an image of the stop S formed by the lens component **L13** when assuming the stop S to be an object point (a back focus of the lens component **L6**).

Then, in order to set the position of the exit pupil at infinity by means of the lens components **L13** and **L14**, it is necessary that the front focus of the lens component **L14** be arranged to coincide with the image point of the image of the stop S formed by the lens component **L13**. Thus, the formula (1) must be satisfied.

$$e4 = d + f4 \tag{1}$$

Here, if the paraxial tracing is performed assuming the stop S to be the object point, formulas (2), (3) and (4) are obtained.

$$\alpha 3 = -h/e3 \tag{2}$$

$$\alpha 4 = \alpha 3 + h/f3 \tag{3}$$

$$d = h/\alpha 4 \tag{4}$$

Therefore, d is represented by:

$$d = \frac{e3 \cdot f3}{e3 - f3} \quad (5)$$

Hence, the formula (1) is replaced by:

$$e4 = \frac{e3 \cdot f3}{e3 - f3} + f4 \quad (6)$$

Thus, if **e4** is changed so as to satisfy the formula (6) according to the change of **e3**, the position of the exit pupil can always be held at infinity. Values **f3**, **f4** and **e3** may be set as desired. Then if the paraxial reverse tracing of the entire lens system **L11–L14** is performed from the image point so as to make the image point constant in space, the position of the object can be obtained as the conjugate point.

A numerical specific embodiment shown in FIG. **1** can be constructed in accordance with the data given in the following table in which:

f: the focal length of the entire system;

f1–f4: the focal lengths of the individual components **L11–L14**, respectively;

e1–e4: the axial spacings between the successive two components and the stop;

s'k: the back focal length;

t'k: the distance of the exit pupil;

s1: the object distance measured from the first component **L11**; and

subscripts A–D: different focusing positions from one another.

	f=52.15	A	B	C	D
L11	f1=60				
		e1A=41.61			
L12	f2=−12				
		e2A=13			
S					
		e3A=2	e3B=4	e3C=6	e3D=8
L13	f3=24				
		e4A=21.82	e4B=19.2	e4C=16	e4D=12
L14	f4=24				
		s'kA=12.18	s'kB=12.8	s'kC=14	s'kD=16
		t'kA=−∞	t'kB=−∞	t'kC=−∞	t'kD=−∞
		s1A=−∞	s1B=−5597 mm	s1C=−1301 mm	s1D=−3139 mm

As is obvious from the table listed above, it will be understood that the position of the exit pupil is left unchanged despite focusing.

An operating mechanism for the lens components **L13** and **L14** may be constructed in the form of cam means or the like.

Though the first embodiment has been illustrated as applied to a fixed-focal length objective, it can be applied to a zoom objective whose zoom components lie on the front side of the stop without any alteration of the paths of focusing movement of the components **L13** and **L14**. In this case, however, the positions of the lens components **L13** and **L14** must be adjusted in accordance with not only the object distance but also the focal length of the entire system. This is so because the distance each focusing component moves from the position with an infinitely distant object to focus on the same object distance varies as zooming is performed. It is also possible to make movable the components on the image side of the stop during zooming to contribute to a variation of the image magnification. If so, it results in the components **L13** and **L14** having both the zooming and focusing functions.

Also if there are at least three components on the image side of the stop, another modification becomes possible. As is generally well known, the optically compensated zoom lens is operated by moving two components as a unit on either side of a component which remains stationary during zooming while still maintaining substantially constant the position of an image plane. In this analogy, for focusing purposes, the intermediate one of the three components is made stationary, and the other two are constructed in the form of an optically compensated zoom lens for the stop as an object and arranged to move axially as a unit to effect focusing on an object to be photographed. This affords the advantage of excluding an elaborate operating mechanism such as cam means when the object of the present invention is accomplished.

FIG. **2** schematically illustrates the configuration of a zoom lens of the rear focus type constituting a second embodiment of the present invention. The zoom lens includes, from front to rear, a positive first component **L21** which remains stationary during zooming, a negative second component **L22** for zooming, a stop S, and a positive third component **L23** for zooming and focusing.

Shown in the lower half of FIG. **2** is a different relation in which the zoom components **L22** and **L23** and stop S move axially to effect zooming.

In the aforesaid configuration, the stop S is arranged to move during zooming, though not essential to the present invention, to maintain the position of the exit pupil constant when zooming.

In this embodiment, the third component **L23**, which lies on the image side of the stop S, is made to also serve as a focusing component. When focusing, this component **L23** moves axially. Therefore, despite the position of the stop S having been adjusted in accordance with the zooming position, moving the third component **L23** later to effect focusing causes the exit pupil to shift as the stop S remains stationary.

On this account, the stop S is made to move in connection with the third component **L23** when focusing, so the position of the exit pupil is always maintained constant even when focusing. This constitutes a feature of this embodiment.

For example, in order always to maintain the exit pupil of the entire lens system at an infinite distance during focusing so as to render the exit pupil constant in the present embodiment, it is sufficient to keep the following relation between the diaphragm DS and the lens group **L23**. Thus, in the present embodiment, as the image of the stop S formed by the lens group **L23** is the exit pupil of the entire lens system, it is enough to move the stop S and the lens group **L23** so as to always make

the space e7 therebetween coincide with the focal length of the lens group L23.

A numerical specific second embodiment can be constructed in accordance with the data given in the following table in which:

f: the focal length of the entire system;

f5–f7: the focal lengths of the first to third components, respectively;

e5–e7: the axial spacings between the successive two components and the stop;

s'k: the back focal length;

t'k: the distance from the component L3 to the exit pupil; and

subscripts W and T: the wide angle and telephoto settings, respectively.

		fW = 20	fT = 53.33
L21	f5 = 80		
		e5W = 20	e5T = 40
L22	f6 = −20		
		e6W = 30	e6T = 5
S			
		e7W = 30	e7T = 30
L23	f7 = 30		
		s'kW = 45	s'kT = 50
		t'kW = −∞	t'kT = −∞

In this second specific example, when in the wide angle position, a forward axial movement of the third component L23 along with the stop S by 0.329 mm results in focusing down to an object distance s1 = −1588.57 mm measured from the first component L21, leaving the position of the exit pupil unchanged from t'k = −∞. This makes it possible to maintain the position of the exit pupil constant during focusing.

Also, in the telephoto position, forward axial movement of the third component L23 along with the stop S by 4 mm results in focusing down to an object distance s1 = −1588.57 mm leaving the position of the exit pupil unchanged from t'k = −∞. This makes it possible to maintain the position of the exit pupil constant during focusing as well as during zooming.

Thus, in the objective having the focusing facility in only one component on the image side of the stop, imparting a concurrent movement with the movement of the focusing component into the stop, makes it possible to maintain the position of the exit pupil constant throughout the entire focusing range. This advantageously eliminates the problem that would otherwise arise were the rear focus type employed in designing photographic objectives for color cameras having the color separation optical system for the purpose of reducing the bulk and size of the camera as a whole.

FIG. 3 illustrates another embodiment of the invention applied to a fixed focal length objective of the telephoto type having a positive front component L31 and a negative rear component L32 for focusing with a stop S therebetween.

As described herein later, the embodiment is limited in the position of the exit pupil so that if the space e9 between the stop S and the lens group L32 is kept constant, the position of the exit pupil measured on the basis of the image plane changes. In such a case, it is necessary to change the space e5 between the stop S and the lens group L32 in correspondence to the focusing. The change of the space e5 may be determined by the following relation. Supposing the space when the lens group L32 has moved d' from the state of the space e9' is e9, and the position of the exit pupil measured from the initial lens group L32 is t'ko,

$$\frac{1}{t'ko} + \frac{1}{e9'} = \frac{1}{f9}$$

$$\frac{1}{t'ko + d'} + \frac{1}{e9} = \frac{1}{f9}$$

From the above relation, the space e9 required for maintaining constant the position of the exit pupil measured on the basis of the image plane can be obtained. An example of an objective of this configuration can be constructed in accordance with the following numerical data:

L31	f8 = 100	
		e8 = 20
S		
		e9 = 30
L32	f9 = −100	

where the focal length of the entire system f = 200; the back focal length s'k = 100; and the exit pupil distance from the negative component L32, t'k = −23.07692 (from the image plane, −123.07692).

Now assuming that the negative component L32 is solely moved axially rearward, for example, 10 mm to effect focusing down to an object distance s1 = −1457.14 mm, then the exit pupil is shifted to t'k = −28.57142 (from the image plane, −118.57143). According to the invention, simultaneously with this, the stop S is made to move forward 9.42528 mm, leaving the exit pupil stationary at t'k = −23.07692 (from the image plane, −123.07692).

Such concurrent movement of the stop with focusing and, in the second embodiment, with zooming can be realized by using cam means. It is also to be noted that upon consideration of preventing the aperture ratio from changing as the stop moves, it is desirable in actual practice to provide a suitable automatic diaphragm aperture adjusting mechanism.

Also in the present invention, the sentence "the exit pupil position is maintained substantially constant" implies, of course, the case when it is held in exactly constant a position, but also another case when the exit pupil position is allowed to shift within an acceptable range for actual performance with respect to the color reproductivity.

The present invention is applicable to other lens types and zoom types than those shown in connection with its embodiments. For example, in fixed focal length objectives, it is applicable not only to the telephoto type, but also to the retrofocus type suited for wide angle objectives, and to various other types for use in standard objectives; in zoom lenses, it is not confined to the 3-component type shown in the foregoing embodiments, but also to more-than-3-component types, for example, the 4-component type; conversely in the 2-component type; and further regardless of what relative position the zoom components take, and the number of zoom components, to all other types of zoom lenses, to effect an equivalent result.

As has been described in greater detail above, according to the present invention, the use of a component or components which lies or lie on the image side of the stop for, focusing purposes, or the employment of the so-called rear focus type in single lenses and zoom

lenses for color cameras provides a possibility of stabilizing good color reproductivity against focusing so that a minimization of the bulk and size of the camera due to the employment of the rear focus type can be advantageously achieved without involving any decrease in optical performance.

What I claim:

1. A photographic objective comprising:
a stop stationary during focusing;
a plurality of lens components located on the image side of said stop and movable for focusing;
said plurality of lens components moving in such a way as to maintain an image point of the stop at a substantially constant position when the stop is assumed as an object point.

2. A photographic objective according to claim 1, further including:
a further lens component arranged on the object side of said stop.

3. A photographic objective according to claim 2, wherein said further lens component is a zoom lens.

4. A photographic objective according to claim 1, further including:
a further lens component for zooming arranged on the object side of said stop and wherein at least one of said plurality of lens components moves together with said further lens component.

5. A photographic objective comprising:
a front lens component stationary during focusing;
a stop located on the image side of said front lens component and movable during focusing;
a movable lens component located on the image side of said stop and movable for focusing;
said stop and said movable lens component moving in such a way as to maintain an image point at a substantially constant position when the stop is assumed as an object point.

6. A photographic objective according to claim 5, wherein said front lens component moves simultaneously with said movable lens component for zooming.

7. A photographic objective according to claim 6, wherein said stop and said movable lens component move contrary to each other during focusing.

8. A photographic objective according to claim 5, wherein said stop and said movable lens component move all together during focusing.

9. A photographic objective comprising:
a plurality of lens components stationary during focusing;
a stop located on the image side of said plurality of lens components; and
a movable lens component located on the image side of said stop and movable for focusing;
said movable lens component moving in such a way as to maintain an image point at a substantially constant position when the stop is assumed as an object point.

[57] **ABSTRACT**

An objective lens comprising a front lens unit and a rear lens unit with the separation between the two lens units being varied to vary the focal length of the entire system, wherein the front lens unit has a positive refractive power and consists of a positive lens of strong convex curvature toward the front, a negative doublet lens of a negative lens and a positive lens cemented together in this order from the front, and a positive lens sub-unit, and the rear lens unit has a negative refractive power and comprises a positive lens and a negative lens. Particularly the double lens is so designed that the comatic aberration in the intermediate zone of the image frame is stabilized throughout the entire range of variation of the focal length, and the halo in the intermediate zone in the telephoto end is well corrected.

VARI-FOCAL OBJECTIVE LENS OF SHORT TOTAL LENGTH

BACKGROUND OF THE INVENTION

1. Field of the Invention:

This invention relates to compact zoom lenses, and more particularly to compact zoom lenses of short total length (the distance from the front vertex to the image plane) suited to lens-shutter cameras, video cameras or the like.

2. Description of the Prior Art:

The recent trend of reducing the size of lens shutter cameras, video cameras, or the like demands for compact zoom lenses of short total length. Particularly in the field of small size cameras whose objective lenses are not interchangeable, too, it is desired to use zoom lenses. For this purpose, the total length of the zoom lens has to be reduced to the same level as the fixed focal length lens that has so far been used has.

Many zoom lenses whose range includes the standard image angle for the ordinary lens-shutter cameras (the total angle of field $2\omega=47°$ with a focal length of about 50mm for 35mm still cameras) have been proposed in, for example, Japanese Patent Publication No. SHO 49-29146. The zoom lens of this kind is constructed by two lens units of which the front is of negative power and rear is of positive power, and its focal length is varied by varying the separation between the two lens units. However, because its refractive power arrangement is negative-positive in this order from the front, the back focal distance is relatively long. This tends to make too long the total length of the lens when it applies to the lens-shutter camera, though it is suited to the single lens reflex camera.

Further in Japanese Laid-Open patent application No. SHO 56-128911 (corresponding to U.S. patent application Ser. No. 243,209 field Mar. 12, 1981 assigned to the assignee of this invention) and Japanese Laid-Open patent application No. SHO 57-201213 there have been proposed compact zoom lenses each comprising a front lens unit of positive power and a rear lens unit of negative power with the separation therebetween being varied to vary the focal length of the entire system. The use of such positive-negative power arrangement leads not only to relatively shorten the back focal distance but also to achieve a zoom lens of short total length.

SUMMARY OF THE INVENTION

A first object of the present invention is to provide a vari-focal objective lens in which the distance from the front lens surface to the image plane is short.

A second object is to increase the zoom ratio while preserving the entire system.

A third object is to correct coma in the intermediate zone of the image frame throughout the entire range of variation of the focal length, and correct halo in the intermediate zone in the telephoto end.

A fourth object is to correct image aberrations that are liable to deteriorate with zooming.

And, in the present invention, by specifying the form of each lens of the front and rear lens units, the amount of aberrations produced in each lens unit is lessened so that variation of aberrations with zooming is lessened. Particularly a second lens of the front lens unit is constructed in the form of a 2-1st lens of negative power and a 2-2nd lens of positive power cemented together, thereby good correction of coma in the intermediate zone of the image frame is maintained stable throughout the entire range of variation of the focal length, and halo in the intermediate zone in the telephoto end is well corrected.

Also, first and second lenses of the rear lens unit are both formed to meniscus shapes of rearward convexity, thereby variation with zooming of image aberrations is improved.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a schematic view of the optical arrangement of a zoom lens according to the present invention.

FIG. **2** is a block diagram of an example 1 of the lens.

FIG. **3** is block diagram of another example 2 of the lens.

FIG. **4** is a block diagram of another example 3 of the lens.

FIGS. **5A–5C** are aberration curves of example 1.

FIGS. **6A–6C** are aberration curves of example 2.

FIGS. **7A–7C** are aberration curves of example 3.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

In the optical arrangement shown in FIG. **1**, when to vary the focal length from the wide angle end to the telephoto end, a front lens unit I and a rear lens unit II are moved forward independently of each other while varying the separation between these two lens units.

The total length of such a zoom lens takes a minimum value at the wide angle end and a maximum value at the telephoto end. Upon consideration of the easiness of carrying the camera around, it is advantageous to reduce the total length of the lens in the wide angle end.

Now letting LW denote the total length of the lens in the wide angle end, SW the back focal distance, eW and eT the intervals between the principal points of the first and second lens units I and II in the wide angle and telephoto ends respectively, ϕW and ϕT the refractive powers of the entire system in the wide angle and telephoto ends respectively, and $\phi 1$ and $\phi 2$ the refractive powers of the front and rear lens units I and II respectively, we have

$$LW = eW + SW$$

$$SW = \frac{1 - eW \cdot \phi 1}{\phi W}$$

From these, the total length of the lens LW becomes

$$LW = eW + \frac{1 - eW \cdot \phi 1}{\phi W} \qquad (A)$$

$$= \frac{1}{\phi W} + \left(1 - \frac{\phi 1}{\phi W}\right) \cdot eW$$

Now assuming that the refractive power of the wide angle end ϕW has a constant value, then, from equation (A), the larger the refractive power $\phi 1$ and the smaller the principal point interval eW, the shorter the total length of the lens becomes.

Meanwhile, the refractive powers ϕW and ϕT of the entire system in the wide angle and telephoto ends may be expressed as:

$$\phi W = \phi 1 + \phi 2 - eW \cdot \phi 1 \cdot \phi 2 \qquad (B)$$

$$\phi T = \phi 1 + \phi 2 - eT \cdot \phi 1 \cdot \phi 2 \quad (C)$$

Here the refractive powers ϕW and ϕT have given values, and the value of the principal point interval eT must be made as small as possible provided that the front and rear lens units do not interfere with each other when in the telephoto end, as is advantageous to minimize the bulk and size of the zoom lens, and, therefore, takes a certain value.

Therefore, the formulae (B) and (C) represent a relationship of the refractive powers $\phi 1$ and $\phi 2$ and the principal point interval eW. For a given value of any one of these variables, simultaneous equations with two unknowns are then obtained. Thus, a refractive power distribution over the zoom lens can be determined.

By taking the refractive power $\phi 1$ of the front lens unit I at a larger value with a corresponding smaller value of the interval between the principal points of the front and rear lens units I and II in the wide angle end, eW, the total length of the lens, LW, can be shortened. However, when the refractive power, $\phi 1$, is made too large, the refractive power, $\phi 2$, of the rear lens unit II, too, becomes large. This results in an increase of the Petzval sum in the negative sense with over-correction of the field curvature, depriving the image surface of flatness. Moreover, the comatic aberration in the intermediate zone of the image frame is increased and becomes difficult to correct for high grade imaging performance. Also when the principal point interval eW is made too small, the refractive powers $\phi 1$ and $\phi 2$ must be both largely increased in the positive and negative senses respectively to obtain the prescribed zoom ratio. Therefore, similar phenomena to the above are caused to take place. This is objectionable.

So, in order to achieve good stability of aberration correction throughout the entire range of variation of the focal length, it is preferred that within the framework of the above-described general lens configuration, the following various conditions are satisfied. That is, the values of the refractive powers $\phi 1$ and $\phi 2$ of the front and rear lens units I and II and the principal point interval eW fall within the following respective ranges:

$$\phi W < \phi 1 < 1.5\phi W \quad (a)$$

$$-1.5\phi W < \phi 2 < -0.5\phi W \quad (b)$$

$$0.4/\phi W < eW < 1.0/\phi W \quad (c)$$

The technical significance of each of the conditions will next be explained.

Either when the refractive power $\phi 1$ of the front lens unit I exceeds the upper limit of inequalities of condition (a), or when the refractive power $\phi 2$ of the rear lens unit II exceeds the lower limit of inequalities of condition (b), though the total length of the lens becomes shorter, as has been described above, over-correction of field curvature results, and large coma is produced in the intermediate zone of the image frame. These aberrations are difficult to correct well. Conversely when the refractive power $\phi 1$ exceeds the lower limit of inequalities of condition (a) or when the refractive power $\phi 2$ exceeds the upper limit of inequalities of condition (b), the total length of the lens becomes longer, and the rear lens unit II will interfere with the image plane, so that it is difficult to use it as the photographic lens.

When the interval between the principal points of the front and rear lens units I and II in the wide angle end, eW, exceeds the upper limit of inequalities of condition (c), the rear lens unit II comes to interfere with the image plane so that similarly to the above, it is difficult to use it as the photographic lens. When the lower limit is exceeded, the refractive powers $\phi 1$ and $\phi 2$ of the front and rear lens units I and II must be increased in the positive and negative senses respectively to obtain the prescribed zoom ratio. This results in over-correction of field curvature, and coma is increased in the intermediate zone of the image frame. These aberrations become difficult to correct well.

The concrete lens figurings that have taken into account all the above-stated conditions are shown in FIGS. 2, 3 and 4.

Each of the zoom lenses depicted in the figures is constructed with two lens units of which the front lens unit I is of positive refractive power, and the rear lens unit II is of negative refractive power, these lens units being axially moved in differential relation to effect zooming, wherein the front lens unit I is made to comprise, from front to rear, a meniscus-shaped first lens of positive refractive power convex toward the front, a second lens of a 2-first element of negative refractive power and a 2-second element of positive refractive power cemented together, whose overall power is negative, and third and fourth lenses of positive refractive powers, and the rear lens unit II is made to comprise a meniscus-shaped fifth lens of positive power convex toward the rear, and a meniscus-shaped sixth lens of negative power convex toward the rear.

To achieve good stability of, in particular, chromatic aberrations throughout the entire zooming range so that all the aberrations are corrected in good balance, it is preferred to satisfy the following conditions:

$$-0.6\,\phi W < (N22 - N21/R4) < -0.1\phi W \quad (1)$$

$$-10 < \nu 22 - \nu 21 < 10 \quad (2)$$

where N21 and $\nu 21$ are the refractive index and Abbe number of the glass of the 2-first lens element, N22 and $\nu 22$ are the refractive index and Abbe number of the glass of the 2-second lens element and R4 is the radius of curvature of the cemented lens surface of the second lens.

Inequalities of condition (1) are to stabilize coma in the intermediate zone of the image frame throughout the entire zooming range and correct well halo in the intermediate zone when in the telephoto end. Particularly when the refractive power of the cemented lens surface is made negative, positive spherical aberration and upward coma are produced. However, by making negative the refractive power of the rearmost lens surface of the second lens, as this surface bears part of the negative refractive power, the amounts of positive spherical aberration and upward coma produced are reduced from those when the cemented surface is not used.

When the upper limit of inequalities of condition (1) is exceeded, the negative refractive power of the cemented lens surface becomes too large, causing production of downward coma throughout the entire zooming range. When the lower limit is exceeded, the negative refractive power of the cemented lens surface becomes too small, causing production of upward coma throughout the entire zooming range, and causing the halo to increase in the telephoto end with decrease in the grade of imaging performance.

Inequalities of condition (2) are to correct longitudinal and lateral chromatic aberrations in good balance. When the upper limit is exceeded, over-correction of longitudinal chromatic aberration and under-correction of lateral chromatic aberration result over the entire zooming range.

When the lower limit of inequalities of condition (2) is exceeded, under-correction of longitudinal chromatic aberration and over-correction of lateral chromatic aberration result over the entire zooming range, each of which causes the imaging performance to lower objectionably.

In the present invention, to obtain an improved optical performance throughout the entire area of the image frame, it is preferred to make at least one of the surfaces of the sixth lens an aspherical surface of such shape that as the radial distance from the optical axis increases, the negative refractive power decreases. By this, the tendency of the curvature of field to vary to under-correction particularly in the intermediate region of the zooming range can be lessened.

For note, in the present invention, focusing is preferably by moving the lens system as a whole because variation of aberrations is little. But, another focusing method of moving only either one of the front and rear lens units I and II may be employed with an advantage of simplifying the operating mechanism.

When the above-stated rules of design of the invention are satisfied, a zoom lens of very compact form of about 1.25 in telephoto ratio for the wide angle end (total length of the lens/focal length in the wide angle end) well corrected for the various aberration can be achieved.

Examples of specific zoom lens of the invention can be constructed in accordance with the numerical data given in the following tables for the radii of curvature, R, the axial thicknesses and air separations, D, and the refractive indices, N, and Abbe numbers, ν, of the glasses of the lens elements with the subscripts numbered from front to rear.

Taking an X-axis in the axial direction, a Y-axis in a direction perpendicular to the optical axis, and the direction in which light advances as positive with the original point at the vertex, an equation for the aspherical surface may be expressed by

$$X = \frac{(1/R)Y^2}{1+\sqrt{1-(Y/R)^2}} + a1 \cdot Y^2 + a2 \cdot Y^4 + a3 \cdot Y^6 + a4 \cdot Y^8 + a5 \cdot Y^{10} + |b1| \cdot Y^3 + |b2| \cdot y^5 + |b3| \cdot y^7 + |b4| \cdot y^9$$

where R is the radius of curvature of the paraxial region of the lens surface of the sixth lens, and a1, a2, a3, a4, a5, b 1, b2, b3 and b4 are aspherical coefficients.

(5) $\nu 22 - \nu 21 = 2.3$

What is claimed is:

1. An objective lens comprising a front lens unit and a rear lens unit with a separation between said two lens unit being varied to vary the focal length of the entire system,

said front lens unit having a positive refractive power and consisting of, from front to rear, a positive lens of strong convex curvature toward the front, a negative doublet lens of negative and positive elements cemented together, and a positive lens sub-unit; and

said rear lens unit having a negative refractive power and having a positive lens and a negative lens.

2. An objective lens according to claim 1, wherein the negative element of said doublet lens is of bi-concave form, and the positive element is of meniscus form.

3. An objective lens according to claim 1, satisfying the following conditions:

$$-0.6\phi W < (N22 - N21/R4) < -0.1\phi W$$

$$-10 < \nu 22 - \nu 21 < 10$$

where N21 and $\nu 21$ are the refractive index and Abbe number of the negative element of said doublet lens, N22 and $\nu 22$ are the refractive index and Abbe number of the positive element, R4 is the radius of curvature of the cemented surface of the negative and positive elements, and ϕW is the refractive power of the entire system in the wide angle end.

4. An objective lens according to claim 1, wherein said positive lens sub-unit consists of two positive lenses.

5. An objective lens according to claim 4, wherein the front one of said two positive lenses is of bi-convex form.

6. An objective lens according to claim 1, wherein said rear lens unit comprises a positive meniscus lens of forward concavity and a negative meniscus lens of forward concavity arranged in this order from front.

7. An objective lens according to claim 6, wherein said rear lens unit has at least one aspherical surface.

8. An objective lens according to claim 1, wherein said front lens unit and said rear lens unit move forward while shortening the separation between said two units as the focal length increases.

9. A zoom lens comprising:

a front lens unit having a positive refractive power and consisting of, from front to rear, a positive lens with its front surface of strong convex curvature toward the front, a negative doublet lens of a bi-convex element and a positive meniscus element cemented together in this order from the front, and a plurality of positive lenses; and

a rear lens unit arranged on the image side of said front lens unit, axially movable along with, and independently of said front lens unit, having a negative refractive power, and comprising a positive meniscus lens of forward concavity, and a negative meniscus lens of forward concavity.

10. A zoom lens according to claim 9, satisfying the following condition:

$$-0.6\phi W22 - N21/R4) < -0.1\phi W$$

$$-10 < \nu 22 - \nu 21 < 10$$

where N21 and $\nu 21$ are the refractive index and Abbe number of the bi-concave element of said doublet lens, N22 and $\nu 22$ are the refractive index and Abbe number of the positive meniscus element, R4 is the radius of curvature of the cemented surface of the negative and positive elements, and ϕW is the refractive power of the entire system in the wide angle end.

SMALL-SIZED WIDE ANGLE ZOOM OBJECTIVE

This is a continuation of application Ser. No. 450,742, filed Dec. 17, 1982, now abandoned.

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to zoom objectives, and, more particularly, to small-sized, wide angle zoom objectives having three lens units with the first two lens units counting from front made movable to effect zooming.

2. Description of the Prior Art

In the past, in order to achieve a reduction of the bulk and size of a zoom objective lens, such lens has been formed by a diverging 1st lens unit and a converging 2nd lens unit with the air separation therebetween being varied to effect zooming, or to the so-called two-component type, and many zoom objectives of this type have been proposed. The present applicant also has made proposals in Japanese Laid Open Patents Nos. Sho 53-132360 and 56-19022. In the former, the diverging front or 1st lens unit is made up of three lens members, and its power is somewhat strengthened to reduce the interval between the principal points of the front and rear lens units in the telephoto position to some extent. In this manner a valuable decrease in the diameter of the front lens members and the total length of the objective (the distance from the front vertex to the image plane) particularly in the wide angle position is achieved. In the latter, on the other hand, the front or 1st lens unit is imparted with linearly progressive axial movement when zooming, thus providing achievement of a valuable decrease in the total length of the objective in the telephoto position, although the power of the diverging front or 1st lens unit is weaker than that in the former zoom objective. To achieve a further advance in the compactness of the zoom lens system, in the former case, the power of the diverging front or 1st lens unit may be further strengthened with an advantage that the total length of the complete objective in the wide angle position can be further shortened. Conversely when in the telephoto position, however, the total length becomes progressively longer, finally exceeding that when in the wide angle position. In the latter case, on the other hand, it is advantageous at shortening the total length in the telephoto position. It is, however, in the wide angle position that the total length tends to increase and further that a large increase in the diameter of the front lens members will result. For a general solution of the problem of most effectively shortening the total length of the zoom objective of the two-component type, it is preferred to employ the rule of design that the total lengths in the wide angle and telephoto positions are equal to each other.

SUMMARY OF THE INVENTION

An object of the present invention is to provide a wide angle zoom objective of reduced size having features found in the two-component type of zoom objective with achievement of shortening the total length by employing a new form and construction and arrangement of the lens members, while still preserving very high grade imaging performance.

Another object of the present invention is to provide a wide angle zoom objective of reduced size with a high range of image magnifications and with limitation of the bulk and size to a minimum while still permitting good correction of aberrations.

To achieve these objects, one of the features of the present invention is that the zoom objective is constructed with three lens units of which the 1st after counting from the front, is divergent and the 2nd is convergent whereby the aforesaid 1st lens unit and 2nd lens unit are made axially movable for zooming in front of the 3rd lens unit, which remains stationary.

Additional features are that the 1st lens unit, 2nd lens unit and 3rd lens unit are given respective appropriate refractive powers, and each lens unit has a suitable configuration. When these features are within the limits stated, greatly improved results are attained.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a schematic view illustrating the zooming method employed in the conventional zoom lenses.

FIGS. **2**-*a* and -*b*, FIGS. **3**-*a* and -*b*, and FIGS. **4**-*a* and -*b*, are schematic views each illustrating the predesigns of the conventional zoom objective in comparison with an embodiment of the zoom objective according to the present invention.

FIGS. **5** through **13** are lens block diagrams of embodiments 1 through 9 of the present invention respectively.

FIGS. **14** through **22** are graphic representations of all aberrations of the objectives of FIGS. **5** to **13** respectively.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

The zoom objective of the present invention may be considered in analogy to the conventional two-component zoom objective as comprising a converging rear or 2nd lens unit which is divided into two parts with the front one of convergence and the rear one of either divergence or convergence, whereby the converging front part only is made axially movable together with the diverging 1st lens unit to effect zooming.

As is known in the art, there has been another proposal for the zoom objective comprising, as illustrated in FIG. **1**, a diverging 1st unit I, a converging 2nd unit II and a diverging 3rd unit III, that the 2nd and 3rd units are moved forward, while the 1st unit is simultaneously moved in non-linear progression, when zooming from the wide angle to the telephone position. With such zoom type, to retain the zoom ratio in somewhat high a level, it is required that the total movement of the 2nd unit be increased, and the paths of movement of the 1st and 3rd unit be changed as indicated by dashed line curves in the same drawing. In this case, the 1st unit tends to project farther ahead in the telephoto setting than in the wide angle setting. The expansion of the total length of the objective in the telephoto position will increase the bulk and size of the lens system.

As the total zooming movement of the 3rd unit reduces, the proportion of that part of the zooming movement of the 1st unit which directs toward the rear increases so that the equivalent zoom ratio can be obtained by a lesser zooming movement of the 2nd unit.

The zoom objective of the present invention has features with use of such properties of the zoom lens and such features of the two-component zoom type to achieve a further minimization of the bulk and size of the zoom lens while still permitting high grade optical performance.

Next, with regard to the zoom lens according to the present invention, taking an example of the lens predesign that the 3rd lens unit is made of divergence, and comparing with that type which has been proven to be advantageous for achieving minimization of the bulk and size of the zoom objective, or the so-called two-component zoom type, the rules of design of the invention, which are suited for facilitating a minimization of the bulk and size of the zoom objective, will be explained by reference to the drawings.

FIGS. 2-*a* and 2-*b* are the predesigns of the conventional two-component zoom objective and of a zoom objective of the present invention respectively. I is a negative 1st lens unit; II is a positive 2nd unit; and F is a film plane. As illustrated in FIG. 2-*b*, the division of the converging rear or 2nd unit into two parts II_I and II_{II} of positive and negative powers respectively gives a similar configuration to that of the zoom objective of the present invention which may be considered for these two parts to constitute a telephoto type lens with the result that the film plane F is shifted forward and takes its place at a position indicated by F', and, therefore, that the back focus is shortened. This makes it possible to shorten the total length of the lens system in both the wide angle and telephoto positions.

What change results in the total zooming movement by that division is illustrated in FIGS. 3-*a* and -*b* and 4-*a* and -*b*. Since the rear part II_{II} has a negative power, the positive power of the front part II_I is necessarily stronger than that of the original unit II. Therefore, the required total zooming movement of the front part II_I for the same zoom ratio can be lessened by a distance ΔD_1 illustrated in FIG. 3-*b* as compared with FIG. 3-*a*. This allows for the interval between the principal points of the diverging 1st unit I and the converging front part II_I to be reduced by the ΔD_1. Thus a further reduction of the total length of the lens system can be achieved.

In addition to the advantage which is produced based on the assumption that the power of the diverging 1st unit is left unchanged from that of the diverging 1st unit of the conventional two-component zoom objective, according to the zoom lens predesign of the invention, it is also made possible to facilitate a further reduction of the total length of the lens system than when the conventional method, i.e., that which has been found to be very effective in reducing the bulk and size of the two-component zoom objective by increasing the power of the 1st unit so as to make the total length in the wide angle position almost equal to that in the telephoto position, is in use.

In this connection, it should be explained that, as has been stated above, the zoom objective of the present invention admits of reducing the total zooming movement of the converging 2nd unit from that of the conventional two-component zoom objective, while still maintaining the constant equivalent zoom ratio. With the wide angle position as the start point, therefore, when zoomed to the telephoto position, the diverging 1st unit I may be located backward at a distance ΔD_2 indicated in FIG. 4-*b* from the point in position of the conventional one illustrated in FIG. 4-*a*. Since, therefore, the total length in the telephoto position becomes shorter than that in the wide angle position, a possibility of shortening the total length in the wide angle position is produced. Thus, a further minimization of the total length of the lens system can be achieved when the power of the diverging 1st lens unit is further strengthened. For a better understanding, the foregoing discussion on the primary features of a new type of zoom objective according to the present invention has been presented as compared with the conventional or two-component zoom type.

In the alternative case where the 3rd unit of the zoom objective of the invention is divergent, the total length of the lens system tends to become slightly longer than when it is convergent. But, because of the convergence of the 3rd unit, particularly regarding a high-range zoom objective, all aberrations become easy to correct throughout the entire zooming range. This allows for the power of the 1st unit to be strengthened. As a result, even when the 3rd unit is divergent, achievement of a valuable decrease in the total length of the lens system is provided as well.

According to the present invention, a zoom objective of the type described above has the rules of design which are sufficient to achieve a valuable decrease in the bulk and size of the lens system and good correction of aberrations. However, with the diverging 3rd unit, in order to obtain a further improvement of the optical performance and to achieve a further reduction of the total length of the lens system, it is preferred to satisfy the following conditions:

The 1st condition is that, letting f_{III} denote the focal length of the 3rd unit, $|f_{III}|$ is equal to or larger than the longest focal length f_T of the entire system, or $|f_{III}| \geqq f_T$. This leads to limit the power of the 2nd unit so as not to produce extremely large aberrations and also to provide a necessary back focus in the wide angle position. When out of this range, the aberrations ascribable to the 2nd unit increase so greatly that it is difficult to perform good correction of image aberrations, and the back focus becomes too short to provide a clearance for mirror-up even in the wide angle position when in use with a 35 m/m TTL type single lens reflex camera.

The 2nd condition is that, letting f_I denote the focal length of the 1st unit, $|f_I|$ is equal to or smaller than f_T, or $|f_I| \leqq f_T$. This results in a shortened total length of the entire system, and a decreased diameter of the front members of the zoom objective. When this condition is violated, the total length of the lens system in the wide angle position and the diameter of the front members of the objective become too large to achieve an advance in the compactness with ease. Further, for a zoom ratio of less than 2 and a full open F-number of about F/4, as in embodiments of the invention to be described later, it is preferred to construct the diverging 3rd unit in the form of a single lens. This is advantageous in order to make the entire system of the zoom objective compact within the scope such that the aberrations of the entire system of the zoom objective are not deteriorated badly. In the case where an aperture stop is positioned within the 2nd unit, with regard to the fact that somewhat strong power of the 1st unit is liable to result in production of large barrel type distortion in the wide angle position, the location of the 3rd unit on the image side of the aperture stop provides assurance that this distortion can be well corrected. To perform such correction effectively, a 1st good method is by constructing the 3rd unit in the form of a meniscus-shaped single lens of concave curvature toward the rear.

While the state of correction of the image aberrations is maintained excellent as such, the zoom lens system as a whole is made compact, provided that the following various conditions, which are severer than the aforesaid ones, are preferably satisfied.

$$0.5 \leqq |f_I|/f_T \leqq 0.9 \quad (1)$$

$$1.4 \leqq |f_{III}|/f_T \leqq 19 \quad (2)$$

Here, when below the lower limit of condition (1), the total length of the lens system in the telephoto position tends to be longer than in the wide angle position, and further it becomes difficult to perform good correction of spherical aberration in the telephoto position. When above the upper limit, the total length in the wide angle position is insufficiently shortened.

When below the lower limit of condition (2), it becomes difficult to take the back focus at a required value in the wide angle position and, further, the construction of the 3rd unit in the simple form becomes difficult from the standpoint of physical characteristics. When above the upper limit, this power of the 3rd unit is too weak to achieve a great advance in the compactness.

As a 2nd method, the 3rd unit is preferably constructed in the form of at least one positive lens and at least one negative lens with the axial separation, t, between the frontmost and rearmost lens surfaces of the 3rd unit falling within the following range:

$$0.04 \leqq t/f_T \leqq 0.25 \quad (3)$$

This also contributes to the reduction of the bulk and size of the entire lens system while still preserving good correction of aberrations.

When the upper limit of condition (3) is exceeded, the excessive thickness of the 3rd unit has an adverse effect on the reduction of the bulk and size of the entire lens system. When the lower limit is exceeded, the lens thickness becomes too thin to give a desired radius of curvature so that it becomes difficult to perform good correction of aberrations.

As to the 1st unit, according to the present invention, it is preferred to arrange a positive lens in the rearmost position with an air lens defined by the front surface of that positive lens and the rear surface of a preceding lens having a converging action. For the 2nd unit, it is preferred to use, first, two or more lenses of positive and negative powers and, second, positive lenses in this order from the front of the zoom lens.

Such construction and arrangement of the constituent lenses enables the spherical aberrations of each unit to be removed to some extent, and, therefore, facilitate an achievement of good stability of correction of spherical aberrations throughout the entire zooming range.

Besides, to achieve the valuable decrease in the bulk and size of the entire zoom lens system in such a manner as to make it possible to maintain good stability of aberration correction throughout the entire zooming range, according to the present invention, it is better to construct the diverging 1st unit of strong power in a very simple form and to suppress the amount of aberrations ascribed to this component to as small a level as possible. In this respect, the 1st lens unit is made up of, from front to rear, a meniscus-shaped negative 1st lens of forward convexity, a bi-concave negative 2nd lens, and a meniscus-shaped positive 3rd lens of forward convexity. The use of the air lens of converging action defined by the negative 2nd and positive 3rd lenses enables good correction of all aberrations to be easily performed in the telephoto positions.

The 1st unit may be otherwise constructed as comprising, from front to rear, a positive lens, a negative meniscus lens of rearward concavity, a negative lens with its rear surface having a stronger refractive power, and a positive lens with its front surface having a stronger refractive power.

With a widened angular field, to correcting the zoom objective of the invention well particularly for distortion in the wide angle positions, it is better to arrange a positive lens at the frontmost position in the 1st unit so that correction of barrel type distortion is performed by this positive lens.

Since the 1st unit has an overall refractive power of negative sign, it is required that the aforesaid positive lens be followed by a plurality of negative lenses in view of the use of an additional positive lens of which the front surface has a strong refractive power in the rear of those negative lenses with the production of an air lens of convergence between the negative and positive lenses, to thereby enable good correction of spherical aberrations in the telephoto position, thus contributing to the good stability of aberration correction over the entire zooming range.

It is to be noted here that when the number of negative lenses stated above is two, it is preferred to form the front or 1st negative lens to a meniscus shape of concave curvature toward the rear, and the negative 2nd lens to a shape of strong refractive power in the rear surface thereof, with an advantage that the spherical aberrations in the telephoto positions and the coma in the wide angle positions are well corrected.

Next, the 3rd unit when constructed by a converging or diverging lens unit has additional featues that a lens of negative power and a lens of positive power are at least included, and that, letting f_{III} denote the focal length of the aforesaid 3rd lens unit and fw the shortest focal length of the entire lens system, the following condition is satisfied:

$$-0.3/fw < 1/f_{III} < 0.2/fw \quad (4)$$

In order to achieve an increase in the zoom ratio up to more than two for the two-component zoom type which has found many use in zoom objectives, while still permitting the entire lens system to take a compact form, according to the prior art, it is required particularly for the positive power of the 2nd unit to be strengthened so that the prescribed equivalent zoom ratio can be obtained despite the total axial movement is lessened. In addition thereto, the negative power of the 1st unit is also strengthened so that the total length of the lens system from the front vertex to the focal plane in the wide angle position can be shortened. As has been stated above, however, the increase in the positive power of the 2nd unit results in the production of very large astigmatism as under-corrected in the wide angle positions and as over-corrected in the telephoto positions, which are difficult to cancel out.

It will be appreciated from this standpoint that the use of the additional or 3rd unit which remains stationary during zooming to the conventional two-component zoom lens system provides assurance that all aberrations can be well corrected with ease over the extended zooming range. For this purpose, the 3rd unit is constructed as comprising at least one negative lens and at least one positive lens. When the refractive power of the 3rd unit lies within the range defined by inequalities (4), good balance of aberrations in the wide angle and telephoto positions can be maintained.

Further, it is preferred that the negative and positive lenses of the third unit are cemented together at their

adjoining surfaces to form a doublet of meniscus shape convex toward the rear, and the index of refraction of the glass from which the negative lens of the third unit is made up is made higher than that of refraction of the glass from which the positive lens of the third unit is made up. Such doublet produces either over-corrected or under-corrected astigmatism when in the wide angle or telephoto positions respectively, thereby the stabilization of the astigmatism can be obtained. The use of the glass having the higher index of refraction in the negative lens of the third unit provides improvement in that the Petzval sum, which would otherwise go negative, is directed toward positive.

For assisting in accomplishing the object of the present invention, the following condition is satisfied:

$$|f_I| \leqq |f_T| \tag{5}$$

In this connection, it should be explained that when an independent focusing movement is imparted into the 1st unit, the required diameter of the front member tends to rapidly increase for an object at shorter distances. To account for this, it is better to strengthen the power of the 1st unit to some extent so that the total forward movement is reduced. The above-stated condition (5) represents a range of refractive powers allowable for the 1st unit. Though too great an increase in the refractive power of the 1st unit is advantageous at reducing the diameter of the front member, the barrel type distortion in the wide angle positions and the spherical aberration in the telephoto positions are caused to rapidly increase. Thus, it becomes difficult to maintain good stability of aberration correction throughout the zooming range. Therefore, it is preferred that the refractive power of the 1st unit is not too strengthened, leaving it to be on the order:

$$|f_I| \geqq |f_T/2|$$

As to the diaphragm, for the zoom objective of the present invention, it is preferred from the standpoint of aberration correction that the diaphragm is positioned in a space within the 2nd unit, or adjacent the front or rear surface thereof and made movable in the same direction as the 2nd unit during zooming. When it is not desired to move the diaphragm, it is better to arrange it in a space between the 2nd and 3rd unit.

Next, explanation will be made about the function and effect of the 3rd unit based on the theory of aberrations. Taking a specific example 2 of the invention, to be described later, with the aperture stop in a space between the 1st and 2nd lenses counting from front in the 2nd lens unit, the 1st, 2nd and 3rd lens units have Seidel's aberration coefficients of 3rd order listed in Table 1.

As is evident from Table 1, the 3rd lens unit has, despite zooming the ability to give constant spherical aberration (SA), but astigmatism (AS) and distortion (DS) both act toward providing over-correction, and astigmatism (AS) is shown to be strong in the wide angle positions, and weak in the telephoto positions. Since, in the zoom objective of the invention, the powers of the 1st and 2nd lens units are strengthened to some extent, the combined lens system of the 1st and 2nd units is liable to produce under-corrected astigmatism particularly in the wide angle positions. To balance out the resultant aberrations, therefore, the aforesaid rules of design for the 3rd unit are very important. Also, since the barrel type distortion is liable to increase in the wide angle positions, such design of the 3rd unit is advantageous to the compensation of this aberration.

It will be appreciated that the zoom objective of the present invention is provided with the 3rd lens unit having the function of compensating for the aberrations produced from the 1st and 2nd lens units. In this respect, as compared with the mere combination of the conventional two-component zoom objective of which the aberration correction is completed in itself and an additional lens releasably inserted into the space between that objective and the image plane, or a so-called rear attachment lens (which is corrected for aberrations of itself only) to convert the range of focal lengths, that is, as compared with an apparent 3-component zoom objective, the zoom objective of the present invention has fundamentally different provisions, features and results. It is therefore remarkably improved over the prior art system obtained by adding a new converter lens to the zoom objective comprised of the negative and positive lens units to change the focal length range.

Another example of the 3rd lens unit when being either converging or diverging is given in Table 2 for the 3rd order aberration coefficients of an embodiment 9 of the invention. With reference to Table 2, what results are practically attained by the use of the 3rd lens unit is concretely clarified below. The sum of the 3rd order astigmatic aberration coefficients produced from the 1st and 2nd lens units is 0.077 in the wide angle position and −0.05 in the telephoto position as seen in Table 2, representing the residual astigmatism as under-corrected when in the wide angle position, and over-corrected when in the telephoto position. On the other hand, the 3rd lens unit gives a value of −0.0551 when in the wide angle position and 0.0504 when in the telephoto position. Therefore, the entire lens system of the 1st through 3rd lens units has values of 0.0219 and 0.0004 in the wide angle and telephoto positions respectively, thus giving good balance. Such improved results are attained when the refractive power of the 3rd lens unit falls within the range defined by the aforesaid inequalities (4). When the lower limit of condition (4) is exceeded, as the negative refractive power becomes too strong, it becomes difficult to retain the required value of back focus in the wide angle positions. Further, as the refractive power of the 2nd lens unit is caused to increase, the good stabilization of aberrations against zooming also becomes very difficult to hold. Conversely when the upper limit is exceeded, the power of the 2nd lens unit becomes too weak to reduce the bulk and size of the lens system without having difficulty in the limitation that the zooming range be maintained in extended manner.

It is to be noted that focusing of the zoom objective of the invention may be performed either by moving the entire lens system, or by moving the 1st and 2nd lens units, while the 3rd lens unit remains stationary during focusing, or by moving only either one of the 1st and 2nd lens units.

Though the embodiments 8 and 9 of the invention has been illustrated in connection with the 3rd lens unit of the cemented form consisting of the negative and positive lenses, it is, of course, also possible to make use of two or more singlets, thereby giving an advantage that the focusing provision can be made at part of the 3rd lens unit by an operating mechanism of simplified structure.

Examples of specific zoom objectives of the invention can be constructed in accordance with the following numerical data for the radii of curvature, R, the axial thicknesses or air separations, D, and the refractive indices, N, and the Abbe numbers, ν, of the glasses of the lens elements, with subscripts numbered consecutively from front to rear.

What I claim is:

1. A wide angle zoom objective of reduced size comprising:
- a first lens unit, a second lens unit, and a third lens unit arranged from the object side;
- said first lens unit being divergent, said second lens unit being convergent, and said third lens unit being stationary during zooming; and
- a diaphragm for controlling a light flux passing through the zoom objective,
- said first lens unit and said second lens unit moving for zooming along the optical axis and said diaphragm being associated with said second lens unit.

2. A wide angle zoom objective of reduced size according to claim 1, wherein said 3rd lens unit is a diverging lens unit.

3. A wide angle zoom objective of reduced size according to claim 2, wherein letting f_{III} denote the focal length of said 3rd lens unit and f_T the longest focal length of the entire lens system, we have

$$|f_{III}| \geqq f_T.$$

4. A wide angle zoom objective of reduced size according to claim 3, wherein letting f_I denote the focal length of said 1st lens unit, we have

$$|f_I| \leqq f_T.$$

5. A wide angle zoom objective of reduced size according to claim 4 wherein said 3rd lens unit comprises a meniscus-shaped lens of negative refractive power concave toward the rear.

6. A wide angle zoom objective of reduced size according to claim 4, wherein said 3rd lens unit has at least one positive lens and at least one negative lens, and the following condition is satisfied:

$$0.04 \leqq t/f_T \leqq 0.25$$

where t is the thickness from the front-most lens surface of the third lens unit to the rear-most lens surface.

7. A wide angle zoom objective according to claim 4, wherein
- said 1st lens unit comprises, from front to rear,
- a meniscus-shaped lens of negative refractive power convex toward the front,
- a bi-concave lens of negative refractive power, and
- a meniscus-shaped lens of positive refractive power convex toward the front.

8. A wide angle zoom objective according to claim 4, wherein
- said 1st lens unit comprises, from front to rear,
- a lens of positive refractive power,
- a meniscus-shaped lens of negative refractive power concave toward the rear,
- a lens of negative refractive power with its rear lens surface having a stronger refractive power, and
- a lens of positive refractive power with its front lens surface having a stronger refractive power.

9. A wide angle zoom objective according to claim 1, wherein
- said 3rd lens unit has at least one negative lens and at least one positive lens; and
- letting f_{III} denote the focal length of said 3rd lens unit, and fw the shortest focal length of the entire lens system,
- the following condition is satisfied:

$$-0.3/fw < 1/f_{III} < 0.2/fw.$$

10. A wide angle zoom objective of reduced size according to claim 9, wherein
- said negative lens and said positive lens are cemented together to form a meniscus-shaped doublet convex toward the rear; and
- the refractive index of the glass of said negative lens is higher than that of the glass of said positive lens.

11. A wide angle zoom objective of reduced size according to claim 10, wherein
- letting f_I denote the focal length of said 1st lens unit, and f_T the longest focal length of the entire lens system,
- the following condition is satisfied:

$$|f_I| \leqq f_T.$$

12. A wide angle zoom objective according to claim 1, in which the first lens unit occupies a position closer to the image when it is at the telescope end of zooming than when it is at the wide angle end.

13. A wide angle zoom objective of reduced size comprising:

a first lens unit, a second lens unit, and a third lens unit arranged from the object side;

said first lens unit being divergent, said second lens unit being convergent, and said third lens unit being stationary during zooming; and

letting f_I denote the focal length of said first lens unit and f_T the longest focal length of the entire lens system, the following condition is satisfied:

$$|f_I| \leqq f_T.$$

14. A wide angle zoom objective of reduced size comprising:

a first lens unit, a second lens unit, and a third lens unit arranged from the object side;

said first lens unit being divergent, said second lens unit being convergent, and said third lens unit being stationary during zooming; and

the following condition is satisfied:

$$0.04 \leqq t/f_T \leqq 0.25$$

where t is the thickness from the front-most lens surface of the third lens unit to the rear-most lens surface.

15. A wide angle zoom objective of reduced size according to claim **14**, wherein said third lens unit has at least one positive lens and at least one negative lens.

16. A wide angle zoom objective of reduced size comprising:

a first lens unit, a second lens unit, and a third lens unit arranged from the object side;

said first lens unit being divergent, said second lens unit being convergent, and said third lens unit being stationary during zooming and being composed of a single lens.

17. A wide angle zoom objective or reduced size comprising:

a first lens unit, a second lens unit, and a third lens unit arranged from the object side;

said first lens unit being divergent, said second lens unit being convergent, and said third lens unit being stationary during zooming and being composed of a cemented lens.

18. A wide angle zoom objective of reduced size comprising:

a first lens unit, a second lens unit, and a third lens unit arranged from the object side;

said first lens unit being divergent, said second lens unit being convergent, and said third lens unit being stationary during zooming and being composed of a negative single lens, and a positive single lens, separated by air from said negative lens.

19. A wide angle zoom objective of reduced size comprising:

a first lens unit, a second lens unit, and a third lens unit arranged from the object side;

said first lens unit being divergent, said second lens unit being convergent, and said third lens unit being stationary during zooming and being composed of a single lens and a cemented lens separated by airs from said single lens.

[57] **ABSTRACT**

A camera system comprising a camera body and an interchangeable lens assembly adapted to be coupled to the camera body. The interchangeable lens assembly has no manipulatable aperture adjusting ring, but has an aperture mechanism and a read-only memory both built therein. The read-only memory stores therein various data peculiar to such lens assembly. The camera body communicates with and power the lens assembly through a set of terminals connectable with associated terminals provided in the lens assembly. The terminals in each of the camera body and lens assembly are arranged in a generally arcuate row with the data transmitting terminal located at one extremity of the arcuate row on the leading side with respect to the direction of turn of the lens assembly which is effected when the lens assembly is to be completely coupled to the camera body.

CAMERA SYSTEM CAPABLE OF INTERCHANGING ITS OBJECTIVE LENS

This is a continuation-in-part application of U.S. application Ser. No. 478,910, filed Mar. 25, 1983, Pat. No. 4,560,267, issued Dec. 24, 1985.

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention generally relates to a photographic camera system utilizing interchangeable objective lens assemblies one at a time and, more particularly, to an improvement in coordination between the camera body and the interchangeable objective lens assembly then coupled thereto.

2. Description of the Prior Art

In a photographic camera system utilizable with interchangeable objective lens assemblies one at a time, one of the most important coordinations between the camera body and the lens assembly then coupled thereto lies in the manual aperture setting required to be performed at the time of manual exposure control, automatic exposure control under the aperture-priority mode, or the like. As is well known to those skilled in the art, interchangeable lens assemblies generally have a manipulatable aperture adjustment such as an aperture setting ring mounted exteriorly on the lens barrel for the access to a photographer.

On the other hand, there is also known a photographic camera system wherein the aperture adjustment is not provided on an interchangeable lens assembly, but on the body of a photographic camera so that the setting of the aperture adjustment can be transmitted to the lens assembly to control the aperture in such lens assembly. In this camera system, since the available aperture range, i.e., the available range from the maximum settable aperture (the smallest available f-stop number) to the minimum settable aperture (the largest available f-stop number), varies from one interchangeable lens assembly to another, a mechanism comprising a mechanical signaling element, provided in any one of the interchangeable lens assemblies and indicating the aperture range available in the respective lens assembly, and an engagement element provided in the camera body for engagement with the signaling element is employed to inhibit the aperture adjustment in the camera body to set the aperture of a value outside the available aperture range.

In either of the above described camera systems, there are many limitations and/or requirements imposed on the manufacture of the interchangeable lens assemblies such as, for example, a space for accommodating an arrangement necessary to permit the aperture setting ring to rotate, a precise arrangement of both the signaling element and the engagement element, the precise machining of the associated component parts and so on. These limitations and/or requirements often render the camera system as a whole to be complicated and expensive.

Another one of the most important coordinations between the camera body and the lens assembly lies in the transmission of various electric signals therebetween. Numerous techniques and arrangements have hitherto been utilized for transmitting electric signals through terminals between the camera body and the lens assembly. As is well known to those skilled in the art, the utmost care is required to permit the electric signals to be correctly transmitted between the camera body and the lens assembly and, therefore, an improvement has long been desired to avoid any possible inadvertent transmission of one or more of the electric signals from the camera body to the lens assembly or from the lens assembly to the camera body which would result in the erroneous operation of the camera.

SUMMARY OF THE INVENTION

An essential object of the present invention is to improve the conventional camera utilizing an interchangeable lens assembly to permit the camera system as a whole to be reasonably constructed and also to simplify the interchangeable lens assembly.

Another important object of the present invention is to provide an improved camera system wherein the manipulatable aperture adjustment is not provided on the interchangeable lens assembly, but on the body of a camera to permit the setting of the aperture of the lens assembly to be carried out on the side of the camera body.

A further object of the present invention is to provide an improved interchangeable lens assembly having its utility in the camera system of the type referred to above.

A still further object of the present invention is to improve the system so as to avoid the possibility that the camera body may process erroneous information in the event of the incorrect mounting of the lens assembly to the camera body.

A yet further object of the present invention is to provide an improved interchangeable lens assembly having its utility in the system of the type referred to in the preceding paragraph.

The present invention provides a camera system that includes a compatible camera body and interchangeable lens assembly particularly adaptable for automatic focusing. The camera body has a series of terminals for providing electrical power, enabling signals and clock signals plus the ability to receive information from the interchangeable lens assembly. The interchangeable lens assembly has complementary terminals and can have the ability to store various data peculiar to the specific lens assembly such as aperture size.

BRIEF DESCRIPTION OF THE DRAWINGS

These and other objects and features of the present invention will be readily understood by those skilled in the art upon the reading of the following description taken in conjunction with a preferred embodiment with reference to the accompanying drawings, in which:

FIG. **1** is a perspective view showing an essential portion of the camera with an interchangeable lens assembly shown as separated therefrom;

FIG. **2** is a perspective view of the camera of FIG. **1** as viewed from a different direction;

FIG. **3**(*a*) is a circuit diagram showing an electric circuit incorporated in the camera body according to the present invention;

FIG. **3**(*b*) is a circuit diagram showing an electric circuit incorporated in the lens assembly according to the present invention;

FIG. **4** is a circuit diagram showing an essential portion of a circuit shown for the purpose of comparison with the operation of the embodiment in FIGS. **3**(*a*) and **3**(*b*) according to the present invention;

FIG. **5** is a circuit diagram showing an essential portion of the embodiment in FIGS. **3**(*a*) and **3**(*b*) accord-

ing to the present invention, shown for the purpose of comparison with the circuit of FIG. 4;

FIG. 6 comprises FIGS. 6(*a*) to 6(*c*) and altogether shows a flow chart of the sequence of operation of the camera system according to the present invention; and

FIG. 7 is a flow chart showing a subroutine executed during the process flow of FIG. 6.

DETAILED DESCRIPTION OF THE EMBODIMENT

Before the description of the present invention proceeds, it is to be noted that like parts are designated by like reference numerals throughout the accompanying drawings.

Referring first to FIG. 1 showing a combination of an interchangeable zoom lens assembly and the body of a photographic camera utilizable with the zoom lens assembly, the zoom lens assembly includes a distance setting ring 1 for setting the camera-to-object distance, and a zooming ring 3 for the adjustment of the focal length of the zoom lens assembly. When the zooming ring 3 is rotated, the focal length of the zoom lens assembly can be adjusted and, at the same time, a slide member provided in a focal length code plate FCP as shown in FIG. 3(*b*) slides a coded pattern in contact therewith to enable the code plate FCP to generate an output data indicative of the focal length to which the lens assembly has been set by the rotation of the zooming ring 3. The lens assembly has a rear end provided with a ring-shaped abutment plate 5 fixed coaxially thereto and carrying five electric terminals JL1 to JL5, said electric terminals JL1 to JL5 being arranged in a circle coaxial with the abutment plate 5 about the optical axis of the lens assembly. Rigidly mounted on the rear end of the lens assembly adjacent the abutment plate 5 is a coupling ring having a plurality of, for example, three, radially outwardly flanged bayonet pawls 7, the function of which will be described later. The lens assembly also has a stop-down pin 9 protruding axially outwardly from the rear end of the lens assembly and normally angularly biased by a spring in a direction shown by the arrow Z, said stop-down pin 9 being so operatively associated with an aperture control mechanism 100 built in the lens assembly that the aperture of the lens assembly can be adjusted to the minimum aperture size (the largest f-stop number) with the pin 9 located at the position shown by solid line and the full open aperture size (the smallest f-stop number) when the stop-down pin 9 is angularly moved to a position 9*a* shown by the broken line in a direction counter to the biasing direction Z.

The camera body 21 has a ring-shaped abutment plate 11 rigidly secured thereto for engagement with the abutment plate 5 fast with the lens assembly and carrying an equal number of electric terminals JB1 to JB5, said electric terminals JB1 to JB5 being so positioned and so arranged that, when and after the lens assembly has been completely coupled to the camera body 21 with the abutment plate 5 held in contact with the abutment plate 11, the terminals JB1 to JB5 on the camera body 21 can be electrically connected with the associated terminals JL1 to JL5 on the lens assembly, respectively. The camera abutment plate 11 has an equal number of bayonet flanges 13 extending radially inwardly therefrom and engageable with the lens bayonet pawls 7 when the lens assembly is mounted onto the camera body and subsequently turned in the direction Z so as to assume a locked position. It is to be noted that the complete coupling of the lens assembly to the camera body 21 is intended to mean that the lens assembly mounted onto the camera body 21 and then turned so as to assume the locked position is held in such locked position and that, although not shown because of the well known expedient in the related art, the camera body 21 is to be understood as provided with a releasable locking member for holding the lens assembly in the locked position. The camera body 21 also has an aperture stop-down control lever 15 having a side edge 15*a* engageable with the stop-down pin 9 when and after the lens assembly has been completely coupled. Accordingly, the aperture of the lens assembly depends on the position of the aperture stop-down control lever 15. Although in practice the aperture stop-down control lever 15 is spring-loaded so as to move in a direction shown by the arrow X, it is held in a position shown by the solid line during a period other than during the exposure control operation and, therefore, the aperture of the lens assembly is set to the maximum aperture size, i.e., the full open aperture size. When the exposure control operation takes place, the control lever 15 is disengaged from the solid line position to move in the direction X accompanied by the angular movement of the stop-down pin 9 in the direction Z with the aperture of the lens assembly consequently stopped down. After the control lever 15 has been moved in the direction X by a predetermined distance corresponding to the stopping-down degree to attain a required aperture size, the control lever 15 is brought to a halt and, at the same time, the stop-down pin 9 having been following to the control lever 15 is brought to a halt with the aperture of the lens assembly consequently set to the predetermined value. The camera body 21 also has a reflective mirror 17 supported for pivotal movement between an up position, at which the incoming light passing through the lens assembly is allowed to reach a photosensitive film, and a down position as shown and at which the incoming light is reflected towards a viewfinder of the camera.

To mount onto the camera body 21, the lens assembly is first inserted into the camera body 21 until the lens abutment plate 5 contacts the camera abutment plate 11 and then is turned in the direction Z to allow it to be held in the locked position. When the lens assembly is so locked, the bayonent pawls 7 are held in position between the bayonet flanges 13 and spring members (not shown) provided in the camera body 21 and positioned on one side of the bayonet pawls 7 opposite to the associated bayonet flanges 13 and, at the same time, the lens terminals JL1 to JL5 are aligned and electrically connected with the camera terminals JB1 to JB5, respectively. The paired terminals JB1 and JL1 are utilized to transmit data from the lens assembly onto the camera body; the paired terminals JB2 and JL2 are utilized to supply an electric power from the camera body onto the lens assembly; the paired terminals JB3 and JL3 are utilized to supply synchronizing clock pulses from the camera body onto the lens assembly; the paired terminals JB4 and JL4 are utilized to supply from the camera body onto the lens assembly a chip select signal necessary to activate a circuit built in the lens assembly; and the paired terminals JB5 and JL5 are utilized to make the ground common to both the camera body and the lens assembly.

As can readily be understood from FIG. 1, it is clear that, except for a mechanical linkage associated with the control of the lens aperture, no other mechanical

linkage intended for the transmission of pieces of information is employed between the camera body and the lens assembly. Accordingly, not only can the lens assembly have enough space to spare, but also no substantial care is required in designing and machining component parts of the mechanical linkage necessitated to transmit a physical information concerned of the lens aperture.

In addition, since the paired terminals for the transmission of the electric signals are arranged in the manner as hereinabove described, the data transfer terminal JB1 on the camera body **21** contacts none of the lens terminals JL1 to JL5 during the mounting of the lens assembly and prior to the complete coupling of the lens assembly to the camera body, but contacts the associated lens terminal JL1 only when the lens assembly has been completely coupled to the camera body having been held in the locked position. Accordingly, as will be described later, even when the lens assembly is incompletely coupled to the camera body, there is no possibility that electric current may flow from any of the other terminals to this data transfer terminal through the circuit built in the lens assembly. This is advantageous in that the possibility is eliminated that the data may be destroyed by the current flowing from any of the other terminals while a microcomputer is in operation to transact the data with blocks other than the lens assembly, thereby permitting the data to be correctly read.

FIG. **2** illustrates the appearance of the camera body viewed from the rear. As shown, the camera body has a shutter release button **22**, a mode selector slide **23**, a liquid crystal display unit **24**, an aperture setting button **25**, an exposure time setting button **26**, an up-shift button **27**, a down-shift button **28** and a frame counter window **29** all arranged at convenient places readily accessible to and noticeable by the photographer. The shutter release button **22** when depressed is moveable in two stages between inoperative and operated positions past an intermediate position, and the first stage of movement from the inoperative position to the intermediate position results in the closure of a light measuring switch S1, shown in FIG. **3**(*a*), to initiate the light measurement, the calculation and the display operation, but the subsequent second stage of movement from the intermediate position to the operated position results in the closure of a release switch S2, shown in FIG. **3**(*a*), to initiate the exposure control if an exposure control mechanism has already been charged. The mode selector slide **23** is selectively movable to any one of the four clock positions marked "A", "P", "S" and "M", respectively. When this mode selector slide **23** is in the A position, the camera is brought in position to operate under an aperture priority mode (hereinafter referred to as A mode) at which the exposure time is automatically controlled in reference to the preset aperture, but when the slide **23** is moved to the P position, the camera is brought in position to operate under a programmed mode (hereinafter referred to as P mode) at which a combination of the exposure time and the aperture are automatically controlled in dependence on the amount of light. It is to be noted that, during the P mode of operation, the program line varies dependent on the data fv fed from the lens assembly indicating the focal length, to which the zooming ring **3** has been adjusted, in such a way that, when $fv > fvt$, wherein fvt represents the data indicative of the focal length of, for example, 80 mm, a Pt mode is established in which a priority is given to the high shutter speed in determining the combination of aperture and exposure time, but when $fvw > fv$, wherein fvw represents the data indicative of the focal length of, for example, 35 mm, a Pw mode is established in which a priority is given to the small aperture in determining the combination of exposure time and aperture. However, when and so long as $fvt \geqq fv \geqq fvw$, a normal Pn mode is established. When the mode selector slide **23** is set at the S position, the camera is brought in position to operate under an exposure time priority mode at which the aperture is automatically controlled in reference to the preset exposure time, which mode is hereinafter referred to as S mode. On the other hand, when the slide **23** is in the M position, the camera is brought in position to operate under a manual mode at which both the exposure time and the aperture can be manually set according to the photographer's desire, which mode is hereinafter referred to as M mode.

The aperture setting button **25** is adapted to be depressed at the time of setting of the aperture, and the depression of this button **25** results in the closure of a switch ASS, shown in FIG. **3**(*a*), to initiate the light measurement, the calculation and the display operation and also to modify the aperture in dependence on the state of any one of the upshift and down-shift buttons **27** and **28**. The exposure time setting button **26** is adapted to be depressed at the time of setting of the exposure time, and when this button **26** is depressed, a switch SSS shown in FIG. **3**(*a*) is closed to initiate the light measurement, the calculation and the display operation and also to modify the aperture in dependence on the state of any one of the upshift and down-shift buttons **27** and **28**. When the up-shift button **27** is depressed, a switch UPS shown in FIG. **3**(*a*) is closed. When at this time the aperture setting button **25** is depressed while the camera is operable under any one of the A and M mode, the aperture size once set changes to a size smaller than it by 0.5 Ev. However, when at this time the exposure time setting button **26** is depressed while the camera is operable under any one of the S and M modes, the exposure time once set changes to a value shorter than it by 0.5 Ev. The depression of the down-shift button **28** results in the closure of a switch DOS shown in FIG. **3**(*a*). When at this time the aperture setting button **25** is depressed while the camera is operable under any one of the A and M modes, the aperture size once set changes to a size larger than it by 0.5 Ev, but when at this time the exposure time setting button **26** is depressed while the camera is operable under any one of the S and M modes, the exposure time once set changes to a value longer than it by 0.5 Ev. The liquid crystal display unit **24** is used to display various pieces of information such as, for example, the ISO value, the combination of the exposure time and the aperture both used for the control, a camera wobbling warning, and the out-of-coupling range warning. The frame counter window **24** is used to display the count of film frames exposed.

FIGS. **3**(*a*) and **3**(*b*) altogether illustrate an electric circuit of the camera system as a whole embodying the present invention, wherein FIG. **3**(*a*) shows the circuit incorporated in the camera body while FIG. **3**(*b*) shows the circuit incorporated in the lens assembly. The circuit incorporated in the camera body, which is hereinafter referred to as camera circuit in contrast to a lens circuit which is the circuit shown in FIG. **3**(*b*) and incorporated in the interchangeable lens assembly, includes a source BA of electric power which may be constituted by one or more batteries. This power source

BA feeds, through a power supply line +E, a microcomputer, a display circuit DSP, a shift register SR, AND gates AN0, AN1, AN2, and NAND gates NA0 and NA1. The camera circuit also includes the switch S1, which is a light measuring switch adapted to be closed upon the first stage of depression of the release button 22; the switch SSS which is a Tv switch adapted to be closed when the exposure time setting button 26 is depressed, the switch ASS which is an Av switch adapted to be closed when the aperture setting button 25 is depressed; the switch UPS which is an up-shift switch adapted to be closed when the up-shift button 27 is depressed; and the switch DOS which is a down-shift switch adapted to be closed when the down-shift button 28 is depressed.

A transistor BTo acts as a power supply transistor and is adapted to conduct, when the microcomputer PC initiates its operation, to supply an electric power from the power supply line +V to a light measuring circuit LMC, a release magnet circuit RLM, an aperture stop magnet circuit APM, a mirror magnet circuit MRM, a leading curtain magnet circuit 1CM, a trailing curtain magnet circuit 2CM, an aperture stop-down pulse generator FEN, an ISO data detecting circuit CAD, and an exposure control mode data generator MOD. Moreover, when and so long as the transistor BTo is in conduction, an electric power is supplied to the camera terminal JB2 through a protecting resistor Ro and then to a power line VL of the lens circuit of FIG. 3(*b*) through the lens terminal JL2 then connected with the camera terminal JB2. The protecting resistor Ro is used to avoid any possible shortcircuiting which may happen to occur between the power supply line +V and the ground when, for example, forceps touch the camera terminal JB2. It is to be noted that, except for the circuits LMC, RLM, APM, MRM, 1CM, 2CM and FEN, the camera circuit is fabricated in C-MOS.

The operation of the camera system as a whole will now be described with reference to the flow charts of FIGS. 6 and 7 showing the sequence of operation of the microcomputer PC. Assuming that the microcomputer PC is in the inoperative position, terminals P2, P3 and P4 are all in a low level state. When any one of the light measuring switch S1, the Tv switch SSS and the Av switch ASS is subsequently closed, an input to an interruption terminal itA sets down to a low level state and the microcomputer PC consequently starts its operation from the initial step #1. At step #1, a terminal P11 is rendered in a low level state wherefor the transistor BTo is caused to conduct to initiate the electric power supply from the power supply line +V and also the electric power supply through the resistor Ro. By rendering the terminals P2, P3 and P4 in a high level state, a terminal P14 is rendered in a high level state. When the terminal P14 is rendered in the high level state, ISO data and mode data are latched in the shift register SR in response to the positive edge of the high level signal emerging from the terminal P14. An ISO data output circuit CAD is a circuit operable to read a coded pattern indicative of the ISO data, which coded pattern is provided on a film container as is well known to those skilled in the art, whereas the mode data generator MOD is operable to generate the mode data from a coded pattern depending on the position of a slide member movable together with the mode selector slide 23 shown in FIG. 3(*a*). In addition, at the same time as the terminal P14 is rendered in the high level state, the NAND gate NA1 and the AND gates AN0 and AN2 are brought in position ready to be enabled. At step #4, the microcomputer PC undergoes a serial input and output operation with the consequence that eight clock pulses are outputted from a terminal CKO on the one hand and data fed to a data input terminal SIN are taken in a serial input/output register SIOR, provided internally of the microcomputer PC, in response to the negative edge of each positive edge of the eight clock pulses on the other hand. Substantially at the same time, the shift register SR sequentially outputs the data, which have been latched therein, on the basis of the eight clock pulses successively fed to the AND gates AN2. When the data so outputted are in the high level state, and output from both of the gates AN0 and NA1 is in a low level state and, accordingly, a field-effect transistor To is brought in a conductive state thereby permitting a high level signal to be fed to the data input terminal SIN. On the other hand, when the data outputed from the shift register SR are in the low level state, an output from both of the gates AN0 and NA1 is in a high level state and, accordingly, a field-effect transistor T1 is brought in a conductive state thereby permitting a low level signal to be fed to the data input terminal SIN. It is to be noted that, when and so long as the terminal P14 of the microcomputer PC is in a low level state, the NAND gate NA1 and the AND gate AN0 generate high and low level signals, respectively, and therefore both of the field-effect transistors T0 and T1 are held in a non-conducting state, thereby avoiding any possible adverse influence which would otherwise occur when data taken from the lens circuit of FIG. 3(*b*) are fed to the data input terminal SIN. Upon termination of step #4, of the data taken in the serial input/output register SIOR, the mode data are set in a register MOR, and the ISO data are, after having converted the data taken in into data for the calculation, set in a register SVR. Then, the microcomputer PC renders the terminal P14 in a lower level state and proceeds to step #7.

At step #7, a decision is made as to whether or not data appropriate to the law of the coded pattern on the film container have been read out from the ISO data taken in the serial input/output register SIOR. If it proves that the data appropriate to the law of the coded pattern have been read out, the contents of the register SVR remain unchanged, but if it proves to the contrary, it connote that the film container having no coded pattern is loaded or any film container is not loaded and, in such case, data representative of the ISO sensitivity which is most often utilized, for example, ISO 100, can be set in the register SVR.

Subsequently, the microcomputer PC proceeds to the reading of data out from the lens circuit shown in FIG. 3(*b*). In the first place, the content of a register k is rendered "0" and a terminal P12 is rendered in a high level state. The register k serves to select one of the data setting registers LDR0 to LDR5 according to the content stored therein. More specifically, when the content of the register k is "0", "1", "2", "3", "4" or "5", the register LDR0, LDR1, LDR2, LDR3, LDR4 or LDR5, can be selected, respectively. When the terminal P12 is rendered in the high level state as hereinabove described, this high level signal is fed to the lens circuit through the terminal JB4 and then the terminal JL4. By this high level signal, all of the AND gates AN3 and AN4, the NAND gate NA2 and a decoder DE are brought in position ready to be enabled and, on the other hand, counters CO0 and CO1 are released from their reset states. Then, the microcomputer undergoes

the serial input and output operation to sequentially read in the data, which are fed to the data input terminal SIN from the lens circuit through the coupled terminals JL1 and JB1, in response to the negative edge of the same clock signal as the clock signal outputed from the clock output terminal CKO, the data so read in being subsequently set in a register LDRK to add "1" to the register k. Then, a decision is made as to whether or not the content of the register k has become "6". If the content of the register k is determined "6", the process flow proceeds to step #15, but if it is not, the process flow proceeds to step #11 to read in the next succeeding data fed from the lens circuit. By repeating the above described process flow, six types of data can be read in the microcomputer PC and set in the register LDR0 to LDR5, respectively.

Referring to FIG. 3(*b*) showing the lens circuit, that is, the circuit built in the interchangeable lens assembly, a counter CO0 is a 3-bit counter operable to count the number of negative edges of the respective clock pulses which have been fed from the clock output terminal through the coupled terminals JB3 and JL3 and then the AND gate AN3 and subsequently inverted by an inverter IN0, that is, the number of positive edges of the respective clock pulses outputed from the clock output terminal CKO. The decoder DE sequentially generates a high level signal from its left-hand terminal to its right-hand terminal in correspondence with an output from the counter CO0, thereby bringing AND gates AN10 to AN17 in position ready to be enabled. Accordingly, each of the AND gates is held in position ready to be enabled during a period from the positive edge of one clock pulse to the positive edge of the next succeeding clock pulse, thereby generating one-bit data. On the other hand, when the outputs from the counter CO0 are all rendered in a low level state upon completion of its counting operation up to eight clock pulses and an AND data AN5, therefore generates a high level output, a counter CO1 receives the clock pulses, which have been outputed from an AND gate AN3 and subsequently delayed by a delay circuit DL, and counts the number of negative edges of the clock pulses so received thereby. The delay circuit DL is utilized to inhibit the AND gate AN6 from outputing a pulse in response to the positive edge of the first clock pulse. Accordingly, each time the eight clock pulses are fed thereto, one clock pulse is counted. Reference character DSL represents a data selector adapted to output the input data, which have been fed to an input section A, when and so long as the most significant bit of the counter CO1 is in a low level state, but to output the input data, which have been fed to an input section B, when and so long as it is in a high level state. And, RO fixedly stores various data of the interchangeable lens assembly at respective addresses. When one of the addresses is specified by address data fed from the data selector, the data stored and fixed at such specified address are then outputted through the AND gates AN10 to AN17 bit to bit from the least significant bit. The data outputted from the AND gates AN10 to AN17 emerges from an OR gate OR0 and, when and so long as the output from the OR gate OR0 is in a high level state, a field-effect transistor T2 is rendered conductive with the high level signal consequently fed to the data input terminal SIN through the coupled terminals JL1 and JB1. However, when and so long as the output from the OR gate OR0 is in a low level state, a field-effect transistor T3 is rendered conductive with the low level signal consequently fed to the data input terminal SIN through the coupled terminals JL1 and JB1.

Hereinafter, the reason will be discussed that, even if the lens assembly is incompletely coupled to the camera body, the transmission of various data between the lens assembly and the camera body will not be adversely affected. For this purpose, reference will now be made to FIGS. 4 and 5. It is to be noted that FIG. 4 illustrates the case employed only for the purpose of comparison, in which the power terminal on each of the camera body and the interchangeable lens assembly is positioned at one extremity of the arcuate row of the terminals and the lens assembly is incompletely coupled to the camera body. FIG. 5 illustrates the case in which the lens assembly incorporating the lens circuit of FIG. 3(*b*) is incompletely coupled to the camera body incorporating the camera circuit of FIG. 3(*a*).

Referring first to FIG. 4, the lens assembly is incorrectly coupled to the camera body such that a data terminal JB2' and a clock terminal JB3', both on the camera body, are electrically connected with a power terminal JL1' and a data terminal JL2' both on the lens assembly, respectively. At the outset, a discussion will be made as to what will happen when, in the incomplete condition, the clock pulses are generated from the clock terminal CKO to permit data from other data output sections, that is, the shift register SR, provided internally of the camera body, to be read in the data input terminal SIN. A high level signal of the clock is generated upon the conduction of a field-effect transistor T4. Then, a voltage from the power supply line +V is supplied through the field-effect transistor T4 and the coupled terminals JB3' and JL2' to the lens assembly and then to a power supply line VL in the lens assembly through a diode D2 which is essentially formed by a CMOS circuit. This signal is in turn fed to the data input terminal SIN in the camera body through the coupled terminals JL1' and JB2'. At this time, it is assumed that the data from the shift register SR in the camera body are in the low level state, an N-channel field-effect transistor T1 is conducting and the low level signal is to be read in the data input terminal SIN. However, when and so long as the field-effect transistor T1 is conducting, the potential at the data input terminal SIN is equal to the potential of the electric power +E divided by the on-resistance of a field-effect transistor T4, and the on-resistance of both the diode D2 and the field-effect transistor T1 and is not clear as to whether it becomes a high level state or whether it becomes a low level state. Accordingly, there is a possibility that incorrect data will be read in the data input terminal SIN. (It may be contemplated to employ a resistor of relatively high resistance between the terminal JB2' and the data input terminal SIN or between the clock output terminal CKO and the terminal JB3' to avoid the reading of the incorrect data. However, where such a resistor is employed, it may happen that a low-pass filter having a large time constant will be formed by the above described resistor and the parasitic capacitance of the data transfer line or the clock transfer line, in which case a high speed data transmission will be hampered.) On the contrary thereto, in the embodiment according to the present invention, since the data terminal JL1 for transmitting the data from the lens assembly to the camera body is positioned on the leading extremity of the row of the lens terminals with respect to the direction of turn of the lens assembly which is effected when the lens

assembly is coupled to the camera body, even if any erroneous connection between the terminals such as corresponding to that described with reference to and shown in FIG. 4, no voltage will be imposed on the data terminal JB1 on the camera body as shown in FIG. 5 and, therefore, no adverse effect will occur when the data input terminal SIN in the camera body reads in the output from the shift register SR. In general, in the case of the embodiment according to the present invention, the terminal JB1 for receiving the data of the camera is electrically connected with the terminal JL1 only when and after the interchangeable lens assembly has been completely coupled to the camera body and hence held in the locked position, and will not be connected to any one of the other terminals JL2 to JL5 during the mounting of the lens assembly. Accordingly, even if while the lens assembly is incompletely coupled to the camera body the ISO data are read in through the data input terminal SIN, there is no factor that adversely affect the data and the ISO data are, therefore, correctly read in by the microcomputer PC. It is to be noted that, in the case of the embodiment according to the present invention, although a current tends to flow in through the transistor BTo, the resistor Ro, the coupled terminals JB2 and JL1, the diode D2, a power source VL and the coupled terminals JL2 and JB3, the waveform of the clock signal will not be adversely affected because the impedance is increased by the protecting resistor Ro.

The relationship between the data stored and fixed in a read-only memory RO and the addresses of the read-only memory RO as well as the operation necessary to specify the addresses will now be described.

TABLE 1

Counter (CO1)	Addresses	Data	Registers
000	000 00000	Check data	LDR0
001	000 00001	AVo: Full Open Aperture Size	LDR1
010	000 00010	Avmax: Minimum Aperture Size (maximum F-number)	LDR2
011	000 00011	Wv: Error in Full Open Aperture Metering	LDR3
100	100 *****	Avz: Deviation in Effective Aperture Size from A Standard	LDR4
101	101 *****	fv: Focal Length	LDR5

Table 1 illustrates the relationship among the output from the counter CO1, the address of the read-only memory RO to be specified, the data stored at the specified address, and the register to which the data are set within the microcomputer PC. Each time the eight clock pulses are fed to the counter CO1, the latter increases its count by one increment. Accordingly, at the outset, the output from the counter CO1 is "000". As a result, the data, "000 00000", from an input section A are outputed from the data selector DSL to the read-only memory RO. Subsequently, check data (for example, "10101010") common to all of the available interchangeable lens assemblies is transferred from the read-only memory RO to the camera body. When the output from the counter CO1 subsequently become "001", an address data "000 00001" from the input section A is outputed from the data selector DSL and a data Avo representative of the full open aperture size is outputed from the read-only memory RO. In the case of the zoom lens assembly having its effective aperture variable with change in focal length, a data representative of the full open aperture size at the shortest focal length, that is, the greatest aperture size available in the lens system, is outputed. When the output from the counter CO1 becomes "010", an address data "000000010" from the input section A is outputted from the data selector DSL and a data Avmax representative of the minimum aperture size (the maximum f-stop number) is outputted from the read-only memory RO. Also, as for this minimum aperture size, in the case of the zoom lens assembly having its effective aperture variable with change in focal length, a data representative of the minimum aperture size at the shortest focal length is outputed. When the output from the counter CO1 becomes "011",an address data "00000011" is outputted from the data selector DSL and a data Wv representative of an error in full open aperture metering is outputted. When the output from the counter CO1 becomes "100", an address data "100*****" from the input section B is outputtted from the data selector DSL. The five-bit data represented by "*****" is a data outputted from the focal length code plate FCP in correspondence with the focal length set by the zooming ring 1. At this address, a data representative of the deviation in effective aperture size from that at the shortest focal length is fixedly stored. It is, however, to be noted that, in the case of a zoom lens assembly having its effective aperture not variable with change in focal length, a data "00000000" is fixedly stored. In addition, in the case of a lens assembly of a fixed focal length, no focal length code plate is employed and, at the same time, no data selector DSL is employed, and the address in the read-only memory RO is specified "00000100" and, therefore, data "00000000" is outputted from the read-only memory RO. When the output from the counter CO1 becomes "101", a data "101*****" from the input section B is outputted from the data selector DSL and a data fv corresponding to the focal length set be the zooming ring 1 is outputted. In the case of the lens assembly of a fixed focal length, the address of "00000101" is specified and a data fv representative of the fixed focal length is outputted.

Referring to the flow chart of FIG. 6, the operation of the microcomputer PC will now be described. After the data has been taken in from the lens circuit, the analog-to-digital conversion of an output from the light measuring circuit LMC is carried out at step #15. The output from the light measuring circuit LMC is fed to an analog input terminal AN1 so that a reference voltage created within the light measuring circuit LMC can be utilized as a reference voltage for a digital-to-analog converter build in the microcomputer PC for the analog-to-digital conversion and the output from the light measuring circuit LMC is subjected to the analog-to-digital conversion on the basis of this reference voltage. Subsequently, at steps #16 and #17, both the full open aperture size and the minimum aperture size at the focal length once set are calculated, the resultant data being designated by Avo and Avmax, respectively. Then, at step #18, the error Wv, included in the data of the output from the light measuring circuit LMC which has been subjected to the analog-to-digital conversion, and a factor of the full open aperture size Avo are subtracted on the basis of the data read out from the lens assembly to calculate Bv to which the film sensitivity data set in a register SVR is added to calculate an exposure value EV.

Upon the completion of the above described operation, an exposure calculation operation starting from step #20 starts. At step #20, based on the data taken in a register MOR, a decision is made as to whether or not it is the P mode. If it is the P mode, the program flow

proceeds to step #21 at which a decision is made as to whether or not the focal length data fv from the lens assembly is greater than fvt. If fv>fvt, the programmed calculation for the high speed shutter priority is performed at step #21 which is followed by step #35. However, if the determination at step #21 shows fv≦fvt, a decision is made at step #23 to find if fv<fvw. If fv<fvw, the program flow proceeds to step #25 at which the programmed calculation for the small aperture priority is performed, which step #25 is subsequently followed by step #35. When the determination at step #23 shows fv≧fvw, the normal programmed calculation is performed at step #24 which is followed by step #35. On the other hand, if the determination at step #20 is such that it is not the P mode, a decision is made at step #26 to find if it is the A mode. If it is the A mode, the aperture is set in a register AVR1 depending on the states of the respective buttons 25, 27 and 28, and at subsequent step #26, the calculation for the A mode is performed, followed by step #35. If it is not the A mode as determined at step #26, a decision is performed at step #29 to determine if it is the S mode. If it is the S mode, an exposure time is set in a register TVR1 at step #30 in dependence on the states of the respective buttons 26, 27 and 28 and, after the calculation for the S mode has been performed at step #31, the program flow proceeds to step #35. If it is not the S mode as determined at step #29, this means the M mode and, therefore, at step #32, the aperture determined in dependence on the states of the respective buttons 25, 27 and 28, and the exposure time determined in dependence on the states of the respective buttons 26, 27 and 28 are set in registers AVR1 and TVR1, respectively, at step #32 which is followed by step #34 at which the calculation for the M mode is performed, the program flow thereafter proceeding to step #35.

The aperture for the control obtained from one of the above described calculations for the respective modes is set in a register AVR2 while the exposure time for the control obtained from one of the above described calculations for the respective modes is set in a register TVR2. Moreover, an over exposure warning, an under exposure warning, a camera wobbling warning and the data of the displacement from a proper exposure during the M mode are all set in a register DMR. The preset aperture and exposure time are set in the registers AVR1 and TVR1. If during the calculation for the S mode the calculated aperture AV is such that AV>Avmax, Avmax and the data on the preset exposure time are set in the registers AVR2 and TVR2, respectively, with the over exposure warning effected. On the other hand, if Av<Avo, Avo and the data on the preset exposure time are set in the registers AVR2 and TVR2, respectively, with the under exposure warning effected. During the P mode, if Avmax+Tvmax<Ev, Avmax and Tvmax are set in the registers AVR2 and TVR2, respectively, with the over exposure warning effected. Moreover, if the calculated Av is smaller than Avo, Avo is set in the register AVR2 and, if Tv which is obtained by Ev−Avo=Tv is higher than Tvmin, the Tv so obtained is set in the register TVR2, but if Tv<Tvmin, Tvmin is set in the register TVR2 with the under exposure warning effected. At step #35, the number of steps to be stopped-down is calculated from both the data on the aperture size for the control and the data on the full open aperture size, the calculated data being set in a register PVR. At the subsequent step #36, data Avd on the aperture for the display, of which minimum unit is 0.5 Ev, is calculated from the data on the aperture for the control and is then set in a register AVR3. At step #38, data Tvd on the exposure time for the display, of which minimum unit is 0.5 Ev, is calculated from the data on the exposure time for the control and is then set in a register TVR3. After the above described operation has been completed, the program flow proceeds to step #39 at which a subroutine for the transfer of the data to be displayed is executed.

The subroutine for the transfer of the data to be displayed will now be described. At step #60, a terminal P13 is rendered in a high level state, the AND gate AN1 is brought in position ready to be enabled, and the display circuit DSP is set in position ready to receive inputs. The content of the register DMR is set in a serial input/output register SIOR and the serial input and output operation is performed. Thereby, the content of the register DMR is taken in the display circuit DSP. Subsequently, the content (ISO data) of the register SVR is set in the register SIOR and the serial input and output operation is performed. After the data in the register AVR3 on the aperture for the display and the data in the register TVR3 on the exposure time for the display have been fed to the display circuit DSP, the terminal P13 is rendered in a low level state, followed by the return to the main routine. Then, the display circuit DSP outputs a signal, corresponding to the data so read out, to a segment terminal SEG and a display corresponding to the data fed together with a signal from a common terminal COM is carried out by means of a liquid crystal display unit LQ.

After the completion of the transfer of the data to be displayed, and at step #40, interruption to a terminal itB is enabled. This is such that, if the release switch S2 shown in FIG. 3 is closed and, at the same time, the exposure control mechanism has been charged with the switch S4 consequently closed, the output from the NAND gate NA0 changes to a low level state with an interruption signal consequently fed to the terminal itB, and the microcomputer performs an exposure control operation from step #70 if the interruption to the terminal itB is in condition ready to be enabled, no matter what operation it has performed. When the interruption to the terminal itB is enabled, the terminals P2, P3 and P4 are rendered in a low level state and a decision is made as to whether or not an input terminal P0 is rendered in a low level state as a result of at least one of the switches S1, SSS and ASS having been closed. If the terminal P0 is rendered in the low level state, the program flow returns to step #2, thereby repeating the above described operation. On the other hand, if the terminal P0 is in the high level state, the program flow proceeds to step #43 at which the interruption to the terminal itB is disabled and a blank data BLD for turning off the display is set in the registers AVR3 and TVR3 and, further, the register DMR in which display data such as for warning is set is reset, followed by the subroutine for the transfer of the data to be displayed. After the completion of the data transfer starting from step #60 in the manner as hereinbefore described, the terminal P11 is rendered in a high level state to interrupt the power supply by means of the transistor BTo while the interruption to a terminal itA is enabled to interrupt the operation of the microcomputer PC. Accordingly, at the time of interruption of the operation of the microcomputer, the display unit LQ merely displays only the ISO data.

Hereinafter, a subroutine for the aperture setting will be described with reference to FIG. 7. At step #101, a decision is made to find if the switch ASS is closed. This is to determine if, while a terminal P4 is rendered in a low level state, the terminal P0 is rendered in a low level state and to render the terminal P4 in a high level state. If the switch ASS is not closed, a flag SEF is set to "0" at step #115 followed by step #116. On the other hand, if the switch ASS is closed, a decision is made at step #102 as to whether or not the switch UPS is closed. This operation is to determine if, while the terminal P3 is rendered in a low level state, the terminal P1 is rendered in a low level state and to render the terminal P3 in a high level state. If the switch UPS is closed, a decision is made at step #103 as to whether or not the down-shift switch DOS is closed. This operation is to determine if, while the terminal P4 is rendered in a low level state, the terminal P1 is in a low level state and to render the terminal P4 in a high level state. If the down-switch DOS is, too, closed, it means that the up-shift button 27 and the down-shift button 28 are simultaneously depressed and, therefore, the program flow proceeds to step #116 with no set value altered. If it proves at step #103 that the switch DOS is not closed, a decision is made at step #104 to find if the flag SEF is "1". If the flag SEF has been found to be "1", this means that the up-shift button 27 is kept depressed and, therefore, the program flow proceeds to step #116. On the other hand, if the flag SEF has been found to be "0", this means that the up-shift button 27 is first depressed and, therefore, the flag SEF is set to "1" at the subsequent step #105 followed by step #106 at which 0.5 is added to the content of the register AVR1. At step #107, the minimum aperture size Avmax obtained at step #17 is compared with the content of the register AVR1. If (AVR1)>Avmax, Avmax is set in the register AVR1 at step #108 followed by step #116. On the other hand, if (AVR1)≦Avmax, the data of the register AVR1 remains unchanged and the program flow proceeds to step #116.

If the determination at step #102 is such that the switch UPS is not closed, step #102 is followed by step #109 at which a decision is made to find if the switch DOS is closed. If the switch DOS is not closed, too, the flag SEF is set to "0" at step #115 followed by step #116. On the other hand, if the switch DOS is closed, a decision is made at step #110 to find if the flag SEF is set to "1". If the result at step #110 indicates that the flag SEF is "1", this means that the down-shift button 28 is kept depressed and, therefore, the program flow proceeds to step #116 without the data being altered. On the other hand, if the result at step #110 indicates that the flag SEF is "0", this means that the down-shift button 28 is first depressed and, at this time, the flag SEF is set to "1" at step #111 followed by step #112 at which 0.5 is subtracted from the content of the register AVR1. If the result of comparison carried out at the step between the content of the register AVR1 and the data Avo of the full open aperture size obtained at step #16 shows (AVR1)≧Avo, the content of the register AVR1 remains unchanged and the program flow proceeds to step #116. On the other hand, if it shows (AVR1)<Avo, the full open aperture size Avo is set in the register AVR1 at step #114, followed by step #116.

At step #116, a decision is made as to whether or not the content of the register AVR1 is greater than the value representative of the minimum aperture size Avmax, and if it not greater than Avmax, the content of the register AVR1 remains unchanged, but if it is greater than Avmax, the minimum aperture size Avmax is set in the register AVR1 at step #117 in place of the original content in the register AVR1. At step #118, a decision is made as to whether the content of the register AVR1 is smaller than the value representative of fuller open aperture size Avo determined at step #16. If the result of comparison at step #118 indicates that the content of the register AVR1 is smaller than Avo, Avo is set in the register AVR1 at step #119 in place of the original contents in the register AVR1, but if it shows the content of the register AVR1 not smaller than Avo, the content of the register AVR1 remains unchanged and the program flow subsequently returns to the main routine. The program flow from step #116 to step #119 is provided for the purpose of avoiding any possible departure of the data, set in the register AVR1 prior to the lens assembly being interchanged, from a controllable range when the lens assembly is interchanged. In addition, as shown in the subroutine, a single depression of any one of the up-shift and down-shift buttons results in the change of the set value by 0.5 Ev.

The subroutine for the determination of the exposure time is similar to the subroutine shown in FIG. 7 except that step #101 is substituted by a decision step to determined if the switch SSS is closed; the register AVR1 at each of the steps #106, 107, 108, 112, 113 and 114 is substituted by the register TVR1; Avmax is substituted by the data Tvmax on the shortest exposure time; Avo is substituted by the data Tvmin on the longest exposure time; and steps #116 to #119 are omitted because of no change occurring in any one of the shortest and longest exposure times.

Referring to FIG. 6, particularly to FIG. 6(c), the operation which takes place when an interruption signal is fed to the interruption terminal itB will now be described. At step #60, a decision is made as to whether or not the data of a register PVR associated with the number of f-stop steps to be stopped down is "0". If it is not "0", the content of the register PVR is set in an event counter ECO to enable the interruption by the event counter ECO. And, a low level pulse of a duration To is generated from a terminal P6 to activate the release magnet circuit RLM. Then, the engagement of the control lever 15 shown in FIG. 1 is released and the control lever 15 starts its movement in the direction X to initiate the aperture stop-down operation. In addition, in response to the movement of the control lever 15, the pulse generator FEN generates a pulse which is in turn fed to a clock input terminal of the microcomputer PC at which, in response to each pulse, the data of the number of f-stop steps to be stopped down, which is preset in the event counter ECO, is subtracted. The microcomputer, after the lapse of a time T1 subsequent to the generation of a low level pulse from the terminal P6, generates from a terminal P8 a pulse of a duration To necessary to activate the mirror magnet circuit MRM. When the mirror magnet circuit MRM is so activated, the engagement of the reflective mirror 17 shown in FIG. 1 is released and the reflective mirror 17 is therefore pivoted upwards. After the lapse of a time T2 subsequent to the generation of the low level pulse from the terminal P8, the program flow proceeds to step #81 at which a low level pulse of a duration To is generated from a terminal P9. During a period from the generation of the low level pulse from the terminal to step #81, the aperture spends time enough to allow it to be stopped down from the full open aperture size to the

minimum aperture size regardless of the type of an interchangeable lens assembly, and during this time pulses equal in number of the number of f-stop steps to be stopped down are generated from the encoder FEN and the content of the event counter ECO is zeroed. By this operation, the interruption by the event counter ECO is effected and the operation starting from step #90 is initiated. In this program flow, a low level pulse of a duration To is generated from a terminal P7, thereby returning to the main routine. In this way, the aperture stop magnet circuit APM is activated to stop the movement of the control lever **15** so that the aperture can be controlled to a preset aperture. When a time T2 elapses subsequent to the generation of the low level pulse from the terminal P8, the upward pivotal movement of the mirror **17** has completed, and a low level pulse is generated from the terminal P9 to initiate the travel of the leading curtain.

Upon the initiation of the travel of the leading curtain incident to the generation of the low level pulse from the terminal P9, a time 2^{-Tvc} based on the data Tvc of the exposure time for the control, set in a register TVR2, is counted, and upon the completion of the counting of this time, a low level pulse is generated from a terminal P10 to activate the trailing curtain magnet circuit 2CM so that the travel of the trailing curtain can be initiated. After the completion of the travel of the trailing curtain, and the subsequent closure of a switch S4, the program flow proceeds to step #41 with the subsequent operation taking place in a manner similar to that hereinbefore described.

As hereinbefore fully described, according to the present invention, except for the aperture stop-down quantity transmission means essentially required to control the aperture mechanism of the interchangeable lens assembly from the side of the camera body, neither the aperture adjusting ring in the interchangeable lens assembly nor mechanical component parts such as mechanical linkage members associated with the aperture between the interchangeable lens assembly and the camera body are employed. Therefore, not only can the number of component parts of one or both of the lens assembly and the camera body be minimized, but also they can have enough space to spare. In addition, in these component parts, neither the machining precision nor the accurate positioning, which have hitherto been considered important problems, need be required to be taken into consideration. Furthermore, although information to be transmitted between the interchangeable lens assembly and the camera body includes information on the error in full aperture metering, and, in the case of the zoom lens assembly, the focal length, changes in aperture resulting from the zooming as the case may be, and the like, if these pieces of information are stored in the read-only memory in a manner similar to information of the full open aperture size and the minimum aperture size, the construction of the present invention can be concurrently utilized to transmit these pieces of information between the lens assembly and the camera body. Yet, while in the case of the customary interchangeable lens assembly having an aperture adjusting ring and an aperture mechanism mechanically associated therewith, a manipulation to set the aperture adjusting ring to a particular position to prevent a mechanical control by the aperture adjusting ring from interfering with this is required even though the aperture is set on the side of the camera body, such complicated procedures are not required according to the present invention. What is more, according to the present invention, any possible confusion which would occur in transmitting electric signals between the lens assembly and the camera body in the event of the incorrect coupling therebetween can advantageously be eliminated.

Although the present invention has fully been described in connection with the preferred embodiment thereof with reference to the accompanying drawings, it is to be noted that various changes and modifications are apparent to those skilled in the art. Such changes and modifications are to be understood as included within the true scope of the present invention as defined by the appended claims unless they depart therefrom.

We claim:

1. A camera system capable of interchanging an objective lens assembly with another lens assembly, which comprises:

an interchangeable lens assembly comprising

first and second terminals adapted to receive electrical power from a camera body and connectable respectively to a high voltage side and a ground side;

a lens circuit constituted by a C-MOS construction and adapted to receive the electric power from the first and second terminals;

a third terminal adapted to receive an enabling signal from the camera body for bringing the lens circuit into a condition ready to be enabled;

a fourth terminal adapted to receive the clock pulses from the camera body; and

a fifth terminal adapted to transmit there through to the camera body the various data peculiar to the interchangeable lens assembly which are serially outputted from the lens circuit, said first to fifth terminals being arranged in a row along the direction in which the lens assembly is turned, said fifth terminal being located at one end of said row on the leading side with respect to the direction of the turn of the lens assembly when coupled to the camera body; and

said camera body comprising:

sixth to tenth terminals adapted to be connected respectively with the first to fifth terminals when the lens assembly has been completely coupled to the camera body;

means for outputting a power supply initiating signal in dependence on a manipulation;

a source of the electric power for supplying a voltage on the high voltage side to the sixth terminal through a protective resistor and also for providing the seventh terminal with a ground level;

means for outputting to the eighth terminal a first enabling signal for bringing the lens circuit into a condition ready to be enabled;

means for outputting the clock pulses to the ninth terminal;

a data output means for serially outputting data within the camera body on the basis of the clock pulses;

means for outputting a second enabling signal for bringing the data output means into a condition ready to be enabled at a timing different from the timing at which the lens circuit is enabled; and

a read-out circuit constituted by a C-MOS construction for sequentially reading through a common input terminal on the basis of the clock pulses not only of the various data peculiar to the lens assem-

bly which have been inputted from the tenth terminal, but also the data with in the camera body fed from the data output means.

2. An interchangeable lens assembly capable of connection to a camera body having electrical power and providing control signals comprising:

first and second terminals adapted to receive electrical power from the camera body and connectable respectively to a high voltage side and a ground side;

a lens circuit constituted by a C-MOS construction and adapted to receive the electric power from the first and second terminals;

a third terminal adapted to receive an enabling signal from the camera body for bringing the lens circuit into a condition ready to be enabled;

a fourth terminal adapted to receive the clock pulses from the camera body; and

a fifth terminal adapted to transmit there through to the camera body the various data peculiar to the interchangeable lens assembly which are serially outputted from the lens circuit, said first to fifth terminals being arranged along the direction in which the lens assembly is turned, said fifth terminal being located on the leading side with respect to the direction of the turning of the lens assembly when it is to be coupled to the camera body.

3. In a camera system having a camera body capable of providing electrical power and various control signals and an interchangeable objective lens removably coupled with the camera body, an improvement comprising:

a terminal for receiving electric powder fed from the camera body to the interchangeable objective lens;

a terminal for introducing a digital signal from the camera body into the interchangeable objective lens;

a lens circuit constituted by a C-MOS construction to be powered through the power receiving terminal, including means for outputting data in response to the digital signal; and

a terminal for serially transmitting the data from the outputting means to the camera body;

wherein the above mentioned terminals are arranged in a row around an optical axis of the objective lens, the data transmitting terminal being located at one end of the row on the leading side with respect to the direction of movement of the objective lens when it is coupled to the camera body.

4. A camera system capable of interchanging an objective lens assembly, which comprises an interchangeable lens assembly having an aperture mechanism, but having no manipulatable aperture control member for manually setting the aperture to a predetermined value, and a camera body capable of providing electrical power from a power source having a high voltage terminal and a ground terminal, to which said lens assembly is removably coupled, said lens assembly comprising:

first and second terminals adapted to receive electric power supplied from the camera body;

a lens circuit adapted to receive the electric power from the first and second terminals;

a third terminal adapted to receive a signal fed from the camera body for bringing the lens circuit into a condition ready to be enabled;

a fourth terminal adapted to receive clock pulses fed from the camera body;

a fifth terminal adapted to output data from the lens circuit to the camera body, said lens circuit including a read-only memory in which various data peculiar to the lens assembly includng the full open aperture size and the minimum available aperture size are fixedly stored at particular addresses, means for counting the number of the clock pulses from the fourth terminal to sequentially specify the addresses of the read-only memory, and means for serially outputting the various data, outputted from the read-only memory, to the fifth terminal; and

said camera body comprising:

means for outputting an initiating signal for initiating an exposure calculating operation;

sixth and seventh terminals for supplying the electric power to the first and second terminals on the basis of the initiating signal;

a protective resistor inserted between a high voltage side of the power source and the sixth terminal;

a junction between a ground side of the power source and the seventh terminal;

means for outputting a first enabling signal for bringing the lens circuit into a condition ready to be enabled;

an eighth terminal for supplying the enabling signal to the third terminal;

means for generating the clock pulses;

a ninth terminal for supplying the clock pulses to the fourth terminal;

a data output means provided in the camera body for serially outputting data on the basis of the clock pulses;

means for outputting a second enabling signal for enabling said data output means at a timing different from the timing at which the lens circuit is enabled;

a tenth terminal adapted to receive the various data serially outputted from the fifth terminal;

means for sequentially reading the various data on the basis of the clock pulses;

means for outputting a preset aperture size signal on the basis of a manipulation;

means for adopting, when the preset aperture size signal exceeds the limit of the full open aperture size of the minimum available aperture size based on the data read out by the reading means, the full open aperture size or the minimum available aperture size in place of the preset aperture size;

means for controlling the aperture stop-down quantity in the aperture mechanism of the lens assembly on the basis of the full open aperture size and one of the preset aperture sizes, or the full open aperture size or the minimum available aperture size adopted in place of the preset aperture size; and

a transmission means for transmitting the aperture stop-down quantity to the aperture mechanism of the lens assembly, wherein at least said lens circuit and said reading means are constituted by a C-MOS construction, said reading means capable of reading, in addition to the various data peculiar to the lens assembly, sequentially the data from the data output means through a common input terminal on the basis of the clock pulses, said first to fifth terminals as well as said sixth to tenth terminals, corresponding respectively thereto, being arranged in a respective row extending in a direction in which the lens assembly is turned, said fifth terminal being located on the leading side of said row with respect to the direction of turn of the lens assembly for coupling to the camera body.

[57] **ABSTRACT**

A stereo-microscope is disclosed. It comprises a common objective lens system, a first and second imaging lens systems having optical paths parallel to that of the objective lens system producing intermediate images of an object, a first and second optical path deflecting devices arranged behind the respective imaging lens systems for deflecting the respective ejection bundle of rays outwardly relative to the optical path of the objective lens system, and a first and second ocular systems arranged behind the respective optical path deflecting devices for observing the respective intermediate images. It is characterized in that a stereo angle ω which is to be decided depending on the base length between the first and second imaging lens systems and an observation angle θ which is defined between the observation optical paths of the first and second ocular systems are arranged to be equal. Another stereo-microscope is also disclosed. It comprises an objective optical system, a first and second ocular systems, a first and second erecting optical systems and devices for varying an observation angle θ defined between the observation axes of the first and second ocular systems.

STEREO-MICROSCOPE WITH A COMMON OBJECTIVE LENS SYSTEM

BACKGROUND OF THE INVENTION

This invention relates to an optical constitution of a stereo-microscope and more particularly to an optical constitution of an ophthalmological slit lamp stereo-microscope.

The optical type of a stereo-microscope is largely classified into the Greenough type or the Galileo type. The Greenough type is, as shown in FIG. **1**, constituted as such that two optical paths I,II are crossed on a plane of an object to be observed at an included angle ω. The optical paths I,II have objective lens systems **1***a*,**1***b*, erecting optical systems **2***a*, **2***b* and ocular systems **3***a*, **3***b*, respectively, and are constituted as such that an incident optical axis IA toward the objective lens is parallel to an observation optical path **1**B of the ocular (likewise, in the optical path II, the incident optical axis IIA is parallel to the observation optical axis IIB). In this case, the included angle ω is set to be a convergent angle somewhere between from 10° to 16° which is very close to natural sighting, when an observer's naked eyes e_1, e_2 observe the object E from a near distance without using a microscope. Therefore, the Greenough type microscope has such an advantage as that a natural stereoscopic sighting can be obtained, since the included angle ω (hereinafter referred to as a stereo angle) defined between the incident optical axes IA, IIA toward the objective lens is equal to the included angle θ (hereinafter referred to as an observation angle) defined between the observation optical axes IB, IIB of the ocular systems **3***a*, **3***b* and the stereo angle ω is formed to be equal to the convergent angle of a natural sighting. However, it had such disadvantages that since the optical paths I, II are crossed, machining for mounting optical parts are complicated, and the constitution of the focussing and variable power optical systems (not shown) which are normally arranged between the objective lens system **1***a*, (**1***b*) and the erecting optical system **2***a*, (**2***b*) are also complicated.

On the other hand, the Galileo type stereo-microscope is, as shown in FIG. **2**, constituted as such that the optical paths are parallel to the optical axis, respectively. The optical path III comprises an objective lens system **4**, an imaging lens system **7***a* for producing an intermediate image Pa and an ocular system **6***a* for observing the intermediate image Pa. The optical path IV has the objective lens system **4** as a common objective lens and comprises an imaging lens system **7***b*, an erecting optical system **5***b* and an ocular system **6***b* same as in the case mentioned with regard to the optical path III. The optical axes of the both imaging systems **7***a*, **7***b* are parallel with respect to each other and also parallel to the optical axis **4***a* of the objective lens system **4**. The observation optical axes IIIB, IVB of the ocular systems **6***a*, **6***a* are likewise constituted to be parallel with respect to the axes of the imaging lens systems **7***a*, **7***b*. The stereo angle ω defined between the incident optical axes IIIA, IVA toward the objective lens system **4** is decided depending on the base length l which is defined by the distance between the imaging lens systems **7***a*, **7***b*. Because of the parallax due to this stereo angle ω, the object E can be observed stereoscopically, although the observation angle θ defined between the observation axes IIIB, IVB is 0. The Galileo type stereo-microscope had such advantages as that since the two optical paths III, IV are parallel with respect to each other as mentioned above, the constitution of the optical system is simple, the constitution of the focussing structure and variable power structure is simple, and attached optical paths such as, for example, a camera optical system and a side observation scope can be comparatively easily added.

Generally speaking, human eye does not have a convergence between the lines of sight of the both eyes when it is in the far distance sighting state, and can be maintained in a comfortable observation state with less fatigue and without accomodation of the crystalline lens. This is also true with respect to a microscopic observation. It is said that the Galileo type microscope in which the both observation optical axes IIIB, IVB are arranged to be parallel with respect to each other is advantageous when used for a long time observation compared with the Greenough type microscope in which the both axes are convergent with respect to each other since the former is less fatiguing during observation.

However, a microscope is a device for enlarging and observing a tiny object placed in a near position. In the Galileo type microscope, although the luminous flux is entered into the eye as if it were entered from an infinite far distance, optically, the human brain has a preliminary information that it is looking a near object. Therefore, it had such a disadvantage as that there is a gap between the natural sense of sighting and the optical sense of sighting. Particularly, due to the information of the convolution motion, or due to the observation of parallax caused by the stereo angle ω without the presence of the convergence motion information, the observer had an unnatural stereoscopic sighting stronger than normal stereoscopic sense.

Furthermore, in the case of, for example, a stereo-microscope of a slit lamp which is used in the ophthalmological field, a doctor is often required to observe the eyes to be observed with the naked eye in order to adjust, for example, the illumination position, the width and length of the slit, or to conduct a simple operational treatment, the doctor's observation eye is put in a near range sighting state. Then, the doctor has to look through the microscope and diverges the eye so that it becomes in a far range sighting state for observing the object stereoscopically. However, there was such disadvantage as that instant image separation and stereoscopic sighting were difficult to be effected.

The exaggeration of a stereoscopic sense and the necessity of effecting the divergence motion from the naked eye sighting to the stereoscopic sighting deny the littleness of the observation fatigue hitherto advocated with regard to the Galileo type stereo-microscope. On the contrary, the observation fatigue is found to be greater than the Greenough type microscope. In addition, there found to be such disadvantages as, for example, incorrect observation, or mis-treatment due to erroneous recognition of the actual distance. All these disadvantages with respect to the Galileo type microscope are remained yet to be solved in spite of the afore-mentioned advantages it has.

On the other hand, in the Greenough type microscope, although it had such advantage as that the object can be observed in the same stereoscopic sighting as that with respect to the near sighting with the naked eye even under the microscopic observation as mentioned above, when it is required to observe a very small un-

evenness, there are instances where it is difficult to observe such unevenness with the stereoscopic sense which is close enough to the natural sighting. Therefore, there was a request to strengthen the stereoscopic sense with regard to the Greenough type microscope.

SUMMARY OF THE INVENTION

The present invention is accomplished in order to eliminate the above-mentioned disadvantages and also to meet with the request with regard to the conventional stereo-microscope.

In order to achieve the above object and others there is essentially provided a stereo-microscope comprising a common objective lens system, a first and a second imaging lens system having optical paths parallel to that of the objective lens system and producing intermediate images of an object to be observed, a first and a second optical path deflecting means arranged behind said respective imaging lens systems for deflecting the respective ejection bundle of rays outwardly with respect to the optical path of said objective lens system and a first and second ocular systems arranged behind said respective optical path deflecting means for observing the respective intermediate images, characterized in that a stereo angle ω which is to be decided depending on the base length between said first and second imaging lens systems and an observation angle θ which is defined between the observation optical paths of said first and second ocular systems are equal.

There is also provided a stereo-microscope comprising an objective optical system for producing a first and second intermediate images of an object to be observed, a first and second ocular systems for observing said first and second intermediate images, respectively, a first and a second erecting optical system arranged in front of said first and second ocular systems such that said intermediate images can be observed as erecting images, and means for varying an observation angle θ defined between the observation optical axes of said first and second ocular systems so that the stereoscopic observation sense of an observer can be varied.

BRIEF DESCRIPTION OF THE DRAWING

The novel features and advantages of the present invention will become more apparent from the following description and claims when read together with the accompanying drawings wherein:

FIG. **1** illustrates the optical arrangement showing a conventional Greenough type stereo-microscope;

FIG. **2** is the optical arrangement showing a conventional Galileo type stereo-microscope;

FIG. **3** illustrates the optical arrangement showing the first embodiment of the present invention;

FIG. **4** is a perspective view of the object to be observed which was used for a stereoscopic test;

FIG. **5** is the second embodiment of the present invention wherein the second embodiment is shown by way of only an erecting optical system of one of the optical paths;

FIG. **6** illustrates the third embodiment of the present invention wherein the third embodiment is shown by way of an erecting optical system of one of the optical paths only;

FIG. **7** is the fourth embodiment of the present invention wherein the fourth embodiment is shown by way of only an erecting optical system of one of the optical paths; and

FIG. **8** is the optical arrangement showing the fifth embodiment of the present invention.

DETAILED DESCRIPTION OF THE EMBODIMENTS

Preferred embodiments of the present invention will be described hereunder with reference to the accompanying drawings wherein like numerals denote like or corresponding parts throughout.

FIG. **3** illustrates the optical arrangement of a stereo-microscope of a slit lamp as an example. This stereo-microscope is constituted with a first optical path **100** and a second optical path **200**. The first optical path **100** comprises a common single objective lens system **101**, an imaging lens system **103** for producing an intermediate image **102** and having its optical axis parallel to the optical axis **101***a* of said common single objective lens system **101**, a modified Porro prism as an erecting optical system which serves to deflect the optical path and an ocular lens system **105** for observing the intermediate image **102**. On the other hand, the second optical path **200** comprises the common single objective lens system **101**, an imaging lens **203** for producing an intermediate image **202** and having its optical path parallel to the optical axis **101***a* of said single objective lens system **101** and a modified Porro prism **204** as an erecting optical system which serves to deflect the optical path and an ocular lens system **205** for observing the intermediate image **202**.

The respective apical angle α of prisms **106**, **206** constituting the modified Porro prisms **104**, **204** are arranged to be $90°-\omega/4$. ω is a stereo angle defined between an incident optical axis **100**A of the first optical path **100** and an incident optical axis **200**A of the second optical path **200** toward the object E which is decided depending on the base length l between the two imaging lenses **103** and **203**. Because of the relationship between said α and ω, an observation angle θ defined between the observation optical axis **100**B of the first optical path **100** and the observation optical axis **200**B of the second optical path **200** is constituted to be equal to the stereo angle ω.

The following test results proved the fact that when the stereo angle ω and the observation angle θ are constituted to be equal, an observation sense which is closest enough to the natural stereoscopic sense can be obtained.

As shown in FIG. **4**, the test was carried out as such that an object of a hollow cylindrical member 300 having an inner diameter a=2.0 mm and a depth d=2.0 mm (depth/inner diameter=1) was subjected to the observation with the naked eye of 10 persons shown in Table 1 and thereafter said object was subjected to the observation of the 10 persons using 5 different kinds of stereo-microscopes shown in Table 2. The 10 persons were requested to answer in five grades evaluation from 1 to 5 whether the ratio between the inner diameter a and the depth d under each kind of microscopic observation was larger or smaller compared with that observed with the naked eye. In this case, numeral **3** represents the equal degree as that observed with the naked eye. The numerals **4** and **5** represent the stronger stereoscopic sense, i.e., the larger ratio of the depth/the inner diameter, and the numerals **2** and **1** represent the reversed fashion, i.e., the smaller ratio of the depth/the inner diameter. The results are shown in Table 3.

As apparent from the results shown in Table 3, the observers' stereoscopic sense is most intimately related to the observation angle θ; the smaller the observation angle θ, the stronger the stereoscopic sense regardless of whether the microscope of the present invention, Galileo type, or Greenough type is used. Also, it is confirmed with regard to the both types that when the stereo angle θ and the observation angle θ are equal, a natural stereoscopic sense like that observed with the naked eye can be obtained.

As described in the foregoing, according to the above embodiment, since the optical axes of the imaging lens systems **103, 203** remain parallel with respect to each other, a variable power optical system and a focussing optical lens system (the imaging lens system may serve as this) as well as the driving mechanism thereof, all of which are arranged at the front or back of said imaging lenses **103, 203** can be constituted simply compared with the Greenough type microscope. Furthermore, it has not only an advantage which the Galileo type stereo-microscope has, i.e., attaching optical systems such as a camera optical system and the like can be mounted simply, but also an advantage which the Greenough type stereo-microscope has, i.e., a microscope observation without losing a natural observation sense can be obtained as in the case when observed with the naked eye, thus achieving a new Galileo type stereo-microscope.

In the above first embodiment, the stereo angle ω and the observation angle θ are arranged to be equal. However, the observation angle θ may be varied in the both Greenough type and the Galileo type stereo-microscopes so that the stereoscopic sense under the microscopic observation can be greater or smaller than the one observed with the naked, eye, where necessary.

FIG. **5** illustrates an embodiment of the present invention having such observation angle adjusting means which is the means for deflecting the optical path of the both types shown in FIGS. **1** and **2**, and shows a modified embodiment of an erecting optical system by way of only one optical path of the erecting optical system. An erecting optical system **400** as means for deflecting the optical path comprises two Dove prisms **401** and **402**. The reflection plane **402***a* of the second Dove prism **402** is arranged to be perpendicular with respect to the reflection plane **401***a* of the first Dove prism **401**. The erecting optical system is constituted as such that the reversing image can be observed as an erecting image by means of said both Dove prisms. Furthermore, it has means for adjusting the observation angle by rotating the second Dove prism **402** around a rotary axis **403** so that the observation optical axis **404** can be moved within a horizontal plane and is constituted as such that a varied stereoscopic sense can be obtained by varying the observation angle θ.

FIG. **6** illustrates another embodiment for varying the stereoscopic sense. An erecting optical system **410** as means for deflecting the optical path of one optical path comprises a first right angle prism **411**, a rotary mirror **412**, and a second right angle prism **413** having a ridgeline within a plane perpendicular to the ridgeline of the first right angle prism **411** and has such means for adjusting the observation angle in such a manner as that the rotary mirror **412** and the second right angle prism **413** can be rotated around a rotary axis **412***a* integrally with an ocular **500**. With such constitution, the observation angle θ is varied so that a varied stereoscopic sense can be obtained.

FIG. **7** illustrates another embodiment for varying the stereoscopic sense. An erecting optical system **420** as means for deflecting the optical path of one optical path comprises a roof right angle prism **421** having a roof plane **421***a*, and a second right angle prism **422**. Said second right angle prism **422** is constituted with means for adjusting the observation angle so that it can be rotated integrally with the ocular **500** around a rotary axis **422***b* within the reflection plane **422***a*. With such constitution, the observation angle θ is varied so that a varied stereoscopic sense can be obtained. Furthermore, the distance D between the second right angle prism **422** and the roof right angle prism **421** can be varied so that the observation optical system can be

adjusted in accordance with the distance between the observer's pupils.

The above-mentioned means for adjusting the observation angle can be applied not only to the embodiment in FIG. **3** but also to the Greenough type stereo-microscope in FIG. **1** and the Galileo type stereo-microscope in FIG. **2**. In such cases, the objective lens system and the imaging lens system are commonly used with regard to the Greenough type, and the objective optical system comprises a first objective lens system **1***a* for producing the first intermediate image and a second objective lens system **1***b* for producing the second intermediate image and said first and second objective lens systems **1***a*, **1***b* are crossed with respect to the optical axes in order to define a stereo angle ω.

As described in the foregoing, when a stereo-microscope having means for adjusting the observation angle in FIGS. **5** to **7** is used, a stereoscopic sense under a microscopic observation can be freely chosen and it is very convenient for a stereoscopic observation.

Furthermore although the above-mentioned embodiments use a reflection plane in order to obtain the observation angle θ, the present invention is not limited to it. Alternatively, the refraction action of a prism can be used. FIG. **8** illustrates such one example, wherein a deflection prism **505** is arranged between the objective lens **101** and the imaging lens **103** of the first optical path **100** and a deflection prism **506** is likewise arranged between the objective lens **101** and the imaging lens **203** of the second optical path **200** in order to obtain an observation angle θ. According to this embodiment, the deflection prism **505** is constituted with a rotary prism comprising achromatic tiny prisms **501** and **502**. These employ rotary prisms which are rotated in the opposite direction and in the same amount, respectively, around a rotary axis **505***a*. The deflection prism **506** is likewise constituted with a rotary prism comprising achromatic tiny prisms **503**, **504**. When the rotary prisms as means for adjusting the observation angle are activated, the observation angle θ is varied. In this case, the ocular systems arranged at the right and left sides after the imaging lenses **103**, **203** move with rotary prisms in such a manner that their crossing angle changes with the observation angle θ, so that no axial inconsistency takes place.

While the present invention has been particularly shown and described in its preferred forms with certain degree of particularity, it will be understood by those skilled in the art that the foregoing and other changes may be made without departing from the spirit and the scope of the invention as hereinafter claimed.

What is claimed is:

1. In a stereo-microscope comprising a common objective lens system with a stereo angle ω defined as the angle between an incident optical axis of a first optical path and an incident optical axis of a second optical path toward an object; a first and second imaging lens systems having optical axes parallel to that of the objective lens system and producing intermediate images of said object to be observed; a first and second optical path deflecting means arranged behind said respective imaging lens systems for deflecting the respective ejection bundle of rays outwardly with respect to the optical axis of said objective lens system; and a first and second ocular systems arranged behind said respective optical path deflecting means for observing the respective intermediate images, characterized in that said stereo angle ω and an observation angle θ which is defined as the angle between the observation optical axes of said first and second ocular systems are equal.

2. A stereo-microscope according to claim **1**, wherein said first and second optical path deflecting means serve also as erecting optical systems.

3. A stereo-microscope according to claim **2**, wherein said first and second optical path deflecting means each comprise a first prism having a first and second reflecting plane for inverting the horizontal direction of the bundle of rays ejected from the imaging lens systems, a second prism having a third and fourth reflecting plane for inverting the vertical direction of the bundle of rays ejected from said first prism and for guiding the same to said ocular systems, characterized in that said first and second reflecting planes intersect each other at a crossing angle having the following relation: $\alpha=90°-\omega/4$.

4. A stereo-microscope comprising:

a common objective lens system in front of an object to be observed; said objective lens focusing at said object with a first and a second incident optical axis; said first and second incident optical axis intersecting each other with a stereo angle ω;

first and second imaging systems each having an optical axis corresponding to one of said first and second incident optical axis and producing an intermediate image of said object, said optical axes having a base distance l, said base distance l limiting the amount of said stereo angle ω;

first and second erecting optical systems arranged behind said respective imaging systems for erecting said intermediate images; and

first and second ocular systems arranged behind said respective erecting optical systems for observing said respective intermediate images, said first and second ocular systems having an observation angle θ between each other defined by their observation optical axes, said observation optical axes of said first and second ocular systems being parallel to said first and second incident optical axes respectively, and said observation angle θ being equal to said stereo angle ω.

5. The stereo-microscope of claim **4**, wherein said imaging system comprises a first and a second imaging lens systems having optical paths parallel to that of said objective lens system and producing intermediate images of said object to be observed.

6. The stereo-microscope of claim **5**, wherein said first and second erecting optical systems serve also as optical path deflecting means behind said respective imaging lens systems for deflecting the respective bundle of rays outwardly with respect to the optical axis of said objective lens system such that observation angle is equal to said stereo angle ω.

7. The stereo-microscope of claim **6**, wherein said erecting optical systems each comprise a first prism having a first and second reflecting plane for inverting the horizontal direction of the bundle of rays ejected from the imaging lens systems, a second prism having a third and a fourth reflecting plane for inverting the vertical direction of the bundle of rays ejected from said first prism and for guiding the same to said ocular systems, characterized in that the said first and second reflecting planes intersect each other at a crossing angle having the following relation: $\alpha=90°-\omega/4$.

8. The stereo-microscope of claim **6**, wherein said optical path deflecting means each comprise a first and a second Dove prism each having a reflecting plane and

means for adjusting the observation angle θ by rotating said second Dove prism around a rotary axis.

9. The stereo-microscope of claim **6**, wherein said optical path deflecting means each comprise a first right angle prism, a rotary mirror and a second right angle prism having a ridgeline perpendicular to the ridgeline of said first right angle prism, and means for adjusting observation angle θ by rotating rotary mirror and said second right angle prism around a rotary axis integrally with said corresponding ocular system.

10. The stereo-microscope of claim **6**, wherein said optical path deflecting means each comprise a roof right angle prism and a right angle prism; said right angle prism having means for adjusting said observation angle θ by rotating it integrally with said corresponding ocular system and having means for adjusting the distance between said roof right angle prism and said right angle prism.

11. The stereo-microscope of claim **4**, wherein said imaging system comprises a deflection prism and an imaging lens systems; said deflecting prism arranged between said objective lens and said imaging lens system in order to obtain said observation angle θ.

12. The stereo-microscope of claim **11**, wherein said deflection prism comprises two achromatic tiny prisms which are rotated in opposite direction and in the same amount integrally with said imaging lens system, said erecting system, and said ocular system as means for adjusting said observation angle θ.

[57] **ABSTRACT**

Disclosed is a photographic objective with a long focal length and a fastening device for a stand comprises a tubular structural element carrying optical elements, surrounded by an essentially annular holder. This holder is stationary in the axial direction and rotatable around the structural part. In addition to the fastening element capable of being joined to the stand, there is mounted in the outer wall of the holder means for locking the holder in predetermined positions.

PHOTOGRAPHIC OBJECTIVE WITH A FASTENING DEVICE

BACKGROUND OF THE INVENTION

The present invention relates to a photographic objective having a long focal length with a fastening device for a stand or tripod.

It is known to provide on the external wall of the tube of a photographic objective having a long focal length a permanent platform with a threaded receiver for a stand or tripod. The pivoting of a camera attached to such an objective for the selection of a desired image format is possible only with the use of additional adjustable means, such as, for example, a ball-and-socket joint.

In order to avoid such an unstable configuration, it is known to mount the platform having the threaded receiver for the tripod by means of an annular element which surrounds the tube of the objective, and is rotatable on the objective. The fixing of the pivoting position desired is effected by means of at least one clamping screw or clamping piece. The disadvantage of such an arrangement resides in the deformation of the objective tube by the pressure of the clamping screw(s) or the clamping pieces and the resulting stressing of the optical element mounted in the tube.

For this reason, there are already known certain fastening devices for a stand or tripod which are fixed in predetermined locations by means of notches or detends. The locked in positions are released by means of a push button arranged on one side of the tube. The disadvantages of this arrangement is the poor, cumbersome operability of the push button.

SUMMARY OF THE INVENTION

It is therefore an object of the present invention to provide a photographic objective with a long focal length having a fastening device for a stand or tripod whereby the release of the fastening device locked in a predetermined position may be effected in a simple and convenient manner.

In accordance with the present invention there has been provided a photographic objective having a long focal length and being adapted for attachment to a supporting device, comprising a tubular structural part of the objective which carries at least one optical element; an essentially annular holder which surrounds the tubular part, is stationary in the axial direction and is capable of rotating around the tubular part; a fastening element mounted on the holder for attachment to the support device; and means, mounted in the external wall of the holder, for locking the holder in predetermined positions with respect to the circumference of the tubular part. In a preferred embodiment of the invention, the holder includes a portion on one side thereof which is enlarged in the direction perpendicular to the optical axis of the objective, this enlarged portion forming a widened support element, and the fastening element and the locking means are mounted on the support element.

Further objects, features and advantages of the present invention will become apparent from the detailed description of the invention which follows, when considered in light of the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWING

In the drawing:

FIG. 1 is a rear elevation of an objective tube, partially in section; and

FIG. 2 is a lateral cross-sectional view of the tube.

DETAILED DESCRIPTION OF PREFERRED EMBODIMENTS

According to the invention, a tubular structural part of the objective, which carries the optical components, is surrounded by an essentially annular holder, immobilized in the axial direction and rotatable around the structural part. In addition to the fastening element which is joinable to the stand, means for the locking of the holder in predetermined positions are mounted in the external wall of said holder.

In the drawing the invention is represented schematically by an examplary embodiment, which shall be described in more detail hereinbelow.

In FIG. 1, optical elements are indicated by an iris diaphragm 1. They are carried by a tubular structural element 2 of a photographic objective, which is surrounded by an essentially annular holder 3. The holder 3 is mounted on said element 2 so as to be stationary in the direction of the axis 4, but capable of rotating around the element 2. Considered in section perpendicular to the optical axis 4, the holder 3 is expanded on one side and is widened into a support piece 5, in which a threaded piece 6 (FIG. 2) is mounted in a recessed fashion for the fastening of a photographic objective on a stand or tripod.

Adjacent to the threaded piece 6, a bore hole 7 is provided in the support piece 5, into which a locking bolt or pin 8 is inserted. The locking bolt or pin 8 is equipped with a rectangular nose 9 and with registering slots 10, 11 located perpendicularly to its longitudinal axis and extending parallel to each other. With its nose 9, the locking bolt 8 drops under the pressure of a spring 13, inserted in the bore 7 and resting against a cover plate 12 in the support piece 5, into the corresponding recesses 14, 15, 16 on the tubular structural part 2, thereby locking the holder 3 in the position selected.

A groove 17 is provided on the inside of the carrier piece 5, in which the levers 20, 21 pivot around the axles 18, 19, which extend parallel to the optical axis 4.

With their inner ends 22, 23, the levers 20, 21 engage the registering slots 10, 11 of the locking bolt or pin 8. Their outer ends 24, 25 are connected with the pressure pieces 26, 27, which are supported in the holder 3. Upon the actuation of one of the pressure pieces 26 or 27 the corresponding lever 20 or 21 lifts the nose 9 of the locking bolt or pin 8, against the force of the spring 13, from one of the recesses 14, 15 or 16.

What is claimed is:

1. A photographic objective having a long focal length and being adapted for attachment to a supporting device, comprising:

a tubular structural part of the objective which carries at least one optical element and which has a plurality of recesses arranged radially on the external wall thereof;

an essentially annular holder which surrounds said tubular part, is stationary in the axial direction and is capable of rotating around said tubular part;

a fastening element mounted on said holder for attachment to the support device; and

means, mounted in the external wall of said holder, for locking the holder in said recesses, said recesses arranged in predetermined positions with respect to the circumference of said tubular part;

wherein said holder includes a portion at one side thereof which is enlarged in the direction perpendicular to the optical axis of the objective, said enlarged portion forming a widened support element having a face for application to said supporting device, and wherein the fastening element and the locking means are mounted on said support element.

2. A photographic objective according to claim 1, wherein said locking means comprises at least one latching element inserted in a radially directed bore of the holder and a spring contained in said bore and biasing the latching element toward said tubular part for engaging said plurality of recesses.

3. A photographic objective according to claim 2, wherein said latching element comprises a latching pin.

4. A photographic objective according to claim 3, wherein the inwardly directed end of said latching pin has a conical shaped nose portion for engaging with one of said recesses.

5. A photographic objective according to claim 3, wherein said latching pin includes at least one recess on its side and said holder includes a circumferentially extending recess therein, and wherein said locking means further comprises at least a lever pivotably mounted in said holder recess, with one end of said lever engaging in said recess in said latching pin, and at least one actuating element located on the exterior of said holder and engaging the other end of said lever, for actuating said lever to lift said locking pin out of its locking position.

6. A photographic objective according to claim 5, wherein said latching pin comprises two recesses in opposite sides thereof and said latching means comprises two of said levers and two of said actuating elements positioned on opposite sides of said latching pin.

[57] **ABSTRACT**

A control circuit for automatically opening and closing the diaphragm of the objective lens of a closed circuit television (CCTV) camera, including a variable gain inverting amplifier for amplifying and inverting video signals from the camera, a voltage doubler and rectifier coupled to the output of the inverting amplifier, a reference voltage generator, a diaphragm control assembly for comparing said reference voltage with signals output from said voltage doubler and opening and closing said diaphragm in response to the results of said comparison, and a series circuit including a clipping diode and variable resistor coupled between the input and output of the inverting amplifier. The clipping diode clips negative going portions of signals output from said inverting amplifier and adjustment of said variable resistor selects different light modes by controlling the degree of clipping.

PHOTOMETRIC CIRCUIT INCORPORATED IN OBJECTIVE PROVIDED WITH AUTOMATIC DIAPHRAGM FOR CLOSED CIRCUIT TELEVISION (CCTV) CAMERA

BACKGROUND OF THE INVENTION

The present invention relates to a photometric circuit incorporated in an objective lens assembly including an automatic diaphragm for a closed circuit television (CCTV) camera.

In an objective lens assembly provided with an automatic diaphragm so arranged that the DC voltage obtained by rectifying video signals coming from the television camera are utilized as the control signals for diaphragm control to obtain the optimum image, the photometric circuit serving as means for detection of an object to be picked up is very important, since the photometric or light measuring mode for this objective lens depends on the capabilities of such a photometric circuit.

To obtain the optimum image, not only absolute brightness of an object to be picked up, but also light and shade ratios of different areas in the same object, i.e., contrast, are important factors to be considered. The contrast lies within a range of tens: one even in cloudy daylight and within a range of hundreds: one in cloudless daylight. In the image reproduced by a television, on the contrary, the contrast lies within a range as narrow as of 30 to 40:1. When a bright area and a dark area are simultaneously contained in the same object, therefore, it is necessary to decide whether said bright area is selected as the main object or said dark area is selected as the main object to be picked up, since it is impossible to see both areas at the same time.

In principle, a so-called average light measuring mode is suitable for the case in which the dark area is selected as the main object to be picked up, while a so-called peak light measuring mode is suitable for the case in which the bright area is selected as the main object to be picked up. These light measuring modes for a video system usually employ the video signals coming from the television camera to obtain a diaphragm control signal. However, rigid use of these light measuring modes would cause inconveniences. Specifically, in the case where the same object simultaneously contains the bright area and the dark area as previously mentioned, the average light measuring mode would often make the bright area a white solid area without any gradation while the peak light measuring mode would often make the dark area, which should be adequately discriminated, indiscriminate. The average average light measuring mode and the peak light measuring mode should be selectively adopted depending on whether the dark area or the bright area is used as the main object to be picked up when these two areas simultaneously exist in one and the same object to be picked up. Accordingly, it is preferred that a video signal of the same level is obtained regardless of the modes so far as the object contains no dark area, i.e., no contrast state is concerned.

In view of the fact that a condition of an object to be picked up is sensitive to not only said light and shade ratio, i.e., the contrast of the dark area and the bright area, but also the proportions of whole the object occupied by these areas, respectively, the present invention provides a photometric circuit permitting the light measuring modes to be selectively converted and, at the same time, permitting a video signal of the same level to be obtained even when the light measuring mode conversion takes place so far as the no contrast state is concerned.

FIG. 2(*a*) shows a test pattern in which a central blank area represents a bright area and a shaded area surrounding said blank area represents a dark area. In this test pattern, a proportion of the whole object occupied by the bright area, i.e., the ratio of bright area S_o is expressed by

$$S_o=(a/b)^2\times 100\ (\%).$$

$S_o=100$ (%) is established when the whole object is covered by the bright area and contains no dark area, i.e., in the no contrast state.

SUMMARY OF THE INVENTION

Accordingly, it is a primary object of the present invention to provide a photometric control circuit for automatically adjusting the diaphragm of the objective lens of a closed circuit television (CCTV) camera which takes into account the contrast of the dark and light areas of an object to be picked up.

It is a further object of the present invention to provide a photometric control circuit for the diaphragm in a CCTV camera with the capability of selecting either the dark or light areas of the object as the primary area of interest in forming the object image.

The objects of the present invention are fulfilled by providing a photometric circuit incorporated in the objective lens assembly, provided with an automatic diaphragm for a closed circuit television (CCTV) camera, including an inverting amplifier adapted to amplify and invert video signals coming from the television camera with respect to a reference voltage and a rectifier adapted for voltage doubling rectification of video signals inversely amplified by said inverting amplifier so that video signals thus processed are compared with separately provided reference voltages to obtain diaphragm control signals to open or close the diaphragm. The photometric circuit includes in said inverting amplifier, a limiter having, in parallel to a variable resistance adapted for adjustment of the amplification degree, a diode functioning to limit a negative portion of the amplified and inverted video signal and a variable resistance for current control of said diode.

BRIEF DESCRIPTION OF THE DRAWINGS

The objects of the present invention will become more fully apparent and understood by reference to the detailed description given hereinbelow and the accompanying drawings, which are given by way of illustration only, and thus are not limitative of the present invention and wherein:

FIG. **1** is a circuit diagram illustrating an embodiment of the control circuit according to the present invention;

FIG. **2**(*a*) is a diagram illustrating the relationship between a test object to be picked up and a corresponding waveform of a video signal to be input to the control circuit of FIG. **1**;

FIGS. **2**(*b*) and **3** are diagrams illustrating a signal waveform appearing at the output terminal P_1 in the circuit of FIG. **1**;

FIGS. 4(*a*) and 4(*b*) are diagrams illustrating a signal waveform before and after rectification in a peak light measuring mode by the circuit of FIG. 1;

FIGS. 5(*a*) and 5(*b*) are diagrams illustrating a signal waveform before and after rectification in an average light measuring mode by the circuit of FIG. 1;

FIG. 6 is a diagram showing an input and output characteristic line of the inverting amplifier of FIG. 1; and

FIG. 7 is a diagram showing a photometric characteristic line expressed as a relationship of the area ratio S_o versus a video signal $V_{in}(V_{p\text{-}p})$.

DETAILED DESCRIPTION OF THE INVENTION

The present invention will now be described by reference to an embodiment as shown by the accompanying drawings.

FIG. 1 is a circuit diagram illustrating an embodiment of the present invention. Reference numeral 1 designates a video signal input terminal applied with a video signal V_{in} coming from the television camera and connected via a capacitor 2 to an inverting amplifier I, including an operational amplifier 3. At an output terminal 33 of said inverting amplifier I, an amplified and inverted video signal (inverted signal) V_{33} containing no DC components appears. The video signal input terminal 1 is also connected by a resistance 4 to ground.

The inverting amplifier I includes the operational amplifier 3 having its input terminal 31 connected via a resistance 5 to said capacitor 2, its noninverting input terminal 32 connected via a resistance 7 to a reference voltage input terminal 6, and its output terminal 33 connected via a variable resistance 8 adapted for regulation of amplification degree to said noninverting input terminal 31. Thus, the inverting amplifier I functions to, on the basis of the voltage supplied from the reference voltage input terminal 6, amplify and invert the video signal having its DC component already eliminated by the capacitor 2, and its amplification degree is variable by adjusting said variable resistance 8. Reference symbol A designates a limiter provided in parallel to said variable resistance 8 to limit the negative output of the video signal inversely amplified by the operational amplifier 3. This limiter A consists of a diode 9 and a variable resistance 10 adapted to control electric current flowing through said diode 9, in which the inverting input terminal 31 of the operational amplifier is connected to an anode of the diode 9 while a cathode of said diode 9 is connected via a variable resistance 10 to the output terminal 33 of said operational amplifier 3. This limiter A is arranged, as shown by solid line ② in FIG. 6, so that the negative side of the output voltage from the operational amplifier 3 is forcibly suppressed by the diode 9. Referring to FIG. 6, the abscissa represents an input voltage V_{31} at the inverting input terminal 31 of the operational amplifier 3 and the ordinate represents the output voltage V_{33} appearing at the output terminal 33. Said limiter A functions so that the negative side of the output voltage V_{33} corresponding to the input voltage V_{31}, which would otherwise exhibit the input and output characteristic as shown by broken line ① as said input voltage V_{31} increases in excess of α, may be maintained constant at a level β as shown by solid line ②.

Reference numeral II designates a rectifier adapted for voltage doubling rectification of the video signal V_{33} inversely amplified by said inverting amplifier, and comprises a capacitor 11 for voltage doubling connected to the output terminal 33 of said operational amplifier 3 and a diode 12 via which an output terminal P_2 of said capacitor 11 is connected to the reference voltage input terminal 6. A diode 13 also is serially connected to said output terminal P_2 of the capacitor 11 so that a DC diaphragm control signal may be obtained at an output terminal 15. Reference numeral 14 designates a capacitor connected to the output terminal of the diode 13 and grounded to smooth the rectified signal coming from said diode 13.

In the embodiment of the photometric circuit constructed as described above according to the present invention, it is assumed that a video signal V_{in} of a waveform as shown in FIG. 2(*b*) corresponding to the test pattern of FIG. 2(*a*), is applied to the video signal input terminal 1. The video signal V_{in} has its DC component eliminated by the capacitor 2 and, as a result, a signal VP_1 appearing at an output terminal P_1 has positive and negative areas with respect to the reference voltage which are equal to each other. This signal VP_1 is inversely amplified by the inverting amplifier I with respect to the voltage supplied from the reference voltage input terminal 6, basically as shown in FIG. 4(*a*). It should be noted here that, in FIG. 2(*b*), an upper rectangular portion of the waveform corresponds to the central bright area of an object to be picked up, as illustrated in the test pattern of FIG. 2(*a*), reference symbol V_2 represents a video level and reference symbol V_s represents a synchronous level.

The amplification degree of the inverting amplifier I increases as the resistance value of the variable resistance 8 is adjustably increased, while said amplification degree decreases as said resistance value decreases. The amplification of the inverting amplifier I depends on the resistance value ratio of the resistance 5 and the variable resistance 8. Accordingly, the amplification degree may be regulated by adjustment of the variable resistance 8 to regulate the peak-to-peak amplitude $V_{p\text{-}p}$ of the inverted signal V_{33} appearing at the output terminal 33 of the operational amplifier 3, and thereby achieve sensitivity regulation.

The variable resistance 10 of the limiter A may be adjusted to set the light measuring mode to a peak light measuring mode, an average light measuring mode or an intermediate light measuring mode. When the resistance value of the variable resistance 10 is adjusted to infinity, the limiter A is activated and, therefore, the reversed signal V_{33} takes a waveform which is inverted compared to the signal VP_1 appearing at the output terminal P_1. Upon application of this inverted signal V_{33} to the capacitor 11 of the voltage doubler II, the negative portion of this inverted signal V_{33} changes the diode 12 to its conductive state and charges the capacitor 11. Then the plus portion thereof is additionally charged into said capacitor 11 so that a voltage doubled signal VP_2 appearing at the output terminal P_2 is DC regenerated without any change of the peak-to-peak amplitude $V_{p\text{-}p}$ as shown in FIG. 4(*b*). Thus, the voltage doubled signal VP_2 of the initial peak-to-peak amplitude $V_{p\text{-}p}$ is obtained, so the mode of light measuring is set to the peak light measuring mode in which the video level V_2 is detected, and the bright area is selected as the main object to be picked up. In the case where the resistance value of the variable resistance 10 in the limiter A is adjusted to zero, the diode 9 becomes conductive and the operational amplifier 3 is subjected to the limitation as shown in FIG. 6. More specifically, the input signal

V_{in} passes through the capacitor **2**, appears as the signal VP_1 at the input terminal P_1, as shown in FIG. **3**, and then is applied to the inverting amplifier I in which the portion of the signal increasing in excess of α (corresponding to the bright area) is clipped and an inverted signal V_{33}, indicated by a solid line ②, having no portion indicated by a broken line is formed (see FIG. **6**). In consequence, even when the input signal V_{in} contains a peak value, the resultant inverted signal V_{33} having its portion indicated by a broken line on the negative side is clipped away and said peak value is correspondingly clipped away. When this reversed signal V_{33} is rectified by the voltage doubler, the negative portion thereof turns the diode **12** to its conductive state, as in the case of peak light measuring and charges the capacitor **11**. The subsequent positive portion of the waveform is added to the previously charged voltage. Thus, the voltage doubled signal VP_2, appearing at the output terminal P_2 is DC regenerated, as shown in FIG. **5**(*b*). That is, the voltage doubled signal VP_2 is determined not by the peak-to-peak amplitude $V_{p\text{-}p}$, but a value substantially corresponding to an average value of the whole area of the object to be picked up having its negative portion of the signal clipped away. The above-described operation is the average light measuring mode in which the dark area is used as the primary object to be picked up. By adjusting said variable resistance **10** to an intermediate resistance value, the light measuring mode is converted to a mode intermediate of said peak light measuring mode and said average light measuring mode. In the embodiment shown, the diode **9** in the limiter A and the diodes **12**, **13** in the voltage doubler are so selected that the temperature coefficients of these diodes cancel one another adequately to provide a circuit substantially free from any temperature influence.

With the circuit constructed as has been described hereinabove in accordance with the present invention, sensitivity regulation can be achieved by adjusting the resistance B for regulation of the amplification degree in the inverting amplifier, while the light measuring mode can be selectively set to the peak light measuring mode, the average light measuring mode or the intermediate light measuring mode by adjusting the resistance **10** for current control of the diode **9** in the limiter. In both the average light measuring mode and the peak light measuring mode, the minus portion of the reversed signal V_{33} is rectified by the voltage doubler and, as a result, the rectified signal level, i.e., the diaphragm control signal level, is identical in both modes, particularly in the state of the area ratio $S_o=100$ (%) or in the no contrast state. In consequence, there is provided, according to the present invention, an ideal photometric circuit, in which the video signal V_{in} has an identical reference level in both the peak light measuring mode ① and the average light measuring mode ② as shown in FIG. **7**. Furthermore, the negative side of the signal is under the effect of the limiter in the average light measuring mode so that no useless electric current flows, and thereby energy consumption is effectively saved.

It should be understood that the control circuit of the present invention may be modified as would occur to one of ordinary skill in the art without departing from the spirit and scope of the present invention.

What is claimed is:

1. An automatic control circuit for opening and closing the diaphragm of the objective lens of a video camera comprising:

inverting amplifier means for receiving video signals output from said video camera and amplifying and inverting said signals;

voltage doubler means for doubling and rectifying the signals output from said inverting amplifier means;

reference signal generating means;

diaphragm control means for comparing said reference signal with signals output from said voltage doubler means and opening or closing said diaphragm in response to the results of the comparison;

means for clipping the negative going portion of signals output from said inverting amplifier; and

light mode selector means for adjusting said means for clipping to control the degree of clipping performed on said signals.

2. The control circuit of claim **1**, wherein said means for clipping comprises a diode coupled between an inverting input of said inverting amplifier and an output thereof.

3. The control circuit of claim **2**, wherein said light mode selector means comprises a variable resistor in series with said diode.

[57] **ABSTRACT**

A foldable camera for self-developing film comprises a base housing and a movable member pivotable between a closed position integrated with the housing and an open, elevated position above the housing. The movable member is mounted to a supporting member which is pivotally coupled to the housing at the end opposite from the film exit end of the housing. An objective lens and a reflex mirror are fixedly mounted to the movable member in fixed relationship to each other such that they are in the proper positions for film exposure when the movable member is pivotted to the elevated position.

FIG. 11

FOLDING CAMERA WITH MOVABLE MEMBER MOUNTING AN OBJECTIVE LENS AND REFLEX MIRROR

BACKGROUND OF THE INVENTION

1. Field of the invention

The present invention relates to an improvement of a self-developing camera, also called an instant camera.

2. Description of the prior art

In self-developing cameras for amateur use which use self-developing film, the camera body itself tends to be larger because their image frame size is larger than that of general miniature cameras. However, it would be advantageous that the camera body be smaller and of lighter weight and handles more easily. There have been many proposals relating to such self-developing cameras. For example, U.S. Pat. No. 3,709,122 discloses a self-developing camera that is a finder-collapsible compact single lens reflex camera. This camera has the disadvantage that because of the single lens reflex type, it needs to oscillate the reflex mirror each time when an exposure is made, so that the time lag between the time the shutter button is depressed and the time when an actual exposure is made is so long that an object can move during the time interval or an exposure is made with the mirror insufficiently settled, thus causing the resulting image to be degraded. In addition, because the collapsing of the finder is made by pivotting on 4 pivots, the mechanism is complicated. And if the angle formed by and between the sheet film plane and the reflex mirror plane is made less than 45° and the space between the film plane and the mirror is small, the reflection is repeated many times between the film plane and the reflex mirror, tending to produce a ghost image. Further, if the self-developing camera has an exposure lens-foldaway structure wherein the lens is folded so as not to be superposed upon a film cassette when the camera is in the folded position because the image frame size thereof is relatively large, the camera body can be made flat, but instead its flat area becomes so large that its portability tends to be reduced.

Japanese Patent Publication Open to Public Inspection (hereinafter referred to as Japanese Patent O.P.I. Publication) No. 34530/1975 proposes a self-developing camera wherein an exposure lens member is pivotally coupled to an end of a film cassette holder, and also a reflex mirror is pivotally coupled to the other end of the holder, the two movable members being such as to be folded inwardly toward each other. In this camera, however, the exposure lens, as a barrier type, is difficult to fit inside the camera frame. In order to make the camera more compact, the exposure lens and reflex mirror are required to be located as close to each other as possible. If located too close to each other, the two become difficult to be folded inwardly toward each other, while if a sufficient space is provided between the two, the size of the camera in the picture-taking position becomes larger. In addition, the optical axis of the exposure lens, if brought closer to the film cassette holding position, produces a flare between the reflex mirror and the film plane, so that it may not be brought excessively close to the position. Accordingly, the proposed camera has the disadvantage that if the exposure lens and reflex mirror are to be folded inwardly toward each other with both ends of the holder as pivotal axes, the interval between both ends of the holder must be made larger,

and the camera can be folded flat but tends to become so large that the portability thereof is reduced.

SUMMARY OF THE INVENTION

The present invention has been made from the standpoint of human engineering of the optimum photographing angle of view and the like, and an object of the present invention is to remove the disadvantage of the above-described conventional products. The object is accomplished by the following self-developing camera: In a foldable self-developing camera wherein a film cassette is arranged in the exposure position, and a sheet film loaded inside the film cassette is exposed to the light coming through an exposure lens and a reflex mirror from an object, and then developed by developing rollers or the like, the camera comprises at least a fixed member having a film cassette-holding member, an exposure lens which is movable when folding the camera, a reflex mirror which is also movable when folding the camera's movable member that moves in relation to both the exposure lens and the reflex mirror, a pivotally supporting member which is pivotally coupled to the fixed member and provided at an edge of the reflex mirror, the edge being on the side closer to the film in the exposure position and in the proximity of the side of the film cassette opposite to the film exit side thereof, and a finder member whose optical axis, when the camera is in the picture-taking position, is in parallel or nearly in parallel with the film developing direction and which is located close to the exposure lens. When the camera is in the folded position, the exposure lens, interlockingly with the movement of the camera's movable member, is folded superposedly upon the point near the edge on the film cassette exit side of the image frame or upon a developing member such as the developing rollers. Namely, according to the present invention, the change in the camera position from the folded position to the picture-taking position is effected by a relatively simple operation, in which the opening degree of the camera's movable member can be small. And when in the folded position, the camera is well balanced in longitudinal, transverse and thickness dimensions for portability. Further, by providing the finder on the side of the exposure lens in the folded position, the camera can be of the well-operative box type and also can be of the barrier type structure in which the exposure lens may be readily covered by the movable member when in the folded position.

As is disclosed in Japanese Patent O.P.I. Publication No. 112330/1976, in order to prevent the flare in the image reversing type, the reflex mirror is not allowed to be brought excessively close to the film-holding section side. Therefore if the pivoting of the movable member is made at a point near the intersecting point of the fixed member's upper plane and the reflex mirror plane, the movable part can be made small in size because the optical path of the exposure optical system is considerably narrow, and about half of the optical path of the rectangular pyramidal body formed with the exposure lens as the vertex becomes folded into the lower half, so that the spacing between the fixed part and the movable part in the folded position can be small, thus enabling easily the miniaturization of the camera. Further the spacing in the portions held on both sides of the fixed member of the box type is easily securable, so that the camera may be as stably held by hand as if when a binocular is held. Consequently there could occur no unintentional touch by fingers to the film ejected from

the camera held by hand nor unintentionally covering with the hand the exposure lens of the light-receiving window at the time of shutter releasing, which can occur in conventional cameras.

The present invention which has been described above has the following advantages:

(1) The camera, when folded, has a rectangular form well-balanced in longitudinal, transverse and height dimensions and excellent in portability.

(2) The camera has no finder projection even when in the picture-taking position, so that the camera can be as stably held as a binocular is held. The shutter release button may be provided in any natural position that is readily depressible, so that there occurs little camera-shake and no unintentional touching with the fingers of the film being ejected out of the film exit.

(3) The finder is clearly viewable without use of any complex optical system and, because there is no projection underneath the finder eye piece portion, the finder is easily viewable.

(4) If a simple cover is provided inside, the camera may be carried with no camera case; i.e., may be of the barrier type, so that snap shooting can be readily conducted.

(5) The structure is simple: the operation of the camera from the folded position to the picture-taking position and vice versa is simple.

Other objects of the invention will be obvious evident as described hereinafter.

The invention accordingly comprises an apparatus possessing the construction, combination of elements and arrangement of parts which are exemplified in the following detailed disclosure, and the scope of which will be indicated in the claims.

BRIEF DESCRIPTION OF THE DRAWINGS

For a fuller understanding of the nature and objects of the invention, reference should be made to the following detailed description taken in connection with the accompanying drawings wherein:

FIG. **1** and FIG. **2** are perspective views showing an example of the camera of this invention. FIG. **1** shows the camera in the folded posi while FIG. **2** shows the camera in the ready for-picture-taking position.

FIG. **3**(*a*) and FIG. **3**(*b*) are sectional views of the movable member opening-closing mechanism and film cassette entrance and holding sections viewed from Arrow A of FIG. **1** and Arrow B of FIG. **2**, respectively.

FIG. **4**(*a*) is a plan view and FIG. **4**(*b*) is a sectional view of the film-advancing mechanism viewed from Arrow C and Arrow D, respectively of FIG. **1**.

FIG. **5**(*a*) is a sectional view across the line I—I of FIG. **1**, and FIG. **5**(*b*) is a sectional view across the line II—II of FIG. **2**.

FIG. **6**(*a*) is a sectional view of the finder unit across the line III—III of FIG. **2**, and FIG. **6**(*b*) is a front view of the finder arrangement.

FIG. **7**(*a*) is a plan view viewed from Arrow C of FIG. **1**, and FIG. **7**(*b*) is a front view viewed from Arrow E of FIG. **1**.

FIG. **8**(*a*) is a plan view of the electronic flash unit viewed from Arrow F of FIG. **2**, and FIG. **8**(*b*) is a front view of the electronic flash unit viewed from Arrow G.

FIG. **9**(*a*) and (*b*) sectional views of the camera in the second example of the invention.

FIG. **10**(*a*) and (*b*) are sectional views of the camera in the third example of the invention.

FIG. **11** is a sequential time chart for the examples in the invention.

DETAILED DESCRIPTION OF THE INVENTION

Description of the preferred embodiment

Examples of the self-developing camera of the present invention will be illustrated in detail in the drawings wherein FIG. **1** and FIG. **2** are overall perspective views. FIG. **1** shows the folded nonpicture-taking position of the camera, and FIG. **2** shows the ready-for-picture-taking position of the camera wherein movable member **2** is moved to the up position from fixed member **1**. In these drawings, a shutter button **11** is in the corner of a side of fixed member **1**, and an electronic flash firing button **11A** is located adjacent to shutter button **11**. Shutter button **11** is so located that the shutter can be released with the camera held by hand. As electronic flash-firing button **11A** is adjacent to shutter button **11**, in normal photographing, shutter button **11** and electronic flash firing button **11A** can simultaneously depressed to enable quick shooting.

Numbered **12** is a self-focusing lock button which is moved backward to set a self-timer and moved forward to lock the autofocusing value. Self-autofocusing lock button **12** can also be operated with the camera held by hand.

FIG. **3**(*a*) is a sectional view showing the movable member opening-closing mechanism and film cassette entrance and holding section viewed from Arrow A of FIG. **1**. FIG. **3**(*b*) is a sectional view showing the movable member opening-closing mechanism and film cassette entrance and holding section viewed from Arrow B of FIG. **2**. Movable member **2** which is the picture-taking body having exposure lens **3** and reflex mirror **5** is supported by a pivotally supporting member **21** which is pivotally coupled to fixed member **1** which is the body holding film cassette C. Exposure lens **3** and reflex mirror **5** are fixed to movable member **2** so as to be integral parts thereof. Fixed member **1** comprises a holding means to hold film cassette C, a developing roller unit **72** and sheet film exit **73** from which a developed sheet is ejected. Pivot member **21** is located in the proximity of the intersecting point of the external upper surface plane of fixed member **1** and reflex mirror **5** plane in the picture-taking position.

The opening-closing mechanism of movable member **2** is illustrated below:

Movable member **2** has on both transverse sides thereof a pair of lock arms **22**. An end of each of lock arms **22** is mounted to pivot **23** provided on movable member **2**, and roller **221** provided at the other end of lock arm **22** is slidably fit in along cam slot **14** provided to for moving along the slot according to the opening and closing of movable member **2**. Lock arm **22** is resiliently biased in the clockwise direction by a spring (not shown) provided on pivot **23**. Movable member **2**, when raised in the clockwise direction, turns pivotally on supporting member **21** to move into the ready-for-picture-taking position. And when movable member **2** is moved to the down position by pushing lock arms **22** in the counterclockwise direction, the camera assumes the folded position. The opening and closing of movable member **2** are very simply carried out as has been described above. The front of fixed member **1** is provided

with a light-shield member **19** which is spring-biased in the counterclockwise direction to pivot on pivot member **191** to cover the inside while the camera is in the picture-taking position. In addition, fixed member **1** is provided with an electronic flash switch **91** which is turned ON when the switch is depressed by lock arms **22** at the time of raising movable member **2**, thus starting the charging of the capacitor for the electronic flash.

Next, the opening-closing mechanism of roller cover **7** is illustrated below:

Roller cover **7** is a cover that opens and closes pivoting on the opening-closing pivot **71** and has thereinside a pair of film-advancing rollers **72**. A film sheet ejected by film-advancing rollers **72** is ejected out of film exit **73**. Film exit **73** is provided with a movable cover **74** which serves to intercept light except when a processed film sheet is ejected from the exit.

When roller cover opening-closing button **75** which is slidably movable up and down is pushed upward, a projection **751** provided on the back of the opening-closing button **75** pushes a claw **76** up. When claw **76** is then pushed up in the counterclockwise direction pivoting on pivot member **761**, a projection **77** which is engaged with claw **76** becomes disengaged. Projection **77** is a projection that is provided to roller cover **7**, so that roller cover **7** opens pivoting on opening-closing pivot **71**. Film cassette C is loaded by opening roller cover **7** and pushing the film cassette rightward. Fixed member **1** is provided thereinside with a stopper (not shown), and when film cassette C is pushed as far as it goes, an electric connection with film cassette C is made by electric contact **41**. When roller cover **7** is closed, gear **721** provided on one of film-advancing rollers **72** is engaged with gear G provided inside fixed member **1** (FIG. **4**(*b*)). FIG. **4** shows the principal part of the film-advahcing section. FIG. **4**(*a*) is a sectional view viewed from Arrow C and FIG. **4**(*b*) is a sectional view viewed from Arrow D of FIG. **1**. The revolution of roller drive motor M1 is transmitted from a gear G1 mounted thereto through the gears of gear train G that engage with gear G1 to gear G2 so that gear G2 makes one revolution. Gear G2 is provided on one side thereof with a projection **78**. A movable plate **79** that engages at bent portion **791** thereof with projection **78** is resiliently biased leftward by a spring **792**, and movable plate **79** makes one lateral reciprocating motion by the revolution of gear G2, and then a raised portion **793** provided for pushing film on movable plate **79** pushes a corner of film cassette C to push rightward one film sheet inside cassette C. The film sheet pushed rightward is then ejected out through film exit **73** by film-advancing rollers **72**.

FIG. **5**(*a*) is a longitudinal sectional view as seen in the direction of arrows from the line I—I of FIG. **1**, and FIG. **5**(*b*) is a longitudinal sectional view as seen in the direction of arrows from the line II—II of FIG. **2**. With reference to these figures the operation of the movable mirror and the optical path will be illustrated below:

Exposure lens **3** and reflex mirror **5** are fixed to movable member **2**. When the camera is in the folded position, exposure lens **3** is covered with both fixed member **1** and movable member **2**. As movable member **2** is moved to the up position from the folded position of the camera as shown in FIG. **5**(*a*), reflex mirror **5** is gradually raised along with the movement of movable member **2**. In the picture-taking position, the light coming through the optical axis of exposure lens **3** is bent at an angle of 90 degrees by reflex mirror **5** to strike perpendicularly upon a film sheet. The side of reflex mirror **5** facing the sheet film is spaced from the sheet film so that no ghost appears on the photographed image. The optical path of the exposure optical system is considerably narrow at the reflective plane of reflex mirror **5**, so that the sizes of the reflex mirror and of movable member **2** may be made small.

In order to cover the above-mentioned optical path through exposure lens **3**, there is provided a bellows **54**, a light-shield member in the sleeve form made of cloth, paper, etc., having exposure lens **3** as its one opening and film cassette C mounting frame (aperture) as the other opening. Bellows **54** is in the form of having thereinside reflex mirror **5** and serves to cover the optical path when photographing and is folded to become flat when the camera is in the folded position.

FIG. **6** shows the finder system. FIG. **6**(*a*) is a longitudinal sectional view as seen in the direction of arrows from the line II—II of FIG. **2**. FIG. **6**(*b*) is a front view of the finder system. Finder **10** is a direct view finder provided in fixed member **1** and comprises a finder lens **101** and eye piece **102** and relay lenses **103** and **104** therebetween to define the photographable range (angle of view). A semi-transparent mirror (not shown) is provided in between the lenses of eye piece **102** to define as an Albada finder the autofocusing range. Further, in the visual field, a light source such as a light emission diode (LED) or the like is provided to tell completion of charging the capacitor for the electronic flash. In addition, the SC shown in FIG. **3** is the capacitor for the electronic flash.

FIG. **7** shows the mechanism related to the exposure lens shutter and AE, wherein FIG. **7**(*a*) is a plan view of the principal part viewed from Arrow C of FIG. **1**, and FIG. **7**(*b*) is a front view of the principal part viewed from Arrow E of FIG. **1**.

FIG. **8** shows interlocking relations between the AE, autofocusing unit and electronic flash unit **9** and the raising operation of movable member **2**, wherein FIG. **8**(*a*) is a plan view of the principal part of the electronic flash unit viewed from Arrow F of FIG. **2**, and FIG. **8**(*b*) is a front view of the same from Arrow G of FIG. **2**.

In FIG. **7**(*a*) and FIG. **8**(*b*), **31** is a EE light-receiving unit for exposure provided in movable member **2**. In front of light-receiving element **311** are condensor lens and comma-shaped light-receiving mask **312**. Moving laterally the print density control knob **313** that is an integral part of the light-receiving unit enables to vary the light-receiving area of light-receiving element **311** to thereby control the print density of an image to be photographed.

Autofocusing system **8** shown in FIG. **8**(*a*) is provided in fixed member **1**. Particularly, to avoid parallax, an infrared light emitter **81** for distance measurement is provided close to finder **10**, and the light axis of infrared light emitter **81** is nearly in parallel with the optical axis of finder **10**. **82** is the light receiving unit for distance measurement and is such that a spot light projected upon an object by light emitting element **811** of infrared light emitter **81** and lens **812** is focussed on a distance-measuring semiconductor element **822** by light-receiving unit's lens **821**, and distance measurement is made according to the spot position focussed on semiconductor **822**. Autofocusing system **8** is provided above the developing unit and nearly in parallel with the optical axis of exposure lens **3** inside fixed member **1**, so that the

system is of such a structure that greater accuracy is easily obtainable.

Next, the shutter operation is illustrated in the order of photographing steps with reference to FIG. 7(*b*).

The camera of the present invention has a motor in addition to the aforementioned roller drive motor M1. When shutter button **11** is depressed, photographing motor M2 reverses to rotate gear **321** in the counterclockwise direction. A pin **322** provided on the peripheral surface of gear **321** oscillates intermediate lever **323** in the clockwise direction and further oscillates stop lever **324** in the counterclockwise direction. The oscillation of stop lever **324** disengages the stoppage of lens unit **325** by hook **327** provided thereon, the lens unit being resiliently biased in the counterclockwise direction by spring **326**, to rotate lens unit **325** in the counterclockwise direction. Exposure lens **3** is mounted to lens unit **325**. Because lens unit **325** is helicoidally rotatably mounted to movable member **2**, with the rotation of lens unit **325**, exposure lens **3** is turned out. The rotation of lens unit **325** causes autofocusing position detecting resistor **328** to move slidingly to operate lens stopping magnet Mg1 by providing a comparative input into the comparator the detected voltage with the voltage obtained from autofocusing light-receiving element **822**, and oscillates lock claw **325** in the counterclockwise direction to cause the lock claw to plunge into the ratchet claw provided on lens unit **325** to stop the rotation of lens unit **325**, and then the movement of exposure lens **3** is stopped to effect autofocusing.

Shutter starting magnet Mg2 is then operated to turn fore-blade lever **321** in the counterclockwise direction. The turning of fore-blade lever **331** turns shutter link **332** in the clockwise direction which then moves laterally movable A-blade **333** and B-blade **334**. Namely, A-blade **333** moves leftward and B-blade **34** moves rightward simultaneously, and when the openings of both blades coincide with each other, the shutter diaphragm opens.

When shutter magnet Mg3 operates for closing the shutter due to the information from EE light-receiving unit **31**, after-blade stop lever **335** turns in the clockwise direction to disengage the engagement with after-blade drive member **337** that has been biased in the clockwise direction by spring **336**. After-blade drive member **337** turns in the clockwise direction to turn the foregoing shutter link **332** in the counterclockwise direction to thereby move A-blade **333** rightward and B-blade leftward simultaneously, thus closing the shutter diaphragm.

The autofocusing is made as has been described above, which is then followed by shutter exposure. As to the shutter charge, the aforementioned photographing motor M2 revolves normally, gear **321** rotates in the clockwise direction, and related members including lens unit **325** are restored to the initial conditions.

Interlocking relations between electronic flash unit **9** and the raising operation of movable member **2** are subsequently illustrated. Both FIG. **8**(*a*) and FIG. **8**(*b*) show electronic flash unit **9** in the condition of sticking out (pop-up) away from the optical axis of exposure lens **3**. Electronic flash unit **91** is mounted together with a laterally movable supporting member **92** to movable member **2**. And a projection **921** provided on supporting member **92** is connected to a less-contractive wire **96** one end of which is connected to a projection **95** on fixed member **1**, and further projection **921** is also connected to flexible spring **97** which is biased in the contractive direction. If movable member **2** is lifted, electronic flash unit **91** is pulled by wire **96** to stick out away from the optical axis of exposure lens **3**.

If movable member **2** is pushed down after completion of photographing, the tension of spring **97** moves electronic flash unit **91** into movable member **2**.

In this camera, with the folding of movable member **2**, a finder window **106**, autofocusing windows **83** and **84** which are provided on fixed member **1** are covered with a cover plate **85**. In FIG. **8**(*a*) and FIG. **8**(*b*), fixed member **1** has a pivot **86** and a L-shaped-lever **87** which pivots upon the pivot **86**. One end **871** of L-shaped lever **87** engages with a projection **851** provided on a laterally movable cover plate **85**, and a projection **872** provided on the other end engages with movable member **2**. L-shaped lever **87** is biased in the counterclockwise direction by spring **88**, so that projection **872** provided on L-shaped lever **87** pushes the under surface of movable member **2**. If movable member **2** is now raised, L-shaped lever **87** is turned in the counterclockwise direction by the force of biased spring **88** to move thin cover plate **85** so that the opening in the cover plate coincides with autofocusing windows **83** and **84**, and the cover plate moves out of its position for covering finder windows **106**, and thus finder window **106**, autofocusing windows **83** and **84** are all in the open condition.

And when movable member **2** is pushed down to be in the folded position, L-shaped lever **87** is turned in the clockwise direction by movable member **2** to move cover plate **85** leftward, and then finder window **106**, autofocusing windows **83** and **84** are all covered with cover plate **85** to be in the closed condition.

The first example of the present invention is as has been described above. FIG. **9**(*a*) and (*b*) and FIG. **10** (*a*) and (*b*) are sectional views of the second and third examples, respectively.

In the second example shown in FIG. **9**, what is different from the first example is that finder unit **10***a* is provided in movable member **2***a*. An objective lens **101***a* composed of a concave lens is fixed in parallel with exposure lens **3***a* to movable member **2***a*, and an eye piece **102***a* is mounted to a finder supporting member **103***a* which is movable with respect to movable member **2***a*. Finder supporting member **103***a* is mechanically interlockingly movable with movable member **2***a* or may be moved manually. When in the picture-taking position in which movable member **2***a* is raised, finder **10***a* is in the state of being viewable therethrough, while in the condition that movable member **2***a* is folded, finder **10***a* is also in the state of being folded. In this example, the optical axis of the finder is arranged so close to the optical axis of the exposure lens that the parallax is very small.

In the third example shown in FIG. **10**, what is, different from the foregoing first example is that, whereas in the first example exposure lens **3** and reflex mirror **5** are all fixed to movable member **2**, the third example is such that exposure lens **3***b* is movable with respect to moveable member **2***b* and reflex mirror **5***b* is fixed to movable member **2***b*. Exposure lens **3***b* is fixed to a lock lever **22***b* which has a pivot **23***b* on movable member **2***b* and which is slidably movable along a cam slot **14***b* that is provided on fixed member **1***b*. Therefore, when movable member **2***b* is raised to the up position, the optical axis of exposure lens **3***b* becomes nearly parallel with the sheet film plane and at an angle of about 45° to the plane of reflex mirror **5***b*, while in the folded position

that movable member **2***b* is pushed down, exposure lens **3***b* is in a position as shown in FIG. **10**(*a*). The mechanism in this example is slightly more complex than that in the first example, but has the advantage that the camera becomes thinner and more compact in the folded position.

The structure of the camera of the invention is as has been described above. The handling and mechanical operation of the camera in the examples are subsequently described below:

First, film cassette C is loaded. By depressing opening-closing button **75** of roller cover **7**, roller cover **7** opens. After that, when loading film cassette C and closing roller cover **7**, film-advancing rollers **72** are engaged with film-advancing gears to thereby rock the rollers.

When movable member **2** is raised to the up position, (1) a catch in the portable condition is disengaged, (2) electronic flash unit **91** is popped up, (3) exposure lens **3** and reflex mirror **5** are set, (4) bellows **54** is set, (5) electronic flash switch **91** is ON, (6) light-shield member **19** moves to the light-shield position, and (7) supporting member **4** is locked.

The picture-taking sequence is indicated in the sequence time chart.

The camera folding is made by pushing the lock levers **22** to push down movable member **2**.

Since certain changes may be made in the above photographic film assemblage and photographic apparatus without departing from the scope of the invention herein involved, it is intended that all matter containing in the above description or shown in the accompanying drawings shall be interpreted as illustrative and not in a limiting sense.

What is claimed is:

1. In a folding camera of the type having a base housing for holding a film cassette containing a plurality of film sheets, means for exposing a film sheet to light received from a subject by an objective lens and reflected from a reflex mirror to the film sheet at an exposure position in the base housing, and means for developing the film sheet and advancing it from an exit end of the base housing, the improvement wherein said means for exposing comprises a movable member supporting said objective lens and reflex mirror which is movable between a closed position forming a closure to the base housing and an open position in which said movable member is elevated above said base housing, said objective lens being riddily fixed to said movable member at a distal end thereof in an operative position for exposure, and a supporting member connected to the other end of said movable member and being pivotally coupled to said base housing at an end thereof opposite from the film exit end.

2. The folding camera as defined in claim **1**, wherein said objective lens is moved to an inoperative position within said base housing when said movable member is moved to the closed position.

3. The folding camera as defined in claim **1**, wherein said reflex mirror is mounted to said movable member so as to form an angle in the open position with an upper surface of said base housing, and said supporting means is pivotally coupled at a position of the upper surface of said base housing in proximity to one end of said reflex mirror.

4. The folding camera as defined in claim **1**, further comprising a built-in flash unit which is movable to an operative position in accordance with the movement of said movable member to said open position.

5. The folding camera as defined in claim **4**, wherein said flash unit includes a condenser, wherein a charging operation of said condenser is automatically started when said movable member is moved to the open position.

6. The folding camera as defined in claim **1**, further comprising a light shielding member for shielding an opening formed between said base housing and said movable member in the open position, said light shielding member being spring biased to close said opening when said movable member is moved to the open position.

7. The folding camera as defined in claim **1**, wherein said objective lens and said reflex mirror are rigidly mounted to said movable member in a fixed positional relationship to each other for exposing the film sheet at the exposure position when said movable member is in the open position.

8. In a folding camera of the type having a base housing for holding a film cassette containing a plurality of film sheets therein, means for exposing a film sheet with light from a subject received by an objective lens and reflected from a reflex mirror to the film sheet at an exposure position in the base mounting, and means for developing the film sheet and advancing it out from exit end of said housing, the improvement comprising a movable member mounting said objective lens and said reflex mirror which is movable between a closed position forming a closure to said base housing and an open position in which it is elevated above said base housing, and a supporting member connected to one end of said movable member and being pivotally coupled to the base housing, wherein said objective lens is rigidly mounted to a lock arm, one end of which is pivotally connected to a distal end of said movable member, and the other end of which is held in cam slot defined within said base housing and movable between an operative position for said objective lens and an inoperative position wherein said objective lens is folded in the base housing, and wherein said reflex mirror is rigidly mounted to said movable menber so as to be in an operative positional relationship with said objective lens when said movable member is moved to the open position.

AUTOMATIC DIAPHRAGM CONTROL DEVICE OF OBJECTIVE PROVIDED WITH AUTOMATIC DIAPHRAGM FOR CLOSED CIRCUIT TELEVISION (CCTV) CAMERA

BACKGROUND OF THE INVENTION

The present invention relates to an automatic diaphragm control device for an objective lens provided with an automatic diaphragm in a closed circuit television (CCTV) camera. The objective lens diaphragm is controlled in response to brightness levels of video signals received by the television camera.

For the closed circuit television (CCTV) cameras in video systems, it has usually been necessary for the objective lens provided with an automatic diaphragm to contain a complicated control circuit comprising many elements and having functions not only of a light measuring mode conversion, but also of sensitivity regulation. Consequently, the objective lens has been too bulky to be easily handled. Further, there has recently been a tendency to provide lower source voltages for energization of such control systems as the development of a small-sized cameras has progressed, and there has developed a demand for a novel control circuit compatible with the lower power sources and small-sized cameras.

SUMMARY OF THE INVENTION

Accordingly, it is a primary object of the present invention to provide an automatic diaphragm control circuit for the objective lens of a closed circuit television (CCTV) camera with a reduced number of circuit elements , which results in a compact objective lens assembly that is compatible with small-sized cameras.

It is a further object of the present invention to provide an automatic control circuit for the automatic diaphragm of the objective lens of a CCTV camera which facilitates the desired diaphragm control at a relatively low source voltage.

The objects of the present invention are fulfilled by providing an automatic diaphragm control circuit for the objective lens of a closed circuit television (CCTV) camera comprising an inverting amplifier with a variable gain adapted to be applied to a video signal coming from the television camera and to invert and amplify said video signal, a voltage doubler including a capacitor with charging voltage adjustment means therefor for voltage doubling and rectification of the output signal coming from said inverting amplifier, a level shifter adapted to lower the level of the rectified signal by a predetermined voltage, an intermediate voltage supplying circuit adapted to supply an intermediate voltage with respect to a power source voltage, and a diaphragm driving circuit adapted to compare the intermediate voltage supplied from said intermediate voltage-supplying circuit with the rectified signal coming from said level shifter and to adjust the diaphragm on the basis of a result of such comparison.

BRIEF DESCRIPTION OF THE DRAWINGS

The objects of the present invention will become more fully understood from the detailed description given hereinbelow and the accompanying drawings which are given by way of illustration only and thus are not limitative of the present invention and wherein:

FIG. **1** is a circuit diagram illustrating an embodiment of the device according to the present invention;

FIG. **2** is a series of diagrams schematically illustrating the relationship established between a test object to be picked up by the camera and signal waveforms in each stage of the circuit of FIG. **1**; and

FIG. **3** is a diagram illustrating the signal waveform appearing at the output terminal P_3 of FIG. **1** when a relatively dark object is picked up by the camera.

DETAILED DESCRIPTION OF THE DRAWINGS

The present invention will be described in more detail with reference to an embodiment shown by the accompanying drawings.

FIG. **1** is a circuit diagram showing an embodiment of the device constructed according to the present invention, in which reference numeral **1** designates a plus voltage side and reference numeral **2** designates a grounded side, respectively, of a power source circuit. Reference numeral IV designates an intermediate voltage-supplying circuit connected to said power source circuit and adapted to provide a voltage of intermediate (preferably $\frac{1}{2}$) level with respect to a power source voltage at an intermediate voltage terminal **84**. In the embodiment shown, a smoothing capacitor **28** and series resistances **24**, **25** are connected in parallel across the positive voltage side **1** and the grounded side **2** of the power source. A node P_4 between said resistances **24**, **25** is connected to a noninverting input terminal **82** of an operational amplifier **8** while an inverting input terminal **81** is directly connected to an output terminal **83**, and said noninverting input terminal **82** and said output terminal **83** are connected via capacitors **26**, **27**, respectively, to the grounded side **2** so that said voltage of $\frac{1}{2}$ level relative to the power source voltage is output at the intermediate (middle point) voltage terminal **84**.

Reference numeral **3** designates a video signal input terminal adapted to input video signals from a television camera to the control circuit according to the present invention, and is connected via a resistance **18** to the grounded side **2** on one hand, and via a capacitor **11** to an inverting amplifier I, on the other hand.

In the inverting amplifier I, an inverting input terminal **51** of an operational amplifier **5** is connected via a resistance **12** to said capacitor **11** while a noninverting input terminal **51** is connected via resistance **29** to the intermediate voltage terminal **84**. A variable resistance **16** is connected, as a feedback resistance, between said inverting input terminal **51** and an output terminal **53**. The inverting amplifier I is adapted for amplifying and inverting the video signal of which the DC component has been eliminated in said capacitor **11** and permits an amplification degree of the operational amplifier **5** which may be controlled by adjusting the variable resistance **16**.

Reference numeral II designates a voltage doubler functioning to rectify the video signal which has been amplified and inverted by said inverting amplifier I and comprises a voltage doubling capacitor **13** connected to the output terminal **53** of said operational amplifier **5** in parallel with a variable resistance **17**, a diode **30** via which the intermediate voltage terminal **84** is connected to an output terminal P_2 of said capacitor **13**, and another diode **14** serially connected to said output terminal P_2. The variable resistance **17** is provided to regulate a charging voltage for the voltage doubling capacitor **13** so that when the charging voltage becomes zero, the

capacitor **13** is not activated at a resistance value of zero and the charging voltage rises as the resistance value increases. The diode **14** is adapted for DC rectification of the signal at the output P_2 of the capacitor **13**. Further, there is connected a capacitor **19** between the output terminal of the diode **14** and the grounded side **2** to smooth said rectified signal.

Reference numeral III designates a level shifter comprising a resistance **21**, a Zener diode **20** and a resistance **22** via which the plus voltage side of power source **1** is connected to the grounded side **2**, and a resistance **23** via which the minus side (i.e., anode side) of the Zener diode **20** is connected to an output terminal P_3 of the voltage doubler II. This level shifter functions to reduce the rectified signal from the voltage doubler toward the minus side of the power supply by a predetermined voltage, and thereby to level-shift said rectified signal so that the behaviour range thereof extends on the plus and minus sides with respect to the intermediate voltage.

Reference numeral V designates a diaphragm driving circuit adapted to compare the output signal from the level shifter III with the intermediate voltage and to drive the diaphragm in a direction according to a result of this comparison. In the diaphragm driving circuit V, an operational amplifier **6** has its inverting input terminal **61** connected via a resistance **15** to the output terminal P_3 of the voltage doubler II, its noninverting input terminal **61** connected via a resistance **34** to the intermediate voltage terminal **84**, and its output terminal **63** connected via a resistance **64** to the commonly-connected basis of transistors **65**, **66**. The transistor **65** functions as a switching element which takes a conductive state when the base voltage rises to a level higher than a predetermined value while the transistor **66** functions as a switching element, which takes a non-conductive state when the base voltage drops to a level lower than a predetermined value. The transistor **65** is of the NPN type with its collector connected to the emitter of the transistor **66**, the latter being of the PNP type. This transistor **66** has its collector connected to the grounded side **2**. To eliminate any unresponsive ranges of these switching transistors **65**, **66**, a feedback resistance **67** is connected between a common emitter terminal P_6 and the reversed input terminal **61** of the operational amplifier **6**, while a pair of mutually opposed Zener diodes **36**, **37** are arranged in parallel to said feedback resistance **67**. Said emitter terminal P_6 is connected via the resistance **38** to the inverting input terminal **71** of an operational amplifier **7**, while a noninverting input terminal **72** of said operational amplifier **7** is connected via a resistance **39** to the intermediate voltage terminal **84**. An output terminal **73** of the operational amplifier **7** is connected via a resistance **74** to the commonly-connected basis of transistors **75**, **76**. The transistor **76** functions as a switching element, adapted to take a conductive state when the base voltage drops to a level lower than a predetermined value. The transistor **75** is of the NPN type with its collector connected to the plus voltage side **1** of the power source circuit, and its emitter commonly connected to the emitter of transistor **76**, which is of the PNP type. The transistor **76** has its collector connected to the grounded side **2** of the power source circuit. To eliminate any unresponsive ranges of these switching transistors **75**, **76**, there is connected a feedback resistance **77** between a common emitter terminal P_7, and the inverting input terminal of the operational amplifier **7**. There is provided a diaphragm driving coil **9** between both common emitter terminals P_6, P_7, so that the diaphragm is driven in an opening direction as electric current flows in the direction of an arrow A. A braking coil **10**, adapted for control of the diaphragm speed is connected via a series resistance **32** and a parallel resistance **33** between the inverted input terminal **61** of the operational amplifier **6** and the intermediate voltage terminal **84**.

Reference numeral VI designates a remote voltage supplying circuit for remote control of sensitivity regulation and comprises a remote voltage input terminal **4** connected via a resistance **31** to the inverting input terminal **61** of the operational amplifier **6**, on one side, and connected via a capacitor **35** to the intermediate voltage terminal **84**.

In the embodiment of the device constructed, as has been described above according to the present invention, it is now assumed that the video signal input terminal **3** is supplied with a video signal V_{in} having a waveform as shown in FIG. **2**(*b*), corresponding to a test pattern of an object, as shown in FIG. **2**(*a*). Of this waveform, a rectangular portion of the plus side corresponds to a bright area of the image. Reference symbol V_d represents a video level and reference symbol V_s represents a synchronous level. Such video level V_{in} is inversely amplified, as shown in FIG. **2**(*c*) by the inverting amplifier I and appears in the form of an inverted signal V_{53}, with its DC component already eliminated by the capacitor **11**. In consequence, a steady state is established in which the positive and negative portions of the waveform occupy equal areas with respect to the base line (i.e., the line **0**—**0** corresponding to the intermedate voltage). The amplification degree of the reversing amplifier I may be increased as the variable resistance **16** is adjusted toward a higher resistance value, and may be decreased as said variable resistance **16** is reduced. By adjusting the amplification degree in this manner, it is possible to adjust an amplitude $V_{p\text{-}p}$ of the inverted signal V_{53}, and thereby achieve sensitivity regulation.

The inverted signal V_{53} is then rectified by the voltage doubler II. When the resistance value of the variable resistance **17** is adjusted to zero, the capacitor **13** is not activated at all, and a signal VP_2 appearing at the output terminal P_2 of said capacitor **13**, coincides with the inverted signal V_{53}, as shown in FIG. **2**(*d*). In this case, the diode **30** is responsive to the minus portion of the inverted signal V_{53} to become conductive; but this minus portion is passed through the resistance **17**(R=O) and never charged into the capacitor **13**. Thus, the plus voltage V+ is given in the form of an average value, so that such light measuring mode may be referred to as the average light measuring mode suitable for picking up an object to which is covered substantially by a relatively dark area. When the resistance value of the variable resistance **17** is adjusted to infinity, the diode **30** is responsive to the minus portion of the inverted signal V_{53} to become conductive, and this minus portion is charged into the capacitor **13**. The subsequent plus portion of the signal is added to the previously charged voltage, and the output signal VP_2 is subjected to DC regeneration as shown in FIG. **2**(*e*), so that it is possible to detect the amplitude of the video level V_d even when the width d of the lighter portion is small. Accordingly, the light measuring mode with the variable resistance **17** having a resistance value adjusted to infinity, may be referred to as the peak light measuring mode suitable for picking up an object which is

covered substantially by a relatively light area. Further, another mode of light measuring, referred to as the intermediate light measuring mode, is also possible. This mode is intermediate of said average light measuring mode and said peak light measuring mode, and achieved by adjusting the resistance value of the variable resistance **17** to an intermediate value.

The signal rectified by said voltage doubler II takes the similar waveform to the plus portion of the output signal VP_2 from the capacitor **13** and is positive with respect to the intermediate voltage (line **0—0**), as shown in FIG. **3**(*a*), even in the darkest object conditions, since the input signal V_{in} contains the synchronous level V_s. However, the device according to the present invention should function on the basis of the intermediate voltage. To meet this requirement, the rectified signal is level-shifted by the level shifter toward the minus side so that the signal level is lowered by a predetermined voltage, and the video signal corresponding to a relatively dark image is on the minus side with respect to the intermediate voltage. Thus, the signal VP_3, appearing at the output terminal P_3 has, as shown in FIG. **3**(*b*), its waveform on the minus side and is responsive to a darker video signal incoming to be lowered relative to the intermediate voltage. In this manner, the signal VP_3 at the output terminal P_3 can be used within equal ranges on both the plus side (when an object to be picked up is relatively bright) and the minus side (when the object is relatively dark), respectively.

The signal which has left the level shifter III is applied to the inverting input terminal **61** of the operational amplifier **6**. In the optimum video condition, an input voltage V_{61} is equal to the intermediate voltage, while an output voltage V_{63} at the output terminal **63** is equal to the intermediate voltage e/2, and neither the transistor **65** nor the transistor **66** is activated, so that the driving coil **9** is not energized. When an object to be picked up is relatively bright, i.e., the input voltage $V_{61}>e/2$, such input voltage V_{61} is inversely amplified by the operational amplifier **6** with respect to the intermediate voltage so that a relationship of the output voltage $V_{63}<e/2$ is established, thereby the transistor **66** becomes conductive across its collector and emitter, and a voltage $VP_6<e/2$ appears at the emitter terminal P_6. When this voltage VP_6 is inversely amplified again by the operational amplifier **7** with respect to the intermediate voltage, an output voltage $V_{73}>e/2$ appears at the output terminal **73** of said amplifier **7**, and the transistor **75** becomes conductive across its collector and emitter. The transistors **66**, **75** which have become conductive in this manner, permit the plus side **1** of the power source circuit to provide electric current flowing through the transistor **75**, and then in the direction opposite to the direction indicated by the arrow A. The diaphragm driving coil **9** is thereby activated to close the diaphragm.

When an object to be picked up is relatively dark, i.e., the input voltage $V_{61}<e/2$, on the contrary, such input voltage V_{61} is inversely amplified by the operational amplifier **6** with respect to the intermediate voltage so as to produce the output voltage $V_{63}>e/2$, and the transistor **65** becomes conductive across its collector and emitter, resulting in the voltage $VP_6>e/2$ appearing at the emitter terminal P_6. When this voltage VP_6 is inversely amplified again by the operational amplifier **7** with respect to the intermediate voltage, the output terminal **73** of this operational amplifier **7** now provides the output voltage $V_{73}>e/2$, in response to which the transistor **76** becomes conductive across its collector and emitter. Once the transistors **65**, **76** have become conductive in this manner, the electric current flows from the plus side of the power source circuit through the transistor **65**, and then, in the direction of the arrow A, through the diaphragm driving coil **9** which is thereby activated to open the diaphragm. Such opening and closing movement of the diaphragm generates an electromotive force in the braking coil **10**, so as to apply the inverted input terminal **61** of the operational amplifier **6** with feedback, and thereby prevents the diaphragm from oscillating. This assures that said opening or closing movement occurs at a constant speed. Application of a plus or negative constant voltage via the remote input terminal **4** to the inverted input terminal **61** of the operational amplifier **6** permits the signal level to be raised or lowered, and sensitivity regulation to be achieved by remote control without adjustment of the variable resistance **16** for the inverting amplifier I.

As will be clear from the foregoing description, the automatic diaphragm control circuit for the objective lens of a closed circuit television (CCTV) camera according to the present invention permits sensitivity regulation to be achieved by regulating the amplification degree of the inverting amplifier, and permits a relatively compact objective lens assembly to be employed therein, since the number of circuit elements used can be substantially reduced. Furthermore, the output voltage of the diaphragm control signal can be used over equal extensions on both the plus side and the minus side, because an intermediate voltage to the power supply voltage is used as the reference voltage according to the present invention. Thus, it is possible to achieve the desired diaphragm control within a range as wide as possible, even when the power source voltage is relatively low.

It should be understood that the present control circuit may be modified as would occur to one of ordinary skill in the art without departing from the spirit and scope of the present invention.

What is claimed is:

1. An automatic control circuit for opening and closing the diaphragm of the objective lens for a video camera comprising:

power source means foı providing a bias voltage to said control circuit;

inverting amplifier means for receiving video signals output from said video camera and amplifying and inverting said signals;

voltage doubler means including capacitor means for doubling and rectifying the signals output from said inverting amplifier means;

means for adjusting the sensitivity of said control circuit;

level shifter means for lowering the level of the doubled and rectified signals output from said doubler means by a predetermined voltage;

intermediate voltage supply circuit means for supplying said control circuit with a voltage which is intermediate with respect to said bias voltage; and

diaphragm control means for comparing said intermediate voltage with signals output from said level shifter means and opening or closing said diaphragm in response to the results of the comparison.

2. The control circuit of claim **1**, wherein said means for adjusting the sensitivity of said control circuit comprises a variable gain control for said inverting amplifier

and means for adjusting the charging current to the capacitor means.

3. The control circuit of claim 2, wherein said means for adjusting the charging current comprises a variable resistor in parallel with said capacitor.

4. The control circuit of claim 1, wherein said means for adjusting said sensitivity of said control circuit comprises control voltage for superimposing a sensitivity control voltage on the signals output from said level shifter means.

[57] **ABSTRACT**

A camera system having an interchangeable objective lens selectively mountable to at least two different types of camera bodies of a, first type and second type, is involved. The camera system has a ROM located in the interchangeable objective lens for storing a plurality of compensation data: one is suitable for the first type camera body; and the other is suitable for the second type camera body. Each data compensates an error in fully-open aperture light measurement for each type of camera. The compensation data is transmitted from the lens to the camera body. A register is provided in the camera body for storing a selected compensation data which is necessary for the type of camera body mounted with the lens. A device is provided in the camera body for practicing a fully-open aperture light measurement through the interchangeable objective lens to produce a light measuring information including the light measurement error. A calculator is provided in the camera body for calculating a correct exposure information using the compensation data stored in the register and the light measuring signal, whereby the error included in the light measuring signal can be removed.

CAMERA SYSTEM WITH INTERCHANGEABLE OBJECTIVE LENS

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to a camera system with an interchangeable objective lens and, more particularly, to a compensation of an error related to the fully-open aperture in the camera system.

2. Description of the Prior Art

In the field of a camera system with an interchangeable objective lens, an error related to the fully-open aperture occurs when the light measuring is carried out through the fully-open aperture under the TTL light measuring system.

Generally, in a TTL camera system with an interchangeable objective lens designed to measure light through the fully-open aperture, the light measuring output characteristics vary with respect to the details of the optical system, e.g., the location and diameter of the exit pupil, or to the details of the light measuring optical system, e.g., a deviation between the position where a light receiving element is located and the optical equivalent position of a film surface or a manner of diffusion of incident light to the light receiving element.

When a light amount of an object having a certain brightness is measured with a camera mounted with a certain interchangeable lens, the camera shows a different measured amount of light with respect to the type of mounted interchangeable lens. Therefore, unless the measured amount of light is compensated, the correct exposure control cannot be accomplished. Generally, the error caused by this measured amount of light (referred to as a fully-open aperture light measurement error) is expressed by a difference between the measured amount of light with a standard interchangeable lens (for example, a 50 mm/F1.4 lens) and that with another interchangeable lens.

Conventionally, various ways to compensate the fully-open aperture light measurement error have been proposed, and they can be divided into two groups. The first group is disclosed, for example, in Japanese Patent Laid-Open Publication No. 56-107221. According to this article, a means for generating a signal corresponding to the fully-open aperture light measurement error inherent to each type of interchangeable lens is provided in each interchangeable lens. The generated signal is transferred to the camera body for compensating the amount of light measured by the camera body. The generating means can be a type that generates a signal directly representing the fully-open aperture light measurement error or a type that generates a signal representing an amount of shift to be effected in a device for transmitting an aperture signal.

The second group is disclosed, for example, in Japanese Patent Laid-Open Publication Nos. 55-143542 and 56-74226. According to these articles, the camera body calculates a fully-open aperture light measurement error based on information of fully-open aperture size or focal length, as obtained from an interchangeable lens. The calculated error is used for compensating a measured light amount.

According to the prior art camera systems, however, the amount of fully-open aperture light measurement error differs not only when a different type of lens is mounted on the same type of camera body, but also when the same type of lens is mounted on a different type of camera body having a different optical system for the light measurement. Therefore, the above-mentioned prior art camera system has follow disadvantages.

In regard to the first group, the generating means provided in each interchangeable lens is stored with a signal corresponding to the fully-open aperture light measurement error, but such a signal can be used properly in one particular type of camera body, and can not be used in the other types of camera bodies having a different light measuring system. In other words, when an interchangeable lens of the first group is mounted on a camera body of a type other than said one particular type, the signal produced from the generating means does not correspond to the fully-open aperture light measurement error and, therefore, the measured light amount will not be corrected properly. Although this disadvantage can be removed by providing the same optical light measurement system to each of different types of camera bodies, this is not appropriate because the design freedom and the specification of light measuring characteristic may be undesirably limited, resulting in a high manufacturing cost.

In regard to the second group, the camera body may be provided with a calculator which calculates various compensation values for different types of interchangeable lens to correct the error. But, such a calculator may be complicated and very difficult to prepare. Thus, according to the prior art, estimated corrections described below are carried out.

In the case of compensating the error of the measured amount of light based on the information of a fully-open aperture, the compensation corresponding to the diameter of the exit pupil of the interchangeable lens is carried out to some degree, but no compensation corresponding to the position of the exit pupil is carried out. And, in the case of compensating the error of the measured amount of light based on the information of focal length, the compensation corresponding to the position of the exit pupil is carried out to some degree, but no compensation corresponding to the diameter of the exit pupil is carried out. Thus, according to the prior art, compensation with a high accuracy can not be accomplished.

An error related to the fully-open aperture also occurs when exposure control is taking place. Generally, an image is formed by a picture-taking lens (objective lens) with a highest illumination at the center, where the optical axis passes, and the illumination is reduced towards the periphery of the image. Such a reduction of illumination at the peripheral portions is great particularly when the lens is set at the fully-open aperture position or around this position because of the phenomenon of the vignetting. Therefore, when the lens is set at the fully-open aperture position, the illumination of the image averagedly estimated within a predetermined extent of area, e.g., an 18 mm diameter circle, including its center will be considerably less than the case of a stopped-down aperture position due to the great reduction of illumination at the peripheral portions; although the central illumination may be identical regardless of the aperture position. Thus, in an exposure control system for controlling the exposure based on the calculated aperture value, the amount of light actually exposed will be averagedly estimated as an under exposure, when the aperture is to be set equal to or near the fully-

open position according to the calculated aperture value. In such a way, an exposure error takes place.

SUMMARY OF THE INVENTION

Accordingly, it is an object of the present invention to provide an improved camera system with an interchangeable lens which can compensate errors related to the fully-open aperture.

It is another object of the present invention to provide an improved camera system with an interchangeable lens which can control the exposure with a high accuracy.

It is a further object of the present invention to provide an improved camera system with an interchangeable lens which can compensate the fully-open aperture light measurement error.

It is a still further object of the present invention to provide an improved camera system with an interchangeable lens which can compensate the fully-open aperture light measurement error not only when a different type of interchangeable lens is mounted but also when an interchangeable lens is mounted on a different type of camera body.

It is another object of the present invention to provide an improved camera system with an interchangeable lens which can compensate the fully-open aperture light measurement error with a simple structure.

It is yet another object of the present invention to provide an improved camera system with an interchangeable lens which can compensate an error of exposure control which occurs when the aperture is set to its fully-open position, so as to provide an accurate exposure control.

In accomplishing these and other objects, an improved camera system according to the present invention has an outstanding feature in that the data necessary to compensate the error related to the fully-open aperture is stored in each interchangeable lens in digital form. The error is compensated in the camera body by reading and taking the data into the camera body.

According to the present invention, a camera system having a camera body and an interchangeable objective lens selectively attachable to the camera body and to at least one different camera body is involved. The camera system according to the present invention comprises: means located in the interchangeable objective lens for storing a plurality of compensation values suitable to the first mentioned camera body and to the at least one different camera body, respectively, to prepare for each case of compensating an error in fully-open aperture light measurement; means located in the interchangeable objective lens for transmitting the compensation data to the camera body to which the interchangeable objective lens is attached; means located in the first mentioned camera body for registering the compensation from the transmitting means; means located in the first mentioned camera body for controlling the camera system so that a predetermined one of the compensation values stored in the storing means is registered in the registering means; means located in the first mentioned camera body for practicing a fully-open aperture light measurement through the interchangeable objective lens to produce light measuring information including the error; and means located in the first mentioned camera body for calculating correct exposure information in response to the compensation data registered in the registering means and the light measuring signal, in which the error included in the light measuring signal is removed by utilizing the compensation value registered in the registering means.

By the above arrangement, the fully-open aperture light measurement error can be compensated with a high accuracy.

Also, according to the present invention, the camera system, having a camera body to be combined with an interchangeable objective lens which stores an exposure compensation value, which relates to exposure information other than the aperture size, such as the exposure time, for compensating an exposure error upon fully-open aperture size control, comprises: means for receiving the exposure compensating value from the interchangeable objective lens; means for practicing a light measurement to produce exposure information; means for providing aperture size information and exposure time information in response to the exposure information; means for determining whether or not the calculated aperture size information corresponds to the fully-open aperture size; means responsive to the determining means for modifying the exposure time information by the exposure compensating value when the calculated aperture size information corresponds to the fully-open aperture size, and for adopting the exposure time information as it is when the calculated aperture size information does not correspond to the fully-open aperture size; means for controlling the aperture size in response to the providing means; and means for controlling the exposure time in response to the modifying and adopting means.

By the above arrangement, the exposure error that takes place when the aperture is so controlled to be set to the fully-open position can be compensated with a high accuracy.

BRIEF DESCRIPTION OF THE DRAWINGS

These and other objects and features of the present invention will become apparent from the following description taken in conjunction with preferred embodiments thereof with reference to the accompanying drawings, throughout which like parts are designated by like reference numerals, and in which:

FIG. **1** is a block diagram of a camera system according to a preferred embodiment of the present invention;

FIGS. **2***a* and **2***b* show a flow chart of the operation of the camera system according to one preferred embodiment of the present invention;

FIG. **2***c* is a flow chart of an interruption operation to be carried out within the flow chart of FIGS. **2***a* and **2***b;*

FIGS. **3***a*, **3***b*, **3***c* and **3***d* show a detailed flow cart of an exposure calculation step #32 shown in FIG. **2***b;*

FIGS. **4***a* and **4***b* show an exemplified circuit diagram of an interface circuit IF shown in FIG. **1**;

FIG. **5** shows an exemplified circuit diagram of a data producer **7** shown in FIG. **1**;

FIGS. **6** and **7** are time charts showing waveforms obtained from the circuit shown in FIGS. **4***a*, **4***b* and **5**;

FIG. **8** is a block diagram of a camera system according to another embodiment of the present invention;

FIG. **9** shows an exemplified circuit diagram of a serial data reading portion shown in FIG. **8**;

FIG. **10** is a time chart showing waveforms obtained from the circuit of FIG. **9**;

FIG. **11** is a time chart showing waveforms obtained from the circuit of FIG. **8**; and

FIGS. **12***a* and **12***b* show a flow chart according to said another embodiment of the present invention.

DESCRIPTION OF THE PREFERRED EMBODIMENT

Referring to FIG. **1**, a camera system according to the present invention comprises a first portion to be employed in a camera body (not shown) and a second portion to be employed in a camera accessory, which is mountable on the camera body. The first portion is shown on the left-hand side of a line L—L shown in FIG. **1** and the second portion is shown on the right-hand side thereof. In a circuit diagram of FIG. **1**, and also in FIGS. **4***a*, **4***b*, **8**, **9** and **11**, a broad line indicates a bundle of wires for transmitting a signal comprising a plurality of bits.

In FIG. **1**, a reference number **1** designates a micro-computer or a micro-processor which sequentially controls the thorough operation of the camera system and also calculates to provide exposure information. When a battery BA is loaded in the camera, a power-on-reset circuit PO1 produces a power-on-reset signal PR1 which is applied to a reset terminal RE of the micro-computer **1**. Accordingly, the micro-computer **1** is turned to a reset condition. A clock pulse generating means defined by an oscillator OSC is provided for producing a train of reference clock pulses CP which are applied to a clock terminal CL of the micro-computer **1** and also to other circuits for synchronizing the entire operation of the camera system shown in FIG. **1**. A display device DP is formed, for example, by a liquid crystal and is operated in a time divided manner by signals obtained from segment terminal SEG and common terminal COM of the micro-computer **1** for the display of exposure control value, exposure control mode, warning indication, and so on. The micro-computer **1**, the oscillator OSC and the display device DP, as well as other circuits, such as interface circuit IF, data selector MP1, inverters IN1 to IN5 and IN40, and AND gate AN0, receive electric power directly from the battery BA through a power line +E.

A normally open switch MS is a light measuring switch that closes when carrying out the light measuring operation. When the light measuring switch MS closes, an inverter IN1 produces a "HIGH" which is applied to an input i1 of the micro-computer **1**. In response to the "HIGH" to the input il, the micro-computer **1** reads data necessary for the exposure control and, at the same time, starts A-D (analog to digital) conversion of the signal from the light measuring circuit, exposure calculation and display operation. Furthermore, when the light measuring switch MS closes, a transistor BT1 conducts to provide electric power to a power line +VB, thus permitting the electric power supply to circuits in the camera body other than those which have been already receiving power from the power line +E. Moreover, when the transistor BT1 conducts, a power-on-reset PO2 produces a reset signal PR2, which is applied to each of exposure time control device CT and aperture control device CA, described later, for resetting them.

A circuit **3** enclosed by a broken line is an exposure control portion comprising exposure time control device CT, aperture control device CA, and pulse generator PG. The exposure time control device CT receives a fixed, or calculated, exposure time data Tvc. Tvc represents a value of time given in APEX numbering system. Similarly, other reference characters with a suffix of v, such as Av, Avo, Bv, Sv, Ev, represent values in APEX numbering system. Tvc is received from an output terminal OP1 of the micro-computer **1** and the time control device CT establishes a period of time relative to the data Tvc (i.e., a period of time 2^{-Tvc} from open-operation to close-operation of a shutter mechanism) using clock pulses CP so as to control the exposure time. The aperture control device CA receives a fixed, or calculated, stop-down degree data dAv from an output terminal OP2 of the micro-computer **1**, and also pulses from the pulse generator PG. The pulse generator PG is provided operatively in association with a ring **13**, which rotates together with a pin **15** in the interchangeable lens LE, and produces a number of pulses corresponding to the degree of rotation of the ring **13**. More particularly, the interchangeable lens LE has a pin **15** connected to a diaphragm for the simultaneous movement about the axis of the lens LE with respect to the change of aperture size of the diaphragm, and is also connected to a first spring (not shown) for urging the diaphragm to fully open the aperture. On the other hand, the ring **13** has a projection which is held in contact with the pin **15** by an urging force of a second spring (not shown) connected to ring **13**. The ring **13** further has a rack (not shown) which is engageable to a pawl (not shown). Since the second spring connected to the ring **13** is stronger than the first spring connected to the pin **15**, the ring **13** starts to rotate by the force of the second spring when the pawl disengages from the rack, and, at the same time, the rotation of the ring **13** is transmitted to the pin **15** causing reduction of the aperture size of the diaphragm. During the rotation of the ring **13**, the aperture control device CA counts the number of pulses from the pulse generator PG; the number of pulses corresponds to the degree of reduction of aperture size of the lens LE. The counted number is compared with the stop-down degree data dAv from the output OP1 of the micro-computer **1**, and when these two match with each other, the pawl is so actuated as to stop the rotation of the ring **13**, thus setting the diaphragm to a controlled aperture size.

A switch LS is a normally open switch provided for detecting whether the interchangeable lens LE is properly mounted on the camera or not. The switch LS closes when the interchangeable lens LE is mounted and locked to a camera mount, but it is maintained open when the locking is incomplete. When the switch LS closes, an inverter IN40 produces a "HIGH" which is applied to the micro-computer **1** through an input i4. In response to this, the micro-computer **1** starts to read data from the mounted lens LE and carries out an exposure calculation. On the contrary, when the switch LS is maintained open to provide a "LOW" to the input **4**, the micro-computer reads no data from the lens, but carries out other calculations as will be described later.

Referring back to FIG. **1**, a circuit portion enclosed by a broken line **5** is provided for producing exposure control data, and it includes light measuring circuit ME, A-D (analog to digital) converter AD, set aperture size signal producing device AS, set exposure time signal producing device TS, film sensitivity signal producing device SS, and mode signal producing device MS. The light measuring circuit ME is, for example, a TTL (through-the-lens) fully-open aperture metering type, and it produces a signal Bv-Avo-Avc in analog form and it is determined by the brightness Bv of an object, fully-opened aperture size Avo, and fully-open aperture light measurement error Avc (the error determined by the deviation of the light receiving element, which should be positioned at a predetermined distance from

the film surface, and by the position of the exit pupil of the mounted lens) caused by the change of the lens. The A-D converter AD receives the signal Bv-Avo-Avc in analog form from the light measuring circuit ME, and converts it to digital form by a clock pulse CP in response to a positive going pulse from an output 03 of the micro-computer 1. The converted signal Bv-Avo-Avc in digital form is applied to a data selector MP1 at an input IP2.

The set aperture size signal producing device AS produces a data Avs-Avo and provides it to the data selector MP1 and an input IP3.

The set exposure time signal producing device TS produces a digital signal representing a manually set exposure time by way of an exposure time setting device (not shown) provided in the camera body. The output of the set exposure time signal producing device TS is connected to input IP4 of the data selector MP1.

The film sensitivity signal producing device SS produces a digital signal representing a manually set film sensitivity by way of a film speed setting device (not shown) provided in the camera body. The output of the film sensitivity signal producing device SS is connected to input IP5 of the data selector MP1.

And, the mode signal producing device MS produces a digital signal representing a manually selected mode by way of a mode selecting device (not shown), from a number of modes which are: exposure control mode; and a flash-light photographing mode wherein the mode signal producing device MS receives from the flash-light device FL through terminal JF1 of flash-light device side and terminal JB5 of camera body side, a charge completion signal indicating that a main capacitor (not shown) in the flash-light device FL is fully charged. The output of the mode signal producing device MS is connected to input IP6 of the data selector MP1.

An interface circuit IF sequentially reads various data from the lens LE when it receives a "HIGH" from an output O2 of the micro-computer 1. When the interface circuit IF completes reading the data from the lens LE, the read data is sequentially produced from the interface circuit IF and transmitted through data selector MP1 and external data bus DB to the micro-computer 1 in response to the 4-bit data from an output OP3 of the micro-computer 1. A detail of the interface circuit IF is shown in FIGS. 4*a* and 4*b* and will be described later. The data selector MP1 has inputs IP1 to IP6 for receiving various data and transmits this data through the data bus DB to the micro-computer 1 in a selected sequence controlled by a 4-bit signal applied thereto at a selection terminal SL from the output OP3 of the micro-computer 1. A relationship between the data applied to the selection terminal SL of the data selector MP1 and the data produced from the data selector MP1 through the data bus DB is shown in Table 1 below.

TABLE 1

Selection SL	Terminal	Data Selector (MP1) Data Bus (DB) Selected terminal	Signification
0 0 0 0	(0H)	IP4	Tvs
0 0 0 1	(1H)	IP5	Sv
0 0 1 0	(2H)	IP6	Mode
0 0 1 1	(3H)	IP2	Measured light amount
0 1 0 0	(4H)	IP3	Avs-Avo
0 1 0 1	(5H)	IP1	Interface

TABLE 1-continued

Selection SL	Terminal	Data Selector (MP1) Data Bus (DB) Selected terminal	Signification
:	:	"	"
1 1 0 1	(DH)	"	"

As apparent from Table 1, the data applied to the selection terminal SL is 4-bits long, and for the sake of brevity, this 4-bit signal is also indicated with a hexadecimal numbering system, as shown in parentheses in Table 1. When the data applied to the selection terminal SL from the output OP3 is "0H" (i.e., 0 hexadecimal), the data selector MP1 selects exposure time data Tvs inputted to the terminal IP4; when the data to the selection terminal SL is "1H", the data selector MP1 selects film sensitivity data Sv inputted to the terminal IP5; when the data to the selection terminal SL is "2H", the data selector MP1 selects exposure control mode data inputted to the terminal IP6; when the data to the selection terminal SL is "3H", the data selector MP1 selects measured light amount data inputted to the terminal IP2; when the data to the selection terminal SL is "4H", the data selector MP1 selects set aperture size data Avs-Avo inputted to the terminal IP3; and when the data to the selection terminal SL is any one of "5H" to "DH", the data selector MP1 selects data concerning the lens LE inputted to the terminal IP1 from the interface circuit IF. The selected data by the data selector MP1 is applied to the micro-computer 1 through the data bus DB.

It is to be noted that the interface circuit IF produces the read data from the lens LE in a sequence controlled by the data "5H" to "DH" from the output OP3. It is also to be noted that the micro-computer 1 only produces data "0H" to "3H" when the signal to the input i4 is "LOW", i.e., when the lens detecting switch LS is maintained off, whereby no signal related to the lens LE is fed to the micro-computer 1.

A reference character FC designates a flash-light control for controlling the amount of flash-light to be emitted from the flash-light device FL from the camera side. The flash-light control FC produces an emission-start signal which is applied to the flash-light device FL through terminal JB6 of camera side and terminal JF2 of flash device side for effecting the emission of flash-light. Also, the flash-light control FC produces an emission-stop signal which is applied to the flash-light device FL through terminal JB7 of camera side and terminal JF3 of flash device side for stopping the emission of flash-light. The emission-start signal is produced, e.g., when the shutter is fully opened, and the emission-stop signed is produced, e.g., when an integrated amount of light reflected from an object to be photographed and passed through an objective lens and further reflected on a film surface reaches a predetermined level. When the main capacitor (not shown) provided in the flash-light device FL is charged to a predetermined level, the flash-light device FL produces a "HIGH" representing the completion of electric charge, which is applied to the terminal JF1 and, thereafter, by the emission-start signal from the terminal JF2, a xenon lamp (not shown) provided in the flash-light device FL starts to emit light. Then, by an emission-stop signal from the terminal JF3, the xenon lamp stops the light emission.

A release switch RS is provided to close relative to the operation of a shutter release mechanism. A safety switch CS is provided, which closes upon completion of film wind-up for one frame and opens upon completion of exposure control operation, thereby preventing the shutter from being released before it is ready to take a photograph. The release switch RS and the safety switch CS are connected, respectively, to inverters IN3 and IN4, which are in turn connected to two inputs of an AND gate AN0. An output of the AND gate AN0 is connected to an interruption input i5 of the micro-computer 1.

The micro-computer 1 has an output O1 which is connected to a release circuit RL. When the output O1 produces a "HIGH", the release circuit RL starts the shutter release operation. The output O1 is also connected to an inverter IN2 which is further connected to a base of a transistor BT1 through a suitable resistor. Therefore, even if the light measuring switch MS is turned off during the shutter release, the transistor BT1 is maintained in the conductive state.

As a means for producing a start signal, the micro-computer 1 has an output O2 connected to the interface circuit IF. The output O2 produces a "HIGH" while the interface circuit IF is reading data from the lens. The output O2 is further connected to an inverter IN5 and, in turn, to a base of a transistor BT2 through a suitable resistor. The transistor BT2 is provided as a means for providing electric power to the camera accessory. Thus, when the output O2 is producing a "HIGH", the inverter IN5 produces a "LOW" causing turn on of the transistor BT2. Thus, electric power is supplied through the power lines +VB and +VL, terminal JB1 of camera body and terminal JL1 of lens, to circuits in the lens.

In the lens LE, a data producer 7 is provided including a ROM RO1 (FIG. 5) serving as a fixed data storing means and previously stored with various fixed data related to the lens. The clock pulses CPL produced from the interface circuit IF in the camera body are applied to the data producer 7 as a synchronizing signal through a terminal JB2 on camera and a terminal JL2 on lens so as to control the transmission of address signals from the interface circuit IF to the data producer 7 and the transmission of read out data from the data producer 7 to the interface circuit IF through the same path defined by a line SB, a terminal JB3 on the camera and terminal JL3 on the lens. A block 9 encircled by a broken line is an information producing device, and it includes a focusing distance data producing device DS, which produces data corresponding to a focusing distance of a mounted interchangeable lens as set by the turning of a focusing distance control ring (not shown), and a focal length data producing device FS, which produces data corresponding to a focal length of a mounted zoom lens as set by the turning of a zooming ring (not shown). The data produced from the focusing distance data producing device DS and from the focal length data producing device FS are applied to the data producer 7 as address signals specifying a particular location in the ROM RO1. Thus, the ROM RO1 produces data corresponding to the set focusing distance (in absolute amount) or set focal length (in absolute amount). The operation of the above described camera system is given hereinbelow.

Referring to FIGS. 2*a*, 2*b* and 2*c*, a flow chart of sequential operation of the micro-computer 1 is shown. In the step #1, it is determined whether the input i1 is carrying "HIGH" or not, i.e., whether the light measuring switch MS is turned on or not. If the light measuring switch MS remains open to provide "LOW" to the input i1, the procedure advances to the step #2 and further to the step #3 or to the step #4 and #5; the detail will be described later. When the light measuring switch MS is turned on to provide "HIGH" to the input i1, the procedure advances from the step #1 to #6 so as to reset a timer register TR for counting time. A detail of this timer register TR will also be described later.

Then, in the step #7, it is determined whether the input i4 is carrying "HIGH" or not, i.e., whether the lens detecting switch LS is turned on or not. When the input i4 is receiving "LOW", the procedure advances to the step "9" for setting "HIGH" in a 1-bit discrimination register JF and, then, advances to the step #10. On the other hand, when the input i4 is receiving "HIGH", the procedure advance to the step #8 so as to produce "HIGH" from the output O2 of the micro-computer 1. Thus, the inverter IN5 produces "LOW" to conduct the transistor BT2, resulting in supply of electric power to the circuits 7 and 9 in the lens LE and, at the same time, interface circuit IF is so actuated to read data from the lens. Thereafter, the procedure advances to the step #10.

A further detailed operation will be described later in connection with FIGS. 4*a* and 4*b*, but here, it is to be noted that the circuits in lens are reset by a power-on-reset signal that starts the power supply to the lens caused by a "HIGH" produced from the output O2, and thereafter, the system is in a condition ready to transmit data from the lens to the camera body. By the above arrangement, the terminal for the power supply to the lens can also be used for transmitting a start signal for starting the data read out, thereby reducing the number of terminals that interconnect the camera body and camera accessory, e.g., lens. Such a reduction of the number of the terminals not only reduces the manufacturing cost, but also increases the reliability and durability of the camera system.

In the step #10, the micro-computer 1 produces "HIGH" from its output 03 and, in the succeeding step #11, the output O3 is turned to "LOW", whereby an A-D conversion start pulse is applied to the A-D converter AD for starting the A-D conversion of a light signal produced from the light measuring circuit ME. Then, a 4-bit data "0H" is set up in a register DR (not shown) and then, the micro-computer 1 produces the 4-bit data "0H" from its output OP3. In response to the 4-bit data "0H", the data selector MP1 produces the exposure time data Tvs inputted to the terminal IP4, as shown in Table 1, and the produced data Tvs is sent through the data bus DB to the micro-computer 1 wherein the data Tvs is stored in a certain resistor. Then, in the step #15, "1" is added to the content of the register DR. And, in the step #16, it is determined whether the register DR is carrying "4H" or not. If not, the procedure returns back to repeat the steps #13, #14 and #15.

Therefore, until the register DR carries "4H", the micro-computer 1 sequentially reads in various data from the data selector MP1 such that: when the register DR is carrying "0H", the exposure time data Tvs is read in as mentioned above; when the register DR is carrying "1H", the film sensitivity data Sv is read in; when the register DR is carrying "2H", the data representing the exposure control mode is read in; and when the register DR is carrying "3H", the data Bv-Avo-Avc

representing the brightness of the object is taken in. It is to be noted that by the time when the register DR is carrying "3H", the A-D conversion of the light signal in the A-D converter AD is completed and, therefore, by this time, the A-D converter AD is applying the converted light signal to the input IP2 of the data selector MP1. Then, when the register DR carries "4H", the procedure advances to the step #17.

In the step #17, it is determined whether the content of the 1-bit register JF is "1" or not. If the content is "1" as occurred when the lens detecting switch LS is maintained off, the procedure advances to the step #18 in which exposure calculation effected in the case of no lens, as will be described later, is carried out. Contrary, if the content of the register JF is "0" as occurred when a lens is mounted and the lens detecting switch LS is turned on, the procedure advances to the step #20 wherein the content of the register DR, which is at present "4H", is outputted from the output OP3. By this signal, the data selector MP1 takes in the data Avs-Avo applied to its terminal IP3 and, in the step #21, the micro-computer 1 reads in the data Avs-Avo through the data bus DB. Then in the step #22, "1" is added to the content of the register DR, thus, the register DR is now holding "5H".

Then, in the step #23, the micro-computer 1 waits until the input i3 receives "HIGH" from the interface circuit IF indicating that all the fixed and variant data from the lens are now stored in the interface circuit IF. Since the moment when the output 02 produces "HIGH" at the step #8, the interface circuit IF has been repeating a cycle of operation of producing serially an address signal which is applied through the line SB and terminals JB3 and JL3 to the ROM RO1 provided in the data producer 7 and receiving serially fixed data stored at a designated location in the ROM RO1 through the same path. When this cycle of operation is repeated for a number of times to store all the fixed data in the interface circuit IF, the information producing circuits DS and FS provided in the lens are actuated to produce address signals for designating locations in the ROM RO1, whereby variant data such as focusing distance as set by the amount of shift of the lens and focal length data as set by zooming the lens are transmitted from the ROM RO1 to the interface circuit IF in the camera body. When all the fixed and variable data are stored in the interface circuit IF, the interface circuit IF produces "HIGH" which is applied to the input i3 of the microcomputer 1.

When the input i3 receives "HIGH", the procedure advances to the step #24 for producing "LOW" from the output 02, thereby turning the transistor BT2 to a non-conductive state for stopping the power supply from the power-line +VL to the lens. Then, in the steps #25 et seq., the micro-computer 1 reads in the data stored in the interface circuit IF.

Before describing the operations carried out in the steps #25 et seq., the operations up to the step #24 are summarized hereinbelow.

First, the address data for designating a location in the ROM RO1 provided in the data producer 7 is transmitted from the camera body to the lens, and the fixed data stored in the designated location in the ROM RO1 is transmitted from the lens to the camera body. This operation is repeated for a number of times to transfer all the fixed data to the camera body. Then, coded information data produced from the information producing circuit 9 is used without any change as address data to designate locations in the ROM RO1, thereby variant data stored in the ROM RO1 is transmitted to the camera body.

With the above arrangement, the fixed data and the variant data are transmitted from the ROM RO1 to the camera body through the same path, whereby only one pair of interconnecting terminals are necessary; one terminal JB3 on camera body and other terminal JL3 on lens. The information producing circuit 9 produces coded data corresponding to an amount of shift from a reference position. Since the ROM RO1 produces data in absolute value based on the data from the information producing circuit 9, the arrangement of the information producing circuit 9 is very simple when compared with an arrangement of a prior art producing circuit that directly produces the data in absolute value from the coded pattern, because the information producing circuit 9, according to the present invention, produces data which has less bits than that produced from the prior art producing circuit. Furthermore, the information producing circuit 9, according to the present invention, can be assembled in a compact size with a small coded pattern. Moreover, since the transmission of an address signal from the camera body to the lens and the signal transmission of read out data from the lens to the camera body are carried out alternately at different times, only one pair of interconnecting terminals is necessary for the mutual transmission, thereby reducing the number of terminals between the camera body and the lens.

Referring back to FIG. 2*b*, when the input i3 receives "HIGH", the micro-computer 1 starts to sequentially read in the data temporarily stored in the interface circuit IF, in the step #25. This operation is carried out in the follow steps. The output OP3 sequentially produces data "5H" to "DH", each designating a particular data. The produced data "5H" to "DH" are sequentially applied both to the interface circuit IF and to the data selector MP1. When the data produced from the output OP3 is "5H", the interface circuit IF produces check data. Similarly, when the output is "6H", data Ave representing the light measurement error caused by the change of the lens is produced; when the output is "7H", data Avm representing the minimum aperture size is produced; when the output is "8H", data Avo representing the maximum aperture size is produced; when the output is "9H", data fw representing the shortest focal length is produced; when the output is "AH", data ft representing the longest focal length is produced; when the output "BH", data dEvo representing the error compensating data necessary to compensate an exposure error upon exposure control under the fully-open aperture is produced; when the output is "CH", data representing set focusing distance is produced; and when the output is "DH", data representing set focal length is produced. In this case, the data applied to the terminal IP1 of the data selector MP1 is outputted through the data bus DB in a manner shown in Table 1. And, the micro-computer 1 sequentially takes in the data through the data bus DB. When the micro-computer 1 has taken in all the data from the interface circuit IF, the content of the register DR becomes "EH", whereby the step advances from #28 to #29.

The transmission of the data from the lens to the micro-computer 1 can be summarized as follows. First, each data is transmitted serially to the interface circuit IF in which the data is temporarily latched, each data comprising a plurality of bits. Then, in response to the

signals from the micro-computer **1** each designating a particular data, the temporarily latched data is transmitted to the micro-computer **1** one after another, with each data being transmitted parallelly. While the interface circuit IF is temporarily storing the data from the lens, the micro-computer **1** is reading other data. This arrangement has an advantage in time saving when compared with an arrangement wherein data is taken into the micro-computer serially bit-by-bit.

In the step **#29**, it is determined whether or not a check data, which is produced when and while the lens is properly mounted on the camera, is included in the data from the interface circuit IF. If the lens is mounted properly, the micro-computer **1** first receives the check data having a code which is common to all the lens. When the check data is present, the procedure advances to the step **#30**; but when it is absent, the procedure advances to the step **#18**. The absence of the check data occurs not only when the lens is improperly mounted, but also when a camera accessory, such as a bellows, a reverse adaptor, a teleconverter, an extension ring, or the like, is mounted between the camera body and the lens.

In the step **#30**, the following calculation is carried out using the read in data Avc and A-D converted data Bv-Avo-Avc,

$$(Bv-Avo-Avc)+Avc=Bv-Avo.$$

Then, in the step **#31**, the following calculation is carried out using the calculated data Bv-Avo and the fully-open aperture data Avo,

$$(Bv-Avo)+Avo=Bv$$

thereby obtaining the data Bv representing the brightness.

Then, in the step **#32**, an exposure calculation based on the selected mode of exposure control is carried out. The details of the calculations carried out in each mode of operation will be described later in connection with FIGS. *3a*, *3b*, *3c* and *3d*.

When the calculations carried out in the step **#32** end, the micro-computer displays various control values, exposure control mode, and warnings, if any, using the calculated value, through the display device DP. Thereafter, the micro-computer carries out the step **#34**.

In the meantime, when it is determined in the step **#29** that no check data from the lens LE is dispatched, the procedure advances to the step **#18**. Before describing the calculation carried out in the step **#18**, it is to be noted that the step advances from **#17** to **#18** even when it is determined that the lens LE is not mounted, so long as the content of the register JF is "1". In the case where the selected mode is an automatic mode, i.e., any one of program mode, aperture preferred mode, or shutter speed preferred mode, it is understood that the photographer desires to obtain the proper exposure settings automatically. When the effective aperture value of the automatically set aperture is given as Avn, the light measuring circuit LM produces a signal:

$$Bv-Avn$$

and, in the step **#18**, a calculation

$$(Bv-Avn)+Sv=Tv$$

is carried out, so as to control the shutter speed with the calculated value Tv. On the other hand, as to the aperture size, an output "0" is produced so as not to carry out the stop-down of the aperture. In other words, in the TTL stop-down light measuring system, the shutter speed is controlled automatically.

On the other hand, when the selected mode is a manual mode, the shutter speed is controlled by a manually set amount and, in this case, an output "0" is produced so as not to carry out the stop-down of the aperture.

Furthermore, when the selected mode is a flash-photographing mode, the shutter speed is controlled by Tvf representing the limit of synchronizing shutter speed. In this case, "0" is produced so as not to carry out the stop-down of the aperture. The amount of light to be emitted from the flash device is determined by the detected light which has been reflected on the film surface and the sensitivity of the film in use. Then, in the step **#19**, data of the exposure control value, selected mode, warnings, if any, are displayed through the display device DP. Thereafter, the procedure advances to the step **#34**. In this case, the data related to the aperture size of the lens is transmitted to the camera side and, therefore, such a data will not be displayed.

In the step **#34**, exposure time control data Tvc is transmitted from the output OP1 to the exposure time control device CT, and in the step **#35**, the stop-down degree data dAv is transmitted from the output OP2 to the aperture control device CA. Then, in the step **#36**, the interruption terminal **i5** is brought to a condition ready to receive "HIGH", thereby enabling the interruption procedure shown in FIG. *2c*, which will be described later. Then, "0" is stored in the register JF and, thereafter, the procedure returns back to "START". Here, it is to be noted that "enabling of interruption" means that the terminal **i5** is in a condition ready to receive an interruption signal.

When the procedure returns back to "START", it is determined whether or not the input terminal **i1** is receiving "HIGH", as occurred when the light measuring switch MS is turned on. If yes, the procedure so advances as to repeat the above described steps **#6** and **#37**. This procedure is repeated again and again so long as the light measuring switch MS is maintained on. If no, as occurs when the input **i1** is receiving "LOW", the procedure advances to the step **#2**, in which it is determined whether a register TR used as a timer is holding a value greater than a predetermined value K, or not. If not, the procedure advances to the step **#3** for adding "1" to the content of the register TR and further advances to the step **#7** for repeating the above described procedure of data reading, calculation and display. The purpose of providing a routine of steps **#1**, **#2**, **#3**, **#7** is to carry out the procedure of **#7** to **#36** repeatedly for a predetermined number of times (K times) even after the turning off of the light measuring switch MS. Then, when the content of the register TR becomes greater than K, the procedure advances to the step **#4** for producing data that effects disabling of the display device DP. Then, in the step **#5**, it is prohibited to transmit the interruption signal through the input terminal **i5** for disabling the interruption. Thereafter, the procedure returns back to the step **#1**. Then, until the light measuring switch MS is turned on again, a routine of steps **#2**, **#4**, **#5** and **#1** is repeated again and again.

In summary, the micro-computer **1** operates as follows. While the light measuring switch MS is turned on,

a successive operation of data reading, calculation and display is repeated again and again, and this successive operation is carried out for a predetermined number of times (until the content of the timer register TR becomes K+1) even after the light measuring switch MS is turned off. This extra repetition is repeated, for example, 15 seconds after the turn-off of the light measuring switch MS.

When one cycle of operation is completed for the first time after the turn-on of the light measuring switch MS, the terminal i5 is brought to a condition ready to receive an interruption signal. Then, after completing the film wind-up of one frame, and when the release switch RS is turned on with the safety switch CS being turned on, the AND gate AN0 produces "HIGH" which is applied to the terminal i5. At this moment, since the system has completed the exposure calculation and is ready to receive the interruption, an interruption procedure, as shown in FIG. 2*c*, is carried out. It is to be noted that once the exposure data is calculated and, interruption is enabled, the interruption procedure as shown in FIG. 2*c* can be inserted at any time during the procedure other than the routine procedure of steps #1, #2, #4, #5. When the micro-computer 1 receives the interruption signal to the input i5, the procedure in the micro-computer 1 jumps to a particular address and carries out a procedure stored in the particular address. In order to cope with the interruption procedure requested during the data reading from the lens LE, "LOW" is produced from the output O2 in the step #40, and the data for disabling the display device DP is produced in the step #41. Then, in the step #42, "HIGH" is produced from the output O1 for actuating the release circuit RL and, at the same time, maintaining the transistor BT1 on by "LOW" from the inverter IN2. Thereafter, even if the light measuring switch MS is turned off, the transistor BT1 continues to hold the conductive state. When the release circuit RL actuates, an exposure control mechanism (not shown) starts its operation.

In the first place, the stop-down operation is carried out by the ring 13, and from the pulse generator PG, a number of pulses corresponding to the degree of rotation of the ring 13 are produced. The aperture control device CA counts the pulses from the pulse generator PG and compares the counted number with the stop-down degree data dAv obtained from the output OP2 of the micro-computer 1. When the counted number coincides with the data dAv, the aperture control device CA so controls the ring 13 as to stop its rotation, thereby defining the aperture size. In the case where the camera provided with the system shown in FIG. 1 is a single-reflex camera, the flip-up operation of a reflex mirror (not shown) is also carried out simultaneously with the above mentioned aperture setting. When the aperture setting and the flip-up operation of the reflex mirror are complete, a leading curtain (not shown) starts to scan and, at the same time, the exposure time control device CT starts to count exposure time determined by the data Tvc obtained from the output OP1.

Particularly, if the selected mode is the flash-photographing mode, the flash control device FC produces, e.g., when the shutter is fully opened, an emission-start signal which is applied to a the flash-light device FL through terminal JB6 of camera side and terminal JF2 of flash device side for effecting the emission of flash light. The flash-light control FC integrates the light which has been reflected from an object to be photographed and has passed through an objective lens and further reflected on a film surface, and when the integrated amount reaches a predetermined level, it produces an emission-stop signal which is applied to the flash-light device FL through terminal JB7 of camera side and terminal JF3 of flash device side for stopping the emission of flash-light.

Then, regardless of the selected mode, whether it be the flash-photographing mode or daylight-photographing mode, the trailing curtain (not shown) starts to scan when the shutter speed control device CT has a number corresponding to the exposure time data obtained from the output OP1. When the scanning of the trailing curtain completes, the safety switch CS turns off and, thereafter, the reflex mirror flips down and the aperture is fully opened to its maximum size, thereby completing the exposure operation.

By the turning off of the safety switch CS as occurs upon completion of the exposure operation, the inverter IN4 produces "LOW", thereby producing "LOW" from the output O1 at the step #44. By the "LOW" from the output O1, the release circuit RL is turned to inoperative and, at the same time, self-holding of the transistor BT1 to conductive state is released. Then, in the step #45, the acceptance of the interruption signal to the interruption terminal i5 is prohibited and, thereafter, the procedure returns back to "START". In this case, if the light measuring switch MS is held turned on, or if it is within 15 seconds from the turn off of the light measuring switch MS, the successive operation of the data reading, calculation and display is carried out repeatedly. Also, if the light measuring switch MS is held turned on with the safety switch CS being turned off, the successive operation of the data reading, calculation and display is carried out repeatedly and, at the same time, the micro-computer 1 is in a condition ready to accept the interruption signal. Under this condition, even if the release switch RS is also turned on, the turn on of the safety switch CS prevents the signal from the release switch RS from being transmitted through the AND gate AN0 and, therefore, no interruption signal will be applied to the micro-computer 1 through the input terminal i5. Therefore, it is possible to prevent the micro-computer 1 from erroneously carrying out the exposure control.

It is to be noted that the successive operation of data reading, calculation and display can be stopped immediately upon turn off of the light measuring switch MS, when the turn off of the light measuring switch MS is carried out after the completion of exposure control operation and before the completion of the film wind up operation, i.e., while the safety switch CS is turned off. This can be done by the following procedure. When it is determined that the input i1 is not receiving "HIGH" in the step #1, it is further determined whether the input i2 is receiving "HIGH" or not in a step before the step #2. When it is determined that the input i2 is receiving "HIGH", the procedure advances to the step #2, but it is determined that the input i2 is not receiving "HIGH", a data K+1 is set up in the timer register TR and, thereafter, the procedure advances to the step #2. In this case, since the content of the timer register TR is already greater than K, the procedure advances from the step #2 to the step #4 and further to the step #5 and, thereafter, repeating the routine procedure of steps #1, #2, #4 and #5. Thus, the successive operation of data reading, calculation and display can be stopped immediately upon turn off of the light measuring switch MS.

FIGS. 3*a*, 3*b*, 3*c* and 3*d* show a detailed flow chart of the step #32 shown in FIG. 2*b* for carrying out the exposure calculations under a mode selected from any one of: flash-photographing mode (FP mode) in which a photograph is taken with an aid of auxiliary light; programmed mode (P mode) in which the shutter speed and aperture size are automatically determined according to the set program; shutter speed preferred mode (S mode) in which the aperture size is automatically determined with respect to the preferred shutter speed; aperture size preferred mode (A mode) in which the shutter speed is automatically determined with respect to the preferred aperture size; and manual mode (M mode) in which the shutter speed and aperture size are manually set.

Referring particularly to FIG. 3*a*, it is determined in the step #50 whether or not the charge completion signal has been transferred from the flash-light device FL through the terminals JF1 and JB5 to the mode signal producing device MS, that is whether or not the selected mode is the flash-photographing (FP) mode. If the selected mode is the FP mode, the procedure advances to the step #51 in which the data Tvf representing the limit of flash synchronizing shutter speed (for example Tv=6) is changed to the exposure time control device Tvc. Then, a calculation

$$Bv+Sv-Tvf+k=Avf1$$

is carried out, wherein k is equal to or greater than zero. By the above calculation, an aperture size data Avf1, which is equal to kEv degrees stopped down from the appropriate shutter speed for the flash synchronizing shutter speed, is obtained. Then, in the step #53,

$$Iv+Sv-Dv=Avf2$$

is calculated, wherein Iv represents data in APEX numbering system corresponding to the maximum light amount that the flash-light device FL can produce, and Dv represents data in APEX numbering system corresponding to the set focusing distance of the mounted lens LE. Therefore, the calculated data Avf2 indicates the limit of aperture value under the photographing with the aid of flash light.

In the step #54, the two calculated values Avf1 and Avf2 are compared with each other. When the comparison results as:

$$Avf1 \leqq Avf2,$$

it is understood that the calculated value Avf1 is within said limit of aperture value under the photographing with the aid of the flash light. Thus, in this case, the procedure advances to the to the step #55. In the steps #55 and #56, it is determined whether the calculated value Avf1 is within an available range of aperture size of the mounted lens LE. More particularly, in the step #55, the determined:

$$Avf1 \geqq Avo$$

is carried out, and in the step #56, the determination:

$$Avf1 \leqq Avm$$

is carried out. If the calculated value Avf1 has a value between Avo and Avm, the procedure advances to the step #57 in which

$$Avf1-Avo$$

is set up as a degree of stop down dAv. Thereafter, the procedure continues from the step #33 described above in connection with FIG. 2*b*.

Contrary, if it is determined that

$$Avf1<Avo$$

in the step #55, the procedure advances to the step #58 for setting a data that produces a warning indicating that the calculated value Avf1 is beyond the full-open aperture size, and further to the step #59 for setting 0 for the degree of stop down dAv. Then, the procedure continues from the step #33.

Furthermore, in the step #56, if it is determined that

$$Avf1>Avm,$$

the procedure advances to the step #60 for setting a data that produces a warning indicating that the calculated value Avf1 is below the minimum-open aperture size, and further to the step #61 for setting Avm−Avo for the degree of stop down dAv.

Back to the step #54, if it is determined that

$$Avf1>Avf2,$$

meaning that the amount of light will be insufficient if photographed with an aperture size controlled with a value Avf1, the procedure advances to the step #62. Similar to the above, it is determined in the steps #62 and #63, whether the calculated value Avf2 is within an available range of aperture size of the mounted lens LE. More particularly, in the step #62, the determination:

$$Avf2 \geqq Avo$$

is carried out, and in the step #63, the determination:

$$Avf2 \leqq Avm$$

is carried out. If the calculated value Avf2 has a value between Avo and Avm, the procedure advances to the step #64 in which

$$Avf2-Avo$$

is set up as a degree of stop down dAv. Thereafter, the procedure continues from the step #33 described above in connection with FIG. 2*b*.

Contrary, if it is determined that

$$Avf2<Avo$$

in the step #62, the procedure advances to the step #58 for producing a warning described above and continues to carry out the steps #59, #33 et seq.

Furthermore, in the step #63, if it is determined that

$$Avf2>Avm,$$

the procedure advances to the step #60 for producing a warning described above and continues to carry out the steps #61, #33, et seq.

According to the above described operation under the flash-photographing mode (FP mode), the calculated aperture value Avf1 is equal to a value which is

stopped down by an amount of kEv from a preliminarily calculated aperture value plainly determined by the brightness Bv of the object, film sensitivity Sv and flash synchronizing shutter speed limit Tvf. The reason for this is explained below. First of all, the light receiving elements for the average measurement are generally distributed not with an equal density within a picture taking frame but with an intensive distribution at the center and sparse at the peripheral portions. When taking a photograph, the main object is usually located at the center, and particularly, when taking a photograph under the flash-photographing mode, the main object located at the center is less bright than the background. Thus, from the light receiving elements distributed densely at the center and sparsely at the perimeter, a signal based on the brightness of the center object, which is less bright than the surrounding object, will be produced. If the aperture size is controlled by this signal, the photograph will be over-exposured. From this view point, the calculated aperture value Avf1 is made equal to a value which is stopped down by an amount of kEv from the preliminarily calculated aperture value so as to properly expose the main object located at the center of the frame. The amount kEv can be selected empirically by taking a number of scenes, and picking a most desirable amount, for example, 1 Ev.

As has been described before, since the flash-light control device FC controls the amount of the flash light in relation to the received light from the object through the aperture and reflected on the film surface, the object will be properly exposed with the aid of flash light controlled by the device FC. Also, when there is a high possibility that the flash-light is insufficient because the focusing distance data Dv is relatively great, the control is carried out with the use of calculated aperture value Avf2 corresponding to the focusing distance so as to avoid the under-exposure of the main object due to the lack of total light amount of the flash-light device FL.

Referring now to FIG. 3*b*, the description is directed to the automatic exposure control operation and particularly to the operation under the programmed mode (P mode). When it is determined in the step #50 that the selected mode is not the flash-photographing mode, the procedure advances to the step #65 in which it is determined whether the selected mode is the programmed mode or not. When the selected mode is the programmed mode, the procedure advances to the step #66 in which a calculation

$$p(Bv+Sv)=Av \quad 0<p<1$$

is carried out. Then, in the steps #67 and #68, it is determined whether the calculated aperture value Av is within a controllable range between Avo and Avm or not. If

$$Avo \leqq Av \leqq Avm,$$

the procedure advances to the step #69 in which Av—Avo is set up as a degree of stop down dAv. Then, in the step #70,

$$Ev-Av=Tv$$

is carried out. And in the step #71, it is determined whether the aperture is fully opened or not, i.e., whether

$$dAv=Av-Avo=0$$

is satisfied or not. When the aperture is not fully opened, a relation

$$dAv \neq 0$$

is obtained and, therefore, in the step #73, the calculated aperture value Tv is used as a control data Tvc. Thereafter, the procedure continues from the step #33. Contrary, when the aperture is fully opened, a relation $dAv=0$,

is obtained. In this case, the exposure error will occur if the light amount is evaluated uniformly on every spot within the picture taking frame. Thus, using an exposure error compensating data dEvo, a calculation

$$Tv-dEvo$$

is carried out, and the calculated amount is used as a control data Tvc, in the step #72. Thereafter, the procedure continues from the step #33.

It is to be noted here that, when the aperture is so controlled as to be fully opened, the calculated amount Tv is varied by an amount dEvo. The reason for this is explained below. It is found that phenomenon of making the center bright and the peripheral portions dark due to the vignetting will not take place when the aperture is set to a position between the most reduced aperture size and one step stopped down from the fully-opened aperture size, but said phenomenon takes place when the aperture is set to the fully-opened aperture size. More particularly, when the aperture size becomes close to the fully-open aperture size, the amount of incident light on the picture taking frame at positions away from the optical axis is reduced in a greater degree than the $\cos^4$ law. Therefore, when the light amount is averagedly evaluated within a predetermined extent of area including the center of the picture taking frame, the photograph will be taken with an under-exposure. Thus the exposure operation requires compensation. The compensation is carried out such that when the aperture is so controlled as to be fully opened, the exposure time is prolonged for a period corresponding to the exposure error, thereby obtaining a correct exposure when the light amount is averagedly evaluated within the predetermined extent of area. It is preferable to carry out the compensation to each aperture size, which is close to the fully opened aperture size, by an amount corresponding to respective aperture size. To this end, however, it is necessary to provide a memory means for storing exposure error data corresponding to various aperture sizes in each lens. The employment of such a memory means results in complication of the circuit arrangement in the lens and, at the same time, in increase of processing time delaying the data transmission from the lens to the camera.

Furthermore, the cases that require the aperture to be set close to the fully opened size are rare, when compared with the cases that require the aperture to be set to the fully opened size. Thus, from a practical point of view, according to the embodiment shown, the compensation is effected only when the aperture is set to the fully opened size. In this way, the circuit necessary for the compensation can be prepared with a simple structure (only one data is needed to be memorized).

Referring again to FIG. 3*b*, when it is determined in the step #68 that

$Av > Avm$,

the procedure advances to the step #74 in which a calculation

$Ev - Avm = Tv$

is carried out. Then, in the step #75, it is determined whether a relation

$Tv \leqq Tvmax$

is satisfied or not. If the relation

$Tv \leqq Tvmax$

is satisfied, the procedure advances to the step #76 in which the calculated exposure time Tv is used as a control data Tvc. Then, in the step #77, a data Avm−Avo is set up as a degree of stop down dAv, and, thereafter, the procedure continues from the step #33. If it is determined in the step #75 that the relation

$Tv \leqq Tvmax$

is not satisfied, the procedure advances to the step #78 in which an alarm indicating that the calculated exposure time Tv is shorter than the minimum available exposure time. In this case, the data Tvmax is set up as an exposure time control data Tvc. Then, in the step #80, a data Avm−Avo is set up as a degree of stop down dAv, and, thereafter, the procedure continues from the step #33.

Back to the step #67, if it is determined that

$Av < Avo$,

the procedure advances to the step #81 in which 0, representing the fully opened aperture, is set up as a degree of the stop down dAv. Then, in the step #82, a calculation

$Ev - Avo = Tv$

is carried out. Since the aperture is controlled to be fully opened, a calculation

$Tv - dEvo$

is carried out, and the calculated result is used as an exposure control data Tvc in the step #83. Then, in the step #84, it is determined whether a relation

$Tvc \geqq Tvmin$

is satisfied or not. If is it determined that the relation

$Tvc \geqq Tvmin$

is satisfied, the procedure continues from the step #33. Contrary, if it is determined that the relation is such that $Tvc < Tvmin$,

the procedure advances to the step #85 in which an alarm data indicating that the calculated exposure time Tv−dEvo is longer than the maximum available exposure time. In this case, the data Tvmin is set up as an exposure time control data Tvc. Thereafter, the procedure continues from the step #33.

If the selected mode is shutter speed preferred mode (S mode), the procedure advances from the step #65 to the step #87 and further to the step #88 in which a calculation

$Bv + Sv - Tvs = Av$

is carried out. Thereafter, the procedure continues from the step #67 with the use of aperture data Av as calculated in the step #88.

Next, the operation when the selected mode is aperture size preferred mode (A mode), is described.

Referring to FIG. 3c, when the selected mode is aperture size preferred mode, the procedure advances from the step #87 to the #89 and further to the step #90 in which it is determined whether the aperture is set to the fully opened size or not, i.e., whether a relation

$Avs - Avo = 0$

is satisfied or not. When the aperture is set to the fully opened size, a relation

$Avs - Avo = 0$

is satisfied and, in this case, the procedure advances to the step #91 in which a calculation

$Bv + Sv - Avo = Tv$

is carried out. Then, in the step #92, a calculation

$Tv - dEvo$

is carried out, and the calculated data is set up as a control data Tvc. Then, in the step #93, it is determined

$Tvc < Tvmin$,

or not. If

$Tvc < Tvmin$,

the procedure advances to the step #94 in which 0 is set up as a degree of stop down dAv. And in the step #95, an alarm data indicating that the calculated exposure time Tvc is longer than the maximum available exposure time. Then, Tvmin is set up as a data Tvc for controlling the exposure time. Thereafter, the procedure continues from the step #33.

Back to the step #93, if

$Tvc \geqq Tvmin$,

the procedure advances to the step #97 in which it is determined

$Tvc > Tvmax$,

or not. If

$Tvc > Tvmax$,

the procedure advances to the step #98 for carrying out a calculation

$Ev - Tvmax = Av$.

And then, in the step #99, it is determined

$Av \leqq Avmax$,

or not. If

$Av \leqq Avmax$,

the procedure advances to the step #100 in which Tvmax is set up as a control data, and in the step #101, Av−Avo is set up as a degree of stop down data. Thereafter, the procedure continues from the step #33. In the step #99, if it is determined that

$Av > Avmax$,

the procedure advances to the step #102 an alarm data indicating that the calculated exposure time Tvc is shorter than the minimum available exposure time. Then, Tvmax is set up as a data Tvc for controlling the exposure time. Thereafter, the procedure continues from the step #33. In the step #97, if it is determined that

$Tvc \leqq Tvmax$,

the procedure advances to the step #105 in which 0 is set up as a degree of stop down dAv. Thereafter, the procedure continues from the step #33.

Back to the step #90, if it is determined that

$Avs - Avo \neq 0$,

the procedure advances to the step #106.

Referring to FIG. 3*d*, in the step #106, a calculation

$$Bv + Sv - Avs = Tv$$

is carried out. Then, in steps #107–#123, in a similar manner described above, when

$Tvmin \leqq Tv \leqq Tvmax$,

the calculated Tv is used as an exposure time control data Tvc, and, at the same time, Avs−Avo is set up as a degree of stop down dAv. If

$Tv < Tvmin$,

a calculation

$$Ev - Tvmin = Av$$

is carried out, and the calculated Av is compared with Avo. If,

$Avo \leqq Av$,

Av−Avo is set up as a degree of stop down dAv, and Tvmin is set up as an exposure time control data Tvc. If,

$Avo > Av$,

0 is set up as a degree of stop down dAv, and Tvmin is set up as an exposure time control data Tvc. And at the same time, an alarm is produced. Furthermore, if,

$Tv > Tvmax$,

a calculation

$$Ev - Tvmax = Av$$

is carried out, and the calculated Av is compared with Avm. If,

$Av \leqq Avm$,

Av−Avo is set up as a degree of stop down dAv, and Tvmax is set up as an exposure time control data Tvc. Contrary, if,

$Av > Avm$,

Avm−Avo is set up as a degree of stop down dAv, and Tvmax is set up as an exposure time control data Tvc. And at the same time, an alarm is produced.

Referring again to FIG. 3*c*, when it is determined in the step #89 that the selected mode is not an aperture size preferred mode, that is when the selected mode is a manual mode, the procedure advances to the step #124 for carrying out the control under the manual mode. In the step #124, a calculation

$$Bv + Sv = Ev$$

is carried out, and in the step #125, it is determined whether

$$Avs - Avo = 0,$$

or not. If it is determined that

$$Avs - Avo = 0,$$

the procedure advances to the step #126 in which a calculation

$$Ev - Avo - (Tvs - dEvo) = dEv$$

is carried out. Then, in the steps #127 and #128, Tvs is set up as an exposure time control data Tvc, and 0 is set up as a degree of stop down dAv. Then, the procedure continues from the step #33.

In the step #125, if it is determined that

$Avs - Avo \neq 0$,

the procedure advances to the step #129 for carrying out a calculation

$$Ev - Avs - Tvs = dEv.$$

Then, in the steps #130 and #131, Tvs is set up as an exposure time control data Tvc, and Avs−Avo is set up as a degree of stop down dAv. Then, the procedure continues from the step #33.

FIGS. 4*a* and 4*b* show a circuit diagram which is an example of the interface circuit IF shown in FIG. 1, FIG. 5 shows a circuit diagram which is an example of data producer 7 shown in FIG. 1, FIG. 6 shows a time chart of initial operation of the interface circuit IF, and FIG. 7 shows a time chart of ending operation of the interface circuit IF. Next, the description will be directed to the interface circuit IF and data producer shown in FIGS. 4*a*, 4*b*, and 5. First, various data stored in a ROM at various locations with various addresses and the significance of such data will be described with reference to Tables 2 and 3 given below.

The description is now directed to the data stored in ROM RO1 with reference to the above given Tables 2 and 3. It is to be noted that the data in Table 2 under the column "Data Example in ROM" are given as an example, and such data are for a zoom lens having a range of focal length between 50 mm and 135 mm, and a range of aperture size between F 3.5 and F 22. At a location specified by an address "00000001", data "11100" necessary for checking whether the lens is properly mounted or not is stored. The data "11100" is stored at the address "00000001" not only in the case of the above given zoom lens, but also in any other types of lenses. Also, the data for checking is not necessarily "11100", but can be any other combination of 5-bit data, so long as such data is common to all other types of lenses.

In the location specified by the address "00000010", a data dEvo, representing the fully-open aperture exposure error compensating data, is stored. Since the data dEvo for the exemplary zoom lens is dEvo=2/8, data "00010" corresponding to dEvo=2/8, as shown in Table 3, is stored. In the address "00000011", data Avm representing the minimum aperture size is stored, and in the exemplary case, Avm is F22 (=9 Av). Thus, a data "10010" representing F22 as indicated in Table 3, is stored in the address "00000011". In the address "00000100", a data Avo, representing the fully-open aperture size, is stored, and in the exemplary case, it is Avo=3.62 (=F 3.5). Thus, a data "01010" representing Avo=3.62, as indicated in Table 3, is stored in the address "00000100".

In the address "00000101", a data fw, representing the minimum focal length of the zoom lens, is stored, and in the exemplary case, the actually stored data is "01011" representing the focal length 50 mm, as understood from Table 3. In the address "00000110", a data ft, representing the maximum focal length of the zoom lens, is stored, and in the exemplary case, the stored data is "10001" representing the focal length 135 mm, as understood from Table 3. In the case where the interchangeable lens is not a zoom lens, i.e., a lens with a fixed focal length, a data indicating such a fixed focal length is stored in the address "00000101", and a data "11111" indicating that the interchangeable lens has a fixed focal length is stored in the address "00000110".

In each of the addresses "00001000", "00001001" and "00001010", data Avc representing the light measurement error caused by the exchange of the lens is stored. The reason for providing a plurality of data for the light measurement error is because, even when the lens to be mounted is the same, the light measurement error shows a different amount when the camera body has a different arrangement of the light receiving element, that is when the light receiving element is located at a different position relative to the exit pupil of the lens. According to the preferred embodiment, the ROM RO1 is prepared not only applicable to one type of the camera

body, but also to a number of types, such as 3, types of the camera bodies. From this point of view, if ROM RO1 is stored with only one data for the light measurement error, there will be an exposure error when the same lens is mounted on another type of camera body.

When a lens is mounted on a first type of the camera body, an address "00001000" is designated, when a lens is mounted on a second type of the camera body, an address "00001001" is designated, and when a lens is mounted on a third type of the camera body, an address "00001010" is designated. It is to be noted that, according to the embodiment described herein, the circuit shown in connection with FIGS. 4*a* and 4*b* is designed for the second type of the camera. And, according to the exemplification shown in Table 2, a data stored in the address "00001000" for the first type camera is "01010", representing Avc= +2/8; a data stored in the address "00001001" for the second type camera is "00101", representing Avc= $-\frac{3}{8}$; and a data stored in the address "00001010" for the third type camera is "01001", representing Avc= $+\frac{1}{8}$.

An example of data representing the light measurement error to be stored in other lenses is shown in Table 4 below.

TABLE 4

Lens	Address	Camera Type	Avc	Data
28 mm/F 2.8	08H	1st	0	01000
	09H	2d	+1/8	01001
	0AH	3d	−1/8	00111
35 mm/F 2.8	08H	1st	−1/8	00111
	09H	2d	0	01000
	0AH	3d	−2/8	00110
50 mm/F 1.4	08H	1st	0	01000
	09H	2d	0	01000
	0AH	3d	0	01000
85 mm/F 2	08H	1st	−2/8	00110
	09H	2d	−4/8	00100
	0AH	3d	−1/8	00111
135 mm/F 2.8	08H	1st	−4/8	00100
	09H	2d	−3/8	00101
	0AH	3d	−1/8	00111
300 mm/F 5.6	08H	1st	−4/8	00100
	09H	2d	+1/8	01001
	0AH	3d	0	01000

According to the example shown in Table 4, a 50 mm/F 1.4 lens is considered to be a standard lens. Accordingly, the light measurement error Avc for each of the first, second and third cameras in combination with the standard lens is rendered 0, and other errors Avc are calculated relatively to the standard lens. The above data are fixed data for the lens.

In the addresses "00010000" through "00011111", data of various focusing distances are stored as variable data. From the focusing distance data producing device DS, a 4-bit data corresponding to the shifted amount of the distance ring (not shown) from the nearest-focusing position is produced; and the produced 4-bit data is applied through a data selector MP2 to four least significant inputs r3, r2, r1 and r0 of the ROM RO1 for designating a particular location therein, thereby a data of focusing distance in absolute value stored in the designated location is read out from the ROM RO1. According to the example given in Table 3, if the data produced from the focusing distance data producing device DS is "0010", an address "00010010" defined by the data "0010" designates a particular location in the ROM RO1, whereby the ROM RO1 produces a data "01100" representing the focusing distance of 2 m (Dv=2). If the data produced from the device DS is "1011", an address "00011011" defined by the data "1011" is produced, designating a particular location in the ROM RO1, whereby the ROM RO1 produces a data "10101" representing the focusing distance of 9.5 m (Dv=6.5). It is to be noted that, since the focusing distance data is used for the flash-photographing calculation and, therefore, the data is given by the APEX numbering system, the produced data corresponds to a value $2^{\frac{1}{2}Dv}$ m wherein Dv changes with a rate of $\frac{1}{2}$. In contrast to this, it is possible to increase the range of data with a more precise rate of change by increasing the number of bits in the address data from the focusing distance data producing device DS and, at the same time, increasing the number of bits in the ROM RO1.

In the addresses "00100000" through "00101111", data of various focal lengths set by the zooming ring are stored for the case of zoom lens, and fixed data of "11111" indicating the fixed focal length is stored for the case of fixed focal length lens in each of said addresses. In a similar manner to the focusing distance, a 4-bit data corresponding to the shifted amount of zoom ring (not shown) from the minimum focal length is produced from the focal length data producing device FS; and the produced 4-bit data is applied through a data selector MP2 to four least significant inputs r3, r2, r1 and r0 of the ROM RO1 for designating a particular location therein, thereby a data of focal length in absolute value stored in the designated location is read out from the ROM RO1. According to the example given in Table 3, if the data produced from the focal length data producing device FS is "0010", an address "00100010" defined by the data "0010" designates a particular location in the ROM RO1, whereby the ROM RO1 produces a data "01011" representing the focal length of 50 mm. If the data produced from the device FS is "1010", an address "00101010" defined by the data "1010" is produced, designating a particular location in the ROM RO1, whereby the ROM RO1 produces a data "10000" representing the focal length of 105 mm. It is to be noted that, in the example shown in Table 3, the ROM RO1 is stored with various data of popular focal lengths, such as 50 mm, 85 mm, 100 mm, and so on; that is, focal lengths of fixed focal length lenses are available. In contrast to this, it is possible to obtain data of further precise focal lengths by increasing the number of bits in the address data and the focal length data.

Referring next to FIGS. 4*a* and 4*b*, the description is directed to the interface circuit IF. When the switches LS and MS close, the micro-computer 1 produces from its output O2 a "HIGH" (waveform O2 shown in FIG. 6) as a start signal for starting the data reading. The positive edge of this start signal actuates the one-shot circuit OS1, whereby the one-shot circuit OS1 produces a positive going pulse (waveform OS1 shown in FIG. 6). By the negative edge of this pulse, a flip-flop FF1 is turned to a set condition. The flip-flop FF1 is turned to a reset condition by a negative edge of a pulse from an OR gate OR1 which receives a pulse PR2 from the power-on-reset circuit PO2 (FIG. 1) or a pulse end 2 from an AND gate AN18 indicating the completion of data reading of the interface circuit IF, as will be described in detail later. The Q output of the flip-flop FF1 is connected to one input of AND gate AN1 and D input of D flip-flop DF1. The other input of the AND gate AN1 is connected to oscillator OSC shown in FIG. 1 for receiving a train of clock pulses CP. The output CPL of the AND gate AN1 is connected to clock termi-

nal CL of the D flip-flop DF1 and also to a terminal JB2, and further to a terminal JL2, when the lens LE is mounted, for supplying clock pulses CPL to the lens LE. Therefore, the D flip-flop DF1 accepts D input and produces "HIGH" (waveform DF1 in FIG. 6) from its Q output by the negative edge of a clock pulse CPL which is produced immediately after the setting of the flip-flop FF1. The Q output of the D flip-flop DF1 is connected to reset terminal of each of counters CO1, CO2 and CO3 and also to enable terminal of each of decoders DE2 and DE3, thereby releasing the reset condition of the counters CO1, CO2 and CO3 and turning the decoders DE2 and DE3 in a condition ready to produce a signal, by the "HIGH" from the Q output of the D flip-flop DF1. In other words, by the "HIGH" from the Q output of the D flip-flop DF1, it is ready to carry out the data transmission between the interface circuit IF and the lens. The output of the OR gate OR1 is also connected to a reset terminal of each of flip-flop FF3 and D flip-flops DF1, whereby the flip-flop FF3 is turned to a reset condition by the positive edge of the pulse from the OR gate OR1 and the D flip-flop DF1 is turned to a reset condition by the negative edge of the pulse from the OR gate OR1.

Referring now to FIG. 5, when the micro-computer 1 produces "HIGH" from its output 02, the transistor BT2 (FIG. 1) is turned on for supplying power from the camera body to the lens through the terminals JB1 and JL1. Accordingly, a power-on-reset circuit P03 is so actuated as to produce a pulse from its output. The output of the power-on-reset circuit PO3 is connected to each of flip-flops FF7 and FF5 and D flip-flop DF5. Thus, by the positive edge of the pulse from the power-on-reset circuit PO3, the flip-flop FF7 and D flip-flop DF5 are turned to reset condition, and by the negative edge of the pulse from the power-on-reset circuit PO3, the flip-flop FF5 is turned to set condition. It is to be noted that the power-on-reset PO3, flip-flop FF3 and D flip-flop DF5 are provided as a means for turning a timing control means (described later) to a condition ready to operate in response to the power supply to the lens through the terminals JB1 and JL1. Thereafter, by the negative edge of a clock pulse CPL, which is transmitted from the AND gate AN1 (FIG. 4*a*) through the terminals JB2 and JL2, the D flip-flop DF5 takes in a "HIGH" from the Q output of the flip-flop FF5 and, thus, the Q output of the D flip-flop DF5 produces "HIGH". The Q output of the D flip-flop DF5 is connected to reset terminal of counters CO4 and CO5 and also to enable terminal of a decoder DE4, whereby the "HIGH" from the Q output of the D flip-flop DF5 releases the reset condition of the counters CO4 and CO5 and, at the same time, turns the decoder DE4 to a condition ready to produce an output.

It is to be noted that by making the pulse width of the "HIGH" pulse from the one-shot-circuit OS1 wider than that from the power-on-reset PO3, the flip-flop FF1 shown in FIG. 4*a* will be turned to a set condition after the flip-flop FF5 shown in FIG. 5 is turned to a set condition. By the set condition of the flip-flop FF1, the AND gate AN1 produces a train of clock pulses and, therefore, by the negative edge of the first clock pulse CPL from the AND gate AN1, the D flip-flops DF1 and DF5 positively produce "HIGH" from their Q output, thereby the circuits in the camera body and those in the lens are released from the reset condition simultaneously.

The counter CO1 and decoder DE2 shown in FIG. 4*a* and the counter CO4 and decoder DE4 shown in FIG. 5 are provided for producing timing signals which synchronize the circuit operations between the circuits in the camera and the lens.

It is to be noted that the counter CO4 and decoder DE4 are provided as a means for controlling the timing of operations of data selector MP2, focusing distance data producing device DS, focal length data producing device FS, shift registers SR3 and SR4 and ROM RO1, and their associated elements such as, AND gates AN30, AN32, AN33, AN34 and AN35, OR gate OR5, inverter IN10, flip-flops FF6 and FF7, and counter CO5.

The counter CO1 is a 4-bit counter capable of counting 16 pulses, and it counts clock pulses CP. The counter CO4 is also a 4-bit counter, and it counts clock pulses CPL. The decoder DE2 has 3 inputs for receiving 3-bit signal from the least significant digit outputs CB2, CB1 and CB0 of the counter CO1 and, by the combination of 3-bit signal, the decoder DE2 produces a "HIGH" from one of its outputs TB7 to TB0. Similarly, the decoder DE4 has 3 inputs for receiving a 3-bit signal from the least significant digit outputs CL2, CL1 and CL0 of the counter CO4 and, by the combination of the 3-bit signal, the decoder DE4 produces a "HIGH" from one of its outputs TL7 and TL0. The waveforms of pulse signals from the outputs TB7 to TB0, which are identical to the pulse signals from the outputs TL7 to TL0, respectively, are shown in FIGS. 6 and 7. Also, the relationship between the combination of the 3-bit signal from the counter CO1 (or CO4) and the output signal produced from the decoder DE2 (or DE4) is shown in Table 5 below.

TABLE 5

Counter CO1 (CO4)				Decoder DE2 (DE4)						
CB2 or CL2	CB1 or CL1	CB0 or CL0	TB0 or TL0	TB1 or TL1	TB2 or TL2	TB3 or TL3	TB4 or TL4	TB5 or TL5	TB6 or TL6	TB7 or TL7
0	0	0	1	0	0	0	0	0	0	0
0	0	1	0	1	0	0	0	0	0	0
0	1	0	0	0	1	0	0	0	0	0
0	1	1	0	0	0	0	1	0	0	0
1	0	1	0	0	0	0	0	1	0	0
1	1	1	0	0	0	0	0	0	0	1

The counter CO2 shown in FIG. 4*a* is a 4-bit counter for counting pulses produced from output CB0 of the counter CO1, and has four outputs CS3, CS2, CS1 and CS0, which are connected to inputs of the decoder DE3, as well as the output CB0 of the counter CO1. By the combination of a 5-bit signal (CB0, CS3, CS2, CS1 and CS0), the decoder DE3 produces a "HIGH" from one of its outputs S16 to S0. The "HIGH" signal produced from the decoder DE3 is used for determining a transmitting address data from the interface circuit IF to the lens and the steps for reading data from the lens. From this viewpoint, a period in which the terminal S1 is producing "HIGH" is referred to as a period S1, and, in general terms, a period in which a terminal Sn (n is an integer between 1 and 16) is producing "HIGH" is referred to as a period Sn.

The relationship between the combination of the 5-bit signal applied to the decoder DE3 and the output signals produced from the decoder DE3 is shown in Table 6 below.

TABLE 6

Input					Decoder DE3 Output															
CS3	CS2	CS1	CS0	CB3	S0	S1	S2	S3	S4	S5	S6	S7	S8	S9	S10	S11	S12	S13	S14	S15	S16

1	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	1

Referring to FIG. 4*a*, one input of the AND gate AN7 is connected to the terminal TB6 of the decoder DE2, and the other input thereof is connected to the terminal CB3 of the counter CO1 through an inverter IN0. The output of the AND gate AN7 is connected to a clock terminal CL of the counter CO3. The counter CO3 is a 3-bit counter for providing data necessary for defining address data for the ROM RO1 provided in the lens, and has 3 outputs which are connected through a data selector MP0 to inputs Ba3, Ba2 and Ba1 of a shift register SR1. The counter CO3 counts pulses from the output TB6 of the decoder DE2 while the output CB3 of the counter CO1 is producing "LOW". Thus, when the output TB6 of the decoder DE2 produces "HIGH" during the period S0, the counter CO3 produces a 3-bit signal "001". Likewise, when the output TB6 produces "HIGH" during the period S2, the counter CO3 produces a 3-bit signal "010"; when the output TB6 produces "HIGH" during the period S4, the counter CO3 produces a 3-bit signal "011"; when the output TB6 produces "HIGH" during the period S6, the counter CO3 produces a 3-bit signal "100"; when the output TB6 produces "HIGH" during the period S8, the counter CO3 produces a 3-bit signal "101"; and when the output TB6 produces "HIGH" during the period S10, the counter CO3 produces a 3-bit signal "110".

The 3 outputs of the counter CO3 are also connected to 3 inputs of an AND gate AN20 with the output of the counter CO3 carrying the least significant bit being connected to an inverting input of the AND gate AN20. The output of the AND gate AN20 is connected to D input of a D flip-flop DF2. The D flip-flop DF2 has a clock terminal CL connected to the output TB0 of the decoder DE2, and a Q terminal connected to a select terminal SL of the data selector MP0. Thus, in response to the output "110" from the counter CO3 as produced when the output TB6 produces "HIGH" during the period S10, the AND gate AN20 produces a "HIGH". And then, when the output TB0 produces "HIGH" during the period S11, the D flip-flop DF2 produces "HIGH" from its Q terminal. Since the data selector MP0 is so designed that it produces an 8-bit signal as applied to its inputs in a group w0 when the signal applied to the select terminal SL is low, and that it produces an 8-bit signal as applied to its inputs in a group w1 when the signal applied to the select terminal SL is high, the data selector MP0 now produces an 8-bit signal as applied to its inputs in the group w1. The inputs in the group w1 have the lowest bit and the four upper bits connected to ground, as shown, and the remaining 3-bits connected to the counter CO3. While on the other hand, the 8 inputs in the group w2 are so connected to the ground and the power source +E as to produce a fixed signal "00010010".

Therefore, from the data selector MP0, a signal of the group w1 determined by the output of the counter CO3 is produced up to the period S10, and from the period S11 on, the signal of the group w0, i.e., the address data indicating the location where the light measurement error data Avc for the camera body is stored is produced.

The shift register SR1 shown in FIG. 4*a* is an 8-bit shift register having 8 inputs Ba0 to Ba7. While the switching terminal SP of the shift register SR1 is receiving "HIGH", and when the positive edge of a clock pulse CP is applied to the clock terminal CL, the shift register SR1 simultaneously and parallelly stores an 8-bit signal applied to its 8 inputs Ba7 to Ba0. Contrary, while the switching terminal SP of the shift register SR1 is receiving "LOW", the positive edges of the clock pulses CP sequentially send out the stored 8-bit signal bit-by-bit from the most significant bit serially through the output terminal.

One input of an AND gate AN2 is connected to the output TB6, and one input of an AND gate AN3 is connected to the output TB7. The other inputs of the AND gates AN2 and AN3 are connected to the pulse generator for receiving clock pulses CP. The output of the AND gate AN2 is connected to a set terminal of a flip-flop FF2, and the output of the AND gate AN3 is connected to a reset terminal of the flip-flop FF2. A Q output of the flip-flop FF2 is connected to the switching terminal SP of the shift register SR1. Therefore, the flip-flop FF2 is turned to a set condition by the negative edge of a clock pulse CP produced while the terminal TB6 is "HIGH", and is turned to a reset condition by the negative edge of a clock pulse CP produced while the terminal TB7 is "HIGH" (See waveforms FF2 shown in FIGS. 6 and 7.). Accordingly, the shift register SR1 stores the 8-bit signal by the positive edge of the "HIGH" from the terminal TB7, and sequentially sends out the stored 8-bit signal by the sequential "HIGH" signals from the terminals TB0 and TB6. The counter CO3, D flip-flop DF2, data selector MP0, flip-flop FF2, shift register SR1, AND gates AN2, AN3, AN7 and

AN20, and inverter IN0 define a means for producing address data for the camera accessory.

Referring to FIG. 4*a*, a set terminal of a flip-flop FF3 is connected to an output of AND gate AN16 (FIG. 4*b*) for receiving a signal end1. The AND gate AN16 has one input connected to the terminal TB6 of the decoder DE2 and the other input connected to the terminal S14 of the decoder DE3. Therefore, during a period S14 and when the terminal TB6 produces a pulse, the signal end1 is produced from the AND gate AN16 and is applied to the set terminal of the flip-flop FF3. The signal end1 is produced when the reading of fixed data from the lens is completed. Therefore, after the signal end1, it is not necessary to produce any address data from the interface circuit IF. Thus, when the flip-flop FF3 is turned to a set condition by the signal end1, it produces "LOW" from its $\overline{Q}$ terminal, whereby an AND gate AN4, having its one input connected to the $\overline{Q}$ terminal, produces "LOW" to turn a switching circuit SC1 off. The other input of the AND gate AN4 is connected to the output CB3 of the counter CO1. Thus, the AND gate AN4 produces "HIGH" when the terminal CB3 of the counter CO1 produces "HIGH" while the $\overline{Q}$ terminal of the flip-flop FF3 is producing "HIGH", i.e., during a period from the generation of "HIGH" from the OR gate OR1 until the generation of the signal end1. When the AND gate AN4 produces "HIGH", the switching circuit SC1 is turned on to transmit address data produced from the shift register SR1 to the lens through the terminals JB3 and JL3.

An OR gate OR3 has two inputs: one input is connected to the Q terminal of the flip-flop FF3; and the other is connected to the terminal CB3 of the counter CO1 through an inverter IN6. The output of the OR gate OR3 is connected to a control terminal of a switching circuit SC2 and also to one input of an AND gate AN5. The other input of the AND gate AN5 is connected to the terminal TB5 of the decoder DE2, and the output of the AND gate AN5 is connected to a latch terminal L of a latch circuit LA. The switching circuit SC2 is connected between the terminal JB3 and an IN terminal of a shift register SR2, provided as a means for reading accessory data. The shift register SR2 sequentially stores the signal applied at its IN terminal in synchronized relation with the negative edge of the clock pulse CP, and produces the stored signal from its outputs Bb0 and Bb4. Thus, the OR gate OR3 produces "HIGH" when the output CB3 of the counter CO1 produces "LOW" and when the flip-flop FF3 is in reset condition producing "HIGH" from its Q output (a period from the start of data reading in the lens until the end of fixed data reading of all the data in the lens). And, when the OR gate OR3 is producing "HIGH", the switching circuit SC2 is turned on to transmit signals from the terminal JB3 to the shift register SR2.

As apparent from the above, the switching circuits SC1 and SC2 are turned on alternately, thus preventing the simultaneous turn of the switching circuits SC1 and SC2. In this manner, the address data produced from the shift register SR1 is transmitted through the switching circuit SC1 and terminals JB3 and JL3 to the lens while the switching circuit SC1 is turned on, and the lens data from the lens is transmitted through the terminals JL3 and JB3 and the switching circuit SC2 to the shift register SR2 while the switching circuit SC2 is turned on, thereby preventing any interference between the address data and lens data. The outputs Bb4 and Bb0 of the shift register SR2 are connected to a latch circuit LA, so that the latch circuit LA latches the data at the outputs Bb4 to Bb0 in response to the positive edge of a pulse from the terminal TB5 while the OR gate OR3 is producing "HIGH". The switching circuits SC1 and SC2, flip-flop FF3, AND gate AN4, OR gate OR3 and inverter IN6 define a first switching means provided in the camera body for switching the direction of signal propagation between the camera body and the lens through the terminals JB3 and JL3.

Referring to FIG. 4*b*, the output of the latch LA is connected to each of registers REG0 to REG8. The registers REG0 to REG8, each having a latch terminal L, are connected to AND gates AN10 to AN18, at respective latch terminals L. One of the inputs of AND gates AN10 to AN18 are connected to each other and further to the terminal TB6 of the decoder DE2, and other of the inputs thereof are connected to terminals S2, S4, S6, S8, S10, S12, S14, S15 and S16 of the decoder DE3, respectively. The output of the AND gate AN18 produces an end2 signal indicating that reading and storing of all data from the lens are completed. The output of the AND gate AN18 is connected not only to the latch terminal L of the register REG8, but also to a set terminal S of a flip-flop FF4 (FIG. 4*a*). The Q terminal of the flip-flop FF4 is connected to the input i3 of the micro-computer 1 (FIG. 1), and the reset terminal R thereof is connected to an OR gate OR2. The OR gate OR2 has two inputs: one is connected to the output PR2 of the power-on-reset PO2 (FIG. 1); and the other is connected to output a8 of a decoder DE1, which will be described below. Therefore, the flip-flop FF4 is turned to reset condition when the power-on-reset circuit PO2 produces a pulse from its output PR2 in response to the turn on of the light measurement switch MS, and is turned to set condition when the AND gate AN18 produces the signal end2 upon completion of data reading and storing from the lens. The output a8 of the decoder DE1, as will be described below, produces "HIGH" at the end of data transmission from the interface circuit IF to the micro-computer 1 and, therefore, the flip-flop FF4 is turned to reset the condition at the end of data transmission from the interface circuit IF to the micro-computer 1.

Referring to FIG. 4*a*, the decoder DE1 receives data from the output OP3 of the micro-computer 1 and produces a "HIGH" from one of its outputs a0 to a8 depending on the received data from the micro-computer 1. A relationship between the input data and output data of the decoder DE1 is shown below in Table 7.

The outputs a0 to a8 of the decoder DE1 are connected to chip select terminals CS of the registers REG0 to REG8, respectively. When the chip select terminal CS of a particular register receives "HIGH" from the decoder DE1, said particular register provides data stored therein to the input IP1 of the data selector MP1 and further to the micro-computer 1.

Referring to FIG. 5, an AND gate AN30 has two. inputs: one is connected to the output CL3 of the counter CO4; and the other is connected to output $\overline{FD}$ of $\overline{Q}$ terminal of the flip-flop FF7. The output of the AND gate AN30 is connected to the switching circuit SC3, which is connected between the terminal JL3 and input of a shift register SR3. Furthermore, the clock input CL of the shift register SR3 is connected to the terminal JL2 for receiving a train of clock pulses CPL. Thus, while the switching circuit SC3 is on, the shift register SR3 sequentially stores the address data a from the camera body through the terminals JB3 and JL3 in response to the negative edge of the clock pulses, thereby producing an address data from its terminals La0 to La6. An AND gate AN35 is provided having its one input connected to the output La3 of the shift register SR3, and the other input connected to the terminal TL7 of the decoder DE4. When the output La3 produces "HIGH" while the terminal TL7 is producing "HIGH", the AND gate AN35 produces "HIGH". That is, the AND gate AN35 produces "HIGH" when the last address data, which is either "00001000", "00001001" or "00001010" for designating the fixed data of light measurement error data Avc, is sent from the camera body to the lens. The output of the AND gate AN35 is connected to a set terminal of a flip-flop FF7. Therefore, the flip-flop FF7 is turned to a set condition when the output La3 produces "HIGH" (i.e., when the last address for the fixed data is applied to the shift register SR3) while the terminal TL7 is producing "HIGH". When the flip-flop FF7 is turned to the set condition, its output FD of Q terminal produces "HIGH" and its output $\overline{FD}$ of $\overline{Q}$ terminal produces "LOW". An AND gate AN32 has two inputs: one is connected to the output FD of Q terminal of the flip-flop FF7; and the other is connected to the terminal TL6 of the decoder DE4. The output of the AND gate AN32 is connected to a clock terminal CL of a counter CO5. Therefore, the outputs Ca1 and Ca0 of the counter CO5 produce a 2-bit signal "01" when the flip-flop FF7 produces "HIGH" from its output FD of the Q terminal and when the output TL6 produces "HIGH" during a period S12 in the next sequence. Furthermore, the outputs Ca1 and Ca0 of the counter CO5 produce a 2-bit signal "10" when the output TL6 produces "HIGH" during a period S13 in the next sequence.

The outputs Ca1 and Ca0 of the counter CO5 are connected to the data selector MP2 and, more particularly, to the data input portions d2 and d3 and also to selection terminal SL. The data input portion d1 of the data selector MP2 is connected to the outputs La0 to La6 of the shift register SR3. The data input portion d2 has its most significant bit terminal grounded, the second and third bit terminals from the most significant bit terminal are connected to the outputs Ca1 and Ca0 of the counter CO5, and the remaining 4 bit terminals are connected to the outputs of the focusing distance data producing device DS. The data input portion d3 has its most significant bit terminal grounded, the second and third bit terminals from the most significant bit terminal are connected to the outputs Ca1 and Ca0 of the counter CO5, and the remaining 4 bit terminals are connected to the outputs of the focal length data producing device FS.

When the selection terminal SL receives "00", the data selector MP2 produces data applied to its input portion d1. Similarly, when the selection terminal SL receives "01", the data selector MP2 produces data applied to its input portion d2, and when the selection terminal SL receives "11", the data selector MP2 produces data applied to its input portion d3. Therefore, until the terminal TL6 produces "HIGH" during a period of S14, the data selector MP2 produces address data which has been transmitted from the camera body through the shift register SR3. And from that time until the terminal TL6 produces a "HIGH" during a period S15, the data selector MP2 produces address data concerning the focusing distance applied to the input portion d2, and thereafter, the data selector MP2 produces address data concerning the focal length applied to the input portion d3. It is to be noted that the shift register SR3, data producing devices DS and FS and data selector MP2 are provided as a means for designating address in the ROM (RO1).

The 7 outputs of the data selector MP2 are connected to the lower 7 inputs r6 to r0 of the ROM RO1. The remaining input r7 of the ROM RO1 is connected to ground. As shown in Table 2, various data is stored in the ROM RO1 at various locations which can be specified by the addresses. Therefore, by the address data applied to the inputs r0 to r7 of the ROM RO1, data stored in a particular location is read out and produced as a 4-bit signal from the ROM RO1. The 4 outputs of the ROM RO1, serving as an accessory data producing means, are connected to 4 upper-bit inputs Lb4 to Lb7 of a shift register SR4. The remaining 3 inputs Lb2 to Lb0 of the shift register SR4 are grounded. The shift register SR4, AND gates AN33 and AN34, and flip-flop FF6 are arranged in the same manner as the above described shift register SR1, AND gates AN2 and AN3, and flip-flop FF2 shown in FIG. 4*a*. Thus, by the positive edge of a pulse from the terminal TL7, the shift register SR4 simultaneously stores the data applied to its inputs Lb7 to Lb0 and, thereafter, by the positive edge of clock pulses applied to the clock terminal CL, the stored data is sequentially sent out from its output bit-by-bit.

An OR gate OR5 has two inputs: one is connected to an output CL3 of a counter CO4 through an inverter IN10; and the other is connected to the output FD of the Q terminal of the flip-flop FF7. The output of the OR gate OR5 is connected to a control input of a switching circuit SC4, which is connected between the output of the shift register SR4 and the terminal JL3. By the arrangement of the OR gate OR5, switching circuit SC4, and by the arrangement of AND gate AN30 and switching circuit SC3, the switching circuits SC3 and SC4 turn on alternately. More specifically, the switching circuit SC3 turns on when the output FD of Q terminal of flip-flop FF7 is "LOW" (i.e., while the fixed data of the lens is transmitted) and when the output CL3 of the counter CO4 produces "HIGH", thereby transmitting address data from the camera body to the shift register SR3 through the terminals JB3 and JL3. And, the switching circuit SC4 turns on when the output CL3 of the counter CO4 produces a "LOW", thereby transmitting the data read out from the ROM RO1 to the camera body through the same terminals JL3 and

JB3. In this manner, address data and fixed data from the ROM RO1 are transmitted alternately through the same and single transmission line between the terminals JB3 and JL3. Thereafter, when the output FD of Q terminal of the flip-flop FF7 produces "HIGH", only the switching circuit SC4 is maintained turned on, thereby transmitting variable data, such as focusing distance data and focal length data, to the camera body through the same terminals JL3 and JB3. It is to be noted that the switching circuits SC3 and SC4, flip-flop FF7, AND gate AN30, OR gate OR5 and inverter IN10 define a second switching means provided in the lens for switching the direction of the signal propagation between the camera body and the lens.

Next, the description is directed to the operation of circuits of FIGS. 4*a*, 4*b* and 5 with reference to the time chart shown in FIGS. 6 and 7. When the output 02 of the micro-computer 1 produces "HIGH" (FIG. 6, waveform 02), the one-shot circuit OS1 produces a pulse (FIG. 6, waveform OS1) for turning the flip-flop FF1 to a set condition. Then, by the positive edge of a next clock pulse, the D flip-flop DF1 produces "HIGH" from its Q output, thereby releasing the reset condition of the counters CO1, CO2 and CO3 and, at the same time, setting the decoders DE2 and DE3 in a condition ready to produce an output. Furthermore, when the flip-flop FF1 is turned to the set condition, the AND gate AN1 produces clock pulses CPL (FIG. 6, waveform CPL), which is applied to the circuit of FIG. 5 provided in the lens through the terminals JB2 and JL2.

In the meantime, by the "HIGH" from the output O2 of the micro-computer 1, the power supply transistor BT2 conducts to supply electric power to the circuit of FIG. 5 through the terminals JB1 and JL1. When the terminal JL1 receives power from the camera body, the power-on-reset circuit PO3 produces a pulse; and by the positive edge of this pulse, the flip-flop FF7 and D flip-flop DF5 are turned to the reset condition; and also by the negative edge of this pulse, the flip-flop FF5 is turned to the set condition. Then, by the positive edge of the first clock pulse CPL, the Q output of the D flip-flop DF5 produces a "HIGH", thereby releasing the reset condition of the counters CO4 and CO5 and, at the same time, putting the decoder DE4 in a condition ready for producing an output. This completes the initial preparation for the data transfer operation.

Next, referring particularly to FIG. 4*a*, when the terminal TB6 produces "HIGH" during a period S0, the counter CO3 produces a data "001" which is applied to the shift register SR1 through a data selector MP0. Then when the terminal TB7 produces "HIGH" immediately thereafter, the shift register SR1 stores the data "001", thus, the shift register SR1 is now holding an 8-bit data "00000010". Then, in the next period S1, the shift register SR1 sequentially sends out the data "00000010" bit-by-bit in response to the positive edges of the pulses from the terminals TB0 to TB7. Thus sent out data is transmitted serially through the switching circuit SC1, terminals JB3 and JL3 to the lens. During this moment, since the switching circuit SC3 in FIG. 5 is on, the data is sequentially stored in the shift register SR3 in response to the negative edges of the clock pulses CPL (FIG. 6, waveforms La0, La1 and La2). It is to be noted that the shift register SR1 sends out 8 bits of signal, but the shift register SR3 accommodates only 7 bits. Therefore, when the shift register SR3 stores the upper 7 bits "0000001" from the shift register SR1, the stored data "0000001" is transmitted through the data selector MP2 to the inputs r6 to r0 of the ROM RO1 as a part of address data (FIG. 6, waveforms SB, La0, La1 and La2), and, thereupon, the ROM RO1 receives 8-bit address data "00000001" to its inputs r7 to r0, thereby producing a data stored in the designated address "00000001". More specifically, by the negative edge of a clock pulse produced when the terminal TL6 is "HIGH" during the period S1, the shift register SR3 produces from its outputs La6 to La0 the data "0000001" (FIG. 6, waveforms La0, La1 and La2), thereby specifying a location in the ROM RO1 with an address "00000001". In the specified location in the ROM RO1, a data for check "11100", as shown in Table 2, is stored, and is produced from the ROM RO1. The data "11100" produced from the ROM RO1 is stored in the shift register SR4 in response to the positive edge of a pulse from the terminal TL7.

Then, in the next period S2, since the output CL3 of the counter CO4 produces "LOW" while the terminals TL0 to TL7 produce pulses, the data sequentially produced from the outputs Lb7 to Lb0 of the shift register SR4 in response to the positive edges of the pulses from the terminals TL0 to TL7 is serially transmitted through the switching circuit SC4, terminals JL3 and JB3 to the camera body (FIG. 6, waveform SB).

In FIG. 4*a*, during the period S2 in which the data is transmitted from the lens to the camera body, the output CB3 of the counter CO1 is maintained "LOW", thereby turning on the switching circuit SC2. Thus, the data for check "11100" transmitted to the camera body through the terminals JL3 and JB3 is applied through the switching circuit SC2 and stored in the shift register SR2 in response to the negative edges of the clock pulses CP (FIG. 6, waveform Bb0 to Bb4). Then, by the negative edge of the clock pulse CP produced from the terminal TB4, the shift register SR2 produces "11100" (FIG. 6, waveforms Bb0 to Bb4). And by the positive edge of the pulse produced from the AND gate AN5 in response to the pulse from the terminal TB5 (FIG. 6, waveform AN5), that data from the shift register SR2 is latched in the latch circuit LA. Then, by the pulse from the terminal TB6, the AND gate AN10 produces a pulse. By the positive edge of this pulse, the register REG0 stores the data from the latch circuit LA (FIG. 6, waveform AN10).

During the period S2, the AND gate AN7 produces a pulse in response to the pulse from the terminal TB6, thereby producing data "010" from the counter CO3. Then, by the pulse produced from the terminal TB7, the shift register SR1 stores the data "010" from the counter CO3. Thus, the shift register SR1 is now holding a data "0000001". Then, in the next period S3, the output CB3 of the counter CO1 produces "HIGH", thereby turning the switching circuit SC1 on and, furthermore, the output CL3 of the counter CO4, shown in FIG. 5, produces "HIGH", thereby turning the switching circuit SC3 on. As a consequence, the upper 7-bit data "0000010" from the shift register SR1 is transferred to the shift register SR3 (FIG. 5), in a similar manner described above. The data "0000010" is further transferred through the data selector MP2 to the ROM RO1 at its terminals r6 to r0. Thus, the ROM RO1 receives an address data "00000010" to its inputs r7 to r0, thereby producing a data dEvo representing the exposure difference. According to the example given in Table 2, the exposure difference dEvo is shown as dEvo=2/8 (the address for this data in ROM RO1 is

"00010"), but in the time chart given in FIG. 6, the exposure difference dEvo is shown as dEvo=4/8 (the address for this data in ROM RO1 is "00100").

During a period S4, both the output CB3 of the counter CO1 and the output CL3 of the counter CO4 produce "LOW". Therefore, the switching circuits SC2 and SC4 turn on so as to transfer the data "00100" stored in the shift register SR4 to the shift register SR2 in a similar manner described above. And, thereafter, by a pulse produced from the terminal TB5, the data "00100" in the shift register SR2 is latched in the latch circuit LA. And then, by a pulse produced from the terminal TB6, the AND gate AN11 produces a pulse (FIG. 6, waveform AN11), thereby the data "00100" representing the exposure difference dEvo is stored in the register REG1.

In a similar manner, during a period S5, the address data "00000110" (which will be revised to "00000011" in later stage) is transmitted to the lens and, during a period S6, the Avm data representing the minimum aperture size, such as "11010" shown in Table 2, is transmitted from the ROM RO1 to the camera body and, in response to a pulse from the terminal TB6, the Avm data "11010" is stored in the register REG2.

During a period S7, the address data "00001000" (which will be revised to "00000100" in a later stage) is transmitted to the lens and, during a period S8, the data Avo representing the fully-opened aperture size, such as "01010" shown in Table 2, is transmitted from the ROM RO1 to the camera body and, in response to a pulse from the terminal TB6, the data Avo "00001" is stored in the register REG3.

During a period S9, the address data "00001010" (which will be revised to "00000101" in a later stage) is transmitted to the lens and, during a period S10, the fw data representing the minimum focal length, such as "01011" shown in Table 2, is transmitted from the ROM RO1 to the camera body and, in response to a pulse from the terminal TB6, the fw data "01011" is stored in the register REG4.

During a period S11, the address data "00001100" (which will be revised to "00000110" in a later stage) is transmitted to the lens and, during a period S12, the ft data representing the maximum focal length, such as "10001" shown in Table 2, is transmitted from the ROM RO1 to the camera body and, in response to a pulse from the terminal TB6, the ft data "10001" is stored in the register REG4.

During the period S10 and in response to a pulse from the terminal TB6, the counter CO3 produce "110" causing AND gate AN20 to produce a "HIGH". Then during the period S11 and in response to a pulse from the terminal TB0, the D flip-flop DF2 produces a "HIGH" from its Q terminal. Accordingly, the data selector MP0 produces a fixed data "00010010" as obtained from its inputs w0. This fixed data "00010010" indicates that the type of the camera body is the second type among the above-mentioned various types. And, during the period S11 and in response to a pulse from the terminal TB7 the fixed data "00010010" is transferred to and stored in the shift register SR1. Then, during a period S12, the stored data "00010010" are sequentially sent out from the shift register SR1 through its output OUT. Since, during the period S12, the switching circuit SC1 is de-activated, the data "00010010" will not be sent to the lens circuit (FIG. 5). During the period S12 and in response to a pulse from the terminal TB7 the fixed data "00010010" (which will be revised to "00001001" in a stage) is again transferred from the data selector MP0 to the shift register SR1. And, during a period S13, the data "00010010" stored in the shift register SR1 is transferred through the switching circuit SC1, terminals JB3 and JL3 to the lens circuit of FIG. 5, particularly to the shift register SR3. Then, during the period S13 and in response to a pulse from the terminal TL7, the data "00010" (Avc=−6/8) indicating the light measuring difference Avc as stored in ROM RO1 at the address "00001001", is transferred and stored in the shift register SR4, and this data "00010" will be sent to the camera body. FIGS. 4*a* and 4*b* show an embodiment of a camera body of the second type, but if it were the first type, a data "00010000" will be applied to the inputs w0 of the data selector MP0. This data "00010000" will be revised as an address data "00001000" in a later stage for designating a location in the ROM RO1, from which data of light measuring error of the first type camera will be produced. In a similar manner, if the camera body is the third type, a data "00010100" will be applied to the inputs w0 of the data selector MP0. Thus, the ROM RO1 is designated with an address "00001010" for producing data of light measurement error of the third type camera body. The above procedure completes the reading of fixed data from the lens.

During the period S13, by the negative edge of a clock pulse produced from the terminal TB6, the shift register SR3 produces "HIGH" from its output La3 (FIG. 7 waveforms La3). Then, by the positive edge of a pulse produced from the AND gate AN35 in response to the pulse produced from the terminal TL7, the flip-flop FF7 is turned to a set condition, thereby producing "HIGH" from the output FD of the Q terminal and "LOW" from the output $\overline{FD}$ of $\overline{Q}$ terminal. Thereupon, the AND gate AN30 produces "LOW" and the OR gate OR5 produces "HIGH" regardless of the output from the terminal CL3 of the counter CO4 and, therefore, the switch circuit SC3 turns off and the switch circuit SC4 turns on, ready for sending various variant data from the lens to the camera body in a manner described below.

During a period S14, the data transfer of the light measuring error data is carried out, and in response to a pulse produced from the terminal TB6 and applied through the AND gate AN16, the register REG6 stores the above-mentioned data and, at the same time, in response to pulse from the output end1 of the AND gate AN16, the flip-flop FF3 is turned to the set condition (FIG. 7 waveforms AN16, end1 and FF3). After that, regardless of signal produced from the output CB3 of the counter CO1, the AND gate AN4 produces a "LOW" and the OR gate OR3 produces a "HIGH". Thus, the switching circuit SC1 is de-activated and the switching circuit SC2 is activated. Thereafter, the data from the lens is transferred to the camera body.

During a period S14 and when the terminal TL6 produces a "HIGH", the counter CO5 counts a pulse from the AND gate AN32 so as to produce "01" (FIG. 7, waveforms Ca0 and Ca1) from its output, thereby actuating the data selector MP2 to select data from the data input portion d2. Thus, the ROM RO1 receives data from the input portion d2. It is to be noted that, in this case, the lower 4-bit inputs r0, r1, r2 and r3 of the ROM RO1 receive data from the focusing distance data producing device DS, the intermediate 2-bit inputs r4 and r5 thereof receives data "01" from the outputs Ca0 and Ca1 of the counter CO5, and the upper 2-bit inputs

r6 and r7 thereof receives data "00". Therefore, if the data from the focusing distance data producing device DS is "0000", the final address data applied to the ROM RO1 is "00010000". In this case, the ROM RO1 produces a focusing distance data Dv of "01010" indicating that the focusing distance is 1.4 m, as understood from Table 2. If the data from the device DS is "0001", the final address data applied to the ROM RO1 is "00010001". In this case, the ROM RO1 produces a Dv data "01011" indicating that the focusing distance is 1.7 m. Furthermore, if the data from the device DS is "1110", the final address data applied to the ROM RO1 is "00011110". In this case, the ROM RO1 produces a Dv data "11000" indicating that the focusing distance is 16 m, and, if the data from the device DS is "1111", the final address data applied to the ROM RO1 is "00011111". In this case, the ROM RO1 produces a Dv data "11111" indicating that the focusing distance is infinite.

The focusing distance data Dv produced from the ROM RO1 is stored in the shift register SR4 in response to a pulse produced from the terminal TL7, and by the positive edges of the clock pulses CP produced from the terminals TB0 to TB4 during a period S15 (FIG. 7, waveforms Bb0 to Bb4), the data Dv is stored in the shift register SR2 (FIG. 4*a*). And, thereafter, by a pulse from the terminal TB5, the data Dv is latched in the latch LA, and then, by a pulse from the terminal TB6, the AND gate AN16 produces a "HIGH" (FIG. 7, waveform AN16), thereby storing the data Dv in the register REG6.

In the step S15 and when the terminal TL6 produces "HIGH", the AND gate AN32 produces "HIGH", thereby producing "10" (FIG. 7, waveform Ca0 and Ca1) from the counter CO5. By the signal "10" from the outputs Ca0 and Ca1 of the counter CO5, the data selector MP2 selects data input portion d3. Thus, the ROM RO1 receives data from the input portion d3. It is to be noted that, in this case, the lower 4-bit inputs r0, r1, r2 and r3 of the ROM RO1 receives data from the focal length data producing device FS, the intermediate 2-bit inputs r4 and r5 thereof receives data "10" from the outputs Ca0 and Ca1 of the counter CO5, and the upper 2-bit inputs r6 and r7 thereof receives data "00". Therefore, if the data from the focal length data producing device FS is "0000", the final address data applied to the ROM RO1 is "00100000". In this case, the ROM RO1 produces a focal length data of "01011" indicating that the focal length is 50 mm, as understood from Table 2. If the data from the device FS is "1010", the final address data applied to the ROM RO1 is "00101010". In this case, the ROM RO1 produces a data "01111" indicating that the focal length is 105 mm. Furthermore, if the data from the device FS is "1111", the final address data applied to the ROM RO1 is "00101111". In this case, the ROM RO1 produces data "10001" indicating that the focal length is 135 mm.

The focal length data produced from the ROM RO1 is stored in the shift register SR4 in response to a pulse produced from the terminal TL7 during the period S15 in a similar manner as described above, and by the positive edges of the clock pulses CP produced from the terminals TB0 to TB4 during a period S16 (FIG. 7, waveforms Bb0 to Bb4), the focal length data is stored in the shift register SR2 (FIG. 4*a*). And, thereafter, by a pulse from the terminal TB5, the focal length data is latched in the latch LA, and then, by a pulse from the terminal TB6, the AND gate AN18 produces a "HIGH" (FIG. 10 waveform AN18), thereby storing the focal length data in the register REG8. At this moment, the "HIGH" produced from the AND gate AN18 serves as a signal end2 which is applied to the set terminal of the flip-flop FF4, thereby producing "HIGH" from the Q output of the flip-flop FF4 (FIG. 7, waveforms AN18, end2 and FF4). The "HIGH" from the Q output of the flip-flop FF4 is applied to the input i3 of the micro-computer 1. Thus, the micro-computer 1 is informed that reading of all the data from the lens has been completed and that the read out data is temporarily stored in the interface circuit IF and, thereupon, it produces "LOW" from its output 02 for stopping the power supply to the lens.

Next, the micro-computer 1 starts to read data from the interface circuit IF through the data bus DB. First, when the data from the output OP3 of the micro-computer 1 is "5H", the output a0 of the decoder DE1 produces a "HIGH" and, therefore, the check data stored in the register REG0 is transmitted through the data selector MP1 and data bus DB to the micro-computer 1. Then, when the data from the output OP3 of the micro-computer 1. Then, when the data from the output OP3 of the micro-computer 1 is "6H", the output a1 of the decoder DE1 produces "HIGH" and, therefore, the dEvo data stored in the register REG1 is transmitted to the micro-computer 1. Likewise, the various data stored in the other registers REG3 to REG8 is sequentially transmitted to the micro-computer 1. When all the data from the interface circuit IF has been transmitted to the micro-computer 1, the micro-computer 1 carries out the procedure described above in connection with FIGS. 2*a*, 2*b* and 2*c*.

It is to be noted that the shift register SR1 shown in FIG. 4*a* and provided for outputing address data, and the shift register SR4 shown in FIG. 5 and provided for outputing accessory data, operate such that, as shown in FIGS. 6 and 7, by the positive edge of the pulse produced from the terminal TB7 (TL7), the data is parallelly stored in at once and, thereafter, by the positive edges of the pulses produced from the terminals TB0 to TB7 (TL0 to TL7), the stored data is sent out bit-by-bit serially from its output OUT from the most significant bit. This type of shift-register can be formed as follows. First, 8 flip-flops are provided for parallelly receiving 8 bits of data at a time at respective present terminals. A flip-flop which receives the least significant bit signal has its output connected to the input of a flip-flop which receives the second significant bit signal. The other flip-flops are connected in the same manner, and the flip-flop which receives the most significant bit signal is connected to an input of another (ninth) flip-flop. Thus, by a clock pulse applied to all the flip-flops, the signal present in the Nth flip-flop (N is an integer between 1 and 8) is sent to the (N+1)th flip-flop. Therefore, by a train of clock pulses applied to all the flip-flops, the 8-bit signal is sequentially produced out bit-by-bit from the output of the 9th flip-flop with a delay of one clock pulse.

The camera system according to the preferred embodiment of the invention as described above can be modified as follows. First of all, most of the control operations for controlling the aperture size and the shutter speed can be carried out by the micro-computer, and from this view point, many external parts can be eliminated. Secondly, it is possible to send the data already stored in the interface circuit IF parallel from the interface circuit IF to the micro-computer 1 during

the reading and serial transmission of other data to the interface circuit IF. In this manner, the time for the data transmission from the lens to the micro-computer 1 can be shortened.

Furthermore, according to the flow chart shown in FIGS. 2a, 2b and 2c, the micro-computer 1 operates constantly and, therefore, it consumes electric power rather quickly. To prevent this, it is possible to reorganize the program so as to cut off the power when it is not necessary to run the micro-computer. Since such a reorganization of the program is not difficult to those skilled in the art, a further description therefor is omitted.

According to the first embodiment described above, the fixed data storing means, i.e., the ROM RO1, provided in each interchangeable lens is stored with 3 different address data for the light measurement error data corresponding respectively to 3 types of optical systems of the camera body. When one of the three different address data corresponding to the type of camera body on which the interchangeable lens is mounted is designated from said camera body, only a particular light measurement error data necessary for said camera body is read out and taken in to the camera body. It is to be noted that, according to the present invention, the manner in which the data is read out is not limited to the one described above, but can be done in other ways. For example, an address counter corresponding to the counter CO3 described as provided in the camera body can be provided in the interchangeable lens such that the address counter sequentially designates 3 different addresses, thereby producing 3 different light measurement error data. And in the camera body, only a necessary light measurement error data is selected. To this end, the camera body must be provided with a selecting means, which can be accomplished, for example, by providing a particularly designed input-device which permits the transmission of light measurement error data in a certain timed relation for a camera having a certain type of optical system. A second embodiment employing such an arrangement is described later in connection with FIGS. 8 to 12. As will be apparent from the description below, it is not necessary for the second embodiment to designate the address of ROM of the interchangeable lens from the camera body.

Furthermore, according to the first embodiment, the data producing device of the interchangeable lens is arranged such that the light measurement error data Avc is transferred as it is to the camera body. According to an alternative arrangement, the data Avc can be transferred to the camera body in a combined form with other data. For example, the ROM in the interchangeable lens may carry a combined data of Avo+Avc for each of 3 different camera bodies, so that when the interchangeable lens is mounted on one type of camera body, a combined data corresponding to said one type of camera body may be transferred from the lens to the camera body. Alternatively, instead of providing the set aperture size data to the camera body mechanically, as described in the above embodiment, it is possible to store the data Avs - Avc in ROM corresponding to the plurality of types of the camera bodies, in a similar manner to the other data, such as focusing distance data or focal length data, so that the aperture size data can be electrically transmitted from the lens to the camera body.

According to the first embodiment, although it is described that the signal corresponding to the light measurement error is transmitted in an electrical and digital form from the interchangeable lens to the camera body, such a signal can be prepared in other forms, for example, a mechanical signal. More specifically, the interchangeable lens may be provided with a plurality of signal producing elements (such as a plurality of pins each projecting in an amount corresponding to the amount of light measurement error) each having a mechanically arranged amount corresponding to the light measurement error for a particular type of camera body. In this case, the camera body may be so arranged as to receive a necessary light measurement error from one of the signal producing elements.

Moreover, according to the first embodiment, it has been described that the light measurement error signal has 3 different amounts, but can be any number other than 3 depending on the number of different optical systems available in the respective different camera bodies.

Referring now to FIG. 8, there is shown a block diagram of an interchangeable lens type camera system according to the second embodiment of the present invention. A circuit portion shown on the right-hand side of a chain line LEC is provided in an interchangeable lens, and the other is provided in a camera body. A reference character BA designates a battery, and MAS designates a manually operable switch for the power supply. When the switch MAS turns on, an electric power is supplied from a power supply line +E to the micro-computer 1 and also to the oscillator OSC, thereby resetting the micro-computer 1 and, at the same time, starting the sending of clock pulses from the oscillator OSC to the clock terminal CL of the micro-computer 1. The train of clock pulses is also applied to each of exposure time control circuit TIC, aperture control circuit APC, release circuit RLC and mirror release circuit MRC.

A reference character MS designates a light measuring switch that closes when a shutter release button (not shown) is depressed down to a first level. When the switch MS closes, an inverter IN50 produces "HIGH" from its output, and this "HIGH" is applied to an interruption input it1 of the micro-computer 1. When the micro-computer 1 receives "HIGH" to its interruption input it1, an output O1 produces "HIGH", whereby an inverter IN52 produces "LOW" causing a transistor BT50 to go to a conductive state. Thus, electric power is supplied from the power supply line +V to the circuit elements in the camera side other than the oscillator OSC and the micro-computer 1. Electric power is further supplied through a buffer BF, terminals JB1 and JL1 to a power supply line +VF in the interchangeable lens.

When the power supply starts from the power line +V in response to the turning on of the transistor BT50, a power-on-reset circuit POR2 so actuates as to provide a pulse to the exposure time control circuit TIC, aperture control circuit APC, release circuit RLC and mirror release circuit MRC, thereby resetting these circuits.

A reference character ME designates a light measuring circuit which produces an analog form output signal representing:

$$Bv-Avo-Avc$$

wherein Bv is the brightness of the object, Avo is the full open aperture value, and Avc is full open aperture

light measurement error. The signal produced from the light measuring circuit ME is applied to an A/D conversion input terminal ANI of the micro-computer **1**. Furthermore, an input terminal REV of the mirco-computer **1** is provided for inputting reference voltage for being used in an D/A converter provided in the micro-computer **1**. To the input terminal REV, a reference voltage from a constant voltage source provided in the light measuring circuit ME is applied.

A reference character TS designates a device for producing data of set exposure time which is applied to an input port IP1 of the micro-computer **1**. A reference character AS designates a device for producing data of set aperture amount which is applied to an input port IP2 of the micro-computer **1**. A reference character SS designates a device for producing data of film sensitivity which is applied to an input port IP3 of the micro-computer **1**. A reference character MS designates a device for producing data corresponding to the set exposure calculation mode which is applied to an input port IP4 of the micro-computer **1**. A reference character DP designates a display circuit for displaying various data, such as exposure control value. The data to be displayed is controlled by signals obtained from common terminal COM and segment terminal SEG which are provided to the micro-computer **1**.

An output O3 of the micro-computer **1** is connected through terminals JB3 and JL3 to a reset terminal RE of each of counters CO50 and CO52. The output O3 produces "HIGH" while reading data from the mounted interchangeable lens, thereby releasing the counters CO50 and CO52 from the reset condition. A terminal SIC of the micro-computer **1** is provided for producing clock pulses, and in a synchronized manner with the clock pulses, data from the lens is serially read out and taken into the micro-computer through a terminal SID. The terminal SIC is connected through terminals JB2 and JL2 to a clock input terminal CL of the counter CO50, and the terminal SID is connected through terminals JL5 and LB5 to an output of an OR gate OR **50**.

FIG. **9** shows an exemplary circuit to be provided in the micro-computer **1** and connected to the above-mentioned terminals SIC and SID for reading the serial data, and FIG. **10** shows waveforms of signals appearing in the circuit of FIG. **9**. In FIG. **9**, when a data-reading request signal SIIN (FIG. **10**, SIIN) is applied to a flip-flop FF50, the flip-flop FF50 turns to a set condition (FIG. **10**, FF50). Thus, an AND gate AN70 produces a train of clock pulses DIC. The clock pulses DIC are produced from a frequency divider provided in the micro-computer **1** so that the clock pulses DIC have a frequency lower than that of the clock pulses produced from the oscillator OSC. The clock pulses DIC are outputted from the terminal SIC and, at the same time, are applied to clock terminal CL of each of 3-bit binary counter CO60 and 8-bit shift register SR50. In response to the negative edge of each clock pulse applied to the clock terminal CL, the shift register SR50 takes in the data through the terminal SID. Then, in response to the positive edge of the 8th clock pulse, a carry terminal CY of the counter CO60 produces "HIGH" (FIG. **10**, CY), and in response to the negative edge of the 8th clock pulse, an AND gate AN72 produces "HIGH" (FIG. **10**, AN72), thereby resetting the flip-flop FF50 and counter CO60. Furthermore, the "HIGH" from the AND gate AN72 causes a flag SIFL (FIG. **10**, SIFL) to become "HIGH" for inputting serial data, thereby completing the operation.

Referring again to FIG. **8**, a switch RS is a release switch which closes when the shutter release button is depressed down to a second level, and a switch EXS is a switch that closes when an exposure control mechanism (not shown) completes its operation and opens when the exposure control mechanism is set to a charged condition ready to start its operation. When the switch EXS opens upon completion of charging of the exposure control mechanism, an inverter IN56 produces "LOW". While the inverter IN56 is producing "LOW", and when the release switch RS closes, an AND gate AN60 produces "HIGH" which is applied to the interruption terminal it2 of the micro-computer **1**. In response to the positive edge of the "HIGH" applied to the interruption terminal it2, the micro-computer **1** starts to carry out the exposure control operation no matter what operation has been carried out. Contrary, when the switch EXS is held closed as it is before the completion of charge of the exposure control mechanism, the inverter IN56 produces "HIGH". While the inverter IN56 is producing "HIGH", the AND gate AN60 continues to produce "LOW" even when the release switch RS closes. Thus, in this case, the micro-computer **1** will not carry out the exposure control operation.

An output port OP1 of the micro-computer **1** produces an exposure time data Tv and applies it to an exposure time control circuit TIC, and an output port OP2 produces aperture stop down data Av-Avo and applies it to an aperture control circuit APC. Furthermore, an output O2 of the mirco-computer **1** produces a pulse that effects the start of exposure control, and the produced pulse is applied to a release circuit RS. An output O4 of the micro-computer **1** also produces a pulse, but this pulse effects the start of mirror-up operation. The pulse produced from the output O4 is applied to the mirror release circuit MRC.

It is to be noted that the input ports IP1 to IP4 and output ports OP1 to OP2 can be replaced with a common data bus so that the signal transmission between the micro-computer **1** and each of the circuits TS, AS, SS, MS, TIC, and APC can be carried out in a time divided manner.

Next, the description is directed to the circuit provided in the lens. The counter CO50, which is a 3-bit binary counter, counts the positive edges of the clock pulses produced from the terminal SIC, and the counter CO52, hich is also a 3-bit binary counter, counts negative edges of the pulses produced from the carry terminal CY of the counter CO50. The three outputs h2, h1 and h0 of the counter CO50 are connected to the decoder DE50, which produces output relatively to the counted number of pulses from the counter CO50, as shown in Table 7 below.

TABLE 7

Counter CO50			Decoder DE50							
h2	h1	h0	e7	e6	e5	e4	e3	e2	e1	e0
0	0	0	H	L	L	L	L	L	L	L
0	0	1	L	L	L	L	L	L	L	H
0	1	0	L	L	L	L	L	L	H	L
0	1	1	L	L	L	L	L	H	L	L
1	0	0	L	L	L	L	H	L	L	L
1	0	1	L	L	L	H	L	L	L	L
1	1	0	L	L	H	L	L	L	L	L
1	1	1	L	H	L	L	L	L	L	L

The three outputs h2, h1 and h0 of the counter CO52 are connected to the decoder DE52. Thus, the decoder

DE52 produces a 4-bit signal from its output g3, g2, g1 and g0 in response to the signal from the counter CO52, as shown in Table 8, below.

TABLE 8

Counter CO52			Decoder DE52			
h5	h4	h3	g3	g2	g1	g0
0	0	0	0	0	0	0
0	0	1	0	0	0	1
0	1	0	0	0	1	0
0	1	1	0	0	1	1
1	0	0	0	1	0	0
1	0	1	0	1	0	1
1	1	0	0	1	1	0
1	1	1	1	0	0	1

Of the outputs of the decoder DE52, the output g3 is connected to the select terminal SE of the data selector MP50. When the data selector MP50 receives "LOW" to its select terminal SE from the output g3, it produces a signal applied to its input r1 and when the same receives "HIGH", it produces a signal applied to its input r2. The signal produced from the data selector MP50 is applied to a ROM RO50 as an address signal. The input r1 includes 8 terminals in which the terminals of the upper 5 bits are grounded, and the terminals of the lower 3 bits are connected to the outputs g2, g1 and g0 of the decoder DE52. Therefore, the ROM RO50 receives an address signal "00000000", "00000001", . . . , or "00000110" in response to the output "000", "001", . . . , or "110", respectively, of the counter CO52. The input r2 also includes 8 terminals in which the terminals of the upper 3 bits are connected to the outputs g2, g1 and g0 of the decoder DE52 and the terminals of the lower 5 bits are connected to a code plate of a focal length setting device (not shown) of a zoom lens. Therefore, when the counter CO52 produces "111", the data selector MP50 produces "001ØØØØØ" as an address signal, wherein the lower 5 bits ØØØØØ carry a signal obtained from the code plate COD.

Next, the signals stored in the ROM RO50 are described with reference to the Table 9 given below.

TABLE 9

Address	Significance
00000000	Zoom/Fixed Focal length
00000001	Fully-Open Aperture Value Avo
00000010	Maximum Open Aperture Value Avmax
00000011	Minimum/Fixed Focal length fw
00000100	
00000101	Fully-Open Aperture light measurement
00000110	error Avc
00100000	
	Set Focal length
00111111	

At the address "00H" (H indicates that the number is given in a hexadecimal numbering system) of the ROM RO50, a data "F8H" is stored if the mounted lens is a zoom lens, and "F0H" if it is a Fixed focal length lens. If neither of the data "F8H" or "F0H" is read-in in the camera, it is determined that no lens is mounted on the camera body. In this case, the exposure control is carried out under an aperture stop down light measuring mode. If either of the data "F8H" or "F0H" is read-in in the camera, the exposure control is carried out under fully-open aperture light measuring mode.

At the address "01H", data Avo representing the fully-opened aperture size is stored. At the address "02H", data Avmax representing the maximum aperture size is stored. At the address "03H", data representing the focal length of the lens, if the lens is fixed focal length type, is stored or data representing the minimum focal length, if the lens is a zoom lens, is stored.

At the addresses "03H", "04H" and "05H", three different data Avc representing the fully-opened aperture light measurement error for the three different types of camera bodies are stored.

If the mounted lens is a zoom lens, a number of focal length data corresponding to the data obtained from the code plate COD are stored at the addresses "00100000" to "00111111". Such data representing the focal length of the zoom lens is used for producing a warning signal of wobbling when the focal length becomes long.

Referring to FIG. 11, a time chart of various waveforms is given, showing the operation of data reading from the lens of the second embodiment of FIG. 8. Now, the description is directed to the data reading from the lens with reference to the time chart of FIG. 11. First, the output O3 of the micro-computer 1 produces "HIGH" so as to release the counters CO50 and CO52 from the reset condition. As has been described above in connection with FIGS. 9 and 10, the clock terminal SIC of the micro-computer 1 produces a train of 8 clock pulses each time a data of 1 bit-long is read-in. In the period S0 for reading the first data, a location in the ROM RO50 is specified by an address "00000000" so as to produce a check data "F0H" or "F8H". Then, as the counter CO50 counts up, the decoder DE50 sequentially produces "HIGH" from its outputs e0 to e7. Accordingly, AND gates AN68 to AN61 open one after another to transmit the 8-bit data produced from the terminals f0 to f7 of the ROM RO50 to an OR gate OR50, which then serially produces the 8-bit data bit-by-bit from the least significant bit. The serially produced 8-bit data is transmitted through the terminals JL5 and JB5 to the input SID of the micro-computer 1. The signal serially applied to the input SID is serially stored in the shift register SR50 of the micro-computer 1, in a similar manner described in connection with FIGS. 9 and 10, in response to the negative edges of the clock pulses which are the same as those applied to the terminal SIC.

In response to the positive edge of the 8th clock pulse, the counter CO50 produces "HIGH" from its carry terminal CY, thereby starting a new period S1. Then, in response to the positive edge of the 1st clock pulse, the counter CO50 produces "LOW" from its carry terminal CY, thereby effecting the count up of the counter CO52 by 1. Then, the ROM RO50 receives an address data "00000001" as obtained from the input r1 of the data selector MP50.

Thereafter, a similar operation is carried out repeatedly until the period S6 ends, whereby the micro-computer 1 reads data stored in various locations in the ROM RO50 as specified by the address "00H" to "06H". When the carry terminal CY produces "LOW" at the end of the period S6, the counter CO52 produces "111", thereby the decoder DE52 produces "1001". Thus, the data selector MP50 selects input r2, thereby producing an address data "001ØØØØØ", which is applied to the ROM RO50. Here, ØØØØØ represents a 5-bit signal obtained from the code plate COD. Thereupon, the ROM RO50 produces a data representing the set focal length in a similar manner described above, and the produced data is read-in in the micro-computer 1, thereby completing the data reading from the mounted zoom lens. When the data reading from the zoom lens

completes, the micro-computer 1 produces "LOW" from its output O3, thereby turning the counters CO50 and CO52 to the reset condition. In the case where the mounted lens is a fixed focal length type, the micro-computer 1 produces "LOW" from its output O3 at the end of the period S6, thereby turning the counters CO50 and CO52 to the reset condition and, at the same time, completing the data reading from the mounted lens.

Referring to FIGS. 12*a* and 12*b*, a flow chart is given, showing an operation of the micro-computer 1 according to the second embodiment. Now, the operation of the circuit of FIG. 8 is described with reference to the flow chart of FIGS. 12*a* and 12*b*.

When the light measuring switch MS turns on, an interruption signal is applied to the interruption terminal it1, thereby start actuating the micro-computer 1 from the step #201. In the step #201, it is determined whether the terminal it1 is receiving "HIGH" or not. When the interruption terminal it1 receives "HIGH", the procedure advances to the step #202 in which the output O1 produces "HIGH", whereby the inverter IN52 produces "LOW". Thus, the transistor BT50 conducts to supply power to the power line +V. The "HIGH" from the output O1 is also applied to through the buffer BF, terminals JB1 and JL1 to the lens. Then, the set data from the input ports IP1, IP2, IP3 and IP4 are sequentially transmitted and stored in registers MO, M1, M2 and M3 in the steps #203, #204, #205 and #206.

Then, in the step #207, the output O3 produces "HIGH", thereby releasing the counters CO50 and CO52 from the reset condition, and at the same time, setting "4H" in a k-register. And, in the step #209, the serial reading of the data from the lens to the camera is carried out in the manner described above until the completion flag SIFL holds "1". When the flag SIFL holds "1", the read-in data is stored in a register Mk (initially, it is M4) and, thereafter, it is determined in the step #212 whether the k-register is carrying "AH" or not. If the k-register is not carrying "AH", "1" is added to the content of the k-register and the procedure advances to the step #215, wherein it is determined whether k-register is carrying "CH" or not. In the step #215, if it is discriminated that the k-register is not carrying "CH", the procedure returns back to the step #210 to read in the next data. After carrying out the above procedure for a number of times and, when it is determined that the step #212 that the k-register is carrying "AH", it is further determined in the step #213 whether the content of the register M4 is "F8H" or not. If it is determined that the register M4 is not carrying "F8H", it is understood that the mounted lens is a focal length fixed type, or that no lens is mounted. In such a case, it is not necessary to further read-in any data from the lens and, accordingly, the procedure advances to the step #216. Contrary, if it is determined that the register M4 is carrying "F8H", it is understood that the mounted lens is a zoom lens. In such a case, the procedure advances to the step #214 and further to #215 to carry out the data reading Then, in the step #215, if it is determined that the k-register is carrying "CH", the procedure advances to the step #216. Thus, in the registers M4 to MB, various data as indicated below are stored.

register M4: check code;
register M5: Avo;
register M6: Avmax;
register M7: fw;
register M8: Avc1 for the first type of the camera;
register M9: Avc2 for the second type of the camera;
register MA: Avc3 for the third type of the camera; and
register MB: fs.

Then, in the step #216, the output O3 produces "LOW", thereby resetting the counters CO50 and CO52. And then, referring to FIG. 12*b*, in the step #217, the analog signal produced from the light measuring circuit ME is converted into digital form, and the converted digital signal Bv-Avo-Avc2 is stored in a register Mc. Then, in the step #219, the content Bv-Avo-Avc2 of the register Mc is added with the contents Avo, Avc2 and Sv of the registers M5, M9 and M2, respectively, thereby calculating an exposure value Ev as follows:

$$EV=(Bv-Avo-Avc2)+Avo+Avc2+Sv=Bv+Sv.$$

The obtained sum, i.e., the exposure value Ev is again stored in the register Mc.

It is to be noted that the above calculation is carried out when the camera body has the optical system of the second type. If the camera body has the optical system of the first type, the content of the register M8 should be added; and if the camera body has the optical system of the third type, the content of the register MA should be added. Then, using the obtained sum Ev, the exposure calculation is carried out in the step #220.

When the exposure calculation completes, the flag LMF carries "1" in the step #221, and then, the interruption routine is permitted in the step #222. In the next step #223, it is determined whether the flag RLF is carrying "1" or not. If the flag RLF is carrying "1", the procedure advances to the step #233, and if not, the procedure advances to the step #224 for displaying the exposure information. A detailed description on the flag RLF will be given later.

In the step #225, it is determined whether the interruption terminal it1 is receiving "HIGH" or not. If the interruption terminal it1 is receiving "HIGH", the procedure returns back to the step #203 to repeat the operation thereafter. If the terminal it1 is receiving "LOW", the output O1 produces "LOW", thereby cutting the power supply to the power line +V and also to the circuits in the lens. Then, in the step #227, nothing is displayed (blank display), and in the step #228, flag LMF for the light measuring carries "0". Then, the interruption routine is permitted (step #229) and ending the operation of the micro-computer 1 (step #230).

When the shutter release switch RS closes under the condition that the exposure control mechanism is charged and that the switch EXS is held open, the AND gate AN60 produces "HIGH", thereby providing "HIGH" to the interruption terminal it2. Then, the micro-computer 1 immediately starts the procedure from the step #201 (FIG. 12*a*) no matter what operation it is carrying out. Then, the procedure advances from the step #201 to the step #230 (FIG. 12*b*), because it is determined in the step #201 that the interruption terminal receiving "HIGH" is not it1, but it2. In the step #230, the flag RLF for the release holds "1", and in the step #231, the output O3 produces "LOW" just in case the interruption routine is requested while carrying out the serial reading of data. Then, in the step #232, it it determined whether the flag LMF is carrying "1" or not, i.e., whether the calculation for obtaining the exposure control data is completed or not. If not, the proce-

dure returns back to the step #202 to carry out the exposure calculation through the steps #202 to #223, and continues again from the step #233. If the flag LMF is carrying "1" in the step #232, the procedure advances directly to the step #233.

In the step #233, exposure time data Tv is supplied from the output OP1 to the exposure time control circuit TIC. Then, in the step #234, aperture stop down data Av-Avo is supplied from the output OP2 to the aperture control circuit APC. And, in the step #235, a pulse for the shutter release is supplied from the output O2 to the release circuit RLC of the exposure control mechanism.

In the next step #236, a predetermined time is counted and, thereafter, a pulse for effecting the shutter release is supplied to the mirror-up release circuit MRC. Then, the program waits until the input terminal i2 receives "HIGH", i.e., until the switch EXS closes upon completion of the exposure control operation. When the input terminal i2 receives "HIGH", the flag RLF holds "0", and thereafter, the procedure continues from the step #225. If the light measuring switch MS is held closed the procedure follows the steps of #225, #203 et seq., and if it is held open, the procedure follows the steps of #225, #226 et seq., thereby cutting the power supply, turning off the display, setting "0" in the flag LMF, and ending the operation of the micro-computer 1. Now it is ready to carry out another cycle of operation as carried out when an interruption signal is applied to the terminal it1 while the light measuring switch MS is held closed.

Although the present invention has been fully described with reference to several preferred embodiments, many modifications and variations thereof will now be apparent to those skilled in the art, and the scope of the present invention is therefore to be limited not by the details of the preferred embodiments described above, but only by the terms of appended claims.

What is claimed is:

1. In a camera system with an interchangeable objective lens a combination of, a camera and an interchangeable objective lens selectively attachable to said camera body and to at least one different camera body, comprising:

means located in said interchangeable objective lens for storing a plurality of compensation data suitable to said first mentioned camera body and to the at least one different camera body, respectively, to prepare for each case of compensating an error in a fully-open aperture light measurement;

means located in said interchangeable objective lens for transmitting said compensation data to the camera body to which said interchangeable objective lens is attached;

means located in said first mentioned camera body for registering said compensation data from said transmitting means;

means located in said first mentioned camera body for controlling the camera system so that a predetermined one of said compensation data stored in said storing means is registered in said registering means;

means located in said first mentioned camera body for practicing a fully-open aperture light measurement through said interchangeable objective lens to produce light measuring information including the error; and

means located in said first mentioned camera body for calculating correct exposure information in response to said compensation data registered in said registering means and said light measuring signal, in which the error included in said light measuring signal is removed by utilizing said compensation data registered in said registering means.

2. The invention of claim 1, wherein said controlling means includes means for forwarding a digital signal to said interchangeable objective lens, and said storing means includes a read only memory with a plurality of addresses at which said compensating data is located, respectively, and wherein said interchangeable objective lens further comprises means for determining an address of said storing means in response to said digital signal, whereby said compensation data located at the determined address is transmitted by said transmitting means.

3. The invention of claim 2, wherein said forwarding means includes means for selectively producing a predetermined address data as said digital signal for designating an address at which the predetermined one of said compensation data is stored, and said determining means includes means for passing said predetermined address data from said producing means to said storing means, whereby the predetermined one of said compensation data is transmitted to be registered in said registering means.

4. The invention of claim 2, wherein said forwarding means includes means for generating a train of clock pulses as said digital signal, and said determining means includes means for designating the addresses of said storing means one by one in response to said clock pulses from said generating means to transmit said plurality of compensation data one by one by means of said transmitting means, and wherein said controlling means further includes means for actuating said registering means to register the predetermined one of said compensation data in a timing when the predetermined one of said compensation data arrives at said first mentioned camera body.

5. The invention of claim 2, wherein said storing means further includes an address for storing exposure compensating data to be transmitted to said first mentioned camera body for the purpose of compensating an exposure error upon fully-open aperture size control, and said calculating means further includes means for providing aperture size information and at least another exposure factor information in response to said correct exposure information, and wherein said first mentioned camera body further comprises means for discriminating whether or not the calculated aperture size information corresponds to the fully-open aperture size, means responsive to said discriminating means for modifying said other exposure factor information by said exposure compensating data when the calculated aperture size information corresponds to the fully-open aperture size, and for adopting said other exposure factor information as it is when the calculated aperture size information does not correspond to the fully-open aperture size, means for controlling the aperture size in response to said providing means, and means for controlling another exposure factor in response to said modifying and adopting means.

6. In a camera system with an interchangeable objective lens, a camera body to be combined with an interchangeable objective lens which stores a plurality of compensation data suitable to the camera body and at

least one different camera body, respectively, to prepare for each case of compensating an error in fully-open aperture light measurement, comprising:

means for registering the compensation data to be transmitted from the interchangeable objective lens;

means for controlling the camera system so that a predetermined one of the plurality of compensation data is registered in said registering means;

means for practicing a fully-open aperture light measurement through the interchangeable objective lens to produce light measuring information including the error; and

means for calculating correct exposure information in response to said compensation data registered in said registering means and said light measuring signal, in which the error included in said light measuring signal is removed by utilizing said compensation data registered in said registering means.

7. The invention of claim 6, wherein said controlling means includes means for ordering the interchangeable objective lens to selectively transmit the predetermined one of the plurality of compensation data to said registering means.

8. The invention of claim 6, wherein said controlling means includes means for making the interchangeable objective lens transmit the plurality of compensation data one by one, and means for actuating said registering means to register the predetermined one of the compensation data in a timing when the predetermined one of the compensation data arrives at the camera body.

9. In a camera system with an interchangeable objective lens, an interchangeable objective lens selectively attachable to a plurality of different camera bodies each capable of fully-open aperture light measurement, comprising:

read only memory having a plurality of addresses for storing a plurality of compensation data suitable to the plurality of camera bodies, respectively, to prepare for each case of compensating an error in fully-open aperture light measurement;

means for receiving a digital signal from the camera body to which said interchangeable objective lens is attached;

means for determining an address of said read only memory in response to said digital signal; and

means for transmitting the compensation data stored in the determined address to the camera body to which said interchangeable objective lens is attached.

10. The invention of claim 9, wherein said receiving means includes means for introducing address data as said digital signal, and said determining means includes means for passing said address data from said introducing means to said read only memory to designate an address.

11. The invention of claim 9, wherein said receiving means includes means for introducing a train of clock pulses as said digital signal, and said determining means includes means for designating the address of said read only memory one by one in response to said clock pulses.

12. In a camera system with an interchangeable objective lens, an interchangeable objective lens attachable to a camera body capable of an automatic exposure control, comprising:

a read only memory having a plurality of addresses, one of which stores an exposure time compensating data for compensating an exposure error upon fully-open aperture size control;

means for receiving a digital signal from the camera body;

means for determining an address of said read only memory in response to said digital signal; and

means for transmitting the data stored in the determined address to the camera body.

13. In a camera system with an interchangeable objective lens, a camera body to be combined with an interchangeable objective lens which stores exposure compensating data for compensating an exposure error upon fully-open aperture size control, comprising:

means for receiving the exposure compensating data from the interchangeable objective lens;

means for practicing a light measurement to produce exposure information;

means for providing aperture size information and at least another exposure factor information in response to said exposure information;

means for discriminating whether or not the calculated aperture size information corresponds to the fully-open aperture size;

means responsive to said discriminating means for modifying said other exposure factor information by said exposure compensating data when the calculated aperture size information corresponds to the fully-open aperture size, and for adopting said other exposure factor information as it is when the calculated aperture size information does not correspond to the fully-open aperture size;

means for controlling the aperture size in response to said providing means; and

means for controlling an exposure factor in response to said modifying and adopting means.

14. A camera system capable of compensating an exposure error upon fully-open aperture size control comprising:

means for preparing exposure compensating data;

means for practicing a light measurement to produce exposure information;

means for providing aperture size information and at least another exposure factor information in response to said exposure information;

means for discriminating whether or not the calculated aperture size information corresponds to the fully-open aperture size;

means responsive to said discriminating means for modifying said other exposure factor information by said exposure compensating data when the calculated aperture size information corresponds to the fully-open aperture size, and for adopting said other exposure factor information as it is when the calculated aperture size information does not correspond to the fully-open aperture size;

means for controlling the aperture size in response to said providing means; and

means for controlling an exposure factor in response to said modifying and adopting means.

[57] **ABSTRACT**

An objective lens comprises an iris diaphragm (D_1) at the front and an optical assembly disposed behind the iris diaphragm. The optical assembly comprises a plano-convex front lens unit (G) with its plane surface facing the front of the lens, whereby the lens is suitable for use in media with different refractive indices (in practice, air and water). It further comprises a rear lens unit (G') adapted to apply the necessary correction to maintain abberations within reasonable limits and to achieve a required distance from the lens to the focal image plane. The invention is applicable, in particular, to discreet surveillance using a camera.

OBJECTIVE LENS

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention is concerned with an objective lens for a camera, comprising diaphragm disposed at the front of the lens and an optical assembly disposed behind the diaphragm.

2. Description of the Prior Art

French Pat. No. 2 321 713 filed Aug. 22, 1975 discloses a camera whose essential characteristic is that the iris diaphragm of its objective lens, that is to say the diaphragm of the objective lens which delimits the incident beam and thus conditions the aperture number, is situated in front of the objective lens.

It has become clear that this arrangement, originally devised in order to facilitate and simplify the practical implementation of underwater cameras, can with advantage by applied to cameras for discreet surveillance applications, including still cameras, movie cameras and video cameras, whether the need is for surveillance in an air or water medium, for monitoring the presence of persons therein.

A condition for the success of any surveillance system is that the camera by virtue of which it is exercised be hidden from view of the greatest possible extent.

If, as is usual, the iris diaphragm is disposed inside the objective lens, the entry lens elements thereof are necessarily of relatively large diameter, making it difficult to hide them.

This does not apply if, as described in the aforementioned French patent, the iris diaphragm of the objective lens is situated at the front of the lens.

The entry lens elements of the objective lens may then have a relatively small diameter, and the corresponding camera may thus be easily hidden behind a partition or closet door or any appropriate support, a small hole in the front surface, difficult to see, constituting the iris diaphragm of the objective lens of the camera thus hidden.

In practice, apart from this capacity for being hidden, it is desirable for other constraints to be met to obtain the widest possible application.

First of all, as already mentioned, it is desirable for the objective lens to be equally suitable for use in air or water.

It is also desirable to obtain a relatively large distance between the lens and the corresponding focal image plane to provide for the installation of any necessary accessory device, such as a shutter, reflex mirror or filter, for example.

These requirements are mutually contradictory, and are difficult to reconcile in practice.

In the aforementioned French patent, the objective lens described is in practice suitable only for underwater cameras, and the distance between it and the focal image plane is relatively small.

A general objective of the present invention is to provide an objective lens which provides a particularly satisfactory solution to the problem of meeting the stated requirements.

SUMMARY OF THE INVENTION

The invention consists in an objective lens for a camera, comprising an iris diaphragm disposed at the front of the lens and an optical assembly disposed behind the iris diaphragm and comprising a plano-convex front lens unit with its plane surface facing the front of the lens, whereby the lens is suitable for use in media with different refractive indices, and a rear lens unit adapted to apply the necessary correction to maintain abberations within reasonable limits and to achieve a required distance from the lens to the focal image plane.

The term "lens unit" used herein designates, in the usual manner, an optical component consisting of a single lens, a doublet pair of lenses or a multiple assembly of lenses, and designed to fulfil a specific function.

The plane entry optical surface of the front lens unit of the objective lens in accordance with the invention offers the advantage of enabling the lens to be used equally well in air or in water, and eliminates the unwanted "cat's eye" effect experienced with side lighting, an effect which would be unavoidable if the entry optical surface were curved, by virtue of the resulting focusing action. Also, by virtue of its convex exit optical surface, it provides the advantage of concentrating the incident beam and thus facilitates the minimizing of the inevitable abberations in the rear lens unit.

Thus in practice it has a two-fold function.

As a corollary to this, the rear lens unit of the objective lens in accordance with the invention provides the advantage that, after the divergence of the incident beam which is necessary to its expansion, the consequences of which are minimized, however, as indicated above, by virtue of the convergence previously brought about by the front lens unit, sufficient progressive convergence of the beam is brought about for the required distance to the focal image plane to be obtained.

Thus the objective lens in accordance with the invention represents a particularly advantageous compromise between the various requirements to be fulfilled.

Also, when applied to a camera, it enables the camera to be hidden particularly easily, since its overall dimension may be less than 50 mm, for example, for an iris diaphragm aperture of less than 3 mm, for example, and an overall focal length of the order of 11.3 mm.

Finally, if required, the invention is equally applicable to projection apparatus, for the purpose of projection between two walls, for example.

Other objects and advantages will appear from the following description of an example of the invention, when considered in connection with the accompanying drawing, and the novel features will be particularly pointed out in the appended claims.

IN THE DRAWING

The drawing is a cross-sectioned view in elevation of an objective lens in accordance with the invention, illustrating the application of the latter to a camera.

DESCRIPTION OF THE PREFERRED EMBODIMENT

In the embodiment shown in the drawing, the objective lens in accordance with the invention is used for purposes of surveillance, and is therefore disposed behind a panel or wall P formed for this purpose with a hole T.

For preference, and as shown, this hole T is generally frustoconical, its area increasing from the front towards the rear, with a cone angle sufficient to permit the objective lens in accordance with the invention to be tilted and thus aimed at different points in the field of view, without the incident light beam being obstructed.

In an alternative arrangement (not shown) particularly suitable for applications other than discreet surveillance, diaphragm D_1 may, for example, be formed by the rear surface of panel or wall P, the area of the frusto-conical hole T in which then decreases from the front towards the rear.

Be this as it may, as shown in the drawing, the objective lens in accordance with the invention is formed by a series of component parts, optical surfaces or diaphragms.

First of all, at the front, is a diaphragm D_1 constituting the iris diaphragm.

As represented schematically in full line in the drawing, diaphragm D_1 forms an integral part of the objective lens support device or body-tube, which will not be described in detail herein.

In practice, assuming a overall focal length of 1 mm, the effective aperture diameter of diaphragm D_1 may be of the order of 0.26 mm.

To the rear of diaphragm D_1, the objective lens in accordance with the invention comprises an optical assembly whose optical components are, in accordance with the invention, grouped and combined to form a front lens unit G and a rear lens unit G'.

In accordance with the invention, front lens unit G is plano-convex with its plane surface facing the front, that is to say towards diaphragm D_1.

In practice, in the embodiment shown, front lens unit G consists of a single plano-convex lens L which, in the usual manner, is defined by two optical surfaces, namely an optical surface D_2 which constitutes its front surface and which is plane, and an optical surface D_3 which constitutes its rear surface and which is convex.

Lens L has a refractive index of 1.45 and an Abbe number of 68. It may, for example, be manufactured from the material marketed under the trade name "Herasil", this kind of material having advantageous chemical and physical properties enabling it to withstand corrosive and abrasive environments so as to permit surveillance of such environments.

Assuming, by way of illustrative example, an overall focal length of 1 mm, it is at a distance from diaphragm D_1 consituting the iris diaphragm, as measured relative to its entry optical surface D_2, between 0.02 and 0.04 mm, its thickness at the center is between 0.08 and 0.11 mm, and the radius of optical surface D_3 which constitutes its rear surface is between 0.92 and 0.93 mm.

For preference, and as shown, rear lens unit G' is at a distance from front lens unit G which, as measured between exit optical surface D_3 of front lens group G and entry optical surface D_5 of rear lens group G', is between 0.14 and 0.18 mm, for an overall focal length of 1 mm.

Also for preference, and as shown, a diaphragm D_4 is disposed substantially midway between front lens unit G and rear lens unit G'.

For example, the distance between exit optical surface D_3 of front lens unit G and diaphragm D_4 may, given the conditions stated, be between 0.07 and 0.09 mm and, likewise, its distance from entry optical surface D_5 of rear lens unit G' may be between 0.07 and 0.09 mm.

Be this as it may, the effective diameter of diaphragm D_4 is for preference of the order of 0.25 mm, for an overall focal length of 1 mm.

In the embodiment shown, rear lens unit G' comprises a succession of six lenses L'_1, L'_2, L'_3, L'_4, L'_5, and L'_6.

Lens L'_1 is biconcave, delimited by an optical surface D_5 which constitutes the entry optical surface of rear lens unit G', and which also constitutes its front surface, and an optical surface D_6 which constitutes its rear surface.

Given the assumed overall focal length of 1 mm, it has a thickness at the center between 0.06 and 0.08 mm, an entry surface radius between 0.39 and 0.40 mm and an exit surface radius between 1.03 and 1.04 mm.

Its refractive index is in the region of 1.8, its Abbe number is 25, and it may be made, for example, from the optical material with reference E 05-25.

Lens L'_2 is biconvex and in contact with the preceding concave lens L'_1.

In other words, these two lenses share optical surface D_6, which constitutes the exit surface of one and the entry surface of the other.

In addition to optical surface D_6, lens L'_2 is further delimited by an optical surface D_7, which constitutes its exit surface.

Given the assumed overall focal length of 1 mm, lens L'_2 has a thickness at the center between 0.49 and 0.51 mm, an inlet surface radius between 1.03 and 1.04 mm and an exit surface radius between 0.71 and 0.72 mm.

Its refractive index is 1.49, its Abbe number is 70, and it may be made, for example, from the optical material with reference A 87-70.

Lens L'_3 is concave-convex with its concave side facing preceding lens L'_3.

It is defined by two optical surfaces D_8 and D_9, the former constituting its entry surface and the latter its exit surface.

It is disposed at a distance from preceding lens L'_2 which, as measured between corresponding optical surfaces D_7 and D_8 and given the assumed overall focal length of 1 mm, is between 0.01 and 0.02 mm.

For the assumed overall focal length of 1 mm, it has a thickness at the center between 0.39 and 0.41 mm, an entry surface radius between 1.62 and 1.63 mm and an exit surface radius between 1.28 and 1.29 mm.

Finally, its refractive index is 1.62, its Abbe number is 53, and it may be made, for example, from the optical material with reference C 23-53.

The fourth lens L'_4 is biconvex.

It is delimited by optical surfaces D_{10} and D_{11}, the former constituting its entry surface and the latter its exit surface. It is disposed at a distance from preceding lens L'_3 which, as measured between corresponding optical surfaces D_9 and D_{10} and given the assumed overall focal length of 1 mm, is between 0.01 and 0.02 mm.

For the assumed overall focal length of 1 mm, it has a thickness at the center between 0.60 and 0.62 mm, an entry surface radius between 5.08 and 5.14 mm and an exit surface radius between 1.65 and 1.66 mm.

Finally, its refractive index is 1.62, its Abbe number is 53, and it may be made, for example, from the optical material with reference C 23-53.

The fifth lens L'_5 is concave-convex, and has its convex side facing preceding lens L'_4.

It is defined between two optical surfaces D_{12} and D_{13}, the former constituting its entry surface and the latter its exit surface.

Given the assumed overall focal length 1 mm, it is disposed at a distance from preceding lens L'_4 which, as measured between corresponding optical surfaces D_{11} and D_{12}, is between 0.01 and 0.02 mm.

For the assumed overall total length of 1 mm, it has a thickness at the center between 0.13 and 0.15 mm, an

entry surface radius between 3.24 and 3.25 mm and an exit surface radius between 0.89 and 0.90 mm.

Finally, its refractive index is 1.72, its Abbe number is 30, and it may be made, for example, from the optical material with reference D 17-29.

Lens L'_6 is biconvex and is in contact with preceding lens L'_5.

Optical surface D_{13} thus forms its entry surface, whereas an optical surface D_{14}, which is the exit optical surface of rear lens unit G', constitutes its exit surface.

Given the assumed overall focal length of 1 mm, its thickness at the center is between 0.97 and 0.99 mm, its entry surface radius is between 0.89 and 0.90 mm and its exit surface radius is between 5.08 and 5.14 mm.

Finally, its refractive index is 1.62, its Abbe number is 53, and it may be made, for example, from the optical material with reference C 23-53.

Some of the numerical values specified hereinabove are summarized in table Ia below, which lists, for the references of the component parts, optical surfaces or diaphragms in question, the nature of the component and, in millimeters for the assumed overall focal length of 1 mm, the minimum and maximum distances from the adjacent component, the minimum and maximum radius, in the case of an optical surface, and the effective diameter.

In order to specify the orientation of the optical surfaces, the radii are assigned a sign, positive if the radius of the optical surface is on the other side thereof relative to the iris diaphragm, and negative in the contrary case.

Table Ib is based on the same numerical values and the same conditions, but relates these to the lenses involved, giving the distance from a lens to the preceding lens.

Table Ib also gives the nature and refractive index of each lens.

With the values indicated above, the distance between exit optical surface D_{14} and the focal image plane F, as shown in the drawing, is between 1.2 and 1.4 mm for the assumed overall focal length of 1 mm. Its overall dimension is thus between 4.11 and 4.55 mm.

TABLE Ia

Component (optical surface or diaphragm)	Nature of component	Distance to next component (mm) min	Distance to next component (mm) max	Radius (optical surface) (mm) min	Radius (optical surface) (mm) max	Effective diameter (mm)

The stated values and specifications show that front lens unit G of the objective lens in accordance with the invention is, generally speaking, adapted to use of the latter in media with different refractive indices, and in particular in air just as well as in water, and that rear lens group G' is, generally speaking, adapted to apply the necessary correction to maintain abberations within reasonable limits and to achieve a required value of focal length.

Tables IIa and IIb below give, by way of non-limiting example and in a manner similar to that of tables Ia and Ib above, numerical values for an objective lens with an overall focal length of 11.27 mm which is especially advantageous.

TABLE IIa

The distance to the focal image plane from this objective lens, as defined hereinabove, is then 14.56 mm, and its overall dimension 49 mm.

It will be understood that various changes in the details, materials and arrangements of parts, which have been herein described and illustrated in order to explain the nature of the invention, may be made by those skilled in the art within the principle and scope of the invention as expressed in the appended claims.

For example, lenses could if required be disposed between front lens unit G and rear lens group G', without departing from the scope of the present invention. Likewise, meniscus or biconvex lenses could if required be disposed between lenses L'_2 and L'_5 of rear lens unit G', without departing from the scope of the present invention.

In all cases, note that in the case of an application to industrial surveillance, the front diaphragm advantageously constitutes mechanical protection for the objective lens and the camera it equips, especially where there is risk of spattering of metal cuttings or other materials.

All numerical values cited in the appended claims relate to an overall focal length of 1 mm. Any actual overall focal length can be reduced to this value by application of the appropriate coefficient of division.

It is claimed:

1. An objective lens for a camera, said lens comprising an iris diaphragm being disposed at the front of said lens and an optical assembly being disposed behind said iris diaphragm, said optical assembly comprising a plano-convex front lens unit with its plane surface facing the front of said lens whereby said lens is suitable for use in media with different refractive indices, and a rear lens unit being adapted to apply the necessary correction to maintain abberations within reasonable limits and to achieve a required distance from said lens to the focal image plane, said iris diaphragm having an effective diameter of 0.25 mm., said plano-convex lens being disposed between 0.02 and 0.04 mm. from said iris diaphragm and having a refractive index of 1.45, an Abbe number of 68 and a thickness at the center between 0.08 and 0.11 mm., and wherein the rear surface of said plano-convex lens has a radius of between 0.92 and 0.93 mm.

2. An objective lens according to claim 1, wherein the effective diameter of said iris diaphragm is of the order of 0.25 mm.

3. An objective lens according to claim 1, wherein said rear lens unit is disposed between 0.14 and 0.18 mm from said front lens unit.

4. An objective lens for a camera, said lens comprising an iris diaphragm being disposed at the front of said lens and an optical assembly being disposed behind said iris diaphragm, said optical assembly comprising a plano-convex front lens unit with its plane surface facing the front of said lens whereby said lens is suitable for use in media with different refractive indices, and a rear lens unit being adapted to apply the necessary correction to maintain abberations within reasonable limits and to achieve a required distance from said lens to the focal image plane, said rear lens unit comprising a biconcave first lens which has a thickness at the center of between 0.06 and 0.08 mm, an entry surface radius of between 0.39 and 0.40 mm, an exit surface radius of between 1.03 and 1.04 mm, a refractive index of 1.80 and an Abbe number of 25.

5. An objective lens according to claim 4, wherein said rear lens unit comprises a biconvex second lens in contact with said first lens and which has a thickness at the center of between 0.49 and 0.51 mm, an entry surface radius of between 1.03 and 1.04 mm, an exit surface radius of between 0.71 and 0.72 mm, a refractive index of 1.49 and an Abbe number of 70.

6. An objective lens according to claim 5, wherein said rear lens unit comprises a concave-convex third lens which has its concave side facing said second lens, which is disposed between 0.01 and 0.02 mm from said second lens and which has a thickness at the center of between 0.39 and 0.41 mm, an entry surface radius of between 1.62 and 1.63 mm, an exit surface radius of between 1.28 and 1.29 mm, a refractive index of 1.62 and an Abbe number of 53.

7. An objective lens according to claim 6, wherein said rear lens unit comprises a biconvex fourth lens which is disposed between 0.01 and 0.02 mm from said third lens and which has a thickness at the center of between 0.60 and 0.62 mm, an entry surface radius of between 5.08 and 5.14 mm, an exit surface radius of between 1.65 and 1.66 mm, a refractive index of 1.62 and an Abbe number of 53.

8. A objective lens according to claim 7, wherein said rear lens units comprises a concave-convex fifth lens which has its convex side facing said fourth lens, which is disposed between 0.01 and 0.02 mm from said fourth lens and which has a thickness at the center of between 0.13 and 0.15 mm, an entry surface radius of between 3.24 and 3.25 mm, an exit surface radius of between 0.89 and 0.90 mm, a refractive index of 1.72 and an Abbe number of 30.

9. An objective lens according to claim 8, wherein said rear lens unit comprises a biconvex sixth lens in contact with said fifth lens and which has a thickness at the center of between 0.97 and 0.99 mm, an entry surface radius of between 0.89 and 0.90 mm, an exit surface radius of between 5.08 and 5.14 mm, a refractive index of 1.62 and an Abbe number of 53.

10. An objective lens according to claim 1, wherein the distance between the focal image plane of the lens

and the rearmost surface of said rear lens unit is between 1.2 and 1.4 mm.

11. An objective lens according to claim **4**, wherein the effective diameter of said iris diaphragm is of the order of 0.25 mm.

12. An objective lens according to claim **4**, wherein said rear lens unit is disposed between 0.14 and 0.18 mm from said front lens unit.

13. An objective lens according to claim **4**, wherein the distance between the focal image plane of the lens and the rearmost surface of the said rear lens unit is between 1.2 and 1.4 mm.

14. An objective lens for a camera, said lens comprising an iris diaphragm being disposed at the front of said lens and an optical assembly being disposed behind said iris diaphragm, said optical assembly comprising a plano-convex front lens unit with its plane surface facing the front of said lens whereby said lens is suitable for use in media with different refractive indices, and a rear lens unit being adapted to apply the necesary correction to maintain abberations within reasonable limits and to achieve a required distance from said lens to the focal image plane, said front lens unit comprising a single plano-convex lens with its plane surface facing the front of the lens, and having a thickness at the center of 1.15 mm, a rear surface radius of 10.43 mm and a refractive index of 1.45, and said rear lens unit comprising, in succession, a biconcave first lens which is disposed at a distance of 1.86 mm from a first preceding lens, and having a thickness at the center of 0.77 mm, an entry surface radius of 4.45 mm, an exit surface radius of 11.72 mm and a refractive index of 1.80; a biconcave seconds lens in contact with a second preceding lens and which has a thickness at the center of 5.65 mm, an entry surface radius of 11.72 mm, an exit surface radius of 8.01 mm and a refractive index of 1.49; a concave-convex third lens which is disposed at a distance of 0.19 mm from a third preceding lens with its concave side facing the front, which has a thickness at the center of 4.62 mm, an entry surface radius of 18.371 mm, an exit surface radius of 14.531 mm and a refractive index of 1.62; a biconvex fourth lens which is disposed at a distance of 0.19 mm from a fourth preceding lens, which has a thickness at the center of 6.92 mm, an entry surface radius of 57.652 mm, an exit surface radius of 18.700 mm and a refractive index of 1.62; a concave-convex fifth lens which is disposed at a distance of 0.19 mm from a fifth preceding lens with its convex side facing the front, which has a thickness at the center of 1.54 mm, an entry surface radius of 36.623 mm, an exit surface radius of 10.110 mm, and a refractive index of 1.72; and a biconvex sixth lens in contact with a sixth preceding lens, which has a thickness at the center of 11 mm, an entry surface radius of 10.14 mm, an exit surface radius of 57.652 mm and a refractive index of 1.62, said objective lens having an overall focal length of 11.27 mm and a distance between the rearmost surface of said rear lens units and its focal image plane of 14.56 mm.

15. An objective lens according to claim **14**, wherein the effective diameter of said iris diaphragm is of the order of 0.25 mm.

16. An objective lens according to claim **14**, wherein said rear lens unit is disposed between 0.14 and 0.18 mm from said front lens unit.

17. An objective lens according to claim **14**, wherein the distance between the focal image plane of the lens and the rearmost surface of said rear lens unit is between 1.2 and 1.4 mm.

[57] ABSTRACT

A zoom lens assembly for use with a photographic camera having a capability of functioning two different modes one at a time. In one mode, the lens assembly is of a type having its aperture ratio variable with change in focal length, and in the other mode, it is of a type wherein change in aperture ratio resulting from the change in focal length is compensated for to give a uniform aperture ratio at all focal length settings. For this purpose, a unique change-over mechanism is built in the lens assembly for switching the lens assembly from one of the different modes onto the other of the different modes at the will of a photographer.

OBJECTIVE LENS ASSEMBLY OF VARIABLE FOCAL LENGTH HAVING A DIAPHRAGM MECHANISM WITH ADJUSTABLE APERTURE

BACKGROUND OF THE INVENTION

This invention generally relates to an objective lens assembly of variable focal length for use with an optical picture taking apparatus, for example, a photographic still camera, a movie camera or a television camera. More particularly, this invention relates to a varifocal lens assembly of a type wherein the lens speed or the aperture ratio of the lens assembly varies with a change in the focal length.

Current commercially available zoom lens assemblies are generally classified into fixed speed types whose optical systems are designed such that the lens speed or the aperture ratio does not vary even when the focal length thereof is adjusted for zooming with the diaphragm aperture kept unchanged, and variable speed types whose optical systems are designed such that the lens speed or the aperture ratio varies when the focal length thereof is adjusted with the diaphragm aperture kept unchanged. The variable speed type zoom lens assemblies are furthermore classified into two subtypes: compensated types, wherein a mechanical compensator system is built in for compensating for change in lens speed resulting from an change in the focal length, and non-compensated type wherein the lens speed is allowed to vary with change in the focal length without any compensator system employed. Both of these subtypes have their own merits and demerits, however they play a role in the market to accommodate a diversity of customers' demands.

As is well known to those skilled in the art, for a given diaphragm aperture, the variable speed type is generally faster, i.e., has a smaller F-stop number at the shortest focal length setting than at the longest focal length setting. To compensate for the reduction of the lens speed to make the lens speed constant at all values of focal length, means must be provided for stopping down the diaphragm aperture as the focal length is adjusted to the shortest value, and this is currently embodied in the compensated model such as disclosed in, for example, U.S. Pat. No. 4,258,996. In this compensated model, the maximum available performance of the optical system of the zoom lens assembly cannot be enjoyed, particularly when the focal length is adjusted to a wide angle range. It should be noted that the term "wide angle" hereinabove and hereinafter used and the term "tele-angle" which will hereinafter be used in an opposite sense to the term "wide angle," are a relative notation applicable to a particular adjustable range of focal length of a given zoom lens assembly and correspond respectively to the reading on a focal length setting element such as, for example, a zooming ring, approaching the shortest focal length and that approaching the longest focal length. By way of example, for any zoom lens assembly having it focal length adjustable within a range of 28 mm to 55 mm, the focal length setting to a value on the side of the 55 mm position or the longest focal length may be said to be the setting to the "wide angle" range and that to the "tele-angle" range, respectively.

As hereinbefore described, in the variable speed zoom lens assembly of the compensated type, the maximum available performance of the optical system is sacrificed at the wide angle range to tailor the lens speed or aperture ratio to a value given at the longest available focal length setting. However, this compensated model is generally considered convenient in that, since in practice the smallest available aperture reading, that is, F-stop number, on the aperture setting ring is calibrated to a value given at the longest available focal length setting, the photographer need neither readjust the aperture setting ring in an attempt to compensate for reduction in lens speed resulting from the change of the focal length, nor keep in mind the necessity of such a readjustment, and, also, the lens assembly has a consistency with the exposure control system of a photographic camera. On the other hand, although the variable speed zoom lens of non-compensated type, such as disclosed in, for example, Modern Photography, November 1977, Vol. 41, No. 11, pages 164 to 168, is advantageous in that the maximum available performance of the optical system can be fully enjoyed at any focal length setting, not only does the layout in the non-compensated model of the aperture reading on the aperture setting ring in combination with an index marking pose a problem, but also the lens assembly lacks a consistency with the exposure control system.

Specifically, in the variable speed zoom lens assembly of the non-compensated type referred to above, the smallest aperture reading on the aperture setting ring includes two F-stop numbers available generally at the wide angle range and the tele-angle range, respectively, in combination with the index marking including the juxtaposed aperture-indicating indicia associated respectively with the smallest F-stop numbers. So far as the lens assembly disclosed in the Modern Photography, supra, is concerned, it is described that the 43–75 mm zoom lens assembly is an f/3.5 for most of its zoom, i.e., the focal length setting, but becomes f/4.5 at the maximum 75 mm setting, and two juxtaposed aperture-indicated indicia are employed in the form of a line and a dot on the fixed barrel around which the aperture setting ring can be rotated.

For better understanding of this invention, the merits and demerits of each of the compensated and non-compensated models of the variable speed zoom lens assemblies will be hereinafter discussed in detail under separate headings.

I. NON-COMPENSATED MODEL

Merits: The maximum available optical performance determined by the design of the optical system can be utilized at the short focal length setting or wide angle range. Since in most cases the wide angle range is used more frequently in indoor photography than in outdoor photography and, so far as the indoor photography is concerned, more frequently than the tele-angle range is, the utilizeability of the designed maximum available optical performance at the largest diaphragm aperture setting, i.e., the smallest F-stop number or aperture reading, has a great significance in that the non-compensated model can permit a picture taking in darker indoor condition than the other model does.

Demerits: With a photographic camera having an exterior metering system, not a TTL (through-the-lens) metering system, in which the determination of a particular exposure value depends on the incoming light not passing through the picture-taking lens assembly, or with a photographic camera having no exposure metering system built therein, it is necessary to line up the selected F-stop number or aperture reading with either

one of the two aperture-indicating indicia to be used respectively at the wide angle range and the tele-angle range. In particular, it is practically impossible for less skilled photographers to set an F-stop number intermediate of the available aperture setting range when the focal length is set to a value intermediate of the available focal length range, i.e., the available zooming range. In addition, in view of the necessity of the use of the two aperture-indicating indicia, it often occurs in great possibility that one of the two indicia might be inadvertently taken for the other of the indicia, resulting in the incorrect diaphragm aperture setting.

When it comes to the camera system utilizing an automatic flash unit of a type so designed as to enable the guide number for a given film speed to be manually adjustable by presetting an F-stop number to the aperture scale on the flash unit, there is a possibility that, unless the F-stop number is correctly preset to the aperture scale with due regard paid to the possible change in aperture setting in the lens assembly as a result of the zooming, the amount of flash light emitted from the flash unit may be controlled on the erroneous information to such an extent as to result in the improper exposure.

In addition, in a certain type of camera wherein the transmission of information of the smallest available F-stop number from an interchangeable lens assembly to the camera body is required when and so long as the lens assembly has been mounted on the camera body, the erroneous exposure setting may occur unless means is provided for transmitting information of the two smallest F-stop numbers available on the non-compensated model according to the focal length setting.

A similar erroneous exposure setting may occur when the focal length of the non-compensated model is adjusted to the shortest value after an AE lock has been effected at the longest focal length setting to memorize a particular diaphragm aperture setting at such longest focal length. This technique is known as a substitute for the center-weighted light measurement, taking advantage of the smallest angle of view the zoom lens assembly can achieve at the longest focal length setting. However, the diaphragm aperture setting once locked or memorized at the longest focal length setting does not remain the same when and after the focal length has been adjusted from the longest setting towards the smallest because of inherent change occurring in the lens speed of the non-compensated type with change in focal length.

II. COMPENSATED MODEL

Merits: The compensated type of the variable speed zoom lens assembly is substantially free from the demerits inherent in the non-compensated model and has a good consistency with the camera system.

Demerits: In designing the optical system of any zoom lens assembly of the variable speed type, the aperture ration thereof at a given diaphragm aperture setting is practically meant to be that attained when the focal length is adjusted to the longest setting and, accordingly, as hereinbefore briefly mentioned, for a given diaphragm aperture setting, the zoom lens assembly is lower at the longest focal length than at the shortest focal length. Therefore, in the manufacture of the compensated model wherein the previously described compensating means is incorporated to avoid the change of the lens speed which would result from change in focal length, the employment of unnecessarily large lens elements for the given smallest F-stop number is necessitated if the compensated model which is reasonably and competitively fast at the smallest focal length setting is desired. This means that not only does the resultant lens assembly become bulky and heavy, but also it cannot make the most of the size-increased lens elements. This is because, if it is desired to manufacture the compensated model reasonably and competitively fast at the smallest focal length setting for a given F-stop number, for example, the smallest available F-stop number. The aperture ratio at the longest focal length, which aperture ratio is known as a quotient of the effective aperture divided by the focal length, must be of a relatively small value and this is generally accomplished by the employment of the relatively large-sized lens elements.

The use of the relatively large-sized lens elements in turn results in the increased difficulty in designing the optical system as a whole and tend to constitute a cause of the reduced image forming performance of the resultant lens assembly. One may consider the possibility of designing the smallest F-stop number available at the longest focal length setting to be determined depending on that available at the shortest focal length setting, rather than to design the smallest F-stop number at the shortest focal length setting to be determined on that at the longest focal length setting. However, this is extremely difficult as a matter of practice in view of the previously described increased design difficulty and the extent of possible reduction in optical performance resulting from design errors. (The error sensitivity, which means the extent to which the optical aberrations, the lens-back and/or the focal length vary for a given error, is, in the case of a zoom lens assembly, apt to be higher at the longest focal length setting than at the short focal length setting range and to increase with increase of the size of the lens elements.)

As hereinbefore discussed, the compensated and non-compensated models of the zoom lens assemblies are compatible with each other in the sense that the demerits of one mode are compensated for by the other model, and vice versa.

SUMMARY OF THE INVENTION

Accordingly, this invention has been developed with a view to minimizing the embarrassment a camera hobbist has hitherto suffered in making a decision of what model of zoom lens assembly to purchase and is intended to provide a unique zoom lens assembly which can be used as compensated and non-compensated models one at a time without sacrificing the maximum available optical performance and without the required use of lens elements of substantially increased size.

According to this invention, the zoom lens assembly is provided with a manipulatable change-over mechanism for bringing the lens assembly selectively into one of the two modes, namely, compensated and non-compensated modes: the lens assembly in the compensated mode function in a manner similar to the previously discussed compensated model, and the same lens assembly in the non-compensated mode in a manner similar to the previously discussed non-compensated model.

The zoom lens assembly having the above-described dual function is believed to have a great significance in its existence as it may appeal to amateur and professional camera lovers, who have long been embarrassed with a diversity of choices of lens assemblies in addition to a diversity of makes of cameras available.

BRIEF DESCRIPTION OF THE DRAWINGS

These and other objects and features of this invention will readily be understood from the following description taken in conjunction with preferred embodiments thereof with reference to the accompanying drawings, in which:

FIG. 1 is a longitudinal sectional view showing a zoom lens assembly according to a first embodiment of this invention with its focal length set to the longest value;

FIG. 2 is a longitudinal side view, with a portion broken away, showing the lens assembly of FIG. 1 with the focal length set in a wide-angle range;

FIG. 3 is a perspective view showing a manipulatable change-over mechanism used in the lens assembly of FIGS. 1 and 2;

FIG. 4 is a perspective view, on an enlarged scale, showing a detent arrangement operatively associated with the change-over mechanism of FIG. 3;

FIG. 5 is a longitudinal side view, with a portion broken away, showing the lens assembly according to a second embodiment of this invention;

FIG. 6 is a view similar to FIG. 3, showing the change-over mechanism used in the lens assembly of FIG. 5;

FIG. 7 is a view similar to FIG. 5, showing the lens assembly according to a third embodiment of this invention;

FIG. 8 is a perspective view showing the change-over mechanism used in the lens assemmbly of FIG. 7;

FIG. 9 is a view similar to FIG. 7, showing a portion of the lens assembly of FIG. 7 with the focal length set to the smallest value;

FIG. 10 is a view similar to FIG. 9, showing the lens assembly according to a fourth embodiment of this invention;

FIGS. 11(a) to 11(e) are schematic diagrams showing the sequence of operation of a safety mechanism used in the lens assembly of FIG. 10;

FIG. 12 to FIG. 14 are perspective views of a portion of the change-over mechanism according to fifth, sixth and seventh embodiments of this invention, respectively;

FIGS. 15(a) to 15(d) are schematic diagrams showing the sequence of operation of the change-over mechanism shown in FIG. 14;

FIG. 16 is a graph showing the relationship between the focal length setting and the aperture reading, i.e., F-stop numbers;

FIGS. 17, 19, 21 and 23 are side views of the zoom lens assembly set in a compensated mode, showing first, second, third and fourth embodiments of aperture-indicating marking, respectively;

FIGS. 18, 20, 22 and 24 are views similar to FIGS. 17, 19, 21 and 23, respectively, showing the zoom lens assembly set in a non-compensated mode;

FIGS. 25(a) and 25(b) are diagrams showing a diaphragm aperture adjusting ring of FIGS. 23 and 24 developed in a plane, together with a stopper in different operative positions, respectively;

FIG. 26 is a perspective view showing the change-over mechanism according to an eighth embodiment of this invention;

FIG. 27 is a schematic top plan view of the change-over mechanism of FIG. 26;

FIG. 28 is a view similar to FIG. 27, showing the change-over mechanism according to a ninth embodiment of this invention; and

FIG. 29 is a view similar to FIG. 26, showing a modified form of the change-over mechanism included within the scope of this invention.

DETAILED DESCRIPTION OF EMBODIMENTS

FIGS. 1 to 4 illustrate a zoom lens assembly according to a first embodiment of this invention. Referring to FIGS. 1 to 4, the lens assembly shown particularly in FIGS. 1 and 2 comprises its optical system including, for example, a front lens group 1 and a rear lens group 2, and a diaphragm mechanism movable together with the rear lens group 2 in a direction parallel to the optical axis of the system, the diaphragm mechanism being comprised of a ring-shaped diaphragm holder 8 and a diaphragm operating ring 9. The lens assembly also comprises a zooming ring 5 supported for rotation about the optical axis for the adjustment of the focal length of the lens assembly, a diaphragm aperture adjusting ring 12 operatively coupled to the diaphragm mechanism and mounted for rotation about the optical axis, and a change-over ring 11 mounted for rotation through a limited angle about the optical axis and positioned between the rings 5 and 12 in front of the ring 12, i.e., with respect to the direction in which the lens assembly mounted at its right-hand end to a camera body (not shown) is aimed at a target object to be photographed.

In addition to the diaphragm holder 8 and the diaphragm operating ring 9, the diaphragm mechanism is also comprised of, as best shown in FIG. 3, a plurality of diaphragm blades, only one of which is shown by 24, the blades 24 being so arranged and so supported in a manner known to those skilled in the art that, when the diaphragm operating ring 9 is rotated about the optical axis relative to the diaphragm holder 8, the aperture defined by the blades 24 in coaxial relation to the optical axis can be narrowed and widened one at a time depending on the direction of the relative rotation. It should be noted, however, that, the diaphragm holder 8 can also be rotatable relative to the diaphragm operating ring 9 for the purpose of this invention. The aperture adjusting ring 12 has a lever 44 rigidly secured thereto and extending generally radially inwardly for engagement with an aperture preset ring 19, whereby when the ring 12 is rotated, the rotation of the ring 12 can be transmitted to the diaphragm operating ring 9 through the engagement between a linear groove 21, defined in an axial arm extending axially from the preset ring 19, and a pin 23 received in the linear groove 21 and rigidly secured to the operating ring 9 through an axial lever 22 parallel to the axial arm of the preset ring 19. Thus, it will be readily be seen that, by rotating the aperture adjusting ring 12 to any one of the positions of aperture reading, that is, the F-stop numbers, the diaphragm aperture defined by the blades 24 can be adjusted to a diameter appropriate to the selected F-stop number to which the aperture adjusting ring 12 has been rotated. While the diaphragm mechanism can move together with the rear lens group 2 in a direction axially of the optical system during the zooming with the zooming ring 5 rotated because it is integrally mounted with the rear lens group 2, the rotation of the zooming ring 5 does not result in any angular displacement of the operating ring 9 because the linear groove 21 extends in parallel relation to the optical axis of the lens assembly.

The diaphragm holder 8 has a pin 27 rigidly mounted thereon and extending radially outwardly therefrom for engagement into a continuous guide groove of a generally U-shaped configuration defined in a cam plate 10 rigidly connected to the change-over ring 11, the continuous guide groove being comprised of an axially-extending guide groove portion 40 which extends in parallel relation to the optical axis, a cam groove portion 42 which extends diagonally frontwardly so as to converge with the axial guide groove portion 40 at a point away from the ring 11, and a connecting groove portion 41 located adjacent to the ring 11 and having its opposite ends communicated to the guide and cam groove portions 40 and 42, respectively. In FIG. 3 the pin 27 is shown as engaged in the axial guide groove portion 40 of the continuous guide groove in the cam plate 10 and, in this condition, the diaphragm holder 8 does not undergo any rotation about the optical axis even though the diaphragm mechanism, including the previously described elements 8, 9 and 24, is axially moved as a result of the rotation of the zooming ring 5 during the zooming operation. Thus, so long as the pin 27 is engaged in and guided by the axial guide groove portion 40, the zooming operation does not result in the adjustment of the diaphragm aperture and this means that, for a given diaphragm aperture setting, that is, wherever the aperture adjusting ring 12 is positioned, the lens speed, that is, the aperture ratio of the lens assembly can vary with change in focal length. It is, however, to be noted that the linkage between the holder 8 and the operating ring 9 is so designed as to render the diaphragm aperture at a maximum when the aperture adjusting ring 12 is set or positioned to the smallest available F-stop number.

FIG. 3 illustrates the condition which is attained when the zooming ring 5 has been moved to the shortest focal length position. Starting from this condition, and when the change-over ring 11 is pulled axially frontwardly, or leftwards as viewed in FIGS. 1 to 3, against a compression spring 35 to move the cam plate 10 a predetermined distance shown by 1, in FIG. 3, the pin 27 which has been situated within the axial guide groove portion 40 is brought into alignment with the connecting groove portion 41, the subsequent rotation of the change-over ring 11 from a non-compensated position to a compensated position resulting in the entry of the pin 27 into the cam groove portion 42 through the connecting groove portion 41. When an external pulling force applied to the change-over ring 11 is released therefrom after the ring 11 has been moved to the compensated position about the optical axis with the pin 27 having consequently brought into engagement in the cam groove portion 42, the subsequent zooming operation, that is, the subsequent rotation of the zooming ring 5, results in the angular movement of the diaphragm holder 8 about the optical axis relative to the operating ring 9 as the pin 27 is guided in and along the cam portion 42 in a direction away from the connecting groove portion 41. The result is that the diaphragm aperture defined by the blades 24 varies in a direction required to compensate for a change in aperture ratio resulting from the change in the focal length. This is possible because, as the zooming ring 11 is rotated from the shortest focal length position towards the longest focal length position while the aperture adusting ring 12 is set at a given F-stop number, for example, the smallest F-stop number, the diaphragm mechanism moves axially frontwardly in such a manner that, while the operating ring 9 is moved axially with the pin 23 guided in and along the linear groove 21, the diaphragm holder 8 undergoes axial and rotary motion with the pin 27 guided in and along the cam groove portion 42 of the groove in the cam plate 10.

FIGS. 5 and 6 pertain to a second embodiment of this invention which will now be described in connection with what makes this second embodiment differ from the preceding embodiment. Comparing FIG. 6 with FIG. 3, it will readily be seen that cam and axial guide groove portions 62 and 64, both shown in FIG. 6, take the position of axial guide and cam groove portions 40 and 42, respectively. In addition, the arrangement has been made such that, during the zooming operation, the diaphragm mechanism as a whole can undergo axial and rotary motion with respect to the optical axis with no relative rotation taking place between the diaphragm holder 8 and the operating ring 9 and, consequently, without the diaphragm aperture being varied. This is true when and so long as a pin 68 (which functionally corresponds to the pin 27 shown in FIG. 3) is engaged in the cam groove portion 62. However, when and after the pin 68 has been brought into engagement in the axial guide groove portion 64 (which functionally corresponds to the cam groove portion 42 shown in FIG. 3), and when the zooming operation is subsequently initiated, the diaphragm holder 8 does not rotate, but the operating ring 9 rotates and, accordingly, the diaphragm aperture changes in a manner so as to compensate for the change in aperture ratio resulting from the change in focal length.

FIGS. 7, 8 and 9 pertain to a third embodiment of this invention. While the lens assembly according to the embodiment shown in FIGS. 7 to 9 is basically identical with that according to the embodiment shown in FIGS. 1 to 4, this third embodiment is directed to an improvement in a lock mechanism. In general, in any one of the foregoing embodiments, the change-over of the zoom lens assembly from one of the compensated and non-compensated modes into the other of these modes can be effected when the zooming ring has been rotated to the shortest focal length position. While the lens assembly in any one of the foregoing embodiments employs a click-stop mechanism operable to avoid any unnecessary or accidental change-over of the modes, the lens assembly in this third embodiment shown in FIGS. 7 to 9 employs a lock pin 83.

As best shown in FIGS. 7 and 8, the lock pin 83 is carried by a change-over ring 81 (which functionally corresponds to the change-over ring 11 shown in FIGS. 1 to 4) through an elongated leaf spring 82 and has its free end normally engaged in one of the lock holes 86 and 87 defined in a portion of a fixed barrel 80 thereby to prevent the change-over ring 81 from being accidentally or unnecessarily rotated and, hence, to lock the lens assembly in one of the compensated and non-compensated modes. In this condition, the mode change-over of the lens assembly cannot be effected. However, when the zooming ring is rotated to the shortest focal length position with the rear lens group consequently moving rightwards as viewed in FIG. 7, a tapered area 39 at the righthand, rear end of a movable lens mount 7 for the rear lens group is brought into engagement with the leaf spring 82 ready to depress the latter downwards as viewed in FIG. 7. While the turn of the change-over ring 81 about the optical axis after the lock pin 83 has disengaged from the one of the lock holes 86 and 87 results in the change-over of the lens assembly from the

one of the compensated and non-compensated modes to the other of the compensated and non-compensated modes, this can be accomplished by pulling a change-over pin **85** on the change-over ring **81** in a direction leftwards, as viewed in FIG. **7**, to displace the leaf spring **82** together with the change-over ring **81** in a direction leftwards against a compression spring **84** so that the free end of the leaf spring **82** can be forced to displace downwards, as viewed in FIG. **7**, against its own resiliency in sliding contact with the tapered area **39** with the free end of the lock pin **83** consequently disengaged from the one of the lock holes **86** and **87** as best shown in FIG. **9**, thereby conditioning the lens assembly ready to be switched over from the one of the compensated and non-compensated modes. The actual change-over will be described in detail later.

The fourth embodiment of this invention shown in FIGS. **10** and **11** is similar to the foregoing embodiment shown in FIGS. **7** to **9** in that it pertains to the lock mechanism, but in a modified form.

FIG. **12**, FIG. **13** and FIGS. **14** and **15** pertain, respectively, to fifth, sixth and seventh embodiments of this invention, which will be described later in detail.

FIGS. **17** to **24** illustrate different embodiments of aperture-indicating markings provided on the zoom lens assembly according to this invention. While the aperture-indicating may be a simple aperture-indicating indicium, for example, either a line or a dot, so far as any one of the fixed speed type and the compensated model is concerned, the zoom lens assembly having the capability of functioning as the compensated and non-compensated models such as according to this invention must have two or more aperture-indicating indicia to be used one at a time according to the mode to which the lens assembly has been selected. For this purpose, the embodiments shown in FIGS. **17** to **24** are provided, the details of which will be set forth later.

FIGS. **26** and **27** illustrate different forms of application of this invention to lens assemblies having different types of diaphragm mechanisms, respectively, and FIGS. **28** and **29** illustrate other embodiments of this invention, reference to all of which will be made later.

While the various embodiments of this invention have been described briefly in the foregoing description, the details thereof including the embodiments not mentioned in the foregoing description will now be described.

FIRST EMBODIMENT (FIGS. 1 TO 4)

Referring to FIGS. **1** to **4**, the zooming operation (the focal length setting), the focusing operation (the distance setting) and the diaphragm aperture setting of the zoom lens assembly will be described. The zoom lens assembly shown in this embodiment has a two-component optical system including the front and rear lens groups **1** and **2** which are supported for movement in predetermined directions upon rotation of the zooming ring **5**. Particularly, during the zooming operation, the movement of the front lens group **1** is effected by the utilization of a diagonal cam groove **13** defined in the zooming ring **5**, an axial guide groove **14** defined in a fixed barrel **3**, and a guide pin **15**, and the movement of the rear lens group **2** is effected by the utilization of a diagonal cam groove **16** defined in the zooming ring **5**, an axial guide groove **17** defined in the fixed barrel **3**, and a guide pin **18**. The focusing operation can be done by rotating a focusing ring **4** to move the front lens group guided by a helicoid thread **50** defined in a movable lens mount **6** for the front lens group **1**. The diaphragm mechanism including the diaphragm blades can be moved together with the movable lens mount **7** for the rear lens group **2** in a direction parallel to the optical axis.

The diaphragm aperture setting will now be described. The diaphragm blades **24** have respective pairs of rivets **25** and **26** rigidly mounted thereon in spaced relation, the rivets **26** being engaged in respective cam slots **43** defined in the diaphragm operating ring **9**, while the rivets **25** are pivotally received in respective bearing holes **45** in the diaphragm holder **8**. The pin **27** rigidly mounted on the diaphragm holder **8** and extending radially outwardly therefrom is engaged in the continuous guide groove including the guide, connecting and cam portions **41**, **42** and **43** and defined in the cam plate **10** fast or integral with the change-over ring **11**. On the other hand, the pin **23** rigidly mounted on the axial lever **22** fast or integral with with operating ring **9** is engaged in the linear groove **21** in the preset ring **19**. The preset ring **19** is normally biased by a coil spring **49** in a direction counterclockwise as viewed in the direction in which the lens assembly is aimed (at the target object to be photographed), with the diaphragm blades **24** consequently stopped down to the smallest available aperture, that is, the greatest available F-stop number while the rotation of the preset ring **19** is restricted by the lever **44** fast with the aperture adjusting ring **12**. It is to be noted that, when the aperture adjusting ring **12** is rotated about the optical axis in a direction counterclockwise as viewed in the direction in which the lens assembly is aimed (at the target object), the lever **44** moves angularly together with the adjusting ring **12** and the preset ring **19** rotates as pulled by the coil spring **49** in pursuit of and after the lever **44**, the rotation of the preset ring **19** being consequently transmitted to the operating ring **9** through the arm of the ring **19**, then the pin **23** and, finally, the axial lever **22**, whereby the diaphragm blades **24** can be stopped down towards the smallest available aperture with the rivets **26** guided in and along the respective cam slots **43**.

Hereinafter, the manner of change of the diaphragm aperture defined by the diaphragm blades **24** as a result of the zooming operation will be described. As hereinbefore described, the diaphragm mechanism, including the blades **24**, the holder **8** and the operating ring **9**, can be axially moved together with the rear lens group when the zooming operation is initiated. So long as the pin **27** on the holder **8** is engaged in the axial guide groove portion **40** of the continuous guide groove of generally U-shaped configuration in the cam plate **10**, the cam holder **8** does not undergo rotary motion about the optical axis during the axial movement of the diaphragm mechanism as a whole. Similarly, even the operating ring **9** does not undergo rotary motion about the optical axis, but moves axially with the pin **23** guided in and along the linear groove **21** in the preset ring during the zooming operation. Thus, so long as the pin **27** is engaged in the guide portion **40** as shown in FIG. **3**, the lens assembly is held in the non-compensated mode in which the diaphragm aperture defined by the diaphragm blades **24** does not vary, that is, the aperture ratio of the lens assembly at any diaphragm aperture setting can vary with change in focal length. Given the 28–85 mm, f/3.5–4.5 zoom lens assembly, the smallest aperture ratio of 3.5 available at the shortest focal length setting of 28 mm varies to the aperture ratio of 4.5 when the focal length is adjusted to the longest

setting of 85 mm in a manner as shown in the graph of FIG. 16, so long as the pin 27 is engaged in the axial guide groove portion 40, that is, the lens assembly is held in the non-compensated mode.

However, when the zooming operation is effected while the pin 27 is engaged in the cam groove portion 42, the diaphram holder 8 undergoes not only axial motion, but also rotary motion about the optical axis because of the shape of the cam groove portion 42 while the operating ring 9, though moved axially together with the diaphragm holder 8, does not rotate about the optical axis. In this condition, the diaphragm aperture defined by the diaphragm blades 24 varies with change in focal length and the lens assembly is therefore in the compensated mode.

The change-over mechanism necessary for bringing the lens assembly selectively from one of the compensated and non-compensated modes into the other of the compensated and non-compensated modes at the will of the user will now be described. The change-over mechanism including the change-over ring 11 also includes a click-stop device for avoiding an unnecessary rotation of the change-over ring 11 during the zooming operation. The click-stop device is constituted by, as best shown in FIG. 4, a pair of spaced lock recesses 51 and 52, a pair of spaced lock recesses 31 and 32, and a pair of spaced click recesses 46 and 47. The pair of lock recesses 31 and 32 are utilized to permit the rotation of the change-over ring 11 only when the zooming ring 5 is set to the shortest focal length position so that the diaphragm holder 8 will not be unnecessarily displaced angularly about the optical axis during the zooming operation. More specifically, the fixed barrel 3 has a leaf spring 28 secured at one end thereto by means of a set screw 48 and also has defined therein a slot 30 slightly wider than the diameter of a lock pin 29 carried by the leaf spring 28. When and so long as the rear movable lens mount 7 for the rear lens group 2 is held at a position corresponding to the longest focal length setting as shown in FIG. 1, the lock pin 29 extending loosely through the slot 30 in the fixed barrel 3 is engaged in one of the lock recesses 31 and 32 both defined in the change-over ring 11 to avoid unnecessary or premature rotation of the change-over ring 11. Where the lens assembly is in the compensated mode, the lock pin 29 is engaged in the lock recess 31, but where it is in the non-compensated mode, the lock pin 29 is engaged in the lock recess 32.

However, when and after the rear movable lens mount 7 has been moved to the opposite position corresponding to the shortest focal length setting as a result of the rotation of the zooming ring 5 as shown in FIG. 2, the tapered area 39 at the rear end of the rear movable lens mount 7 is brought into contact with the free end of the leaf spring 28 thereby upwardly, as viewed in FIG. 2, or radially inwardly, shifting the free end of the leaf spring 28 against it own resiliency to disengage the lock pin 29 from the lock recess in the change-over ring 11. It is, however, to be noted that any accidental or premature rotation of the change-over ring 11 should not occur even when the zooming ring is set to the shortest focal length position. For this purpose, the lock recesses 51 and 52 are provided for engagement with a lock screw 53 rigidly threaded to the fixed barrel 3. In order to release this lock, the change-over ring 11 has to be pulled the predetermined distance, shown by 1_1, in FIG. 3, in the frontward direction against the compression spring 35 and then to be rotated until a detent ball 33 is seated in one of the click recesses 46 and 47. By so doing, the mode change-over is completed. The purpose of the provision of the click recesses 46 and 47 is to make the mode positions for the change-over ring 11 clear, and if a biasing spring 34 for the detent ball 33 is employed in the form as capable of exerting a relatively great biasing force, the lock recesses 51 and 52 as well as the lock screw 53 may not be always necessary and can be omitted.

SECOND EMBODIMENT (FIGS. 5 AND 6)

The lens assembly according to the second embodiment shown in FIGS. 5 and 6 is similar to that according to the first embodiment, but has been improved to enable the mode change-over to be carried out by manipulating a change-over knob 70 in the form of a pin rigidly mounted on and extending radially outwardly from a change-over ring 55, and also to simplify the structure by forming lock holes in the change-over ring 55 and a slant guide groove 65 in an axially extending arm of the preset ring 19. In FIGS. 5 an 6 the lens groups are shown as positioned corresponding to the longest focal length setting. When the zooming ring 5 is rotated, the front lens group 1 is axially moved in the leftward direction, that is, in a direction opposite to the film (not shown) in the camera body, by the utilization of the cam groove 13, the axial guide groove 14 and the guide pin 15 while the rear lens group 2 is moved axially inthe rightward direction, i.e., in the direction towards the film, by the utilization of the cam groove 16, the axial guide groove 17 and the guide pin 18, thereby setting the focal length of the lens assembly in the wide angle range. As a matter of course, the rear movable lens mount 7 is moved together with the rear lens group 2 during the zooming operation. When the rear movable lens mount 7 is subsequently moved righwards towards a position corresponding to the short focal length setting, the tapered area 39 at the rear end of the rear movable lens mount 7 is brought into contact with the bent free end of a leaf spring 66. However, at the moment the rear movable lens mount 7 arrives at such position, the free end of the leaf spring 66 is radially inwardly displaced against its own resiliency in sliding contact with the tapered area 39 of the rear movable lens mount 7 to allow a lock pin 67, rigidly mounted on the leaf spring 66, to disengage from one of the lock holes 60 and 61 defined in the change-over ring 55 so that the subsequent manipulation of the change-over pin 70 so as to turn the change-over ring 55 about the optical axis can result in the mode change-over of the lens assembly.

In addition, in the second embodiment shown, an arrangement is made such that, when and so long as the pin 68 fast with the diaphragm holder 8 is engaged in the cam groove portion 62, the zooming operation does not result in any movement of the diaphragm blades 24 and, therefore, the lens assembly is held in the non-compensated mode. In order to set the lens assembly in the compensated mode, it is necessary to turn the change-over pin 70 through a predetermined angular distance about the optical axis in a counterclockwise direction with respect to the aiming direction, i.e., the direction in which the lens assembly is aimed at the target object, while the lock pin 67 has been disengaged from the lock hole 61 at the shortest focal length setting. As the lock pin 67 is turned in this way, the pin 68 on the diaphragm holder 8 is guided in and along a connecting groove portion 63 towards the axial guide groove portion 64.

When the zooming operation is subsequently effected after the pin 68 has been aligned with the cam groove portion 64, the diaphragm holder 8, while moving axially does not rotate, but the operating ring 9 is rotated a predetermined angle about the optical axis during its axial movement together with the diaphragm holder 8. This is possible because a pin 69 rigidly carried by the operating ring 9 through the axial lever 22 is guided in and along the slant guide groove 65 defined in the arm of the preset ring 19. Accordingly, it is clear that, during the zooming operation, while the pin 68 is guided in the axial guide groove portion 64, the diaphragm blades 24 undergo movement to adjust the diaphragm aperture defined thereby with the lens assembly consequently held in the compensated mode. It is to be noted that a biasing spring 71, a detent ball 72 and click recesses 58 and 59 are all provided for preventing the movement from occurring unnecessarily during the mode change-over with the zooming ring set at the shortest focal length position.

THIRD EMBODIMENT (FIGS. 7 TO 9)

In any one of the foregoing embodiments, the release of the change-over ring from a locked condition has been automatically performed by the utilization of the tapered area 39 of the rear movable lens mount 7 when and so long as the zooming ring has been rotated to both of the smallest and longest focal length positions. In such case, the click or lock mechanism is necessitated to avoid unnecessary or accidental movement of the change-over ring at the shortest focal length setting. In addition, since the release from the locked condition is so designed as to take place against the force of the leaf spring, a higher load or resistance tends to be imposed on the rotation of the zooming ring as the latter is rotated towards the smallest focal length position. This problem can be eliminated by the embodiment shown in FIGS. 7 to 9, reference to which will now be made.

Referring first to FIG. 7, the rear movable lens mount 7 is shown as held at a position corresponding to the shortest focal length setting, in which condition the free end of the leaf spring 82 and the tapered area 39 of the lens mount 7 are held in close vicinity with each other. FIG. 9, however, illustrates the condition in which the change-over pin 85 connected with the change-over ring 81 has been manually pulled against the compression or corrugated spring 84 in a direction away from the camera body, i.e., frontwardly of the lens assembly. In this condition shown in FIG. 9, the leaf spring 82 is radially inwardly yielded with its free end slidingly engaged underneath the tapered area 39 of the lens mount 7, and, at the same time, the lock pin 83 fast with the leaf spring 82 has been disengaged from one of the lock holes 86 and 87.

The mode change-over of the zoom lens assembly according to the third embodiment will hereinafter be described with reference to FIG. 8. When the change-over pin 85 is pulled a predetermined distance, shown by l_2 in FIG. 8, in the direction away from the camera body or frontwardly of the lens assembly while the zooming ring is held in the shortest focal length position, in lock pin 83 is disengaged from the lock hole 86. Simultaneously therewith, since the change-over ring 81 has been displaced frontwardly a predetermined distance l_2 together with the frontward pull of the change-over pin 85, the pin 27 fast with the diaphragm holder 8 is brought in position ready to enter a connecting groove portion 89. When the change-over pin 85 is subsequently turned about the optical axis in the counterclockwise direction with respect to the aiming direction, the pin 27 which has been engaged in an axial guide groove portion 91 moves in and along the connecting groove portion 89 and is then brought in position ready to enter a cam groove portion 90. The release of the pulling force applied to the change-over pin 85 results in that the change-over ring 81 is returned rearwardly by the action of the spring 84 to allow the leaf spring 82 to restore the original shape with the lock pin 83 consequently engaged in the lock hole 87 to avoid unnecessary rotation of the change-over ring 81. It is to be noted that a fixed barrel 80 has an escape scuttle 88 defined therein within the range over which the change-over pin 85 is movable. Since the path of movement of the change-over pin 85 during the change-over operation is generally U-shaped, and if the escape scuttle 88 is so shaped as to be similar to and in alignment with the generally U-shaped path of movement of the change-over pin 85, it is possible to prevent the mode change-over from being performed unless the change-over pin 85 is pulled the distance l_2 frontwardly beforehand.

FOURTH EMBODIMENT (FIGS. 10 AND 11)

The fourth embodiment of this invention is directed to modification of the unlocking of a safety mechanism used to avoid unnecessary or accidental change-over of a change-over ring 105. While in the foregoing embodiments an internal movable member such as, for example, the rear lens mount is utilized, it is operatively associated with a zooming ring 100 which is an external operating member, in the embodiment shown in FIGS. 10 and 11. Specifically, while in the foregoing embodiments the mode change-over is possible the shortest focal length setting because the change-over position depends on the position in the direction parallel to the optical axis which corresponds to the zooming movement of the rear movable lens mount 7, the embodiment shown in FIGS. 10 and 11 is such that the mode change-over depends on the operating position of the zooming ring 100, whereby it is possible to design in such a way that the mode change-over can be performed not only at the shortest focal length setting, but also at the longest focal length setting.

Referring now to FIGS. 10 and 11, the zooming ring 100 has a release pin 101 rigidly secured thereto and extending radially inwardly therefrom. The fixed barrel 3 has a stepped bolt 103 rigidly threaded thereto so as to define the point of pivot for a lock lever 102. The lock lever 102 is normally biased counterclockwise by a torsion spring 104. The change-over ring 105 has a pair of spaced lock recesses 109 and 110 defined therein for engagement with the lock lever 102 one at a time for the purpose of avoiding any unnecessary or accidental rotation of the change-over ring 105. The locking and unlocking of the change-over ring 105 performed one at a time by the lock lever 102 will now be described with particular reference to FIG. 11 comprised of FIGS. 11(a) to 11(e).

Referring first to FIG. 11(a), the zooming ring 100 is shown as held at a position other than the shortest focal length position and, in this condition, the release pin 101 fast with the zooming ring 100 is spaced apart from the locking lever 102 while the latter is engaged in the lock recess 109 to lock the change-over ring 105 in a non-rotatable position. When the zooming ring 100 is rotated towards the shortest focal length position and is

then passed a slight distance over the shortest focal length position as shown in FIG. 11(c), the release pin 101 associated with the zooming ring 100 contacts the lock lever 102 and causes the lock lever 102 to pivot clockwise against the torsion spring 104, thereby releasing the lock lever 102 from engagement in the lock recess 109. When the change-over ring 105 is rotated clockwise with respect to the aiming direction while the condition of FIG. 11(c) has been established, the lock lever 102 moves away from the lock recess 109 relative to the change-over ring 105. Thereafter, the change-over ring 105 is rotated clockwise with respect to the aiming direction until a detent ball 107 is clicked into a click recess 106, their condition being shown in FIG. 11(d). When the zooming ring 100 is subsequently rotated counterclockwise with respect to the aiming direction to effect the focal length adjustment, the release pin 101 is disengaged from the lock lever 102 and the lock lever 102 is engaged in the lock recess 110, thereby locking the change-over ring 105 in the non-rotatable position to avoid any unnecessary or accidental rotation of the change-over ring 105.

FIFTH AND SIXTH EMBODIMENTS (FIGS. 12 AND 13)

FIG. 12 and FIG. 13 illustrate an essential portion according to the fifth and sixth embodiments of this invention, respectively. The lens assembly according to any one of the foregoing embodiments is of a design wherein, when and so long as it is set in the non-compensated mode, the aperture ratio thereof can continuously vary with change in focal length in the manner as shown in the graph of FIG. 16. The zoom lens assembly according to any one of the embodiments shown in FIGS. 12 and 13 is of such a design that the diaphragm mechanism can be adjusted to give a greater diaphragm aperture, that is, a smaller F-stop number, only at the shortest focal length setting.

Referring to FIG. 12, instead of the use of the cam plate 10 integral with the change-over ring 11, a change-over ring 116 having a slant cam groove 115 and an axial guide groove 117 contiguous to the cam groove 115 is employed. The function of the cam groove 115 is substantially identical with that of the cam groove 42 shown in FIGS. 1 to 4 and is so shaped and so designed that the diaphragm aperture defined by the diaphragm blades can vary with the zooming with the lens assembly consequently held in compensated mode (see the description of the first embodiment.). Since the function of the change-over ring 116 having the slant cam groove 115 is substantially identical with that of the change-over ring 11 shown in FIGS. 1 to 4, description concerning the possibility of adjustment with the change-over ring 116 to increase the diaphragm aperture to a greater diameter only at the shortest focal length setting will now be made with reference to not only FIG. 12 but also FIGS. 1 to 4.

As the zooming ring 5 is rotated towards the smallest focal length position, the rear movable lens mount 7 is moved together with the diaphragm mechanism towards the camera body with the tapered area 39, consequently displacing the leaf spring 28 radially inwardly against the resiliency of the leaf spring 28 as hereinbefore described. With the leaf spring 28 so displaced, the locking of the change-over ring 116 performed by the lock pin 29 is released (FIG. 2). When the change-over ring 116 is pulled the predetermined distance l_1 against the spring 35 and then rotated a predetermined angle θ counterclockwise about the optical axis with respect to the aiming direction, the diaphragm holder 8 is rotated together with the pin 27 to move the diaphragm blades 24 in such a direction as to increase the diaphragm aperture defined thereby. In this way, at the shortest focal length setting, operation is possible to adjust the diaphragm aperture to a greater diameter, that is, to adjust the F-stop number to a smaller reading.

Shown in FIG. 13 is a version in which the change-over ring 55 shown in FIG. 6 is replaced with a change-over ring 119 having an axial guide groove 118 defined therein for engagement with the pin 68 connected to or integral with the diaphragm holder 8. This version is applicable where the groove defined in the arm of the preset ring 19 is constituted by the slant guide groove 65 shown in FIG. 6. The operation necessary to adjust the diaphragm aperture to a greater diameter, i.e., to adjust the F-stop number to a smaller reading, is similar to that described in connection with the embodiment shown in FIG. 12 and, therefore, the description thereof will not be reiterated for the sake of brevity.

SEVENTH EMBODIMENT (FIGS. 14 AND 15)

Before the description of the seventh embodiment of this invention proceeds, it is to be noted that reference to the first embodiment shown in and described with reference to FIGS. 1 to 4 should be made so far as component parts of the lens assembly used in this embodiment, but neither shown in nor described with reference to FIGS. 14 and 15. The embodiment of FIGS. 14 and 15 is, however, an improved version of any one of the respective embodiments of FIGS. 12 and 13. More specifically, according to the embodiments shown respectively in FIGS. 12 and 13, although both of these embodiments are effective to provide the zoom lens assembly having a high speed at the maximum diaphragm aperture when and so long as the zooming ring is set to the shortest focal length position, it has been found that a problem might occur when the zooming ring is rotated about the optical axis towards the longest focal length position while the diaphragm aperture is set to a large value, that is, a small F-stop number at the shortest focal length setting. This problem is that, when the zooming ring is so rotated, the diaphragm blades 24 may be unnecessarily moved by the action of the slant cam groove 115 in case of the embodiment of FIG. 12 or the slant guide groove 65 in the preset ring 19 in the case of the embodiment of FIG. 13, in an attempt to increase the diaphragm aperture defined thereby to a diameter greater than that achieved at the shortest focal length setting, but do not attain a desired diaphragm aperture. In addition, there is a possibility in that, as the diaphragm blades 24 are so moved, the peripheral edges of these blades 24 adjacent the circumference of the diaphragm holder 8 may interfere with the circumference of the holder 8 to such an extent that deformation and/or breakage may occur.

In view of the above, a separate lock device operable to disable the zooming operation must be employed. Referring to FIG. 14, a change-over ring 122 has defined therein a slant cam groove 120, an axial guide groove 123 and a circumferential groove 121 on one side of the groove 123 opposite to the groove 120, all being continued with each other. FIG. 15 illustrates different positions of the pin 27 in these grooves, wherein FIG. 15(a) illustrates the position of the pin 27 connected to or integral with the diaphragm holder 8 assumed when the zooming ring 5 is in the longest focal

length position; FIG. 15(b) illustrates the condition established when the zooming ring 5 is rotated towards the wide angle range with the pin 27 consequently moved towards a position corresponding to the wide angle range; FIG. 15(c) illustrates the condition established when at the shortest focal length setting, the change-over ring 122 has been displaced a distance l leftwards, as viewed in FIG. 15, against a corrugated spring (not shown); and FIG. 15(d) illustrates the condition established when, starting from the condition of FIG. 15(c), the change-over ring 122 has been rotated an angular distance θ, necessary to increase the diaphragm aperture, that is, the total distance of $\theta_1+\theta_2$. It is to be noted that the angular distance θ_1 is equal to a distance θ used and shown in FIG. 12 and that the angular distance θ_2 is a distance required to cause the pin 27 to be engaged in the circumferential groove 121. Assuming that the pin 27 is positioned in the circumferential groove 121, the rotation of the zooming ring 5 towards the longest focal length position results in the pin 27 tending to move in a direction rearwardly of the lens assembly, that is, towards the camera body, because the pin 27 is rigidly mounted on the diaphragm holder 8. However, since the change-over ring 122, even though rotatable relative to the fixed barrel 3, can axially move only a small distance substantially equal to the amount of the deformation of the corrugated spring, resistance can be imposed on the rotation of the zooming ring 5, thereby disabling the zooming operation when and so long as the diaphragm aperture is large. It is to be noted that, if such a corrugated or compression spring as the spring 35 shown in FIG. 1 is inserted in a portion of the change-over ring 122, any possible entanglement of the pin 27 within the circumferential groove 121 which would occur when the zooming operation is unnecessarily performed, can advantageously be eliminated.

EMBODIMENTS OF APERTURE INDICATOR (FIGS. 17 TO 25)

In case of any zoon lens assembly wherein the aperture ratio does not vary with change in focal length, the aperture-indicating marking to be aligned with any one of the F-stop numbers calibrated on the diaphragm aperture adjusting ring generally comprises a single indicium, usually a line. On the other hand, the aperture-indicating marking generally comprise a pair of spaced indicia, main and auxiliary, in the case of any zoom lens assembly having its aperture ratio variable with change in focal length. When it comes to the zoom lens assembly according to this invention, since it can be considered a combined version of these types of the zoom lens assemblies, that is, it has the capability of functioning as the compensated and non-compensated models, the aperture-indicating marking is used in the form of at least two indicia arranged frontwardly of the diaphragm aperture adjusting ring.

Referring first to FIGS. 17 and 18, there is shown a first embodiment of the aperture-indicating marking to be used in the lens assembly utilizing the mode change-over mechanism according to the first and other embodiments of this invention. In FIGS. 17 and 18, reference numeral 133 represents a common indicium to be aligned with any one of the F-stop numbers 135 calibrated on the aperture adjusting ring 12 in a manner known to those skilled in the art. This common indicium 133 is utilized when and so long as the lens assembly according to this invention is set in the compensated mode. Reference numerals 131 and 132 represent main and auxiliary indicia, respectively, both adapted to be utilized, in a manner, as described subsequently, when and so long as the zoom lens assembly according to this invention is set in the non-compensated mode. Specifically, when the zooming ring is rotated to the shortest focal length position, the main indicium 131 is used to indicate the smallest F-stop number 135 available for such shortest focal length setting, whereas when the zooming ring is rotated to the longest focal length position, the auxiliary indicia 132 is used to indicate the smallest F-stop number 135 available for such longest focal length setting, it being to be noted that the smallest F-stop number available for the shortest focal length setting reads a smaller value than that available for the longest focal length setting. This means that, during the non-compensated mode, for a full diaphragm aperture, the lens assembly is faster at the shortest focal length setting than at the longest focal length setting.

These indicia 133, 131 and 132 are provided on the change-over ring 11 and may be distinguished in different color, for example, the common indicium 133 being colored white, the main indicium 131 yellow and the auxiliary indicium 132 blue. It is naturally desirable that, once the respective colors to be used for the main and auxiliary indicia 131 and 132 have been fixed, respective numerical readings for the shortest and longest focal length positions 134 (28 and 85 so far shown) should also be colored in the same color as that of the main and auxiliary indicia 131 and 132 to make it possible to avoid any possible confusion and to facilitate an easy and quick reading of the F-stop number relative to the focal length setting. Instead of the use of the colored indicia, they may be distinguished by employing different types of marking, for example, a combination of line, triangle and dot, with or without relevant numerical representation.

In FIG. 17, the change-over ring is shown as assuming a position established when and so long as the ring 11 is set in the compensated mode position, while in FIG. 18 it is shown as assuming a different position established when and so long as the ring 11 is set in the non-compensated mode position.

The aperture-indicating marking shown in FIGS. 19 and 20 is designed for use on the lens assembly according to the first and other embodiments of this invention. In FIG. 19, the main indicium 131 shown in FIG. 17 is replaced with a main indicium 137 and, in addition to the above difference, an arrow marking 138 is employed for the indication of the direction in which the change-over ring 11 can be rotated reciprocately. FIG. 20 illustrates the condition in which the lens assembly is set in the non-compensated mode.

Referring now to FIGS. 21 and 22, there is shown the aperture-indicating marking adapted for use on the lens assembly according to the second embodiment of this invention. FIG. 21 illustrates the condition in which the lens assembly is set in the compensated mode while FIG. 22 illustrates the condition in which the lens assembly is set in the non-compensated mode.

While the aperture-indicating marking shown in FIGS. 17 and 18 and FIGS. 19 and 20 has been described as comprising the three indicia and the use of three indicia may be confusing, the embodiment shown in FIGS. 21 and 22 is designed such that any one of the aperture-indicating indicia can be displayed exteriorly through a window 139 defined in the fixed barrel 3 in a manner as shown in FIG. 5. The aperture-indicating

indicia can be selectively brought into alignment with the window 139 for the visual presentation to the photographer by manipulating the change-over knob 70.

In the embodiment shown in FIGS. 24 and 25, the aperture-indicating indicia are so designed and so arranged that, while the respective positions of the aperture-indicating indicia does not vary, the position of a stopper (not shown) for the aperture adjusting ring 12 can be switched by manipulating a change-over lever 140. This embodiment of the aperture-indicating marking shown in FIGS. 23 and 24 is particularly suited for use in a SRL camera having its viewfinder system through which one of the F-stop numbers aligned with the relevant aperture-indicating indicium can be viewable. One method for switching the position of the stopper referred to above is shown in FIGS. 25(a) and 25(b). Although it is a currently employed practice to provide the aperture adjusting ring with an engagement recess in which a stopper pin can be engaged, a bell crank 160 is employed in place of the stopper pin referred to above, as shown in FIGS. 25(a) and 25(b). This bell crank 160 is pivotally mounted on the fixed barrel by means of a pivot pin 161 and has one end bent to define a stopper end 162 and the other end carrying a guide pin 163 rigidly secured thereto and loosely engaged in a guide groove 164. This system is so designed that the bell crank 160 can be pivoted in response to the movement of the change-over lever 140 to cause the position of the stopper to change automatically. It will readily be seen that FIG. 25(a) illustrates the condition assumed when the lens assembly is set in the compensated mode and, therefore, the F-stop number of 2.8 is inoperative, but FIG. 25(b) illustrates the condition assumed when the lens assembly is in the non-compensated mode with both aperture-indicating indicia being utilizeable one at a time according to the focal length setting.

EIGHTH EMBODIMENT FIGS. 26 AND 27)

The mode change-over mechanism according to the eighth embodiment shown in FIGS. 26 and 27 differs from that according to any one of the previously described first and fourth embodiments in the following two aspects. The first difference is that, while in the previously described embodiments the rotation of the aperture adjusting ring 12 can be transmitted to the diaphragm operating ring 9 by the utilization of the linear groove 21 (FIG. 3) and the other elements and the diaphragm holder 8 can be rotated for the compensation purpose by the utilization of the cam groove portion 42 (FIG. 3) and the other elements, the embodiment shown in FIGS. 26 and 27 is such that a groove 21B functionally corresponding to the linear groove 21 defined in the arm of the preset ring 9 for transmitting the rotation of the adjusting ring 12 to the operating ring 9 is constituted by a cam groove defined in a single component part which acts concurrently for the diaphragm aperture setting and compensation purposes. The other difference is that the lens assembly shown in FIGS. 26 and 27 has an automatically presettable diaphragm mechanism incorporated therein and also has the capability of being set selectively in the compensated and non-compensated modes one at a time. The automatically presettable diaphragm mechanism referred to above is operable to stop the diaphragm aperture down to a predetermined value selected in association with the picture taking operation of the camera which is performed after the light measurement has been carried out at the full aperture setting. As a matter of course, this selection can be done even during the picture taking.

The details of the embodiment shown in FIGS. 26 and 27 will now be described. Referring to these figures, reference numeral 141 represents a transmission plate rigidly secured to, or formed integrally with, the change-over ring 11'. As best shown in FIG. 27, the change-over ring 11' is coupled to the diaphragm aperture adjusting ring 12 by means of a coupling pin 142 for rotation together therewith. Therefore, as the aperture adjusting ring 12 is preset to a certain F-stop number, the transmission plate 141 also rotates together with the adjusting ring 12. An aperture control cam plate 143 of generally arcuate or ring-shaped configuration has a radially outwardly extending projection 143A having its free end slidingly engaged in one of the cam and axial guide grooves 21B and 21A, for example, in the cam groove 21B so far shown, both defined in the transmission plate 141. In this illustrated condition, the cam plate 143 can rotate together with the adjusting ring 12 when the latter is preset. By rotating the aperture adjusting ring 12 about the optical axis in a direction shown by the arrow A in FIGS. 26 and 27, the diaphragm aperture can be stopped down.

Reference numeral 144 represents a generally arcuate main drive lever supported for pivotal movement about the axis shown by the chain line in FIG. 26. This main drive lever 144 is normally biased counterclockwise by a biasing spring 145. Operatively associated with this main drive lever 144 is a transmission pawl 146 situated within and protruding radially inwardly in the camera body. This transmission pawl 146 is engaged to the main drive lever 144 through an engagement pin 144A fast with the main drive lever 144, the transmission pawl 146 being operable to urge the main drive lever 144 clockwise about the optical axis against the biasing spring 145 after the completion of actual picture taking. When the main drive lever 144 is so rotated clockwise, an aperture-defining lever 147 of generally arcuate shape which is operatively coupled with the main drive lever 144 through a connecting rod 144B connected with the main drive lever 144 can be pivoted clockwise about the pivot axis shown by the chain line in FIG. 26. This aperture-defining lever 147 is in turn operatively associated with the diaphragm operating ring 9' by means of a spring 148 extending between 9'A connected with the operating ring 9' and a pin 143A connected with the aperture defining lever 147 and, therefore, the pin 9'A is normally biased to contact a lower end of the aperture defining lever 147. For this reason, when the aperture defining lever 147 is rotated clockwise in response to the clockwise rotation of the main drive lever 144 in the manner as hereinbefore described, the operating ring 9' rotates clockwise in pursuit of the lever 147, thereby causing the diaphragm blades 24 to open wide. This operating ring 9' has an arm 9'B extending radially outwardly therefrom and contacting a cam edge 149A of a compensating cam plate 149. When this arm 9'B abuts the cam edge 149A during the clockwise rotation of the aperture defining lever 147 and, hence, that of the operating ring 9', the operating ring 9' can be brought to a halt independently of the aperture defining lever 147 which continues its clockwise rotation with the spring 148 pulled axially outwardly. As is the case with any one of the previously described embodiments, the diaphragm operating lever 9' can move leftwards and rightwards one at a time during the zooming operation as viewed in the drawing. Since the leftward movement

means the setting to the tele-angle range, as the focal length is adjusted towards the longest value, the operating ring 9' can be rotated clockwise a greater angular distance to increase the diaphragm aperture than as it is adjusted towards the shortest value. Therefore, when and so long as the focal length is adjusted towards the longest value, the operating ring 9' can be rotated clockwise a greater angular distance to increase the diaphragm aperture than as it is adjusted towards the shortest value. Therefore, when and so long as the focal length is adjusted to the longest reading, the diaphragm aperture is full open. In view of the foregoing, in a preset condition, the diaphragm aperture attains the maximum diameter at the longest focal length setting, and as the zooming ring is rotated towards the wide angle range, the diaphragm aperture is stopped down to make the maximum diaphragm aperture fixed at any focal length setting. When the aperture adjusting ring 12 is rotated in the direction of the arrow A to a desired aperture reading from smallest F-stop number, the aperture control cam plate 143 is rotated counterclockwise to a predetermined position corresponding to the desired aperture reading. Subsequent retraction of the transmission pawl 146 which takes place in association with the picture taking, causes the main drive lever 144 to rotate counterclockwise against the spring 145. Upon this counterclockwise rotation of the main drive lever 144, the aperture defining lever 147 coupled thereto through the connecting rod 144B is also rotated counterclockwise, thereby causing the aperture operating ring 9' to be rotated counterclockwise by means of the pin 9'A until a pin 147B rigidly mounted on the aperture defining lever 147 abuts a projection 143B integral with the cam plate 143. When the pin 147B on the aperture defining lever 147 is so engaged to the projection 143B integral with the cam plate 143 in the manner as hereinabove described, the aperture defining lever 147 is no longer rotated and the diaphragm aperture is therefore stopped down to a diameter corresponding to the desired, preset aperture reading. FIGS. 26 and 27 illustrate the condition in which the lens assembly is set in the compensated mode. Since the projection 143A integral with the cam plate 143 is engaged in the cam groove 21B, the cam plate 143 rotates, as the zooming ring is turned, with the pin 147B moving in contact with the projection 143B and, therefore, the diaphragm aperture is compensated for change in aperture ratio resulting from the change of the focal length.

Where the lens assembly is desired to be set in the non-compensated mode, the projection 143A integral with the cam plate 143 has to be brought into engagement with the axial guide groove 21A and the cam plate 149 has to be subsequently retracted from the path of angular movement of the arm 9'B integral with the diaphragm holder 9'. A mechanism for this purpose is shown in FIG. 27.

Referring particularly to FIG. 27, the aperture adjusting ring 12 has a pair of deep and shallow recesses 12A and 12B defined therein for engagement with the coupling pin 142 one at a time. The coupling pin 142 fast with the aperture adjusting ring 12 is engaged in the recess 12A so far shown in FIG. 27, in which condition the lens assembly is in the compensated mode. The change-over to the non-compensated mode can be carried out when and so long as the focal length is adjusted to the shortest reading. Assuming that the zooming ring is rotated to the smallest focal length position, and when the change-over ring 11' is pulled leftwards as viewed in FIG. 27 against the spring 35, the projection 143A of the cam plate 143 is brought in position ready to enter a connecting groove 21C. Subsequent turn of the change-over ring 11' in the direction of the arrow to bring the coupling pin 142 into engagement with the recess 12B results in that the projection 143A is brought in position ready to enter the axial guide groove 21A. The manner by which the change-over ring 11' is manipulated is substantially identical with that in any one of the foregoing embodiments and, therefore, the lock mechanism for avoiding the unnecessary or accidental change-over, which has been described in connection with any one of the foregoing embodiments can be employed. In any event, when the coupling pin 142 has been shifted from the recess 12A to the recess 12B in the manner as hereinbefore described, the change-over ring 11' is positioned a slight distance displaced leftwards as viewed in FIG. 27 as compared with the position occupied by the same ring 11' when the coupling pin 142 is engaged in the recess 12A. This is because the recess 12B has a depth smaller than the recess 12A. In this condition, a bell crank 150 engageable with the change-over ring 11' is pivoted clockwise, as viewed in FIG. 27, from the position shown by the solid line. Upon this pivot of the bell crank 150, one end of the bell crank 150 remote from the change-over ring 11' pushes a pin 149B, rigidly mounted on the cam plate 149, and, therefore, the cam plate 149 is moved upwards as viewed in FIG. 27 against a spring 151 with the cam edge 149A consequently brought in position out of the path of angular movement of the arm 9'B integral with the diaphragm operating ring 9', thereby completing the change-over of the lens assembly into the non-compensated mode.

The aperture-indicating marking to be used on the lens assembly according to the embodiment described with reference to and shown in FIGS. 26 and 27 is in the form as including, in addition to the indicia 131, 132 and 133 on the fixed barrel 3, a triangular reference indicium 170 provided on the aperture adjusting ring 12, and a pair of spaced indicia 171A and 171B provided on the change-over ring 11' and signifying the non-compensated mode and the compensated mode, respectively, the indicia 171A and 171B being adapted to be lined up with the reference indicium 170 one at a time to indicate the mode in which the lens assembly is set.

NINTH EMBODIMENT (FIG. 28)

The lens assembly according to this embodiment, shown in FIG. 28, employs the compensating mechanism for the preset aperture which is substantially identical with that shown in FIGS. 26 and 27, but does not employ a full aperture compensating member for the full aperture light metering system. This embodiment is a system wherein the stop-down number over which the diaphragm aperture should be stopped down from the smallest F-stop number is input to a photographic camera of full aperture metering system. A connecting lever 152 for transmitting the stop-down number shown in FIG. 28 is a member provided for this purpose. Even in this embodiment, the lens assembly shown in FIG. 28 is similar to that shown in FIGS. 26 and 27 in that the change-over ring 11' is rotatable together with the aperture adjusting ring 12 to adjust the diaphragm aperture and in that the mode change-over can be effected by selecting the position of the change-over ring 11' relative to the aperture adjusting ring 12. Although the lens assembly so far shown is in the compensated mode in which the diaphragm aperture is automatically compen-

sated with the focal length setting to maintain the diaphragm aperture at a predetermined value, since the lens assembly is not provided with a full aperture compensating cam to be used during the full aperture light measurement as is the case with the embodiment shown in FIGS. 26 and 27, the diaphragm aperture at the smallest F-stop number is fixed irrespective of the zooming operation and, therefore, the intensity of light falling on the light receiving face of a photo-cell forming a part of the light measuring device of the camera may vary to such an extent as to result in erroneous exposure. Therefore, in order to avoid the erroneous exposure, information of the stop-down number variable with the zooming operation is input to the camera instead of the use of the full aperture compensating cam. The function in which the stop-down number information is adjustably coupled to the camera body will now be described with reference to FIG. 28.

A linkage ring **153** for the compensation of the stop-down number has a pair of pins **153A** and **153B** rigidly mounted thereon. So far shown in FIG. 27, the pin **153A** is shown as engaged in the groove **21B'** in the change-over ring while the other pin **153B** is shown as engaged with the connecting lever **152**. During the zooming operation, the ring **153** is axially moved together with, for example, the rear movable lens mount and can also be rotatable freely. Therefore, as the aperture adjusting ring **12** is rotated, the ring **153** is also rotated by the engagement between the pin **153A** and the groove **21B'** in the change-over ring **12** rotatable together with the adjusting ring **12**. the rotation of the ring **153** being transmitted through the lever **152** to the camera body to vary the stop-down number input to the camera. By so doing, change in intensity of the light falling on the light receiving face of the photo-cell of a light meter incorporated in the camera can be compensated for to give a correct exposure value. Where the mode change-over is to be effected, the zooming ring has to be moved to the shortest focal length position and the change-over ring **11'** has to be subsequently moved leftwards, as viewed in FIG. 28, against the spring **35** before it is rotated in the direction of the arrow A. As is the case with the embodiment shown in FIGS. **26** and **27**, when the change-over ring **11**, which moved leftwards, is rotated, the coupling pin **142** can be brought into alignment with the recess **12B**, the actual engagement of the pin **142** into the recess **12B** taking place when an external pulling force applied to the ring **11'** to displace the latter leftwards is released. In this way, the projection **143A**, integral with the cam plate **143**, and the pin **153A** on the ring **153**, are engaged in an axial guide groove **21A** and an axial guide groove **21A'**, respectively, and therefore, not only can the lens assembly be set in the non-compensated mode, but also the adjustment of the stop-down number input to the camera is no longer effected. It is to be noted that a mechanism operable to permit the mode change-over to be performed only at the smallest or longest focal length setting may be the one described in connection with any one of the foregoing embodiments.

MODIFICATION (FIG. 29)

In the first embodiment shown in FIGS. **1** to **4**, the cam plate **10** has been described as rigidly secured to the change-over ring **11** and having the axial guide groove **40** and the cam groove **42** defined therein. However, in the modification shown in FIG. **29**, the cam plate is rigidly secured to the fixed barrel **3** as shown by **10'** and has only a cam groove **42'** corresponding functionally to the cam groove **42** best shown in FIG. **3**. In addition, in this modification, the preset ring is constituted by front and rear ring elements, the front ring element having the linear groove **21** defined in the arm thereof. The ring elements are normally held in a predetermined position relative to each other by a tension spring suspended therebetween, and an arm fast with or integral with the change-over ring **11** rotatable only at the shortest focal length setting is held in position ready to engage the front ring element whenever the necessity occurs. In this modification, where the diaphragm aperture is desired to be increased to a greater diameter, the change-over ring **11** has to be rotated so that the front ring element can be rotated relative to the rear ring element against the tension spring thereby causing the diaphragm, operating ring **9** to be rotated to a position corresponding to the smallest F-stop number available for the longest focal length setting. By so doing, the diaphragm aperture can be adjusted to give the greater diameter.

Although this invention has fully been described in connection with the numerous embodiments with reference to the accompanying drawings, it is to be noted that various changes and modifications are apparent to those skilled in the art upon the reading this disclosure. By way of example, the function of the change-over ring may be utilized to adjust the amount of extension of a signaling pin which is, in most cameras requiring the physical transmission of information concerning the speed of a selected interchangeable lens assembly, necessitated to transmit such information.

In addition, although reference has been made to the zoom lens assembly of a type wherein the optical system is so designed that the position of focus does not vary with the zooming, the concept of this invention can be equally applicable to a so-called varifocal lens assembly wherein the position of focus varies with the zooming.

Therefore, such changes and modification are to be understood as included within the scope of this invention as defined in the appended claims, unless they depart therefrom.

I claim:

1. An objective lens assembly of variable focal length comprising, in combination:

a varifocal lens system having its focal length adjustable within a predetermined range, said lens system including a diaphragm mechanism having an adjustable diaphragm aperture, the aperture ratio being variable during an operation for changing the focal length with the diaphragm aperture kept unchanged;

a diaphragm aperture adjustng mechanism for adjusting the diaphragm aperture for compensating for change in aperture ratio realtive to the change in focal length within the predetermined range;

a diaphragm aperture maintaining mechanism operable to maintain the diaphragm aperture while allowing the aperture ratio to change within a portion of the predetermined range; and

a manually operable change-over mechanism operable to bring the diaphragm aperture adjusting and maintaining mechanisms selectively into an operative position one at a time.

2. An assembly as claimed in claim **1**, wherein said maintaining mechanism is adapted to maintain the diaphragm aperture so as to vary the aperture ratio within the predetermined range.

3. An assembly as claimed in claim 1, wherein said maintaining mechanism is adapted to maintain the diaphragm aperture so as to vary the aperture ratio only at the shortest focal length setting or in the vicinity thereof within the predetermined range.

4. An assembly as claimed in claim 1, wherein said change-over mechanism includes a change-over member rotatable about the optical axis of the lens system and movable in a direction parallel to the optical axis, said adjusting and mantaining mechanisms being selectively brought into the operative position one at a time in response to the rotation and subsequent axial movement of the change-over member.

5. An assembly as claimed in claim 1, further comprising a locking means for releaseably locking the change-over means, said locking means operable to release the change-over mechanism only when the lens system is set to a particular focal length within the predetermined range.

6. An assembly as claimed in claim 5, wherein the lens system includes at least one lens group movable in a direction parallel to the optical axis of the lens system for changing the focal length, and further comprising a movable lens holder for the support of said lens group, said locking means including a locking mechanism for locking the change-over mechanism, and a detection means for detecting the movement of said movable lens holder in the direction parallel to the optical axis to a predetermined position at which the lens system is set at the particular focal length and for causing the locking mechanism to release the change-over mechanism from a locked position.

7. An assembly as claimed in claim 5, further comprising an operating member rotatable about the optical axis for changing the focal length.

8. An assembly as claimed in claim 7, wherein said locking means comprises a locking mechanism for locking the change-over mechanism, and a detection means for detecting the condition in which the operating member is operated to a position at which the lens system is set at the particular focal length and for causing the locking mechanism to release the change-over mechanism from a locked position.

9. An assembly as claimed in claim 1, further comprising a diaphragm preset ring for presetting the diaphragm mechanism, said preset ring having a series of numerical figures provided thereon, said numerical figures representing the F-stop numbers to which the diaphragm mechanism can be preset one at a time, respectively, a first indexing means cooperable with the series of numerical figures to indicate one of the numerical figures when the adjusting mechanism is brought into the operative position by the change-over mechanism, and a second indexing means cooperable with the series of numerical figures to indicate one of the numerical figures when the maintaining mechanism is brought into the operative position by the change-over mechanism.

10. An assembly as claimed in claim 9, wherein said change-over mechanism is rotatable about the optical axis of the lens system and movable in a direction parallel to the optical axis for bringing the adjusting and maintaining mechanisms selectively into the operative position one at a time, and wherein said first and second indexing means are provided on the change-over member in circumferentially spaced relation to each other.

11. An assembly as claimed in claim 9, further comprising a stationary barrel having the first and second indexing means provided in circumferentially spaced relation to each other, a restriction means for restricting the rotatable range over which the preset ring can be rotated, and means for changing the rotatable range of the preset ring in dependence on the selection of one of the adjusting and maintaining mechanisms performed by the change-over mechanism.

12. An objective lens assembly of variable focal length comprising, in combination:

a stationary barrel;

a varifocal lens system having its focal length adjustable within a predetermined range, and including at least one lens group axially movable in a direction parallel to the optical axis thereof for the adjustment of the focal length;

a manually operable member adapted to be operated relative to the stationary barrel for varying the focal length of the lens system;

a diaphragm mechanism including first and second member rotatable relative to each other about the optical axis, and a plurality of diaphragm blades defining a diaphragm aperture of a diameter determined by the relative rotation of the first and second members, said diaphragm mechanism being axially movable in a direction parallel to the optical axis in correspondence with the change in focal length of the lens system to vary the aperture ratio with the diameter of the diaphragm aperture kept unchanged;

a diaphragm aperture adjusting mechanism for varying the relative position between the first and second members at the time of axial movement of the diaphragm mechanism to adjust the diaphragm aperture for maintaining the aperture ratio at a constant value relative to the change in focal length within the predetermined range;

a diaphragm aperture maintaining mechanism for maintaining the relative position between the first and second members at the time of axial movement of the diaphragm mechanism to vary the aperture ratio for maintaining the diaphragm aperture at a constant value; and

a manually operable change-over mechanism for bringing the adjusting and maintaining mechanisms selectively into an operative position one at a time.

13. An assembly as claimed in claim 12, wherein said change-over member is rotatable about the optical axis of the lens system.

14. An assembly as claimed in claim 13, wherein said adjusting mechanism comprises a cam member integral with the change-over member, a cam follower provided on one of the first and second members, and a first cam provided on the cam member so as to be inclined relative to the direction parallel to the optical axis for engagement with the cam follower, wherein said maintaining mechanism comprises said cam member, said cam follower and a second cam provided on the cam member in parallel relation to the optical axis of the lens system for engagement with the cam follower, and wherein said change-over mechanism also includes a guide means on the cam member for guiding the cam follower from one of the first and second cams onto the other of the first and second cams at the time of rotation of the change-over member.

15. An assembly as claimed in claim 14, further comprising an aperture preset ring, a stop-down member for rotating the other of the first and second members relative to said one of the first and second members for

reducing the diaphragm aperture, and a restriction means for restricting the final operative position for the stop-down member in dependence on the position to which the preset ring has been rotated.

16. An assembly as claimed in claim 14, wherein the change-over member is displaceable a predetermined distance from a normal axial position in a direction parallel to the optical axis, said guide means being operable only when the change-over member is axially displaced the predetermined distance to guide the cam follower from the one of the first and second cams onto the other of the first and second cams.

17. An assembly as claimed in claim 16, further comprising a movable lens holder for supporting the lens group, a lock means for locking the change-over member to prevent the change-over member from being rotated, and means for disabling said locking means only when the movable lens holder is held at a position at which the lens system is set at a particular focal length within said predetermined range.

18. An assembly as claimed in claim 16, further comprising a lock means for locking the change-over member for preventing the change-over member from being rotated, and means for disabling the lock means only when the manually operable member is rotated to a position at which the lens system is set at a particularly focal length within the predetermined range.

19. An objective lens assembly of variable focal length which comprises, in combination:

a varifocal lens system having its focal length adjustable within a predetermined range, said lens system including a diaphragm mechanism having an adjustable diaphragm aperture, the aperture ratio being variable during an operation for changing the focal length with the diaphragm aperture kept unchanged;

a diaphragm aperture adjusting mechanism for adjusting the diaphragm aperture for compensating for change in aperture ratio relative to the change in focal length within the predetermined range;

a diaphragm aperture maintaining mechanism for maintaining the diaphragm aperture while allowing the aperture ratio to change within a portion of the predetermined range; and

a manually operable mechanism for setting the diaphragm aperture at a diameter necessary to increase the aperture ratio at the shortest focal length setting or in the vicinity thereof within the predetermined range, whereby the aperture ratio so increased is equal to the aperture ratio given by the diaphragm mechanism at the smallest focal length setting or in the vicinity thereof when no diaphragm aperture adjustment is performed by the diaphragm aperture adjusting mechanism.

20. An assembly as claimed in claim 19, wherein the manually operable mechanism includes a rotatable member adapted to be rotated a predetermined angle about the optical axis of the lens system, and wherein the diaphragm aperture adjusting mechanism includes a cam formed on the rotatable member so as to be inclined relative to the optical axis and a cam follower engaged with the cam for varying the diaphragm aperture.

21. An assembly as claimed in claim 20, wherein the rotatable member is displaceable a predetermined distance from a normal axial position in a direction parallel to the optical axis, said cam having one end extended a distance equal to the predetermined distance to provide a extension of the cam.

22. An assembly as claimed in claim 21, wherein said extension has one end opposite to the cam formed with an engagement cam extending in a direction parallel to the direction of rotation of the rotatable member, said engagement cam being operable to engage the cam follower to inhibit the adjustment of the diaphragm aperture by the diaphragm aperture adjusting mechanism while the aperture ratio has been increased.

[57] **ABSTRACT**

An interchangeable objective with a variable lens aperture for a camera has a stationary support member and a diaphragm-operating member rotatable about an axis between first and second annular positions relative to the stationary support member. A first elongated leaf spring is mounted on the stationary member to bear against the diaphragm-operating member along a first plane perpendicular to the axis. A second elongated leaf spring is mounted on the stationary member to bear against the diaphragm-operating member along a second plane perpendicular to the axis. The second plane is spaced from the first plane in the direction of the axis. A locking groove is formed in the diaphragm-operating member so as to alternatively receive the first and second leaf springs in locking engagement when the diaphragm-operating member is positioned at the first and second angular positions, respectively. An unlocking button is mounted in the diaphragm-operating member over the locking groove to push the respective first and second leaf springs out of engagement with the locking groove upon depression of the unlocking button.

ROTATION CONTROL MECHANISM FOR DIAPHRAGM-OPERATING RING IN INTERCHANGEABLE OBJECTIVE FOR PHOTOGRAPHIC CAMERA

CROSS REFERENCE TO RELATED APPLICATIONS

This application is related to application Ser. No. 520,724, filed on even date herewith by Etsuro Nishio and Zenichi Okura, the disclosure of which is incorporated fully herein by reference.

BACKGROUND OF THE INVENTION

The present invention relates to an interchangeable objective provided with a diaphragm-operating ring which is rotatable between a rotatable range for diaphragm preset and a position for automatic diaphragm regulation and, more particularly, to a rotation control mechanism for the diaphragm-operating ring used for changeover between said rotatable range for diaphragm preset and said position for automatic diaphragm regulation.

A photographic camera of automatic exposure control type conventionally has a diaghragm priority mode in which a diaphragm value is preset by the user and a shutter speed for appropriate exposure is automatically regulated in the camera body, a shutter speed priority mode in which, inversely, a shutter speed is manually preset by the user and a lens aperture for appropriate exposure is automatically regulated, and a programmed mode in which a combination of diaphragm value and shutter speed is automatically regulated for appropriate exposure.

Interchangeable objectives used with a photographic camera adopting said three modes of automatic exposure control function or different exposure control functions must include a diaphragm-operating ring provided with a rotatable range for manually presetting the diaphragm value (referred to hereinafter as M-range), in said diaphragm priority mode and a position for automatic diaphragm regulation (referred to hereinafter as A-position) in said shutter speed priority mode and said programmed mode. Information as to whether the diaphragm-operating ring occupies the M-range or the A-position must be transferred to the camera body because different exposure control mechanisms are activated in these two cases.

Any unintentional changeover between the M-range and the A-position must be reliably prevented and, in consequence, a suitable changeover locking mechanism and unlocking mechanism are required. However, the structure for connection between the lens barrel and the camera body has made it difficult to obtain a large rotation angle for changeover between the end of the M-range and the A-position. This has given rise to various problems with respect not only to the strength but also to the degree of freedom for their design. Particularly in an objective of a relatively large diameter, the rotation angle within the M-range must be large but the rotation angle of a diaphragm information transferring lever which is rotatable together with the diaphragm-operating ring is restricted by the claw angle of the mount ring, so that the strength of the changeover locking mechanism may be compromised.

SUMMARY OF THE INVENTION

According to the invention, an interchangeable objective with a variable lens aperture for a camera has a stationary support member and a diaphragm-operating member rotatable about an axis between first and second annular positions relative to the stationary support member. (One angular position is the A-position and the other angular position is the end of the M-range nearest to the A-position.) A first elongated leaf spring is mounted on the stationary member to bear against the diaphragm-operating member along a first plane perpendicular to the axis. A second elongated leaf spring is mounted on the stationary member to bear against the diaphragm-operating member along a second plane perpendicular to the axis. The second plane is spaced from the first plane in the direction of the axis. A locking groove is formed in the diaphragm-operating member so as to alternatively receive the first and second leaf springs in locking engagement when the diaphragm-operating member is positioned at the first and second angular positions, respectively. An unlocking button is mounted in the diaphragm-operating member over the locking groove to push the respective first and second leaf springs out of engagement with the locking groove upon depression of the unlocking button. As a result of the placement of the leaf springs in different planes, a small rotation angle can be provided for changeover between the M-range and the A-position, without compromising the strength of the changeover locking mechanism.

BRIEF DESCRIPTION OF THE DRAWINGS

The feature of specific embodiments of the best mode contemplated of carrying out the invention are illustrated in the drawings, in which:

FIGS. **1** and **2** are front-sectional view of the pertinent parts of an interchangeable objective embodying principles of the invention, FIG. **1** showing the objective in the M-range and FIG. **2** showing the objective in the A-position;

FIGS. **3** and **4** are sectional views of the objective taken through lines III—III and IV—IV in FIG. **1**, respectively;

FIG. **5** is a side, partially cut-away view of one of the rotation-arresting members shown in FIGS. **1** and **2**;

FIGS. **6***a* through **6***f* are enlarged, front-sectional views of part of the objective in different positions of the diaphragm-operating ring;

FIGS. **7***a* through **7***c* are enlarged, side-sectional views of part of the objective in different positions of the diaphragm-operating ring;

FIGS. **8***a* and **8***b* are top views as seen in the direction of VIII—VIII in FIGS. **6***b* and **6***e*, respectively;

FIG. **9** is a perspective view of another embodiment of the rotation-arresting members; and

FIG. **10** is a perspective view of yet another embodiment of the locking groove in the diaphragm-operating ring and the rotation-arresting members.

DETAILED DESCRIPTION OF THE SPECIFIC EMBODIMENTS

In FIGS. **1** through **4**, reference numeral **1** designates a stationary mount support ring, and reference numeral **2** designates a diaphragm-operating ring rotatably supported by said mount support ring **1**. A mount **3** by which the objective is attached to the camera body is fixed to the mount support ring **1**. The diaphragm-

operating ring 2 is provided in its inner peripheral surface with an interlocking groove 4 into which an interlocking pin 6 fixedly mounted on a diaphragm-rotating ring 5 is engaged so that said diaphragm-rotating ring 5 may be rotated together with said diaphragm-operating ring 2. This diaphragm-rotating ring 5 is rotatably supported along the inner peripheral surface of the mount support ring 1 and is integrally provided with a diaphragm information transferring lever 8 projecting through a notch 7 formed in the mount 3 toward the camera body. Said diaphragm information transferring lever 8 is adapted to transfer information to the camera body whether said diaphragm information transferring lever 8 occupies the M-range or the A-position of the diaphragm operating ring 2. The diaphragm-rotating ring 5 is rotated to activate the diaphragm mechanism of well known type and thereby to preset a desired diaphragm value. Since such diaphragm mechanism is not part of the present invention, it is not described in detail.

The rotation angle of the diaphragm operating ring 2 is restricted by the circumferential length of the interlocking groove 9 formed in the mount support ring 1, in which said interlocking pin 6 rides. Both the M-range and the A-position are contained within an angle θ of the interlocking groove 9. In this embodiment, the M-range is arranged to cover an angle θ_1 and the A-position is arranged to be spaced by an angle θ_2 from one rotational end of said M-range (e.g., the minimum lens aperture position).

The diaphragm-operating ring 2 is provided in its inner peripheral within an angular extent corresponding to said M-range with a plurality of click-grooves 10 equal in number to the number of diaphragm value steps. The mount support ring 1 is formed with a guide hole 12 for containment of a click-ball 11 adapted to be received by said click-grooves 10 and a leaf spring 13 is fixed at one end by a screw 14 to the mount support ring 1 so as to bias said click ball 11 toward the clock-grooves 10.

The present invention is generally directed to the control of the rotation of the diaphragm-operating ring 2 between said one rotational end of the M-range (the minimum lens aperture) and the A-position. To this end, two leaf springs 21M, 21A serving as rotation arresting members are secured at one end by screws 23, 24 respectively to the mount support ring 1. Leaf springs 21M, 21A are mounted in leaf spring receiving grooves 20M, 20A respectively, are offset from each other in the direction of the optical axis, and face toward each other. The diaphragm-operating ring 2 is provided with a locking groove 25 and an unlocking member (button) 26 projecting outwardly from the upper boundary of this locking groove 25. Locking groove 25 is elongated in the direction of the optical axis to overlie both of grooves 20M, 20A in communication therewith. The bottom of unlocking member 26 has a plate that spans the space between grooves 20M, 20A and alternately engages members 21M, 21A as they enter locking groove 25.

The rotation arresting members 21M, 21A each comprise, as one of them is shown by FIG. 5, leaf springs formed at one end with a hole (27M, 27A) for fixation and at the other end with an arresting surface (28M, 28A). The portion of each leaf spring with the hole (27M, 27A) extends away from the receiving groove (20M, 20A) toward the locking groove. These rotation arresting members 21M, 21A are secured to the mount support ring 1 in a symmetrical relationship with respect to the optical axis so that said arresting surfaces 28M, 28A cross one another in a front view. The rotation arresting member 21M has its arresting surface 28M bearing against one of side walls (M-locking side wall) 25M circumferentially defining the locking groove 25 of the diaphragm-operating ring 2, as shown in FIG. 1, to arrest further rotation of said diaphragm operating ring 2, toward the A-position, when the diaphragm-operating ring 2 has been rotated to the minimum lens aperture position within the M-range. Accordingly, this arresting member may be referred to as the rotation arresting member 21M for M.

The other rotation arresting member 21A has its arresting surface 28A bearing against the other side wall (A-locking side wall) 25A circumferentially defining the locking groove 25 of the diaphragm operating ring 2, as shown in FIG. 2, to arrest further rotation of said diaphragm-operating ring 2 toward the M-range, when said diaphragm-operating ring 2 has been rotated to the A-position. Accordingly, this arresting member may be referred to as the rotation arresting member 21A for A.

Said unlocking member 26 is engageable with the outer surfaces of these two rotation arresting members 21M, 21A so that depression of unlocking member 26 permits said both rotation arresting members to be displaced out of the locking groove 25 under the effect of elastic deformation.

Thus, the diaphragm-operating ring 2 of the interchangeable objective constructed according to the present invention is controlled in the following manner. Within the M-range, both rotation arresting members 21M, 21A for M and A, respectively, are forcibly deflected by the inner surface of the diaphragm-operating ring 2 inwardly, as shown in FIG. *6a*, unless said diaphragm-operating ring 2 is rotated to the minimum lens aperture position. In consequence, these arresting members are never received by the locking groove 25 and the diaphram-operating ring 2 is freely rotatable in the directions both of arrows R and L.

When the diaphragm-operating ring 2 has been rotated in the direction as indicated by the arrow L (FIGS. *6a, b, c*) to the minimum lens aperture position, the arresting surface 28M of the rotation arresting members 21M for M bears against the M-locking side wall 25M of the locking groove 25, thereby arresting further rotation of the diaphragm-operating ring in the direction of the arrow L, i.e., toward the A-position, as shown in FIG. *6b*, FIG. *7a* and FIG. *8a*. Now the diaphragm-operating ring 2 is freely rotatable toward the maximum lens aperture position (i.e., upon rotation in this direction, the corner of the locking groove 25 deflects the arresting member 21M downward).

To rotate the diaphragm-operating ring 2 to the A-position, the unlocking member 26 is depressed to disengage the arresting surface 28M of the rotation arresting member 21M for M from the M-locking side wall 25M, as seen in FIGS. *6c* and *7b*. From such a state the diaphragm-operating ring 2 may be rotated in the direction of the arrow L, i.e., toward the A-position. When the diaphragm-operating ring has been rotated to the A-position, the arresting surface 28A of the rotation arresting members 21A for A is engaged with the A-locking side wall 25A of the locking groove 25, as seen in FIGS. *6e*, *7b*, and *8b*, thereby arresting rotation of the diaphragm-operating ring 2 in the direction of the arrow R, i.e., toward the M-range. The rotation in the direction of the arrow L is arrested by the interlocking pin 6 on

the diaphragm-rotating ring **5** abutting an end **9**A of the interlocking groove **9** formed in the support ring **1**.

To bring the diaphragm-operating ring **2** back to the M-range, the unlocking member **26** is depressed to displace the rotation arresting member **21**A for A inwardly, as shown in FIG. *6f*, thereby disengaging the arresting surface **28**A from the A-locking side wall **25**A. From this state, the diaphragm-operating ring **2** may be rotated toward the M-range. In the embodiment described hereinabove, the two rotation arresting members **21**M, **21**A are located in the leaf spring grooves **20**M, **20**A, respectively, and there is provided between these both leaf spring grooves **20**M, **20**A a land (position control surface) **22** adapted to control the maximum displacement of the unlocking member **26**. As a result, smooth operation is assured without extreme deformation of the rotation arresting members **21**M, **21**A.

FIG. **9** shows another embodiment of the rotation arresting members **21**M, **21**A. According to this embodiment, both rotation arresting members **21**M, **21**A for M and A, respectively, are formed in a one piece construction from a single piece of leaf spring material; there is provided between both arresting members a common surface for position control **22**.

In another embodiment shown in FIG. **10**, the locking groove **25** formed in the diaphragm-operating ring **2** comprises a combination of two locking grooves **25**(1), **25**(2) of triangular cross-sections, respectively, including M-locking side wall **25**M and A-locking side wall **25**A. In this embodiment, the rotation arresting members **21**M, **21**A may be formed from a linear, i.e., straight, leaf spring material and the forward ends of the respective rotation arresting members **21**M, **21**A may function as arresting surfaces **28**M, **28**A.

It should be noted here that the mount support ring **1** according to the present invention is a non-rotatable member adapted for rotatable support of the diaphragm-operating ring **2**.

It will be understood from the foregoing description that, in accordance with the present invention, changeover of the diaphragm-operating ring between the M-range and the A-position is accomplished by using two rotation arresting members comprising leaf springs for M-range and A-position, respectively, and the opposite side walls circumferentially defining the locking groove of the diaphragm-operating ring, which may be disengageably engaged with said both rotation arresting members. These both rotation arresting members are offset in the direction of the optical axis and displaceable by depression of the single unlocking member. Thus, it is possible to reduce the rotation angle for changeover between the M-range and the A-position by suitably arranging the positions of the respective leaf springs serving as rotation arresting members so that the degree of design freedom may be improved and the desired strength may be maintained. Furthermore, the change-over between the M-range and the A-position can be achieved merely by depressing the single unlocking member with a high maneuverability.

The disclosure of Japanese Utility Model Application No. 1982-124728, Japanese Utility Model Gazette No. 59(1984)-30123, laid open Feb. 24, 1984, is incorporated fully by reference.

What is claimed is:

1. An interchangeable objective with a variable lens aperture for a camera comprising:

a stationary support member;

a diaphragm-operating member rotatable about an axis between first and second angular positions relative to the stationary member;

a first elongated leaf spring mounted on the stationary member to bear against the diaphragm-operating member along a first plane perpendicular to the axis;

a second elongated leaf spring mounted on the stationary member to bear against the diaphragm-operating member along a second plane perpendicular to the axis, the second plane being spaced from the first plane in the direction of the axis;

locking groove means formed in the diaphragm-operating member so as alternately to receive the first and second leaf springs in locking engagement when the diaphragm-operating member is positioned at the first and second angular positions, respectively; and

an unlocking button mounted in the diaphragm-operating member over the locking groove means to push the respective first and second leaf springs out of engagement with the locking groove means upon depression of the locking button.

2. The objective of claim **1**, in which the stationary members has annular mounting groove means in communication with the locking groove means in which the first and second leaf springs are mounted.

3. The objective of claim **2**, in which each leaf spring comprises a first elongated portion attached to the stationary member in the mounting groove means and extending away therefrom toward the locking groove means and a second elongated portion forming an obtuse angle with the first portion and adapted to fit in the locking groove means.

4. The objective of claim **3**, in which the locking groove means has a rectangular cross-section with opposite corners and each leaf spring additionally comprises a third portion extending at an angle of about 90° from the end of the second portion such that the intersection of the second and third portions fits into one of the corners of the locking groove means when such leaf spring is in locking engagement therewith, the intersections of the leaf springs fitting in the respective opposite corners of the locking groove means.

5. The objective of claim **2**, in which the first and second leaf springs are straight and face toward each other and the locking groove means comprise first and second grooves having oppositely oriented triangular cross-sections with respective apexes adapted to receive the ends of the respective first and second leaf springs.

6. The objective of claim **2**, in which the first and second leaf springs are formed of respective first and second pieces of spring material.

7. The objective of claim **2**, in which the first and second leaf springs are formed of a single piece of spring material.

[57] **ABSTRACT**

A Gauss type objective lens system with a high speed of F1.2 for 35 mm SLR cameras is provided. The lens system consists of seven lenses, the object side surface of the second lens being aspheric, and fulfills the following conditions:

$$0.65 < Da/Db < 1.1$$

$$B < 0 \text{ and } C < 0$$

$$0.55f < R < f$$

wherein: Da represents the sum of axial distance from the object side surface of the second lens to the image side surface of the third lens; Db represents the sum of axial distance from the object side surface of the fourth lens to the image side surface of the fifth lens; B and C represent the aspheric surface coefficients of the fourth degree and of the sixth degree, respectively; f represents the focal length of the whole lens system; and R represents the paraxial radius of curvature of the object side surface of the second lens.

HIGH SPEED OBJECTIVE LENS SYSTEM WITH AN ASPHERIC SURFACE

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to an objective lens system with a high speed of about F1.2 and a field angle of about 46 degrees, and more particularly to such an objective lens system with an aspheric surface.

2. Description of the Prior Art

It is generally known in the prior art that a Gauss-type lens system with a high speed of about F1.2 and a sufficiently long back focal distance achieves such a desirable correction for field curvature that the resolution of the image is satisfactory throughout the entire area. In such a Gauss-type lens system, however, the spherical aberration is generally in an overcorrection condition to remarkably deteriorate the contrast of the image due to the greatly generated sagittal flare. The overcorrection of the spherical aberration is caused by the steep curvatures of the negative lens elements sandwiching the aperture stop, and is hardly corrected even by utilizing a glass material of a high refractive index in the case of such a high speed lens system.

In this field of art, it has been known to utilize an aspheric surface for aberration correction.

Examples of the prior art which discloses a Gauss-type objective lens system with an aspheric surface can be found in U.S. Pat. No. 3,459,468, Japanese Patent Publication No. 47-19386 and Japanese laid open Patent Application No. 56-75613.

The prior art is still seeking to provide a high speed Gauss-type objective lens system with an improved optical performance.

SUMMARY OF THE INVENTION

An object of the present invention is to provide a high speed objective lens system with an improved aberration correction.

Another object of the present invention is to provide a high speed objective lens system capable of forming an image with high contrast.

Still another object of the present invention is to provide a high speed objective lens system utilizing an aspheric surface in an improved manner.

The present invention provides a Gauss-type lens system of seven lenses with an aspheric surface provided at the object side of the second lens, which fulfills the following conditions:

$$0.65 < Da/Db < 1.1$$

$$B < 0$$

$$c < 0$$

$$0.55f < R < f$$

wherein: Da represents the sum of the axial distance from the object side surface of the second lens to the image side surface of the third lens; Db represents the sum of the axial distance from the object side surface of the fourth lens to the image side surface of the fifth lens; B and C represent the aspheric surface coefficients, respectively, in the following equation provided that X represents the distance, measured toward the image side along a direction parallel with the optical axis, from the center of the aspheric surface to a point on the aspheric surface at the height, Y from the optical axis, and r_0 represents the paraxial radius of curvature of the aspheric surface:

$$X = \frac{Y^2}{r_0 + r_0\sqrt{1 - \left(\frac{Y}{r_0}\right)^2}} + AY^2 + BY^4 + CY^6 + DY^8 + \ldots;$$

f represents the focal length of the whole lens system; and R represents the paraxial radius of curvature of the object side surface of the second lens.

The features of the present invention which are believed to be novel are set forth with particularity in the appended claims. The present invention, both as to its organization and manner of operation, together with further objects and advantages thereof, may best be understood by reference to the following description, taken in conjunction with the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** represents a cross sectional view of the lens system according to a first embodiment of the present invention;

FIG. **2** represents a cross sectional view of the lens system according to a second embodiment of the present invention;

FIG. **3** represents a cross sectional view of the lens system according to a third embodiment of the present invention;

FIGS. **4***a* to **4***f* represent the aberration curves of the first embodiment;

FIGS. **5***a* to **5***f* represent the aberration curves of the second embodiment; and

FIGS. **6***a* to **6***f* represent the aberration curves of the third embodiment.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

The following description is provided to enable any person skilled in the optical and camera field to make and use the invention and sets forth the best modes contemplated by the inventor for carrying out his invention. Various modifications, however, will remain readily apparent to those skilled in the art, since the generic principles of the present invention have been defined herein specifically to provide an improved high speed objective lens system. The derivation of the formulas and the relation of the powers set forth herein can be accomplished with the assistance of a computer. The present invention represents the parameters of a compromise balance of acceptable aberrations which can be relatively easily manufactured to provide a high speed objective lens system for utilization with a 35 mm SLR camera.

In the drawings, schematic cross sectional views disclose the position of the lens groups and lens elements, and follow the normal conventions of the object at the left-hand side of the drawing and the image plane at the right-hand side.

As disclosed in FIGS. **1** to **3**, the present invention provides a high speed Gauss-type objective lens system with an aspheric surface comprising, from the object to image side: a front lens group consisting of a first positive lens(L_1), a second positive lens(L_2) and a third negative lens(L_3); and a rear lens group consisting of a fourth negative lens(L_4), a fifth positive lens(L_5) ce-

mented to the fourth negative lens, a sixth positive meniscus lens(L_6) and a seventh biconvex lens(L_7), wherein the second positive lens(L_2) has an aspheric surface at its object side, the shape of the aspheric surface being designed so that the deviation of the aspheric surface from its paraxial radius to the object side is increased in accordance with the increase of the height from the optical axis. Further, the lens system according to the present invention fulfills the following conditions:

$$0.65 < Da/Db < 1.1 \quad (1)$$

$$B < 0 \text{ and } C < 0 \quad (2)$$

wherein: Da represents the sum of axial distance from the object side surface of the second positive lens(L_2) to the image side surface of the third negative lens(L_3); Db represents the sum of the axial distance from the object side surface of the fourth negative lens(L_4) to the image side surface of the fifth positive lens(L_5); B and C represent the aspheric surface coefficients, respectively, in the following equation provided that X represents the distance, measured toward the image side along a direction parallel with the optical axis, from the center of the aspheric surface to a point on the aspheric surface at the height, Y from the optical axis, and r_0 represents the paraxial radius of curvature of the aspheric surface:

$$X = \frac{Y^2}{r_0 + r_0\sqrt{1 - \left(\frac{Y}{r_0}\right)^2}} + AY^2 + BY^4 + CY^6 + DY^8 + \ldots .$$

In utilizing an aspheric surface for a lens system, the location of the aspheric surface should be carefully selected in view of the effect on the aberration correction and the easiness in manufacturing the aspheric surface. As is already mentioned, the contrast of the image formed by the Gauss-type lens system of a high speed such as F1.2 is unsatisfactory due to the flare caused by the steep curvatures of the negative lenses sandwiching the aperture stop. To overcome this disadvantage, it is generally required to relatively moderate the curvature of the surfaces sandwiching the aperture stop for balancing the aberration correction. This requirement is, however, difficult to realize by a lens system consisting of spherical lens elements even if a high index glass is used. Therefore, an aspheric surface is needed at a surface having a positive refractive power so as to lessen the curvature of the surface in accordance with the increase of the height from the optical axis. The effect of the aspheric surface of such a shape, however, depends on the specific location thereof in the lens system. Especially, the location of such an aspheric surface suitable for the correction of both the spherical aberration and coma is limited. Further, the degree of possible deviation of the aspheric surface from its paraxial radius is restricted. With the above factors carefully taken into consideration, the present invention selects the third surface of the lens system numbered from the object side, i.e., the object side surface of the second positive lens(L_2) as the most effective location of the aspheric surface in the case of and objective lens system with a high speed such as F1.2. If should be also noted that the paraxial radius of the aspheric surface is suitably designed.

The requirement in this type of lens system to secure a sufficiently long back focal distance also causes the undesirable steep curvatures of the pair of refractive surfaces sandwiching the aperture stop. To resolve this problem, the present invention provides the above mentioned condition(1), in which the relationship of the axial distance for the second and third lenses to that for the fourth and fifth lenses is defined for securing the sufficient back focal distance with the excessive curvatures of the pair of refractive surfaces sandwiching the aperture stop successfully avoided. If the upper limit of condition(1) is violated, the undesirable flare would increase, while the necessary marginal thickness of the second positive lens(L_2) having the aspheric surface would be insufficient if the lower limit of condition(1) is violated.

In designing the lens system according to the present invention, it should be noted that the above efforts to reduce the sagittal flare contradicts the demand for decreasing the Petzval Sum to improve the field curvature. For the purpose of overcoming such a contradiction, it is recommended to use a high index glass as the lenses of positive refractive power. In view of the selection of glass in the Gauss-type lens system, it is also recommended to use a relatively low Abbe number glass as the positive lenses in the rear lens group for sufficiently correcting both the lateral and longitudinal chromatic aberrations.

Conditions(2) relates to the shape of the aspheric surface located on the object side of the second positive lens(L_2). In utilizing the aspheric surface at the third surface of the high speed Gauss-type lens system for correcting spherical aberration, it is necessary to obtain, in addition to the reduced absolute value of spherical aberration at every ray height, a smooth shape of the spherical aberration curve by balancing between the spherical aberration of lower degree and that of higher degree. Conditions(2) which requires negative values for both the coefficients, B and C is necessary for this purpose. It is needless to say that the desired aspheric surface to correct the spherical aberration would be impossible if condition(2) is violated to result in $B>0$ and $C>0$. Further, if condition(2) is violated so that one of the coefficients, B and C is positive, the spherical aberration curve would show a shape of rough wave to deteriorate the Modulation Transfer Function(MTF) although the absolute value of spherical aberration may be within a limit at every ray height.

The MTF value for the d-line, $w=0°$, discloses a resolution of substantially 1.0 from 0 to 20 lines per millimeter. The MTF value is maintained substantially high through 50 lines per millimeter when condition (2) is maintained.

Further according to the present invention the following conditions are provided:

$$0.55f < R < f \quad (3)$$

$$\frac{N_1 + N_5 + N_6}{3} > 1.75 \quad (4)$$

$$\frac{\nu_5 + \nu_6}{2} > 40 \quad (5)$$

wherein: f represents the focal length of the whole lens system; R represents the paraxial radius of curvature of

the object side surface of the second positive lens(L_2); N_1, N_5 and N_6 represent the refractive index with respect to d-line of the first positive lens(L_1), the fifth positive lens(L_5) and the sixth positive meniscus lens(L_6), respectively; and ν_5 and ν_6 represent the Abbe number of the fifth positive lens(L_5) and the sixth positive meniscus lens(L_6).

Condition(3) defines the paraxial radius of curvature of the aspheric surface, which is located at the object side of the second positive lens(L_2). If condition(2) is violated, the desirable aspheric surface for sufficiently correcting both the spherical aberration and coma cannot be effectively located at the object side of the second positive lens(L_2).

Conditions(4) and (5) define the above mentioned requirements for the selection of glass in more detail. If condition(4) is violated, the correction of the field curvature would be difficult. On the other hand, the requirement of correcting both the lateral and longitudinal chromatic aberrations would not be attainable if condition(5) is violated.

The following Tables 1 to 3 disclose, respectively, the first through third embodiments of the present invention. In the Tables, f equals the focal length, r is the radius of curvature with respective sub numbers indicating the surfaces from the object to image side along the optical axis, d represents the axial distance and includes both the air spaces and the actual thickness of the lenses along the optical axis, N equals the refractive index and again, the sub numbers refer to the particular optical element from the object to image side, and finally, ν equals the Abbe number and the sub numbers refer to the specific lens elements from the object to image side. The asterisk(*) represents the aspheric surface, and its coefficients are shown at the bottom of the respective Tables.

D = $0.5421115 \times 10^{-14}$
$r_0 = r_3'$

As in the above embodiments 1 and 3, the third negative lens(L_3) may be cemented to the second positive lens(L_2).

Further, as in embodiment 3, the second positive lens(L_2) may consist of a spherical lens part(r_3–r_4) and a

thin layer part(r_3'—r_3) coated on the spherical lens part at its object side(r_3), the thin layer part(r_3'—r_3) being made of a transparent refractive material such as UV-curable resins, the object side surface(r_3') of which is molded to serve as the aspheric surface of the second positive lens(L_2). In such a construction of the second positive lens(L_2), the cost of manufacturing the aspheric surface is expected to be lowered.

As can be readily appreciated, it is possible to deviate from the above embodiments of the present invention and, as will be readily understood by those skilled in the optical art, the invention is capable of many modifications and improvements within the scope and spirit thereof. Accordingly, it will be understood that the invention is not to be limited by these specific embodiments, but only by the scope and spirit of the appended claims.

What is claimed is:

1. A high speed objective lens system with an aspheric surface comprising, from the object to image side:

a front lens group consisting of a first positive lens, a second positive lens and a third negative lens; and

a rear lens group consisting of a fourth negative lens, a fifth positive lens cemented to the fourth negative lens, a sixth positive meniscus lens and a seventh biconvex lens, wherein the second positive lens has an aspheric surface at its object side, which increases the deviation from its paraxial radius to the object side in accordance with the increase of the height from the optical axis, the d-line modulation transfer function being substantially 1.0 for a resolution of 0 to 20 lines/millimeter when the lens system fulfills the following conditions:

$$0.65 < Da/db < 1.1$$

$$B < 0$$

$$C < 0$$

wherein:

Da represents the sum of axial distance from the object side surface of the second positive lens to the image side surface of the third negative lens;

Db represents the sum of axial distance from the object side surface of the fourth negative lens to the image side surface of the fifth positive lens;

B and C represent the aspheric surface coefficients, respectively, in the following equation provided that X represents the distance, measured toward the image side along the direction parallel with the optical axis, from the center of the aspheric surface to a point on the aspheric surface at the height, Y from the optical axis, and r_0 represents the paraxial radius of curvature of the aspheric surface:

$$X = \frac{Y^2}{r_0 + r_0\sqrt{1 - \left(\frac{Y}{r_0}\right)^2}} + AY^2 + BY^4 + CY^6 + DY^8 + \ldots.$$

2. The invention of claim **1**, wherein the lens system further fulfills the following condition:

$$0.55f < R < f$$

wherein:

f represents the focal length of the whole lens system; and

R represents the paraxial radius of curvature of the object side surface of the second positive lens.

3. The invention of claim **1**, wherein the second positive lens consists of a spherical lens part and a thin layer part coated on the spherical lens part at its object side, the thin layer part being made of a transparent refractive material, the object side surface of which serves as the aspheric surface of the second positive lens.

4. The invention of claim **1**, wherein the third negative lens is cemented to the second positive lens.

5. The invention of claim **1**, wherein the lens system further fulfills the following conditions:

$$\frac{N_1 + N_5 + N_6}{3} > 1.75$$

$$\frac{\nu_5 + \nu_6}{2} > 40$$

wherein:

N_1, N_5 and N_6 represent the refractive index with respect to d-line of the first positive lens, the fifth positive lens and the sixth positive meniscus lens, respectively; and

ν_5 and ν_6 represent the Abbe number of the fifth positive lens and the sixth positive meniscus lens.

6. The invention of claim **2**, wherein the condition for R is as follows:

$$0.6f < R < f.$$

7. The invention of claim **2**, wherein the condition for R is as follows:

$$0.67f < R < f.$$

8. A high speed objective lens system with an aspheric surface comprising the following design parameters:

$f = 100.0$ $F_{No.} = 1.2$

		Radius of Curvature		Axial Distance		Refractive Index		Abbe Number
L_1	r_1	83.157	d_1	11.982	N_1	1.78850	ν_1	45.68

[57] **ABSTRACT**

A camera system with an auto-focusing system includes a camera body and an interchangeable zoom lens. The interchangeable objective lens stores various data to be sent to the camera body for improving automatic focus adjustment, such as an information necessary to convert the detected defocus information into a movement of the driving power source to carry out the automatic focus adjustment. The driving power source in the camera body is controlled in response to the data from the interchangeable objective lens and the detected focus information, the driving power being transmitted to the interchangeable objective lens. The camera body is further capable of inhibiting the focus adjustment or focus indication in response to a data from the interchangeable objective lens under an unfavorable condition.

CAMERA SYSTEM CAPABLE OF FOCUS DETECTION THROUGH AN INTERCHANGEABLE OBJECTIVE LENS

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to a camera system capable of focus detection by means of receiving light through an interchangeable objective lens. More particularly, it relates to an improvement of the above-mentioned system and also to an improvement of the camera body and the interchangeable objective lens in that system.

2. Description of the Prior Art

Conventionally, a camera system has been proposed wherein the focus adjustment and the display of detected focus condition are controlled in accordance with a signal based on the light which has passed through the interchangeable objective lens and received by light receiving device provided in the camera body.

Generally, according to the camera system, a number of different types of interchangeable lenses can be mounted on a camera body, and one interchangeable lens can be mounted on a number of different types of camera bodies. In other words, according to the camera system to which the present invention pertains, there is a compatibility between a number of camera bodies and a number of interchangeable objective lenses, enabling a number of combinations of a camera body and an interchangeable lens.

In the camera system described above, there are a number of problems to be solved when the focus detection and focus adjustment are to be carried out with a signal based on the light which has passed through the interchangeable objective lens. A problem in the case of focus detection is, for example, the change in conditions, such as in the optical arrangement, every time when the combination of camera body and interchangeable lens changes. To establish a camera system of the above described type which can effect the focus detection with a high accuracy, it is necessary to consider all the possible conditions set up by various combinations, or otherwise, a high reliability on the focus detection can not be ensured. For example, when the fully open aperture size of an interchangeable lens is smaller than a predetermined size, there may be a case wherein a required focus detection can not be carried out properly. Such a case will be described later in connection with FIGS. **1** to **3**.

A problem in the case of focus adjustment carried out automatically by the motor drive of focusing lens in the interchangeable lens in accordance with the result of focus detection is in the driving source and its control. For example, the control of driving source according to even the same result of focus detection would have to vary depending on the various combination of camera body and interchangeable lens changes.

SUMMARY OF THE INVENTION

The present invention has been developed with a view to substantially solving the above described problems and has for its essential object to provide a camera system with an interchangeable lens with an improvement in both camera body and interchangeable lens from the view point of automatic focus detection.

It is also an object of the present invention to provide a camera system of the above described type with an

improvement in the focus adjustment of the interchangeable objective lens in accordance with the result of focus detection.

It is a further object of the present invention to provide a camera system of the above described type with an improvement wherein a camera body can be connected to every possible types of interchangeable lenses without causing any problem in operation.

It is another object of the present invention to provide a camera system of the above described type with an improvement wherein a camera body can be connected to every possible types of interchangeable lenses having different fully open aperture sizes without causing any problem in operation.

It is another object of the present invention to provide a camera system of the above described type with an improvement to make it possible to mount a zoom lens on the camera body without any problem in operation.

It is another object of the present invention to provide a camera system of the above described type with an improvement to make it possible to mount an interchangeable objective lens capable of macro photography on the camera body without any problem in operation.

It is another object of the present invention to improve a camera system with respect to a case that an interchangeable objective lens having no ability of automatic focus adjustment is mounted on the camera body which can carry out the automatic focus adjustment.

It is yet another object of the present invention to provide a camera system with an improvement to prevent a case that the camera system would receive possible disadvantageous affects on focus detection or focus adjustment from an incomplete mounting of the lens on the camera body.

According to one feature of the present invention, a means for generating a driving power for the automatic focus control is located inside the camera body. And, in accordance with a defocusing information, which is the result of focus detection, a first movable member provided in the generating means is moved. This movement is transmitted to interchangeable objective lens to automatically adjust the focus condition. In this case, converting information necessary to convert the defocusing degree in the defocusing information into a degree of movement of the first movable member varies in accordance with the type of mounted interchangeable objective lens, even if the defocusing degree is the same. Thus, according to the present invention, the converting information in the form of digital data is stored in ROM located in each interchangeable objective lens and sent to the camera body. The movement of the first movable member suitable for each particular interchangeable objective lens is determined in accordance with the defocusing degree with the aid of the converting information sent to the camera body from the ROM in the interchangeable objective lens. The converting information varies greatly with respect to the change of type of interchangeable objective lens. Therefore, according to the present invention, in order to effectively send the converting information to the camera body, the converting information is formed as a digital data composed of m-bit of significant digits part and n-bit of floating point coefficient part. In this manner, it is possible to express the converting information in a wide variation range with a small number of bits.

According to another feature of the present invention, an improvement is made to make it possible to mount a zoom lens on the camera body without any problem in automatic focus adjustment. Some zoom lenses have a converting information that changes in response to the change of focal length. In order to properly operate with such a type of zoom lens, it is required to prepare, from an ideal stand point, extremely great numbers of different converting information values corresponding to the change of focal length. But, it is not practical to prepare so many numbers of converting information values. According to the present invention, the variable focal length range of the zoom lens is divided into a plurality of zones, and one converting information value is given to each zone. In other words, within one zone, the variety of ideal converting information values are all approximated to one converting information value which is so selected that it causes an approximately minimum degree of movement of the first movable member within that zone. Accordingly, notwithstanding the use of such an approximate value, a case in which the first movable member overshoots its movement thereby requiring its return movement can be avoided. In other words, the movable member can be brought to a required position with its movement only in one direction.

According to another feature of the present invention, the converting information to be stored in a ROM of an interchangeable objective lens is a data for converting the defocus degree into the degree of movement of a movable member in the interchangeable objective lens for receiving the driving power. While in the camera body, means is provided for providing a supplemental converting data to convert the degree of movement of the the first movable member into that of another movable member to be coupled with the movable member of the interchangeable objective lens. According to this arrangement, any combination between camera body and interchangeable objective lens can be employed without any trouble.

For the automatic focus control, it is necessary to determine the direction of movement of the first movable member. Although the defocusing direction of defocusing information is the same, the direction of movement of the first movable member may differ depending on the type of interchangeable objective lens. Thus, according to a further feature of the present invention, the ROM in the interchangeable objective lens is stored with direction information, in addition to the converting information. This direction information is sent to the camera body. And, based on the direction information and defocusing direction of defocusing information, the direction to move the first movable member is determined to suit each interchangeable objective lens.

According to yet another feature of the present invention, the camera body has a means for inhibiting focus adjustment or focus indication, in the case where one of undesirable conditions owing to the exchange of lens takes place. For example, in the case where the fully open aperture size informed from the mounted interchangeable objective lens is too small to successfully carry out the focus detection, the inhibiting means, according to the present invention, is actuated.

Furthermore, the ROM of the interchangeable objective lens stores a check data for certifying that the interchangeable objective lens is correctly connected to the camera body by means of successful acceptance of the check data by the camera body. In the case where the check data is not accepted successfully by the camera body, the above-mentioned inhibiting means is actuated.

According to a still further feature of the present invention, means for generating a driving power to be transmitted to the interchangeable objective lens, and means for indicating the focus condition, both of which respond to the result of the focus detection, are provided in the camera body. And, in the interchangeable objective lens, in addition to the fully open aperture size information, an auto-focus information indicating whether or not the interchangeable objective lens is capable of automatic focus adjustment in response to the driving power from the camera body is provided to be sent to the camera body. When the fully open aperture size of the mounted interchangeable objective lens is sufficiently large to correctly carry out the focus detection, and at the same time, auto-focus information indicating that the interchangeable objective lens is incapable of automatic focus adjustment is accepted by the camera body, only the above-mentioned generating means is inhibited with the operation of the indicating means maintained. Accordingly, when such an interchangeable objective lens is mounted, a photographer can adjust the focus manually as he watches the focus indication.

When a mounted interchangeable objective lens is a type having a macro-photography mode, the ROM of interchangeable objective lens stores macro-photography information to be sent to the camera body only when the lens is set to macro-photography condition. And, when the macro-photography information is accepted by the camera body, the generating means is inhibited and indicating means is actuated, as similar to that described above. Accordingly, the manual focusing under the macro-photography can be carried out in accordance with the focus indication.

BRIEF DESCRIPTION OF THE DRAWINGS

These and other objects and features of the present invention will become apparent from the following description taken in conjunction with a preferred embodiment thereof with reference to the accompanying drawings, throughout which like parts are designated by like reference numerals, and in which:

FIG. **1** is a diagrammatic view of an optical arrangement of a focus detecting device according to the prior art;

FIG. **2** is a diagrammatic view of an optical relationship between the focus detecting device of FIG. **1** and an interchangeable lens mounted on the camera;

DESCRIPTION OF THE PREFERRED EMBODIMENT

Referring to FIG. **4**, a block diagram of a camera system having an auto-focus system according to the present invention is shown. In the drawing, parts shown on the left-hand side of a chain line belong to a zoom lens LZ, and parts shown on the right-hand side of the same belong to camera body BD. The zoom lens LZ is an interchangeable lens and is mounted on the camera body BD. The transmission of driving force from body BD to lens LZ is effected by a clutch arrangement **106** and **107** and transmission of electric signals between body BD and lens LZ is effected by terminals JL1–JL5 and terminals JB1–JB5. According to the camera system shown, the light beams reflected or emitted from an object to be photographed path through focusing lens FL of the zoom lens LZ, zooming lens ZL, and master lens ML. The light beams further path through the central half-mirror portion of a reflection mirror **108** provided in the camera body BD, reflect on a sub-mirror **109**, and impinges on a light receiving device FLM for the focus detection.

A signal processing circuit **112** is provided to receive signals from light receiving device FLM, and based on such signals, it produces a defocus signal $|\Delta L|$ representing a degree of out of focus and a direction signal representing a direction of out of focus whether it is near focused or far focused. A motor MO is provided to be driven in accordance with these signals and its rotational force is transmitted to the zoom lens LZ through slip mechanism SLP, driving mechanism LDR and clutch **107** provided in the camera body. It is to be noted that the slip mechanism SLP is provided to cut the transmission of rotational force to the driving mechanism thereby preventing the motor MO from being over-loaded such that the slip mechanism SLP slips when a torque above a predetermined level is applied to a shaft after the slip mechanism SLP.

The zoom lens LZ shown has a focus adjustment member **102** for shifting the focusing lens FL. The focus adjustment member **102** is formed with a female-helicoid thread on its inner surface which engages with a male-helicoid thread on the outer surface of a cylinder **101** provided integrally to the lens mount **121**. A large gear **103** is fixedly mounted on the peripheral outer surface of the focus adjustment member **102**. The large gear **103** is engaged to a small gear **104** which is connected through a transmission mechanism **105** to the clutch **107** provided in the lens. By the above arrangement, the rotational force of the motor MO is transmitted to the focus adjustment member **102** through slip mechanism SLP in the camera body, clutch **107** in the camera body, clutch **106** in the lens, transmission mechanism **105** in the lens, small gear **104** and large gear **103**. Then, by the engagement between the male- and female-helicoid threads, the focusing lens FL is shifted in the optical axis direction, thereby effecting the focus adjustment. Also, in order to monitor the amount of shift the focusing lens LF, an encoder ENC is coupled to the driving mechanism in the camera body BD such that the encoder ENC produces a train of pulses with its number corresponding the the amount of shift of the lens FL.

When terms are defined as follows:

NM (rot): the number of rotation of the motor MO;

N: the number of pulses from the encoder ENC;

ρ (1/rot): resolving power of the encoder ENC;

μP: rate of speed reduction in mechanical transmission arrangement between the shaft of motor MO and the shaft of encoder ENC;

μB: rate of speed reduction in mechanical transmission arrangement between the shaft of motor MO and clutch **107** of the camera body;

μL: rate of speed reduction in mechanical transmission arrangement between clutch **106** of the lens and large gear **103**;

LH (mm/rot): a helicoid lead of the focus adjustment member; and

Δd (mm): amount of shift of the focusing lens FL,

following relationships are obtained.

$$N=\rho\cdot\mu P\cdot NM$$

$$\Delta d=NM\cdot\mu B\cdot\mu L\cdot LH$$

Thus,

$$\Delta d=N\cdot\mu B\cdot\mu L\cdot LH/(\rho\cdot\mu P). \quad (1)$$

Also, when a relation between the above given Δd and ΔL (mm) representing the amount of shift of the image forming plane when the lens is shifted Δd (mm) is defined as:

$$Kop=\Delta d/\Delta L, \quad (2)$$

a following equation (3) is obtained using equations (1) and (2).

$$N=Kop\cdot\Delta L\cdot\rho\cdot\mu P/(\mu B\cdot\mu L\cdot LH) \quad (3)$$

When terms are defined as:

$$KL=Kop/(\mu L\cdot LH) \quad (4)$$

and

$$KB=\rho\cdot\mu P/\mu B, \quad (5)$$

a following equation (6) is obtained.

$$N=KB\cdot KL\cdot\Delta L \quad (6)$$

In the equation (6) given above, ΔL is obtained from the signal processing circuit **112** using the defocus signal $|\Delta L|$ and the direction signal. Furthermore, the term

KL in equation (4) corresponds to the focal length of the zoom lens as set by the rotational operation of a zooming ring ZR, and is produced from a lens circuit LEC. In other words, a code plate FCD produces data representing the rotated position of the zooming ring ZR, and the produced data are applied to the lens circuit LEC. In the LEC, the received data are used for designating an address at which KL is stored. Data KL are read out serially bit-by-bit and are supplied to a reading circuit LDC in the camera body. Moreover, the term KB in equation (5) is a data determined by the type of camera body, and is produced from a fixed data producing circuit **110**.

From reading circuit LDC of the camera body to lens circuit LEC of the lens, electric power is supplied through terminals JB1 and JL1, synchronizing clock pulses are applied through terminals JB2 and JL2, and a read-start signal is applied through terminals JB3 and JL3. Contrary, from lens circuit LEC to reading circuit LDC, data KL are transmitted in series through terminals JL4 and LB4. Now, terminals JB5 and JL5 are connected with each other as a common ground.

The code plate FCD is arranged in a predetermined code pattern so as to produce data corresponding to the rotated position of the zooming ring ZR. The lens circuit includes a memory, such as a ROM, in which various data KL corresponding to various focal length set by the zooming ring ZR are stored at different addresses determined by the code plate FCD. Therefore, when the read-start signal is applied, lens circuit LEC produces bit-by-bit the data KL corresponding to the focal length set by the zooming ring in a synchronized manner with the clock pulses. And, the produced data KL are applied serially through terminals JL4 and JB4 to reading circuit LDC in which the data KL are aligned parallelly.

For the zoom lens having a focusing system in which focusing lens FL is disposed in front of zooming lens ZL, i.e., for the zoom lens of front lens shifting type, the above given amount Kop can be expressed as follows:

$$Kop = F1^2/f^2, \quad (7)$$

wherein f1 is a focal length of focusing lens FL. Thus, one zoom lens has a wide variation of a value KL. To memorize a wide variation of a value KL, the data of each value KL are defined by bits representing the significnat digits and bits representing the floating point coefficient. For example, if the data is 8-bit long, the upper four bits may be used as a part for designating the floating point coefficient, and the lower four bits may be used as a part for designating the significant digits. In the preferred embodiment shown in FIG. **4**, a shift circuit **131** receives lower four bits of the data KL for specifying the significant digits, and a shift control circuit **130** receives upper four bits of the data KL for specifying the floating point coefficient. The significant digits established in the shift circuit **131** is shifted to change its floating point in accordance with the data from the shift control circuit **130**. With this arrangement, shift circuit **131** can cover a widely changing value of the data KL.

A multiplication circuit **111** is provided to receive data KL from shift circuit **131** and data KB from fixed data producing circuit **110**, and it carries out a multiplication $KL \times KB = K$. Another multiplication circuit **113** receives defocus signal $|\Delta L|$ from signal processing circuit **112** and data K from multiplication circuit **111**, and it carries out a multiplication $K \times |\Delta L| = N$, thereby calculating the number of pulses to be detected by encoder ENC. A motor control circuit **114** drives motor MO in a clockwise or counterclockwise direction depending on the direction signal from the signal processing circuit **112**. The amount of rotation of the motor MO is controlled by the data N obtained from multiplication circuit **113** and the pulses obtained from the encoder ENC, such that motor MO stops when N pulses are produced from encoder ENC. When this is done, focusing lens FL is shifted a distance Δd towards an in-focus position.

According to the above description, the data K is produced by the multiplication of data KL from the lens by the data KB which is intrinsic to each type of camera body and is stored in fixed data producing circuit **110** in the camera body. Instead of the above steps, the data K can be obtained through other methods.

For example, one method is to arrange zoom lens LZ such that lens circuit LEC produces $K1 = KL \times KB1$ corresponding to a standard type of camera body in response to the setting of focal length. When this arrangement is employed, it is not necessary to provide fixed data producing circuit **110** and multiplication circuit **111** in the standard type camera body such that the data K1 from the reading circuit LDC are applied directly to multiplication circuit **113**. But when this zoom lens is mounted no a nonstandard type camera body having data KB2 ($\neq$KB1), the nonstandard type camera body must have fixed data producing circuit **110** and multiplication circuit **111** such that fixed data producing circuit **110** produces data KB2/KB1 and multiplication circuit **111** calculates

$$K2 = K1 \times KB2/KB1 = KL \times KB2,$$

thereby obtaining a wanted data $KL \times KB2$.

According to another example, every lens may be stored with various data, $K1 = KL \times KB1$, $K2 = KL \times KB2, \ldots$, and $Kn = KL \times KBn$ for the all types of camera body. And when in use, the camera body connected to that lens may selectively pick one data corresponding to the camera body. This can be accomplished by sending all the data in the lens to the camera body so that the necessary data are selected in the camera body, or by sending data representing the type of camera to the lens, and transmitting only the necessary data from the lens to the camera body. If this arrangement is employed, it is not necessary to provide fixed data producing circuit **110** and multiplication circuit **111**.

In the foregoing description, a camera system having an auto-focus system according to the present invention is described from the view point of hardwares, but according to a preferred embodiment, various functions of the circuits are accomplished by microcomputers as will be described below.

In the following description, a system is described in which only a standard type camera body with KB1 is available. And, in this case, a data $KL \times KB1$ is stored in the lens and sent to the camera body, such data $KL \times KB1$ being represented by simply KD hereinafter.

Referring to FIG. **5**, a block diagram of a circuit provided in the camera body is shown, together with a block diagram of a circuit provided in the lens, which is enclosed in a chain line LE. The circuit in the camera body BD is connected to the circuit in the lens through terminal arrays CN1 and CN2 so as to send various data

from lens LE to camera body BD. When a power switch MAS turns on, electric power is supplied through a power line +E to each of power-on reset circuit POR1, microcomputers MC1 and MC2, display control circuit DSC, oscillator OSC, inverters IN1 to IN8, and AND gate AN1. Upon power supply, power-on reset circuit POR1 produces a reset signal PO1, thereby resetting microcomputers MC1 and MC2 and display control circuit DSC.

Microcomputer MC2 is provided to govern the sequence of the overall operation of the camera system, and its operation will be described later in connection with a flow chart shown in FIG. 6. Microcomputer MC1 is provided to sequentially carry out the focus adjustment operation in response to the control signals from the microcomputer MC2, and its operation will be described later in connection with a flow chart shown in FIGS. 11 to 13.

A light measuring switch MES turns on when a shutter release button (not shown) is depressed to its halfway. And when light measuring switch MES turns on, microcomputer MC2 receives HIGH to its input i0 through inverter IN1. In response to this, microcomputer MC2 produces HIGH from its output O0, and thus inverter IN2 produces LOW, thereby turning a transistor BT1 on. By the turn on of transistor BT1, electric power is supplied through a power line VB to each of power-on reset circuit POR3, light measuring circuit LMC, decoder DEC1, transistor BT3 for driving light emitting diodes, film sensitivity setting device SSE, aperture setting device ASE, exposure time setting device TSE, exposure control mode setting device MSE, exposure control device EXC, and latch circuit LA. Upon power supply through power line VB, power-on reset circuit POR3 produces a reset signal PO3, thereby resetting exposure control device EXC. Furthermore, the HIGH from output O0 of microcomputer MC2 is applied through buffer BF and terminal arrays CN1 and CN2 to power line VL, thereby providing power to circuit LEC in the lens LE. Other than the terminals for the power supply, the terminal arrays CN1 and CN2 have other terminals, which are: signal transmission terminals connected to output O6 of microcomputer MC2 for releasing the reset condition of lens circuit LEC; clock transmission terminals for transmitting synchronizing clock pulses from clock output SCO of microcomputer MC2; data input terminals for inputting data from lens LE to serial data input SDI of microcomputer MC2; and common earth terminals. A circuit arrangement of serial data input of microcomputer MC2 is shown in FIG. 7, and circuit arrangement of circuit LEC of lens LE is shown in FIG. 8.

Still referring to FIG. 5, a light measuring circuit LMC provides measured-light signal in an analog form to analog input ANI of micrcomputer MC2, and a reference voltage for the D-A conversion to a reference voltage input VR of microcomputer MC2. Accordingly, using the reference voltage from light measuring circuit LMC, microcomputer MC2 converts the measured-light signal applied to input ANI from analog form to digital form.

Display control circuit DSC receives various data through data bus DB and displays exposure control values through liquid crystal display portion DSP and, also displays light emitting diodes LD10 to LD1n for the warning and other purposes. An output O8 of microcomputer MC2 continues to produce HIGH from the turn on of light measuring switch MES until the start of exposure control operation of the camera, and by an inverter IN8, transistor BT3 enables light emitting diodes LD10 and LD1n to emit light only within this period.

A decoder DEC1 receives signals from output port OP1 of microcomputer MC2 and produces output signals from its outputs a0 to aN+1 for indicating which one of devices MSE, TSE, ASE and SSE, and circuits DSC and LA should carry out data transmission with microcomputer MC2 through data bus DB. For example, when microcomputer MC2 produces from output port OP1 a particular data for effecting exposure control mode setting device MSE, output a0 produces HIGH and other outputs a2 to aN+1 produce LOW, thereby microcomputer MC2 reads data of exposure control mode from exposure control mode setting device MSE through data bus DB and input/output port I/O. In a similar manner, when it is necessary to read data of set aperture value, output a2 produces HIGH. Furthermore, when sending display data to exposure control circuit DSC, one of outputs a4 to aN produces HIGH, depending on the type of data to be sent. Also, when sending a conversion coefficient data KD of a lens, which will be described in detail later, first input/output port I/O produces conversion coefficient data through data bus DB for a period of time, and within this period of time, a particular data is produced from output port OP1 so that output aN+1 produces a pulse for effecting latch circuit LA to latch the conversion coefficient data.

Upon application of HIGH to interruption signal input iT of microcomputer MC2, exposure control device EXC starts an exposure control operation described below. For this purpose, release circuit, mirror drive circuit, aperture control circuit and exposure time control circuit are provided. When output O4 of micrcomputer MC2 produces a pulse, exposure control device EXC receives and intakes F stop-down step data on data bus DB, and thereafter, actuating the release circuit to start the exposure control operation. After a certain period of time from the start of exposure control operation, microcomputer MC2 produces exposure time data through data bus DB, and also a pulse from its output O5. Accordingly, the exposure control device EXC intakes exposure time data, and the mirror drive circuit is so operated as to flip up the reflection mirror. Furthermore, the aperture control circuit is so operated as to reduce the aperture size in accordance with the F stop-down step data. When the reflection mirror flips up completely, a leading shutter starts to scan. At the same time, a count switch COS turns on to actuate exposure time control circuit, thereby start counting a time corresponding to exposure time data. When the time counting ends, a trailing curtain starts to scan and, thereafter, the aperture opens to its maximum available size. Then, the reflection mirror flips down to complete one exposure control operation.

A release switch RLS closes when the release button (not shown) is depressed all the way. When release switch RLS closes, inverter IN3 produces HIGH, which is applied to one input of AND gate AN1, thereby enabling AND gate AN1. A switch EES closes when the exposure control operation completes, and it opens when an exposure control mechanism (not shown) is charged to an operable condition. A signal representing on and off conditions of this switch is applied through inverter IN4 to input i2 of microcomputer MC2 and also to the other input of AND gate

AN1. The output of AND gate AN1 is connected to interruption signal input iT of microcomputer MC2. Therefore, when the exposure control mechanism is not charged, AND gate AN1 is held in a disable condition, thereby producing LOW from AND gate AN1 even when release switch RLS closes. In this case, no interruption signal will be applied and, therefore, no exposure control operation will be started. On the contrary to this, when the exposure control mechanism is charged, AND gate AN1 is held in an enable condition, thereby producing HIGH from AND gate AN1 when release switch RLS turns on. Thus, the interruption signal is applied to interruption input iT of microcomputer MC2, whereby the microcomputer MC2 immediately starts the exposure control operation.

Outputs O1, O2 and O3 of microcomputer MC2 are connected, respectively, to inputs i11, i12 and i13 of microcomputer MC1. Output O1 produces HIGH, when it is necessary to carry out a focus detection by microcomputer MC1, and LOW when the focus detection is not needed. Output O2 produces HIGH, when the mounted lens is a type in which the focusing lens is shifted forward when the motor is driven clockwise, and LOW, when the mounted lens is a type in which the focusing lens is shifted forward when the motor is driven counterclockwise. Output O3 produces LOW when the mounted lens is a type in which the focus adjustment is carried out only by a system wherein the focusing lens is driven towards an in-focus position in accordance with signals representing degree and direction of out-of-focus (such a system is disclosed in U.S. Pat. No. 4,209,241 in detail and, hereinafter, referred to as a predictor system). And, output O3 produces HIGH when the mounted lens is a type in which the focus adjustment is carried out by the predictor system in combination with a system wherein the focusing lens is driven towards an in-focus position in accordance with a signal (front-focus condition, rear-focus condition, or in-focused condition) representing the direction of out-of-focus (such a system is disclosed in U.S. Pat. No. 4,303,321 and, hereinafter referred to as a trinomial indication system).

A switch FAS is a mode selecting switch operated manually. When it closes, AF mode is selected. Under AF mode, the focus adjustment is carried out automatically such that the focusing lens is shifted towards in-focus position in accordance with the result of focus detection. When switch FAS opens, FA mode is selected. Under FA mode, the focus adjustment is carried out manually in accordance with the display indicating the result of focus detection. A signal representing on and off conditions of switch FAS is applied through inverter IN6 to input i1 of microcomputer MC2 and also to input i14 of microcomputer MC1.

Output O16 of microcomputer MC1 is connected through inverter IN5 to the base of transistor BT2. Therefore, when output O16 produces HIGH, transistor BT2 conducts to supply power to each one of power-on-reset circuit PO2, light receiving device FLM for the focus detection, light receiving device FLM control circuit COT, motor drive circuit MDR, encoder ENC, light emitting diode drive circuit FAD and power line VF. By this power supply, power-on-reset circuit PO2 produces reset signal PO2.

Referring to FIG. 9, an example of light emitting diode drive circuit FAD is shown. Based on input signals from output port OP0 of microcomputer MC1, i.e., outputs O17, O18 and O19, circuit FAD drives light emitting diodes LD0, LD1 and LD2. More specifically, when either one of output O17, O18 and O19 produces HIGH, a corresponding one of light emitting diodes LD0, LD1 and LD2 is lit. When the light emitting diode LD0 is lit, it indicates the front-focus condition. When the light emitting diode LD1 is lit, it indicates the in-focused condition. And when the light emitting diode LD2 is lit, it indicates the rear-focus condition. Furthermore, when both outputs O17 and 018 produce HIGH at the same time, light emitting diodes LD0 and LD2 blink on and off repeatedly and simultaneously in accordance with clock pulses CP from oscillator OSC, thereby indicating that it is impossible to carry out the focus detection. Various operating conditions of light emitting diodes LD0, LD1 and LD2 will be shown in Table 1 below.

TABLE 1

Focus detection	OP0	LD0	LD1	LD2	Display
Non-operating	0 0 0	OFF	OFF	OFF	
Front-focus	1 0 0	ON	OFF	OFF	
Rear-focus	0 0 1	OFF	OFF	ON	
In-focused	0 1 0	OFF	ON	OFF	
Detection impossible	1 0 1	Blinking	OFF	Blinking	

Light receiving device FLM is defined by a CCD (Charge Coupled Device) having a plurality of light receiving elements for the focus detection. Control circuit COT so operates as to drive the CCD in accordance with the signal from the microcomputer MC1, to carry out the A-D conversion of output signals from the CCD, and to transmit the converted output signals to microcomputer MC1.

To start the integration operation in CCD FLM, microcomputer MC1 produces a pulse from its output O10 to control circuit COT, and to forcibly stop the integration operation in the CCD, microcomputer MC1 produces a pulse from its output O11 to control circuit COT. When the integration operation is completed in CCD FLM, control circuit COT produces a pulse which is applied to interruption input iT of microcomputer MC1. When the A-D conversion for each light receiving element in CCD FLM is completed, control circuit COT produces a pulse which is applied to input i10 of microcomputer MC1. And, each A-D converted data is applied to input port IP0 of microcomputer MC1. Furthermore, from control circuit COT, the CCD receives a reset signal to its input ØR, a transfer command signal to its input ØT, transfer clock pulses to its inputs Ø1, Ø2 and Ø3, and a reference voltage to its terminal ANB. And, control circuit COT receives from terminal ANB of the CCD a voltage signal representing a light amount received by a receiving element for monitoring, and from terminal AOT of the CCD charged voltage from each light receiving elements in the CCD. A detailed circuit arrangement of control circuit COT will be described later in connection with FIGS. 17 and 18.

Here, a brief description on operations of CCD FLM, control circuit COT and microcomputer MC1 is given. In accordance with the integration start signal from output O10 of microcomputer MC1, control circuit COT sends a reset signal $Ø_R$ to CCD FLM, thereby resetting the CCD, and at the same time, provides a reference voltage to CCD FLM through the terminal ANB. In each light receiving element of CCD FLM, the charge gradually increases in accordance with the

received light rays and, accordingly, a voltage level at terminal ANB decreases gradually. When the voltage level at the terminal ANB is reduced to a predetermined level, control circuit COT produces a transfer command signal $\emptyset_T$ to CCD, so that the charge in each light receiving element in the CCD is transferred to a transfer gate provided in the CCD, and at the same time, control circuit COT provides an integration completion signal to interruption input iT of microcomputer MC1. Then, in a synchronized manner with clock pulses applied to inputs $\emptyset$1, $\emptyset$2 and $\emptyset$3 of the CCD, control circuit COT receives charges at the transfer gate of the CCD, and converts it from analog form to digital form. When one A-D conversion for the charge in one light receiving element in CCD completes, the control circuit COT provides an A-D completion signal to input i10 of microcomputer MC1. In response to the A-D completion signal, microcomputer MC1 reads A-D converted data from control circuit COT through input port IP0. This reading operation is repeated for a number of times equal to the number of light receiving elements in the CCD, and when the final A-D converted data are read, microcomputer MC1 ends the transfer of data from CCD to control circuit COT.

It is to be noted that when microcomputer MC1 receives no interruption signal within a predetermined period of time after the start of integration, it produces from its output O11 a pulse which forcibly stops the integration in the CCD. In response to this pulse, control circuit COT provides the transfer command signal to input $\emptyset$T of the CCD and, at the same time, provides an interruption signal to microcomputer MC1, thereby carrying out the above described A-D conversion and data transfer.

Motor drive circuit MDR is provided to drive motor MO in accordance with the signals from outputs O12, O13 and O14 of microcomputer MC1. When output O12 produces HIGH, motor MO can rotate clockwise, when output O13 produces HIGH, motor MO can rotate counterclockwise, and when both outputs O12 and O13 produce LOW, motor MO stops. Furthermore, when output O14 produces HIGH, motor MO can be driven at a high speed and, when it produces LOW, motor MO can be driven at a low speed. Since the detail of motor drive circuit MDR is not necessary to understand the present invention, and it is known through Japanese Patent Application Laid-open No. 58-154015, assigned to the same assignee as the present application, its detailed description is omitted for the sake of brevity.

Encoder ENC is provided for monitoring the amount of drive effected by transmission mechanism LMD provided in the camera body to transmit the driving force of motor MO and is defined, e.g., by a photocoupler which produces a train of pulses which is in relation to the above-mentioned amount of drive. The pulses from encoder ENC are applied to clock input DCL of microcomputer MC1 in which the number of pulses are counted automatically. The counted value ECD will be used in the operation of microcomputer MC1 for the counter interruption, as well be described later with reference to the flow charts. Furthermore, the pulses are also applied to motor drive circuit MDR so as to control the speed of motor MO in accordance with the pulse width.

Referring to FIGS. 6*a*, 6*b*, 6*c* and 6*d*, a flow chart for the operation of microcomputer MC2 is shown. The operation of microcomputer MC2 can be roughly divided into three flows as described below.

The first flow, which is the main flow, starts from step #1 upon closure of power switch MAS. In the first flow, in response to the closure of light measuring switch MES (step #2), the procedures of: power supply (step #4) to the circuits other than the circuits for the focus adjustment; reading (step #5) exposure control information set in camera body BD; reading (steps #6–#12) data from lens LE; reading (steps #13 and #14) measured light amount; automatic setting (steps #16–#27) under AF or FA mode; calculation (step #28) for the exposure control values; and display (step #31 and #32) are repeated.

The second flow, which is a timer interruption flow, starts from step #45. In the second flow, in response to a timer signal produced periodically from a timer incorporated in microcomputer MC2, the above-mentioned main flow is carried out for a predetermined time (such as 15 seconds) after the opening of light measuring switch MES.

The third flow, which is a release interruption flow, starts from step #59. In the third flow, in response to the closure of release switch RLS, exposure control operations for the camera are carried out. The detail of these three flows will be given hereinbelow.

In response to the closure of power switch MAS, power-on reset POR1 produces a reset signal PO1. By this reset signal PO1, microcomputer MC2 carries out a reset operation at step #1 in the main flow. Then, whein input i0 receives HIGH by the closure of light measuring switch MES, the program advances from step #2 to step #3 at which the timer interruption is prohibited, and thereafter, output O0 produces HIGH at step #4. Accordingly, transistor BT1 conducts to supply power to power supply line VB in the camera body and also through buffer BF to power supply line VL in interchangeable lens. Then, at step #5, data from each one of exposure control mode setting device MSE, exposure time setting device TSE, aperture setting device ASE, and film sensitivity setting device SSE, are sequentially applied through data bus DB to input and output port I/O.

During steps #6 to #12, "0" is set in register A (step #6), output O6 produces HIGH, and the reset condition of lens circuit LEC is released (step #9). Then, "1" is added to register A (step #10). And, it is decided whether the content of register A has reached a predetermined amount, Ac. If (A)≠Ac ((A) means the content of register A.), the program returns back to step #7-2 to read next data. After repeating the reading operation for a predetermined number of times, (A) becomes equal to Ac, which means that all the necessary data from lens LE have been read. Thus, output O6 produces LOW at step #12 to reset the lens circuit LEC.

Referring to FIGS. 7 and 8, the manner for carrying out the data reading from the lens LE is explained in detail. FIG. 7 shows an input structure of microcomputer MC2 for receiving serial data applied to its input SDI from the lens LED in a synchronized relation with clock pulses DP produced from output SCO. As an example, a manner in which the microcomputer MC2 receives 8-bit long data to its input SDI from lens LE is described. When microcomputer MC2 produces input command signal SIIN for start receiving serial data from lens LE, flip-flop FF1 is changed to set condition, thereby releasing the reset condition of 3-bit binary

counter CO1 and, at the same time, enabling an AND gate AN7. Then, clock pulses DP from a frequency divider (not shown) provided in the microcomputer MC2 are transferred through AND gate AN7 and are sent out from output SCO to lens circuit LEC in the lens LE. The clock pulses DP are also applied to counter CO1 and shift register SR1 at respective clock terminals CL. In response to the negative edges of clock pulses DP, shift register SR1 stores 8-bit long data bit-by-bit from lens LE through input SDI, while counter CO1 counts up. When counter CO1 receives the eighth clock pulse, its carry terminal CY produces HIGH until it receives the ninth clock pulse. Before receiving the ninth clock pulse, shift register SR1 completes reading the 8-bit long data. The carry terminal CY of counter CO1 is connected to one input of an AND gate AN5, while the other input of AND gate AN5 is connected through an inverter IN15 to AND gate AN7. Thus, during a pulse interval between eighth and ninth pulses, AND gate AN5 produces HIGH, thereby setting a flag SIFL representing the completion of one data reading and, at the same time, resetting flip-flop FF1. Thus, counter CO1 is reset producing LOW from carry terminal CY, and AND gate AN7 is disabled. Now, it is ready for the next operation. By the flag SIFL, the data stored in shift register SR1 is transferred through a data bus IDB, provided inside microcomputer MC2, to a register M(A).

While the above operation is carried out in the microcomputer MC2, the following operation is carried out in lens circuit LEC. Referring to FIG. 8, when microcomputer MC2 produces HIGH from its output 06, counters CO7 and CO9 are released from their reset condition, thereby enabling these counters CO7 and CO9 to count clock pulses DP from output SCO of microcomputer MC2. The counter CO7, which is a 3-bit binary counter, counts the clock pulses DP in response to respective positive edges, and when it receives the eighth clock pulse, its carry terminal CY produces HIGH until it receives the positive edge of ninth clock pulse. The counter CO9, which is a 4-bit binary counter, is responsive to the negative edge of the pulse from the carry terminal CY of the counter CO7, thereby it counts pulses from the carry terminal CY of counter CO7. Therefore, counter CO9 count up by "1" in response to the positive edge of the first pulse of eight consecutive clock pulses DP.

The counter CO9 produces a 4-bit data representing the counted amount, and the 4-bit data is applied to a decoder DE9, which then changes the 4-bit data to 5-bit data. This 5-bit data is applied to a data selector DS1 which, by using the 5-bit data, produces an 8-bit data for addressing a ROM RO3. A relationship among the 4-bit data from counter CO9, the 5-bit data from decoder DE9, 8-bit data from data selector DS1 and 8-bit data produced from ROM RO3 is shown in Tables 2 and 3, in which Table 2 shows a relationship when the mounted lens is a focal length fixed type, and Table 3 shows a relationship when the mounted lens is a zoom lens.

TABLE 2

CO9 outputs	DE9 outputs	DS1 outputs	RO3 outputs
0000	00000	00000000	Check data (01010101)

Still referring to FIG. 8, outputs b0, b1 and b2 of the counter CO7 are connected to decoder DE7. In accordance with 3-bit data from counter CO7, decoder DE7 produces 8-bit data, as shown in Table 4 below.

TABLE 4

Counter CO7			Decoder DE7							
b0	b1	b2	d0	d1	d2	d3	d4	d5	d6	d7
0	0	0	L	L	L	L	L	L	L	H
0	0	1	H	L	L	L	L	L	L	L
0	1	0	L	H	L	L	L	L	L	L
0	1	1	L	L	H	L	L	L	L	L
1	0	0	L	L	L	H	L	L	L	L
1	0	1	L	L	L	L	H	L	L	L
1	1	0	L	L	L	L	L	H	L	L
1	1	1	L	L	L	L	L	L	H	L

Therefore, in response to the positive edge of clock pulses, the 8-bit data produced from ROM RO3 are transferred bit-by-bit from the least significant bit r0 through AND gates AN20–AN27 and also through OR gate OR5 to terminal SDI of the microcomputer MC2 in the camera body.

In the case where the interchangeable lens is a zoom lens, lens circuit LEC further includes a code plate FCD which produces a 5-bit data representing the focal length changed by a zooming ring ZR mounted on the zoom lens. The 5-bit data from code plate FCD are applied through AND gates AN40–AN44 to 5 least

significant bits of 8-bit input array $\alpha 2$ of data selector DS1.

The data selector DS1 has a select terminal SE which is connected to output h4 of decoder DE9. When output h4 is producing LOW, data selector DS1 produces 8-bit data "0 0 0 0 h3 h2 h1 h0" from the input array $\alpha 1$, and when it is HIGH, data selector DS1 produces 8-bit data "h2 h1 h0 * * * * *" (* * * * * is a 5-bit data from code plate FCD) from the input array $\alpha 2$. The 8-bit data from the data selector DS1 is used for addressing ROM RO3.

Next, the description is given to the operations when counter CO9 changes from "0000" to "0111", as indicated in the above given Tables 2 and 3.

When counter CO9 produces "0000", data selector DS1 produces an 8-bit data "00000000" (The 8-bit data "00000000" can be expressed by a hexadecimal numbering system as "00H", wherein the first "0" represents four zeros in the most four significant bits, the second "0" represents four zeros in the least four significant bits, and H indicates the hexadecimal numbering system.) as an address designating a location in ROM RO3. And in the designated location, a check data, e.g., "01010101", is stored. This check data is common to all the types of interchangeable lenses. The check data is applied to the camera body and is read by microcomputer MC2 through input SDI.

When it is detected that an interchangeable lens is properly mounted on the camera body by the check data, the mode is set to full-aperture light measuring mode, and the aperture control is carried out by exposure control device EXC. On the contrary, when it is detected that the interchangeable lens is not properly mounted on the camera body by the check data, the mode is set to aperture stop-down light measuring mode, thereby carrying out no aperture control.

When counter CO9 produces "0001", data selector DS1 produces an 8-bit address data "01H" for designating a location in ROM RO3 so that ROM RO3 produces a full-open aperture data Avo. In the case where the zoom lens has an optical system in which the aperture value changes with respect to the change of focal length, ROM RO3 produces full-open aperture data Avo for the minimum focal length.

When counter CO9 produces "0010 ", data selector DS1 produces an 8-bit address data "02H" for designating a location in ROM RO3 so that ROM RO3 produces a maximum stop-down aperture data Avmax (data of aperture size when it is reduced to minimum size).

When counter CO9 produces "0011", data selector DS1 produces an 8-bit address data "03H" for designating a location in ROM RO3 so that ROM RO3 produces a data representing a measurement difference, which is the fully open aperture light measurement error.

When counter CO9 produces "0100", data selector DS1 produces an 8-bit address data "04H" for designating a location in ROM RO3 so that ROM RO3 produces a data representing the direction of rotation of motor MO for shifting the focusing lens FL forward, and a data representing whether or not the mounted interchangeable lens is a type which changes its conversion coefficient data KD in accordance with the change of focusing distance. For example, if the mounted lens is such a type that its focusing lens FL shifts forward when the motor is driven clockwise, the least significant bit of the data from ROM RO3 holds "1", but if the mounted lens is such a type that its focusing lens FL shifts forward when the motor is driven counterclockwise, the least significant bit of the data from ROM RO3 holds "0". Furthermore, if the mounted lens is a type which changes its conversion coefficient data KD in accordance with the change of focusing distance, the most significant bit of the data from ROM RO3 holds "1", and if the lens is not that type, it holds "0".

When counter CO9 produces "0101", decoder DE9 produces "00101" when the lens is a fixed focal length type lens. In this case, data selector DS1 produces an 8-bit address data "05H" for designating a location in ROM RO3 so that ROM RO3 produces a data representing $\log_2 f$, wherein f is the fixed focal length of the lens. But, when the lens is a zoom lens, decoder DE9 produces "1001Ø". In this case, data selector DS1 produces an 8-bit address data "001*****" (***** is a 5-bit data from code plate FCD.) capable of designating various locations in ROM RO3 so that ROM RO3 produces a data representing $\log_2 f$, wherein f is the focal length of the lens varied in accordance with the zooming operation.

When the counter CO9 produces "0110", decoder DE9 produces "1010Ø" when the lens is a zoom lens. In this case, the most significant bit (h4) of the data from decoder DE9 is "1". Therefore, the data selector DS1 produces data from its input array $\alpha 2$. Accordingly, data selector DS1 produces an 8-bit address data "010*****" capable of designating various locations in ROM RO3 so that ROM RO3 produces a data ΔAv representing the difference in aperture value between that obtained when the zoom lens is shifted to the minimum focal length and that obtained when the zoom lens is zoomed to other setting position. But, when the lens is a fixed focal length type lens, data $\Delta Av = 0$, and therefore, data selector DS1 produces an 8-bit address data "06H" for designating a location in ROM RO3 so that ROM RO3 produces a data "0".

The data ΔAv is used for the calculation:

$$(Bv - Avo - \Delta Av) - Avo - \Delta Av$$

for eliminating terms related to the aperture from a full-aperture light measured data, and also for the calculation:

$$Av - Avo - \Delta Av$$

for controlling the effective aperture in compliance with set or calculated aperture.

When the counter CO9 produces "0111", decoder DE9 produces "1011Ø" when the lens is a zoom lens. In this case, data selector DS1 produces an 8-bit address data "011*****" for designating various locations in ROM RO3 so that ROM RO3 produces a data representing conversion coefficient KD for the different set focal lengths. But, when the lens is a type having a fixed focal length, data selector DS1 produces an 8-bit address data "07H" for designating a location in ROM RO3 so that ROM RO3 produces a fixed data representing conversion coefficient KD for the set focal length of that lens.

The data of conversion coefficient KD is used for obtaining the amount of drive to be effected by motor drive mechanism LMD through a calculation:

$$|\Delta L| \times KD$$

wherein $|\Delta L|$ is a defocus amount produced from microcomputer MC1.

Furthermore, the data representing the conversion coefficient KD is, e.g., 8-bit long, which can be divided into upper four bits representing the digit place and lower four bits representing the digit number, as indicated in Table 5.

TABLE 5

k7 k6 k5 k4	k3 k2 k1 k0
Digit place	Digit Number

Using the data k7-k0, the conversion coefficient KD can be obtained through the following calculation:

$$KD=(k3\cdot 2^0+k2\cdot 2^{-1}+k1\cdot 2^{-2}+k0\cdot 2^{-3})\cdot 2^n\cdot 2^m$$

wherein

$$m=k4\cdot 2^0+k5\cdot 2^1+k6\cdot 2^2+k7\cdot 2^3$$

and

n=constant (for example −7)

Since k3 is the most significant bit of the digit number, it is always carrying "1". By the above calculation, the conversion coefficient KD having a large variation can be expressed with a small number of bits, and yet the calculation using the conversion coefficient KD in the microcomputer MC1 can be carried out easily.

Referring to FIG. 10, a graph is given for showing a relationship between data of conversion coefficient KD produced from the zoom lens and the focal length of the zoom lens, and wherein abscissa and ordinate represent, $\log_2 f$ (f is a focal length) and conversion coefficient data KD, respectively.

The conversion coefficient KD changes linearly with respect to the change of $\log_2 f$, as shown by lines A, B and C. But, according to the present invention, the relationship between $\log_2 f$ and conversion coefficient data KD is given in tiers, as shown by lines A', B' and C'. In other words, ROM RO3 holds the values of the conversion coefficient KD in steps from level K1 to K33. An example of these levels are given below:

When $K1=2^0$, KD="01111000" (This is read such that when it is defined that $K1=2^0$, ROM RO3 holds KD="01111000" as the value for K1.);

When $K2 = 2^{-1} + 2^{-2} + 2^{-3} + 2^{-4}$, KD = "01101111";

When $K3 = 2^{-1} + 2^{-2} + 2^{-3}$, KD = "01101110";

When $K4 = 2^{-1} + 2^{-2} + 2^{-4}$, KD = "01101101";

$\int$

When $K31 = 2^{-4} + 2^{-6}$, KD = "00101000";

When $K32 = 2^{-4} + 2^{-7}$, KD = "00111001"; and

When $K33 = 2^{-5}$, KD = "00101000".

Each zoom lens has its own zooming range in compliance with the available range of focal length. According to the preferred embodiment, the range of focal length is divided into a plurality of zones. And, code plate FCD provided in the zoom lens is so arranged as to produce a 5-bit signal corresponding to each zone. For example, a zoom lens, which has a focal length zone as depicted by a line A, has nine zones, f17-f25. For each zone, a level of the conversion coefficient is applied. A fundamental rule for choosing a level to each zone for the zoom lens of the above given example is such that a level which is closest to, and smaller than, the smallest point of line A within that zone should be chosen. For example, level K17 is chosen for zone f25, level K16 is chosen for zone f24, level K15 is chosen for zone f23, level K13 is chosen for zone f22, and so on.

As understood from the above rule, the level for the conversion coefficient is chosen to be smaller than the true conversion coefficient given by the straight line. Therefore, in operation, the pulse number $N=KDx|\Delta L|$ obtained by the use of conversion coefficient KD is smaller than the number of pulses produced from encoder ENC for shifting the focusing lens exactly to the in-focus position. Usually, this operation is repeated for a number of times to shift the focusing lens in one direction asymptotically towards the in-focus position, without any overshoot.

In contradiction to the above rule, if a conversion coefficient is chosen to be greater than the true conversion coefficient, the pulse number $N=KDx|\Delta L|$ obtained by the use of conversion coefficient KD becomes greater than the number of pulses produced from encoder ENC for shifting the focusing lens exactly to the in-focus position. Accordingly, the focusing lens overshoots the in-focus position. When this operation is repeated, the focusing lens overshoots in each operation, moving back and forth about the in-focus position. Thus, the focusing lens vibrates in a so-called hunting manner.

Furthermore, since the level of the conversion coefficient is chosen to be closest to the smallest point of line A within that zone, the focusing lens can be shifted towards the in-focus position in a short period of time.

As an exception to the above rule, the level of the conversion coefficient may be chosen to be greater than the smallest point of the line within that zone. For example, as depicted in zones f18 and f12 for the line B', the lines for the levels K20 and K12 are partly greater than the line B. This exception is applicable only when the level of the conversion coefficient is greater by a small amount than the smallest point of the line within that zone. By permitting this exception, the focusing lens may overshoot a small degree, and it can be shifted to the in-focus position in the next focusing operation without causing any hunting, resulting in a very short period of focus adjustment.

There is a zoom lens which changes its conversion coefficient along different lines depending on the set focusing distance such that, when the focusing distance is set to the infinite, its conversion coefficient changes along a real line $C(\infty)$ shown in the graph of FIG. 10, and when the focusing distance is set to the nearest point, its conversion coefficient changes along a chain line C(near) shown in FIG. 10. According to this type of zoom lens, referred to as a variant type zoom lens, the conversion coefficient KD changes, e.g., from $K17=2^{-2}$ to $K15=2^{-2}+2^{-4}$ when the focusing distance is changed from the infinite to the nearest, provided that the lens is zoomed to the zone f1.

In order to operate the camera system of the present invention even with this variant type zoom lens, ROM RO3 is stored with conversion coefficients based on the infinite zoomed position (real line $C(\infty)$). The focusing operation is carried out in such steps that, before the focusing lens reaches a position close to the in-focus position, it is shifted in accordance with the direction

signal of the defocus signal ΔL. When the focusing lens is shifted to the position close to the in-focus position, the focusing lens is then shifted in accordance with the value N obtained using the data KD representing the conversion coefficient and data |ΔL| representing the degree of out-of-focus to seek the accurate in-focus position.

Instead of the above, it is possible to provide, in addition to the code plate FCD, a code plate for producing a signal representing the set focusing distance. The signal produced from this code plate may be used as an address data for ROM RO3, thereby obtaining a precise data of the conversion coefficients for the variant type zoom lens. However, this alternative is not applicable from the practical point of view, because it result in the increase of parts, increase in bit number of address data, increase in the capacity of ROM RO3.

There is another type of zoom lens, which is called a zoom-plus-macro lens or "macro zoom lens". This type of lens is capable of a focusing in macro-photography range in addition to the zooming. For example, such a "macro zoom lens" is constructed to carry out macro photography by means of rotating the zoom ring beyond the conventional shortest focal length position to change over the lens from the zoom mode to macro-focusing mode, so that the lens serves as a closeup lens. When the range is changed to macro range, code plate FCD produces "11111" so that data selector DS1 produces an 8-bit address data "01111111" for designating a location in ROM RO3. When a photograph is taken with the macro range, it becomes difficult to carry out the focus adjustment under the AF mode because of various factors, such as the change in pupil position, reduction of the depth of focus, reduction in F-stop number, and change in the focus adjustment mechanism. Accordingly, ROM RO3 produces "ØØØØ0110", which indicates that the digit place k3 described above in connection with Table 5, i.e., the fourth digit place from the least significant bit, holds "0". Accordingly, by the detection of "0" at digit place k3, microcomputer MC2 decides that the range has changed to macro range, thereby automatically choosing the FA mode, notwithstanding that the mode manually selected by switch FAS is AF mode.

Within the zoom-plus-macro lenses, there is a type in which the change-over from the zooming mode to the macro photography mode is not possible unless the focusing is set to the closest photographic distance. For this type of lens, a switch MCS shown in FIG. **8** is provided. When switch MCS closes in response to a manual change-over operation, e.g. a depression of a button, from zoom mode to macro mode, inverter IN17 produces HIGH and inverter IN19 produces LOW. Thus, all of AND gates AN40 to AN44 produce LOW. Thus, data selector DS1 produces an address data "01100000" designating a location in ROM RO3. Accordingly, ROM RO3 produces "ØØØØ0100". By the detection of "0" at digit places k3 and k1 shown in Table 5, i.e., at the second and fourth digit places from the least significant bit in the produced data "ØØØØ0100", microcomputer MC1 decides that the range has changed to macro range, thereby automatically operating motor MO to shift focusing lens forward to bring the lens in nearest focused condition.

The light receiving portion for the focus detection is so arranged as to aim at a certain exit pupil of the photographing lens. By the diameter of the pupil and the position of the pupil in relation to the light receiving element (located at a position optically equivalent to the film surface), it is determined whether or not the light beams from the target object, which have passed through the photographing lens, impinges on the light receiving element. Accordingly, in some lenses, as is explained with respect to FIGS. **1**, **2** and **3**, a part of light receiving portion may not receive any light beams from the object. Since the focus detection can not be done with a reasonable accuracy with such a type of lenses, it is not preferable to carry out the AF mode or FA mode operation. Therefore, for this type of lenses, data selector DS1 produces address data "011*****" in the case of zoom lens and address data "00000111" in the case of fixed focal-length lens. And, in response to these address data, ROM RO3 produces "ØØØØ0001" as the data KD. By this data "ØØØØ0001", microcomputer MC2 prevents the microcomputer MC1 from carrying out the focus detection operation under AF mode or FA mode in the steps #16–2 described later.

By the change of range from zoom range to macro range, or vice versa, AND gates AN40–AN44 produces "00000", or "11111", whereby data selector DS1 produces address data "00100000", or 00111111", in one sequence, and address data "01000000", or 01011111", in another sequence. In response to the address data "00100000", or 00111111", ROM RO3 produces data corresponding to focal length f under the macro range, and in response to the address data "01000000", or "01011111", ROM RO3 produces data corresponding to ΔAv for the macro range.

Furthermore, in the case where the interchangeable lens is a type which has no mechanism for transmitting driving force from the camera body to the focus adjustment member in the lens, ROM RO3 stores "ØØØØ0110" as the data KD, in the same manner as the range change between the zoom range and macro range, thereby permitting only the FA mode.

Referring back to FIGS. **6***a*, **6***b*, **6***c* and **6***d*, when the data reading from the lens LE completes through the above described operations, A-D conversion of the output from light measuring circuit LMC is carried out (step #13), and the converted data representing the measured light amount is stored in a certain register (step #14).

At step #15, it is decided whether or not the release flag RLF is carrying "1". If the flag RLF is carrying "1", the program advances directly to step #28, but if it is carrying "0", the program advances to step #16–1. It is to be noted here that the release flag RLF carries "1" when release switch RLS is on for carrying out the interruption operation at step #59 et seq. During this interruption operation, if it is detected at step #63 that no exposure control values are calculated, the reading of the above data is carried out in step #5 et seq. Then, at step #15, if it is detected at step #15 that the flag RLF is carrying "1", the operation flow starting from step #16 for the focus detection under AF mode or FA mode is skipped. Therefore, in this case, the program follows the step #28 to calculate the exposure values and through step #30, the exposure control is carried out in step #64 et seq.

At step #16, it is decided whether it is possible to carry out the focus detection operation under AF mode or FA mode. If it is determined that the focus detection is possible, the program advances to step #17, but if not, the program advances to step #28. During the step #16, various conditions are examined sequentially in sub-steps. More particularly, at sub-step #16–1, it is exam-

ined whether the lens is properly mounted, or not; at sub-step #16-2, it is examined whether the conditions determined by the diameter and position of the exit pupil are in conformity with the light receiving portion, or not; at sub-step #16-3, it is examined whether the light beams from the target object are impinging on all the light receiving portion of the focus detection, or not; and at sub-step #16-5, whether or not the light measuring switch is turned on.

Since the focus detection operation under AF or FA mode is impossible when no check data "01010101" is detected at step #16-1, when bits in digit places k3 to k0 are "0001", or when the diameter of the exit pupil of the lens is so small that the data Avo, or Avo+ΔAv representing the full open aperture is smaller than a predetermined value Avc (such as F5.6), a warning is displayed at step #16-4 through display control circuit DSC for the indication that the focus detection can not be carried out after each of the above examination steps #16-1 to #16-3. Thereafter, the program advances to step #28. Furthermore, when input i0 is receiving LOW in compliance with the opening of the light measuring switch MES, the program advances to step #28 for carrying out the focus detection under FA mode only for 15 seconds.

On the contrary to the above, when a check data "01010101" is detected at step #16-1, when bits in digit places k3 to k0 are not "0001", when the diameter of the exit pupil of the lens is such that the data Avo, or Avo+ΔAv representing the full open aperture is greater than a predetermined value Avc, and when input i0 is receiving HIGH, the program advance to step #17.

At step #17, output O1 produces HIGH which is applied to input i11 of microcomputer MC1. Accordingly, microcomputer MC1 starts to carry out the focus detection under AF or FA mode. At step #18, data KD representing the conversion coefficient, which has been transferred from lens circuit LEC to the microcomputer MC2, is produced from input/output port I/O and applied through data bus DB to latch circuit LA. The data KD latched in latch circuit LA will be further transferred to microcomputer MC1 in the later stage at step No.93 described below.

At step #19, in accordance with the data transferred from lens circuit LEC to microcomputer MC2 when counter CO9 is producing "0100", it is detected whether or not the mounted lens is a variant type zoom lens, which changes the conversion coeficient data KD relatively to the change of focusing distance. If it is detected that the mounted lens is a variant type zoom lens, microcomputer MC2 produces HIGH from its output O3, which is applied to input i13 of microcomputer MC1. On the contrary, if the mounted lens is not a variant type zoom lens, microcomputer MC2 produces LOW from its output O3. Accordingly, microcomputer MC1 is so operated as to change the driving mode of motor MO under AF mode in accordance with a detection whether the image forming position is located within near-focusing zone or not, or a detection whether the integration time is longer than a predetermined period of time, as will be described in detail later in connection with steps No.192 to No.197.

At step #22, in accordance with the data transferred from lens circuit LEC to microcomputer MC2 when counter CO9 is producing "0100", the direction of rotation of motor MO is determined for effecting the forward shift of the focusing lens. If it is determined that motor MO should rotate clockwise to effect the forward shift of the focusing lens, microcomputer MC2 produces HIGH from its output O2, which is applied to input i12 of microcomputer MC1. If it is determined as counterclockwise, output O2 produces LOW. Using the signal applied to input i12 and a signal representing the direction of defocus, microcomputer MC1 determines the direction of rotation of motor MO.

At step #25, by the detection of a number, whether it is "1" or "0", given at the fourth digit place k3 of the data KD representing the conversion coefficient, it is determined whether it is possible to carry out the AF mode operation with the mounted lens LE. If the digit place k3 is carrying "1", it is possible to carry out the focus detection under AF mode by the mounted lens LE. In this case, "0" is set in flag MFF and, thereafter, the program advances to step #28. Contrary, if the digit plate k3 is carrying "0", it is impossible to carry out the AF mode operation with the mounted lens LE. In this case, "1" is set in flag MFF and, thereafter, it is detected which one of the two modes, AF or FA modes, is selected by switch FAS. If AF mode is selected to provide HIGH to input i1, a warning is displayed by display control circuit DSC indicating that the mode is automatically changed to FA mode even when the mode selected by switch FAS is AF mode. Thereafter, the program advances to step #28. If FA mode is selected to provide LOW to input i1, there is no need to give out such an warning, and therefore, the program directly advances to step #28.

At step #28, an exposure calculation through known steps is carried out in accordance with data obtained in previous steps #4 to #14, such as set exposure control values, measured light amount, and data from the lens. When data representing exposure time and data representing aperture value are obtained, "1" is set for flag LMF.

At step #30, it is detected whether the release flag RLF is carrying "1" or not. If it is carrying "1", the program jumps to step #64 for carrying out the exposure control operation. Contrary, if it is carrying "0", the program advances to step #31. At step #31, output O8 of microcomputer MC2 produces HIHG, thereby producing LOW from inverter IN8. Thus, a transistor BT3 conducts to permit the warning indication through light emitting diodes LD10 to LD1n. And, in the following step #32, obtained exposure control values are sequentially output at I/O port, which synchronously cause sequential changes into respective "High"'s at terminals a4 to an. In response to these, indication data are sequentially latched by display control part DSC, and display DSP carrys out the liquid crystal display according to the latched data.

At step #33, the on/off condition of light measuring switch MES is detected. If switch MES is on to provide HIGH to input i0, data for counting 15 seconds for the timer interruption is set in register Tc for the timer (step #34). Then, at step #35, timer starts to count 15 seconds, thereby allowing the timer interruption at step #36. Thereafter, the program returns to step #2. In this case, since input i0 is still receiving HIGH, i.e., light measuring switch MES is maintained on, the program advances to step #3, thereby prohibiting the timer interruption. Thereafter, the same procedure is repeated again.

On the contrary, if light measuring switch MES is turned off to apply LOW to input i0, it is detected at step #37 which one of the two modes, AF and FA

modes, is selected by switch FAS. Then, at step #38, the mode determined at step #25 by the data from the lens is detected. Here, the program advances to step #40, when FA mode is selected to provide LOW to input i1 (step #37), or when AF mode is selected, but flag MFF is carrying "1" to permit only FA mode operation in the lens. When AF mode is selected and flag MFF is carrying "0", output O1 produces LOW (step #39) to stop the operation of microcomputer MC1 and, thereafter, the program advances to step #40. In the case where FA mode is detected at step #37 or #38, the program advances to step #40 with output O1 continuously producing HIGH. Accordingly, the operation in microcomputer MC1 continues.

At step #40, it is detected whether switch EES is on or off. When the exposure control mechanism is not in the charged condition, switch EES is on to provide HIGH to input i2. In this case, the program goes to step #47 to carry out the initialization in a manner described later. When the exposure control mechanism is in the chraged condition to turn switch EES on to provide LOW to input i2, the program goes to step #36 and then returns to step #2, at which it is waited until light measuring switch MES turns on to provide HIGH to input i0 or until the timer interruption takes place.

When the timer interruption takes place, 1 is subtracted from the content of register Tc (step #45). Then, at step #46, it is detected whether the content of register Tc is equal to "0" or not. If it is not equal to "0", the program advances to step #5 et seq. to carry out the data reading and exposure calculation in a manner described above. In this case, if the mode is FA mode, since output O1 is producing HIGH, microcomputer MC1 repeats the FA mode operation. Contrary, if the mode is AF mode, microcomputer MC1 is held in non-operative, because output O1 is producing LOW as effected at step #39.

If Tc is equal to "0", outputs O0, O1 and O8 produce LOW (steps #47, #48 and #49), thereby cutting the power supply through transistor BT1 and buffer BF, stopping the operation of microcomputer MC1 under FA mode, and cutting the power supply through transistor BT3. Furthermore, liquid display portion DSP is blanked (step #50) and flags MFF and LMF are reset (steps #51 and #52). Then, the program returns back to step #2.

The above operation can be summarized as follows. During the closure of light measuring switch MES, data reading from the lens, operation by the microcomputer MC1, exposure calculation, and display are carried out repeatedly under both modes AF and FA. Then, when light measuring switch MES opens, the result is different between the modes AF and FA. Under AF mode, the operation by the microcomputer MC1 stops, and data reading from the lens, exposure calculation, and display are carried out repeatedly for 15 seconds. Under FA mode, data reading from the lens, the FA operation by the microcomputer MC1, exposure calculation, and display are carried out repeatedly for 15 seconds. Furthermore, when the charge in the exposure control mechanism is not completed, data reading from the lens, operation by the microcomputer MC1, exposure calculation, and display stops immediately in response to the opening of the light measuring switch MES.

It is to be noted that when a warning is displayed through step #16 -4 or #27-2, a signal for cancelling the warning is applied to display control circuit DSC if no warning is necessary in the subsequent flow.

Next, an operation when release switch RLS closes while the exposure control mechanism is in the charged condition is explained. In this case, microcomputer MC2 immediately starts the release interruption from step #59 no matter what operation it is carrying out. It is assumed that the release interruption is now requested while the data are being read from the lens. When the release interruption is requested, output O6 produces LOW, thereby resetting lens circuit LEC (step #59). Then, output O1 produces LOW to stop the AF or FA mode operation in microcomputer MC1 (step #60). And, output O8 produces LOW to cut off the power supply to light emitting diodes LD10 to LD1n to stop and indication (step #61). Then, flag RLF is set (step #62). At next step #63, it is detected whether flag LMF is set, i.e., carrying "1".

If flag LMF is carrying "1", which means that the exposure control values are calculated, the program advances to step #64. Contrary, if flag LMF is carrying "0", which means that the exposure control values are not ready yet, the program goes to step #5 to calculate the exposure control values, and thereafter, the program advances to step #64.

At step #64, calculated data representing the aperture stop down, such as:

$$Av-Avo;\ Av-(Avo+\Delta Av)$$

is produced on data bus DB. And, output O4 produces pulses for reading the data. Accordingly, exposure control device EXC reads data representing the aperture stop down to start the stop down of the aperture by the exposure control mechanism. This operation completes when the size of aperture is reduced to the required F-stop down.

When a predetermined period of time passes after the generation of pulses from output O4 (step #66), a calculated exposure time data Tv is produced on data bus DB (step #67). Then, output O5 produces pulses for reading data Tv (step #68). By these pulses, exposure control device EXC reads the data Tv and, at the same time, the mirror drive circuit (internally provided in the camera body) is actuated to start the mirror flip-up operation. When the mirror flips up completely, the leading curtain of the shutter mechanism starts to scan and, at the same time, count switch COS turns on to start count the time corresponding to the exposure time data Tv. When the counting of the time data Tv completes, the trailing curtain of the shutter mechanism starts to scan. When the trailing curtain completes its scan, the mirror flips down, and the aperture again opens to its full size. Then, switch EES closes.

When switch EES closes to provide HIGH to input i2 (step #69), release flag RLF resets (step #70). Then, it is detected whether light measuring switch MES is on or off, by the detection whether input i0 is receiving HIGH or LOW. If input i0 is receiving HIGH, which means that light measuring switch MES is on, the program returns back to step #2 to carry out data reading from the lens, operation by the microcomputer MC1, exposure calculation, and display repeatedly. Contrary, if input i0 is receiving LOW, which means that light measuring switch MES is off, the program advances to step #47 to initialize the microcomputer MC2 and, thereafter, the program returns back to step #2.

Referring to FIGS. 11*a*, 11*b*, 11*c*, 12*a*, 12*b*, 12*c*, 13*a*, 13*b*, 13*c* and 13*d*, a flow chart for the operation of mi-

crocomputer MC1 is shown. The flow can be roughly divided into three flows.

The first flow, starting from step No.1, is a main flow initiated by a focus-operation command. In the main flow, many operations are carried out such as: start operation of CCD FLM by control circuit COT (No.8); detection of motor drive (No.10 to No. 13); counting the maximum integration time in CCD and operations after the count of the maximum integration time (No.14 to No.19); detection of termination of focusing lens to the end and counting of maximum integration time (No.35 to No.44); stopping the motor at the termination of focusing lens to the end and restart of rotation when the contrast is low (No.43 to No.48, and No.51 to No.67); initial setting of microcomputer MC1 at a pause of operation (No.25 to No.33); conversion of CCD data when the light intensity is low (No.78 to No.80); calculation of defocus amount and the direction of defocus (No.81 to No.91); detection whether or not the mounted lens is applicable for the AF mode operation (No.92 to No.96); detection of the contrast (No.100); motor drive, under the AF mode operation, for shifting the focusing lens to an infocus zone, and focus detection (No.125 to No.196) (FIGS. **12***a*, **12***b* and **12***c*); focus detection under FA mode operation (No.240 to No.261) (FIGS. **13***a*, **13***b*, **13***c* and **13***d*); and motor drive for shift the zoom lens when the mounted lens is a type which can change the range between zoom range and macro range at near focusing position (No.220 to No.232).

The second flow, covering steps No.70 to No.76, is a terminal interruption flow effected to read data from CCD in accordance with a signal indicating the completion of CCD integration applied from control circuit COT to input terminal iT.

The third flow, covering steps No.200 to No.204, is a counter interruption flow, in which the interruption is carried out when the count number of counter ECC, which is located in microcomputer MC1 and responsive to pulses from encoder ENC, reaches a predetermined number.

Once the terminal interruption is requested, the counter interruption requested thereafter will not be prosecuted before the end of the operation by the terminal interruption. In this manner, there is a priority in the prosecution of two interruption flows. Now, the description is given to the operations under AF and FA modes.

When a main switch MAS turns on, power-on reset circuit POR1 produces a reset signal PO1. By reset signal PO1, microcomputer MC1 carries out a reset operation from a certain address (step No.1). At step No.2, it is detected whether or not switch FAS is on to provide HIGH to input i14. If input i14 is receiving HIGH, flag MOF is reset to "0" indicating that the selected mode is AF mode. If input i14 is receiving LOW, flag MOF is set to "1" indicating that the selected mode is FA mode.

At step No.5, it is detected whether or not input i11 is receiving HIGH from output O1 of microcomputer MC2. If input i11 is receiving LOW, the program returns back to step No.2 to repeat the above operation. Contrary, if input i11 is receiving HIGH, output O16 produces HIGH (step No.6), thereby producing LOW from inverter IN5 and causing transistor BT2 to conduct. Thus, power is supplied through power supply line VF. Then, a fixed data C1 corresponding to the maximum integration time is stored in a register ITR (step No.7) for counting the integration time in CCD FLM. Then, output O10 produces a HIGH pulse (step No.8), thereby starting the integration operation in CCD FLM by control circuit COT. Then, it is permitted to accept the interruption signal from the iT terminal (step 9). Thereafter, the program advances to step No.10.

At steps No.10 to No.13, the operations related to motor MO are detected sequentially. At step No.10, it is detected whether or not the first focus detection operation is being carried out by the detection of flag FPF. At step No.11, it is detected whether or not focusing lens FL is terminated at the end for the infinite focusing or at the other end for the nearest focusing, by the detection of flag ENF. At step No.12, it is detected whether or not the shifted position is located within infocus zone, by the detection of flag IFF. And, at step No.13, it is detected which one of the two modes, AF and FA modes, is selected by switch FAS, by the detection of flag MOF.

If it is assumed that the present situation is either such that the first focus detection operation is being carried out, that the focusing lens is terminated to its end, that the focusing lens is shifted to infocus zone, or that FA mode is selected, motor MO is not rotating. Accordingly, in this case, the program advances to step No.14.

If it is assumed that the present situation is either such that the second focus detection operation is not carried out, that the focusing lens is not terminated to its end, that the focusing lens is not shifted to infocus zone, or that AF mode is selected, motor MO is rotating. Accordingly, in this case, the program advances to step No.35.

It is to be noted that flag FPF is set to carry "1" while the first focus detection operation is being carried out, and it is reset to carry "0" while the focus detection operations of the second et seq. are carried out. The end flag ENF carries "1" when focusing lens FL is shifted all the way to the infinite focusing end or nearest focusing end so that no pulse is produced from encoder ENC even when the motor is further driven. And the focus flag IFF produces "1" when the lens is shifted to an infocus zone, and "0" when it is shifted out of the infocus zone.

At step No.14, "1" is subtracted from the content of register ITR for counting the integration time. Then, it is detected at step No.15 whether the register ITR is producing a borrow signal BRW or not. If it is not producing a borrow signal BRW, low brightness flag LLF is reset to "0" (step No.18). Then, at step No.19, it is detected whether or not input i11 of microcomputer MC1 is receiving HIGH from microcomputer MC2 so as to cause microcomputer MC1 to start its operation. If input i11 is receiving HIGH, the program returns back to step No.14 to repeat the same operation. Contrary, if input i11 is receiving LOW, the program advances to step No.25 to carry out the initialization and, thereafter, advances to step No.2 and waits for HIGH to be applied to input i11. On the contrary, when a borrow signal BRW is detected at step No.15, which means that the maximum integration time has passed, output O11 produces a pulse (step No.16) to forcibly stop the integration operation in CCD FLM and, also to set the low brightness flag LLF with "1". Then, it is waited for the interruption signal to be applied to interruption terminal iT from control circuit COT.

At step No.35, data C2 representing a predetermined period of time is set in a register TWR for counting time. At step No.36, "n" (for example "3") is subtracted

from the content of register ITR and, then, it is detected at step No.37 whether or not a borrow signal BRW is caused by the subtraction at step No.36. If a borrow signal BRW is appearing, which means that the maximum integration time has passed, the program goes to step No.16 to follow the sames steps described above, so that the integration operation in CCD FLM is forcibly stopped and, also the low brightness flag LLF is set with "1". Then, it is waited for the interruption signal to be applied to interruption terminal iT from control circuit COT.

If a borrow signal BRW is not appearing, low brightness flag LLF is reset to "0", and "1" is subtracted from the content of the register TWR. Thereafter, it is again detected whether a borrow signal BRW is caused or not by the subtraction at step No.39 (step No.40). Then, if there is still not appearing a borrow signal BRW, it is detected at step No.41 whether input **i11** is receiving HIGH or not. If input **i11** is receiving HIGH, the program returns back to step No.36, and if input **i11** is receiving LOW, it goes to step No.25. It is to be noted that the abovementioned **C2** is smaller than (**C1**/n) so that before the borrow signal BRW is detected at step No.37, the borrow signal BRW is produced a number of times at the detection of step No.40.

At step No.40, in response to borrow signal BRW, data ECD of the internal counter ECC representing the counted number of pulses from encoder ENC is shifted from the counter ECC to register **ECR1** (step No.42). At step No.43, the shifted data ECD is compared with data set in a register **ECR2**. It is to be noted that register **ECR2** is stored with a counted data obtained in the previous operation. If the content of register **ECR1** does not coincide with that of register **ECR2**, it is understood that the focusing lens is now shifting. In this case, the content of register **ECR1** is transferred to register **ECR2** (step No.44) and, thereafter, the program goes to step No.35.

If the content of register **ECR1** coincides with that of register **ECR2** at step No.43, it is understood that there is no change in the counted data, indicating that encoder ENC is producing no more pulses. Thus, it is understood that the focusing lens is now held still, shifted all the way to the infinite focusing end or nearest focusing end. Therefore, after this step, a condition is caused in which any interruption signal at input terminal iT is not accepted any more (step No.45), and output **O11** produces a pulse (step No.46) to forcibly stop the integration operation in CCD FLM. Furthermore, outputs **O12** and **O13** produce LOW to stop the rotation of motor MO. Thereafter, it is detected whether or not low contrast flat LCF is carrying "1" (step No.48). It is to be noted that when this flag LCF carries "1", it means that the object to be photographed has such a low contrast that the defocus amount ΔL calculated in accordance with the output from CCD FLM lacks the reliability. If it is so detected at step No.48 that flag LCF is carrying "0", end flag ENF carries "1" at step No.49, and thereafter, the program advances to step No.270 (FIG. **13***d*). At step No.270, it is detected whether input **i14** is still producing HIGH or not. If **i14** is still producing HIGH, which means that the AF mode is still selected, the program advances to step #2. On the contrary, if **i14** is producing LOW, which means that the mode is changed to FA mode, flag FPF is set to "1", and outputs **O12** and **O13** produce LOW to stop the motor MO. And, flags LCF, **LCF1** and **LCF3** are reset to "0" and, thereafter, the program returns back to step No.2.

The above operation can be summarized as follows. By the focus detection command from microcomputer **MC2**, the integration in the CCD is started and, at the same time, it is permitted to accept interruption operations, the counter is started to count the maximum integration period. At this time, if the motor MO is not rotating, it is waited to receive an interruption signal during the counting of the maximum integration period. If no interruption signal is applied during the counting of the maximum integration period, the integration in the CCD is forcibly stopped, and it is still waited to receive an interruption signal.

Contrary, if the motor MO is rotating at the start of the integration in the CCD, it is frequently detected whether or not the lens has reached the infinite focusing end or the nearest focusing end, and at the same time, it is waited to receive an interruption signal. If no interruption signal is applied during the counting of the maximum integration period, and if the lens is not shifted all the way to one of the ends, the integration in the CCD is forcibly stopped, and it is still waited to receive an interruption signal. If the lens is shifted all the way to one of the ends, the integration in the CCD is forcibly stopped, and the reception of the interruption signal at terminal iT is inhibited. Furthermore, in this case, motor MO is stopped, and the integration in the CCD is started again. Then, as will be described in detail later, it is detected whether the image is in focus or not by the use of ΔL. And thereafter, microcomputer **MC1** will not carry out the focus detection and focus adjustment operations even if HIGH is applied to input **i11** of microcomputer **MC1** from microcomputer **MC2** with the closure of light measuring switch MES maintained. When this signal at input **i11** once becomes LOW by opening light measuring switch MES and again becomes HIGH by closing light measuring switch MES again, the program returns back to step No.2.

When it is detected at step No.48 that flag LCF is carrying "1", next it is detected at next step No.51 whether flag **LCF1** is carrying "1" or not. Here, if flag **LCF1** is carrying "0", flag **LCF1** is set to "1" (step No.52) and, thereafter, at step No.60, it is detected whether or not infocus direction flag FDF is carrying "1". The flag **LCF1** is provided for scanning the lens to a position at which the contrast is higher than a predetermined level for the detection whether or not the image is extremely out of focus. The flag FDF carries "1" when it is necessary to shift the lens inwardly under the condition $\Delta L > 0$, and "0" when it is necessary to shift lens outwardly under the condition $\Delta L < 0$. In this case, if flag FDF is carrying "1", flag FDF is reset to carry "0", and vice versa. Then, it is detected in both cases (step Nos.63 and 64) whether input **i12** is receiving HIGH. In this way, the direction for rotating the motor to shift the lens outwardly is detected. At step No.63, if input **i12** is receiving HIGH, the program advances to step No.66 to produce HIGH from output **O12** and LOW from output **O13** so that the motor rotates clockwise to shift the lens outwardly. Contrary, if input **i12** is receiving LOW, the program advances to step No.65 to produce LOW from output **O12** and HIGH from output **O13** so that the motor rotates counterclockwise to shift the lens outwardly. Furthermore, at step No.64, if input **i12** is receiving HIGH, the program advances to step No.65 to rotate motor MO counterclockwise to shift the lens inwardly. And, if input **i12** is receiving

LOW, the program advances to step No.66 to rotate motor MO clockwise to shift the lens inwardly. Then, at step No.67, output O14 produces HIGH to rotate motor MO at a high speed. Thereafter, the program advances to step No.270.

At step No.51, if it is detected that flag LCF1 is carrying "1", that means that the image always has a low contrast while the lens is shifted to infinite focusing end or nearest focusing end, motor MO is stopped at step No.53. Then, it is waited until input i11 receives LOW (step No.55) and, thereafter, flags LCF, LCF1 and LCF3 are all reset to "0", and returning back to step No.25.

Next, a series of operations under low contrast will now be described. When an object having a low contrast under AF mode is aimed, output port OP0 produces "101" for the warning display (step No.105). Then, it is detected whether the flag LCF is carrying "1" or not (step No.107 in FIG. 13*d*). If the flag LCF is not carrying "1", and if the low contrast object is aimed for the first time, flags LCF and LCF3 are set to "1" (steps No.108 and No.109). And, at step No.110, it is detected whether the operation is for the first time (FPF=1) or not. If flag FPF is carrying "0", which means that the operations so far done are not under low contrast, there may be an error in the present measuring operation. Therefore, the program advances to step No.280, and through step No.270, it returns back to step No.2 to restart the measuring operation. In this case, the motor runs in a direction based on the calculated result obtained in the previous operation. If end flag ENF is carrying "1", which means that the motor is not running, and when the program advances through step No.110 to step No.280, it is waited until input i11 receives LOW (step No.281). Then, flags LCF and LCF3 are reset to carry "0" (step No.282) and, thereafter, initializations (step No.25 et seq.) are carried out to stop the operation of microcomputer MC1.

Also, at step No.110, if it is detected that the flag FPF is carrying "1", indicating that the operation is carried out for the first time, flags FPF and LCF3 are reset to carry "0" (steps No.111 and 113), and at step No.205, it is detected whether the defocus amount ΔL is positive or negative. If $\Delta L > 0$, which means that the image is focused in front of the ideal focal plane (this is referred to as front focused), flag FDF is set to carry "1" (step No.206). If $\Delta L < 0$, which means that the image is focused behind the ideal focal plane (this is referred to as rear focused), flag FDF is reset to carry "0" (step No.209). Thereafter, in a manner described above for the steps No.63 to No.66, motor MO is driven to rotate counterclockwise or clockwise in accordance with the type of lens to shift the lens outwardly. Then, at step No.212, it is detected whether the time consumed for the integration (which is stored in register ITR) is shorter than a predetermined length C7 or not. If the integration time is less than the predetermined time C7 ((ITR)$\geqq$C7), output O14 produces HIGH to run the motor MO at a high speed (step No.214). Thereafter, the program goes through step No.270 to step No.2 so as to restart the measuring operation. In this manner, unless the measured amount is changed to an amount which is not representing the low contrast, the lens is continuously shifted in a direction initially determined.

If the lens is shifted all the way to one end with the contrast being detected as low all the time, flag LCF1 is set to carry "1" at step No.52 to change the direction of lens shift. Then, the measuring is further carried out while shifting the lens in the opposite direction. If the lens is shifted all the way to the other end with the contrast being detected as low all the time, it means that the lens is shifted from one end to the other end without catching a high contrast point. In this case, the object can be considered as an object having no contrast, such as a plain wall or white cloud. Thus, the program advances to step No.55 to stop the operation. In this operation, if it is found that the contrast determined in accordance with the measurement has a level above the low contrast, the program advances to step No.101 (FIG. 13*b*) to carry out the lens control in accordance with the defocus amount described later. If the detected image shows low contrast suddenly after one or more measuring operations, the determined contrast in the first operation is disregarded of and the measuring operation is carried out again. In such a measurement, if the determined contrast still continues to show the low contrast, the flow advances from step No.107 to step No.112. Since flag LCF3 is set to carry "1" at step No.109, the flow advances from step No.112 to step No.113 to reset flag LCF3 to carry "0" and thereafter, the program advances to step No.205. In accordance with the measurement at this moment, the direction for shifting the lens is determined. Then, a point where the contrast level exceeds above a predetermined level is detected. During the shifting of the lens under the low contrast condition, flag LCF3 is set to carry "0", which causes a repetition of a flow advancing from steps Nos.107 and 112 to step No.270 and then returning again to the step of next measurement. This operation is continued until it is detected, at step No.43 or step No.87 or step No.113, that the lens reaches to one end of its shiftable range.

When an object having a low contrast under FA mode (MOF=1) is aimed, the program advances from step No.106 to No.115 to set flag LCF to carry "1", to reset flags LCF1 and LCF3 to carry "0", to set flag FPF to carry "1" and to reset end flag ENF to carry "0". Thus, outputs O12 and O13 produce LOW. Then, the program advances to step No.258 to carry out the operation described later. Then, the light measuring is carried out again.

When the integration operation in CCD FLM completes and control circuit COT provides HIGH to interruption terminal iT during microcomputer MC1 is carrying out a looped operation of step Nos.14, 15, 18 and 19, step Nos.35 to 40, step Nos.42 to 44, or step Nos.36 to 41, the program immediately jumps to step No.70 to start the interruption procedure, as described below.

In the interruption procedure, first register ECR3 is stored with an amount ECD representing the counted number of pulses from encoder ENC (step No.70). Then, the number of light receiving elements aligned in the CCD, i.e., the number (C3) of pieces of data to be applied to input port IP0 of microcomputer MC1 is stored in register DNR (step No.71). Then, at step No.72, it is waited until input i10 receives HIGH. When input i10 receives HIGH upon completion of analog-to-digital conversion of the CCD output, a piece of CCD output data CD, which has been applied to input port IP0, is stored in register M(DNR) at step No.73. Then, one is subtracted from the content of register DNR (step No.74), and these steps (step Nos.72 to 75) are repeated until a borrow signal BRW appears at step No.74. In this manner, CCD output data CDs are set in register M(DNR) piece by piece. When all the CCD data CDs are taken, return address is set up. And, in

response to that address, a return operation is carried out. Then, the program continues from step No.77 of the main flow.

As step No.77, it is detected whether flag LLF is carrying "1" or not. If flag LLF is carrying "1", data CDs from CCD are scanned for searching the maximum data MACD (step No.78). If the searched maximum data MACD carries "0" at its most significant bit, all the CCD data CDs (ALCD) are doubled (step No.80). If the searched maximum data MACD carries "1" at its most significant bit, all the CCD data CDs remain as they are, and the program directly goes to step No.81. Since if they are doubled, some data CDs may result in overflow. Contrary, if flag LLF is carrying "0", the program directly jumps to step No.81.

Amount of shift of two images on an image forming plain, which is equivalent to the film surface, is calculated at step No.81 and step No.90. More specifically, at step No.81, an integer portion of such an amount is calculated, and at step No.90, a fraction portion of such an amount is calculated. The detail of this calculation itself is known as disclosed in, e.g., U.S. Pat. No. 4,333,007 and, therefore, its description is omitted for the sake of brevity. In steps No.82 to No.85, it is detected whether motor MO is driven or not, in a manner similar to that described above in connection with steps No.10 to No.13. If the motor MO is driven, counted data ECD representing the number of pulses from encoder ENC is stored in register ECR1 (step No.86). Then, the data just now stored is compared with the data previously stored in register ECR2. If (ECR1)=(ECR2), which means that the lens is shifted all the way to the end, the program continues from step No.47 described above. If (ECR1)≠(ECR2), which means that the lens is still shifting, the content of register ECR1 is shifted to register ECR2, and then, the program advance to step No.89. Contrary, if motor MO is not driven, the program immediately advances to step No.89.

At step No.89, it is detected whether input i11 is receiving HIGH or not. If it is receiving LOW, the program advances to step No.25 to stop the focus detection operation and to carry out the initialization. If input i11 is receiving HIGH, the program advances to step No.90 to calculate the fraction portion of the shift amount, and at step No.91, defocus amount ΔL is calculated using the shift amount calculated in steps No.81 and No.90.

At step No.92, it is detected by the flag MOF whether the mode is AF mode or FA mode. If the present mode is AF mode, the program advances to step No.93, and if it is FA mode, the program advances to step No.100. In the case of AF mode, the conversion coefficient KD stored in latch LA from microcomputer MC2 is transferred to microcomputer MC1 through input port IP1 (step No.93). Then, it is detected at step No.94 whether the fourth digit place k3 of the data KD representing the conversion coefficient is carrying "0" or not, and whether the third digit place k2 of the data KD is carrying "1" or not. If the detected result is such that k3=0 and k2=1, it is understood from the above description that the mounted interchangeable lens can not operate under AF mode. Therefore, in this case, mode flag MOF is set to carry "1" (representing FA mode) and, thereafter, the program advances to step No.96. Contrary, if the detected result is such that k3=1 or k2=0, it is understood that the mounted interchangeable lens is a type which can operate under AF mode. Thus, in this case, the program advances to step No.100. Furthermore, at step No.96, it is detected whether or not k1=0. If k1=1, the program advances to step No.100. If k1=0, it is understood that the mounted interchangeable lens is a type wherein the lens must be shifted outwardly to nearest focusing position to change the range from zoom-range to macro-range, and that lens is about to change the range to macro-range. In this case, the program advances to step No.220 (FIG. 13*a*) to produce HIGH from output O14 to drive the motor at a high speed. Then, at step No.221, it is detected whether or not input i12 is receiving HIGH. If input i12 is receiving HIGH, which means that the mounted lens is a type which shifts the lens outward upon clockwise rotation, output O12 produces HIGH. If input i12 is receiving LOW, which means that the mounted lens is a type which shifts the lens outward upon counterclockwise rotation, output O13 produces HIGH. Thereafter, counted data ECD representing the number of pulses from encoder is stored in register ECR2 (step No.224).

Next, register TWR is stored with a constant data C8 (step No.225) representing a predetermined period of time. Then, "1" is subtracted from the content of the register TWR and then, it is detected whether or not a borrow signal BRW is produced. This operations are repeated, and when a borrow signal is produced after a predetermined period of time, counted data ECD representing the number of pulses from encoder is transferred to shift register ECR1 (step No.228). Then, the content of register ECR1 is compared with that of register ECR2 (step No.229). If (ECR1)≠(ECR2), the content of register ECR1 is transferred to register ECR2 (step No.230) and, thereafter, a routine of steps No.225 to No.230 is repeated. Contrary, if (ECR1)=(ECR2), which means that the lens is shifted all the way to nearest focusing position, outputs O12 and O13 produce LOW, thereby stopping motor MO (step No.231). Then, flag FPF is set to carry "1" (step No.232), and thereafter, the program returns back to step No.2. Thereafter, the program is carried out under FA mode operation.

At step No.100, it is detected whether or not the data from CCD is indicating low contrast. The detail of this step will be described later in connection with FIG. 20. If the data indicates low contrast, the program proceeds from step No.105 described above. Contrary, if the data does not indicate low contrast, it is detected whether or not flag LCF is carrying "1" at step No.101 (FIG. 13*b*). If flag LCF is carrying "1", flag FPF is set to carry "1" because the measured amount in the previous operation showed low contrast, and flags LCF, LCF1 and LCF3 are reset to carry "0". Then, the program goes to step No.290 to detect the condition of flag MOF. If MOF=0, that is, selected mode is AF mode, outputs O12 and O13 produce LOW to stop the motor. Thereafter, the program returns back to step No.2 to start the measuring operation again. Contrary, if MOF=1, that is, selected mode is FA mode, the program goes to step No.240 to carry out the operation for the FA mode, which will be described in detail later.

In the case where flag LCF is carrying "0" at step No.101 and when the measured amount in the previous operation did not show low contrast, the program goes to step No.104 to detect the condition of mode flag MOF. In this case, if MOF=1, indicating FA mode, the program advances to step No.240. Contrary, if

MOF=0, indicating AF mode, the program advances to step No.125.

During the procedure of steps No.125 to No.130, it is detected whether or not the defocus amount ΔL is within infocus zone ZN1. First, in the case where flag ENF is carrying "0" (step No.125) indicating that the lens is not shifted to the end and when infocus flag IFF is carrying "1" (No.126) indicating that the lens has once reached the infocus zone, the measured amount |ΔL| obtained in the present measuring operation is compared at step No.127 with infocus zone ZN1. If, |ΔL|<ZN1, infocus display is effected (step No.128). Then, it is waited until output i11 produces LOW (step No.129). Thereafter, the program goes to step No.25 and stops the operation.

On the contrary, if |ΔL|≧ZN1, flag FPF is set to carry "1" and flag IFF is reset to carry "0" and, thereafter, the program goes to step No.135 so as to carry out the lens control operation in accordance with the defocus amount based on the measured amount just obtained.

In the case where the flag ENF is carrying "1" indicating that the lens is shifted to the end, infocus display is effected at step No.128, under the condition that |ΔL|<ZN1 at step No.127. But if |ΔL|≧ZN1, the program goes to step No.129 with the indication of defocus direction being remained the same as before. Then, in the same manner described above, the operation stops when input i11 receives LOW. Here, when |ΔL|≧ZN1, the program goes to step No.129 with the indication of defocus direction being remained the same as before. In this case, the lens will not terminate to an infocus position even if it is shifted to its end position. Therefore, it is no use of shift the lens by the motor MO. Thus, the operation of microcomputer MC1 is forcibly stopped.

If it is detected at steps No.125 and No.126 that the lens is not yet reached its end position or an infocus zone, it is detected at step No.131 whether first-pass flag FPF is carrying "1" or not. If the flag FPF is carrying "0", it is detected whether the lens has shifted to its end position or not at steps No.132 to No.134, in a manner similar to steps No.86 to No.88. Thereafter, the program goes to step No.135. Contrary, if the flag FPF is carrying "1", the program goes directly to step No.135. At step No.135, the focus detection command signal from microcomputer MC2 is detected. If input i11 is receiving LOW, the program goes to step No.25 and then the operation stops. If input i11 is receiving HIGH, the program goes to step No.136.

At step No.136, the calculated defocus amount ΔL is multiplied by read conversion coefficient data KD to obtain data N representing the amount of drive of lens drive mechanism LDR. At step No.136, in more detail, a real conversion coefficient is obtained by means of shifting the lower four bits of read conversion coefficient data KD in accordance with the upper four bits of the data KD. And thus obtained real conversion coefficient is multiplied by defocus amount ΔL to calculate data N, which is the number of pulses expected from the encoder. Then, it is detected at step No.137 whether flag FPF is carrying "1" or not. If flag FPF is carrying "1", it is detected whether data N is positive or negative (step No.140). If data N is positive, focus direction flag FDF is set to carry "1", and if negative, it is reset to carry "0". Thereafter, an absolute of drive amount N, indicated as Nm, is stored in register ECR4 (step No.144). Then, flag FPF is reset to carry "0" and, thereafter, the program goes to step No.166 (FIG. 12*c*).

On the contrary, at step No.137, if flag FPF is carrying "0", the content of register ECR4, storing the data representing the amount of drive effected in the previous operation, is shifted to register ECR5 (step No.150 in FIG. 12*b*) and, then, register ECR4 is stored with a new data ECD representing the counted number of pulses from encoder ENC (step No.151). Accordingly, at this moment, register ECR3 is stored with count data Tc1 at the end of integration of CCD, and register ECR4 is stored with count data Tc2. Then, calculations are carried out to obtain lens-shift amount τ:

$$\tau = Tc0 - Tc1$$

representing the amount of lens shift effected during the integration of CCD, and lens-shift amount t0:

$$t0 = Tc1 - Tc2$$

representing the amount of lens shift effected during the calculation to obtain data N. If it is assumed that data N is obtained at the middle of the integration of CCD, at this moment the lens is shifted by an amount $\tau/2+t0$ from the moment when data N is obtained. Furthermore, a calculation is carried out to obtain corrected data N″m:

$$N''m = N'm - (\tau + t0)$$

wherein N′m is the data obtained in the previous flow, and $(\tau+t0)$ is the amount of lens shift effected after the previous flow. It is to be noted that the corrected data N″m always takes a positive value.

At steps No.155 to No.157, it is detected whether or not the lens-shift direction towards infocus zone has been changed, by the use of defocus amount data N and flag FDF. More specifically, at step No.155, it is detected whether defocus amount data N calculated in the present cycle of operation is positive or negative. If data N is positive, it is detected at step No.156 whether flag FDF is carrying 0 or not. If flag FDF is carrying 0, this means that the direction has been changed, the program goes to step No.158. If flag FDF is carrying 1, this means that the direction is not changed, the program goes to step No.159.

On the contrary to the above, if data N is negative, it is detected at step No.157 whether flag FDF is carrying "1" or "0". If flag FDF is carrying "1", this means that the direction has been changed, the program goes to step No.158. If flag FDF is carrying "0", this means that the direction is not changed, the program goes to step No.159.

When it is detected that the direction is not changed, i.e., when the program goes to step No.159, it is understood that the lens is shifted towards infocus position by the rotation of the motor. Thus, in this case, it is assumed that data N is obtained at the middle of the integration period, thereby carrying out a calculation:

$$|N| - \tau/2 - t0 = N'$$

to correct the shifted amount by the rotation of the motor. Then, it is detected whether the corrected data N′ is negative or not (step No.160). If corrected data N′ is negative, it is understood that the lens has moved passed the infocus position. Therefore, it is made such

that $|N'|=N'$ at step No.163 and, thereafter, the program goes to step No.164. Contrary to the above, if corrected data N' is positive, an average between data N''m obtained in the previous cycle of operation and the corrected data N' is taken to obtain a new data Na (step No.161 in FIG. 12*c*):

$$Na=(N''m+N')/2.$$

The new data Na is adapted as the data Nm (step No.162), and thereafter, the program goes to step No.166.

When it is detected that the direction has been changed, i.e., when the program goes to step No.158, it is understood that the lens is over shifted beyond the infocus position by an amount $\tau/2+t0$ in the defocus direction from the moment when the present data is obtained. Thus, in this case, a correction calculation:

$$|N|+\tau/2+t0=N'$$

is carried out and, thereafter, the program advances to step No.164. At step No.164, an average is taken between N''m and N' to obtain a new data Na:

$$Na=(N''m-N')/2.$$

Then, it is detected whether the new data Na is negative or not (step No.165).

If data Na is positive, the program goes to step No.162 (FIG. 12*c*) described above, and if it is negative, outputs **012** and **013** produce LOW to stop the motor (step No.174). Then, at step No.175, infocus zone data ZN1 is multiplied by conversion coefficient data KD, which has been changed into the real value at step No.136, to obtain data Ni representing the amount of rotation of motor in the infocus zone. Then, it is detected whether $|Na|<Ni$, or not. If $|Na|<Ni$, it is understood that the lens is shifted to the infocus zone. Therefore, in this case, infocus flag IFF is set to carry "1" and then, program follows step No.270 and returns back to step No.2. Contrary, if $|Na|>Ni$, it is understood that the lens has moved passed the infocus zone. Therefore, flag FPF is set to carry "1" and then, program follows step No.270 and returns back to step No.2, again carrying out the measuring operation.

At step No.166, data NZ representing a near-infocus zone is multiplied by data KD to obtain a data indicating an amount of lens shift from the near-infocus zone to infocus zone. Then, at step No.167, using data ZN1 for the near-infocus zone and data KD, a multiplication:

$$Ni=ZN1\times KD$$

is carried out to obtain data Ni representing an amount of lens shift within the infocus zone (step No.167). Then, at step No.168, data Nm is compared with data Nn. When, $Nm\geqq Nn$, i.e., when the lens is outside the near-infocus zone, the program goes to step No.181, thereby producing HIGH from output **O14** to run motor MO at a high speed and, at the same time, counter ECC is stored with Nm-Nn to count down in response to the pulses from encoder ENC (step No.182). Thereafter, the program advances to step No.185.

Contrary to the above, when $Nm<Nn$, i.e., when the lens is inside the near-infocus zone, it is detected at step No.169 whether $Nm<Ni$, or not. If $Nm\geqq Ni$, that means that the lens is within near-infocus zone, but not within infocus zone. Therefore, in this case, output **O14** produces LOW to run the motor MO at low speed (step No.183), and data Nm is stored in counter ECC (step No.184). Thereafter, the program advances to step No.185. In the case when the mounted lens is a type in which the conversion coefficient data KD changes with respect to the change of focusing distance, the lens shift is controlled only in accordance with a signal representing the direction of defocus. For the other types of lens, defocus amount is calculated and, for this purpose, the amount of lens shift is corrected in the procedure starting from step No.150. Therefore, for this correction, data Nm-Nn is stored in counter ECC at step No.182. Furthermore, when $Nm<Ni$, outputs **012** and **013** produces LOW to stop motor MO (step No.171), and then, infocus flag IFF is set to carry "1" (step No.172). Then, the counter interruption procedure is prohibited (step No.173), and thereafter, the program returns to step No.270 to carry out the measurement operation for the proof.

At step No.185, it is detected whether flag FDF is carrying "1" or not. If flag FDF is carrying "1", which means that the image is front focused, output port OP0 produces "100" to lit light emitting diode LD0 for the indication of near focus (step No.186). If flag FDF is carrying "0", which means that the image is rear focused, output port OP0 produces "001" to lit light emitting diode LD2 for the indication of far focus (step No.189). Then, by the content of flag FDF and signal applied to input **i12** for the indication of direction of rotation of interchangeable lens, motor MO is driven in clockwise or counterclockwise direction (step No.188 and No.191). Thereafter, the program advances to step No.192 to detect whether input **i13** is receiving HIGH or not. If the mounted lens is a type which changes the conversion coefficient data KD in accordance with the change of focusing distance, and if input **i13** is receiving HIGH, it is detected at step No.193 whether $Nm<Nn$, or not. In this case, if the lens is located out the near-infocus zone so that the detected result is $Nm\geqq Nn$, motor MO is controlled, irrespectively of the calculated data Nm, only by the signal representing the direction of rotation. Then, it is detected whether or not the integration period is longer than predetermined period of time corresponding to data C7 (step No.194). If it is longer, there may be a possibility that the lens moves past the infocus position. Therefore, output **O14** produces LOW to run motor MO at a low speed (step No.195), and the counter interruption is prohibited (step No.195). Thereafter, the program advances to step No.270 and returns back to step No.2. Contrary to the above, if it is detected that $Nm<Nn$, indicating that the lens is inside the near-infocus zone, it is permitted to carry out the counter interruption procedure (step No.197) and, thereafter, the program returns to step No.270. Furthermore, when input **i13** is receiving LOW, it is permitted to carry out the counter interruption procedure and, thereafter, the program returns to step No.270.

When counter ECC for down counting the pulses from encoder ENC is counted down to zero during the rotation of motor MO, a counter interruption procedure (FIG. 11*b*) starts. At step No.200, it is detected whether $Nm<Nn$, or not. If $Nm<Nn$, it is understood that motor MO has been rotated while the lens is in the near-infocus zone and, therefore, it can be assumed that the lens is now shifted to infocus zone. Thus, outputs

O12 and O13 produce LOW to stop motor MO (step No.203). Then, infocus flag IFF is set to carry "1" and, thereafter, the program returns to step No.270. Contrary, at step No.200, if it is detected that $Nm \geqq Nn$, it is understood that motor MO is now shifted to near-infocus zone. Thus, output O14 produces LOW to run motor MO at a low speed (step No.201), and then, data Nn is stored in counter ECC (step No.202). Then, it returns to an address with an interruption.

Next, when flag MOF is detected as carrying "1" at step No.104 or step No.290 (FIG. 13*b*), an operation under FA mode is carried out in a procedure starting from step No.240. At step No.240, it is detected whether or not flag FPF is carrying "1". If flag FPF is carrying "1", it is understood that the operation under FA mode is carried out for the first time. In case when the mode is changed from AF mode, end flag ENF is reset to carry "0", and infocus flag IFF is reset to carry "0". Furthermore, register IZR for the detection of infocus zone is stored with data ZN2 for indication the infocus zone. It is to be noted that the data ZN2 is greater than data ZN1 for the AF mode. This difference is provided because under the AF mode, the lens can be precisely adjusted by the motor drive, but under the FA mode, the lens is shifted manually and, therefore, it is difficult to adjust the lens with a preciseness as high as the motor drive. Then, at step No,245, first-pass flag FPF is reset to carry "0" and, thereafter, the program advances to step No.246. Contrary, if flag FPF is carrying "0", the program immediately advances to step No.246.

At step No.246, it is detected whether infocus flag IFF is carrying "1" or not. If infocus flag IFF is carrying "1", it is understood that the calculated value obtained through the calculation up to the previous cycle indicates that the lens is shifted to infocus zone. Thus, an average is taken between the calculated value ΔL_{n-1} in the previous cycle and the calculated value ΔL to obtain:

$$\Delta L_n = (\Delta L + \Delta L_{n-1})/2$$

at step No.247. Then, register IZR is stored with data Zw ($>$ZN2) representing the infocus zone (step No.248), followed by step No.250. In consideration of variation in the defocus amount determined in accordance with the measurement, the above operation is to widen the infocus zone once the lens is shifted into the infocus zone, so as to prevent the unstable display of infocus, particularly when the lens is shifted to a position adjacent to the border of the infocus zone at the inside thereof. Contrary, at step No.246, if infocus flag IFF is carrying "0", the measured amount ΔL in the present cycle is rendered as ΔL_n (step No.249), followed by step No.250 (FIG. 13*c*). At step No.250, it is detected whether or not $|\Delta L_n| < (IZR)$, that is whether the calculated value is within infocus zone or not. If it is within the infocus zone, infocus flag IFF is set to carry "1" (step No.251), and the infocus display is carried out by light emitting diode LD1 (step No.252). Then, the program advances to step No.258. If contrary it is outside the infocus zone, it is detected whether $\Delta L_n > 0$, or not (step No.253). If $\Delta L_n > 0$, light emitting diode LD0 is lit for the indication of the front focus. If $\Delta L_n < 0$, light emitting diode LD2 is lit for the indication of the rear focus. Then, infocus flag IFF is reset to carry "0", and data ZN2 is stored in register IZR. Then, the program goes to step No.258. At step No.258, it is detected whether input i14 is receiving HIGH. If it is receiving HIGH, indicating that the mode is changed to AF mode, flag FPF is set to carry "1", flag IFF is reset to carry "0", and flag LCF is reset to carry "0". Then, the program returns to step No.2. If it is receiving LOW, indicating that the mode is still FA mode, the program immediately returns to step No.2, thereby starting the next measuring operation.

In the procedure through step No.25 to step No.33 in FIG. 11*a*, the operations for stopping the focus detection and setting initial condition are carried out. At step No.25, the interruptions are prohibited, and at step No.26, output O11 produces to forcibly stop the integration of CCD. Then, outputs O12 and O13 produce LOW to stop motor MO (step No.27), and output port OP0 produces "000" to disable the light emitting diodes LD0, LD1 and LD2 (step No.28). Then, output O16 produces LOW to cut off power to power supply line VF (step No.32). And, flags ENF, IFF and LCF3 are all reset to carry "0", and flag FPF is set to carry "1" (step No.29 to step No.31, and step No.33). After the initial condition is set, the program returns to step No.2.

Next, a modification of the above described embodiment is given in connection with FIGS. 14, 15 and 16. According to this modification, when the main object is properly focused to be located within the infocus zone through a focus adjustment operation under AF mode, it is possible to detect whether a secondary object is also located with the depth of focus, or not. FIG. 14 is a fragmentary view of a circuit diagram showing only a portion which differs from the circuit diagram of FIG. 5. FIG. 15 is a flow chart showing only the steps which differ from the steps shown in FIG. 6*c*. And, FIG. 16 is a flow chart showing only the steps which differ from the steps shown in FIGS. 11*a*, 11*c*, 12*a* and 13*d*.

When it is detected at step No.127 that the lens is located within the infocus zone, a display indicating the infocus condition is effected at step No.128, flag IFF is set to carry "1" at step No.300, and output O30 of microcomputer MC1 produces HIGH at step No.301. The output O30 is connected to input i5 of microcomputer MC2. Thus, by the HIGH applied to input i5, the microcomputer MC2 detects that the lens is located within the infocus zone.

Then, the program for the microcomputer MC1 goes to step No.270, and if the mode is not changed to FA mode, the program returns back to step No.2 to again carry out the measuring. In this case, since flag IFF is carrying "1", the same procedure as in the case of focus proof is carried out and, thereafter, the program advances to step No.91. According to this modification, step No.91 is followed by detection step No.305 for detecting whether flag IFF1 is "1" or not. If not, the program goes to step No.92, but if flag IFF1 is carrying "1", the program goes to step No.306, at which data applied to input port IP2 are read in. As shown in FIG. 15, step #80 for producing an aperture value Av for the exposure control is provided between steps #30 and #31. This aperture value Av is latched in latch circuit LA1 in response to a pulse from output a_{n+2} of decoder DEC. Therefore, input port IP2 receives data of aperture value for the exposure control.

The read-in data Av is converted from APEX numbering system to F-stop number (step No.307), and a calculation:

$$\Delta D = \delta \times (\text{F-stop number})$$

is carried out at step No.308. Here, δ is a data representing the permissible circle of confusion, and ΔD is a data representing the depth of focus. Next, the data ΔD and the defocus amount |ΔL| obtained at step No.91 of the present cycle of operation are compared with each other at step No.309, and then, the focus condition is displayed in a manner described below, and thereafter, the program goes to step No.270.

When $|\Delta L| \leqq \Delta D$, which means that the measured portion of the object is located within the depth of focus, output port **OP5** produces "010", thereby lighting light emitting diode **LD4** for the indication of infocus. Contrary, if $|\Delta L| > \Delta D$, output port **OP5** produces "100" to light light emitting diode **LD3** for the indication of near focus, or output port **OP5** produces "001" to light light emitting diode **LD5** for the indication of far focus, depending on whether the data ΔL is positive or negative.

By the above operation, after adjusting the lens to infocus position under AF mode, it is possible to detect whether an object other than the object aimed at for the focus adjustment is located within depth of focus or is front or rear focused.

In the above described modification, the depth of focus is calculated with a high accuracy at step No.308. However, since it is difficult to exactly aim a desired spot for the light measuring, particularly when the camera is held by hands, and since the calculated amount ΔL varies during a number of cycle of operations, it is possible to widen the infocus zone in a manner similar to the operation under FA mode, or to widen the infocus zone once the lens is shifted to infocus zone, or to take an average after carrying out a number of cycle of operations. For example, in order to widen the infocus zone, a calculation:

$$\Delta D = I \times \delta \times FNo (I = 2 \sim 3)$$

is carried out.

Furthermore, according to the modification, further steps are added between steps No.33 and No.2 and between steps No.273 and No.2 so as to carry out the initial setting when the operation of microcomputer **MC1** is to be stopped or when the mode is changed to FA mode. More specifically, after step No. 33 or No.273, flag **IFF1** is reset to carry "0" (step No.320 or No.325), then output port **OP5** produce "000" to disable light emitting diodes **LD3**, **LD4**, and **LD5** (step No.321 or No.326), and thereafter, output **O30** produces LOW (step No.322 or No.327).

Also, according to the modification, step #81 shown in FIG. **15** is provided to produce data representing Av from input and output port I/O, and in order to continue the display of focusing condition for a predetermined period of time even after the turn off of light measuring switch MES, step #81 for detecting whether input **i5** is receiving HIGH or not is inserted between steps #38 and #39. More specifically, when light measuring switch MES is turned off and when it is detected that the present mode is AF mode, output **O1** continues to produce HIGH, so long as input **i5** is receiving HIGH to continue the operation of microcomputer **MC1** for detecting whether it is within the depth of focus mentioned above.

Referring to FIG. **17**, a detailed circuit diagram of control circuit COT for controlling CCD FLM is shown. Counter **CO24** counts negative edges of pulses **DP2**, which are clock pulses CP frequency divided by counter **CO22**. In response to the signals produced from outputs **p0** to **p4** of counter **CO24**, decoder **DE20** produces ten bit long binary signal from its output **T0** to **T9**. The signals produced from counter **CO24** and outputs from decoder **DE20**, flip-flops **FF22**, **FF24**, **FF26** and **FF28** are given in Table 6 below.

As apparent from Table 6, Q output **Ø1** of flip-flop FF26 produces HIGH while counter **24** is producing "11101" to "00101", Q output **Ø2** of flip-flop FF24 produces HIGH while counter **24** is producing "00100" to "10111", and Q output **Ø3** of flip-flop FF22 produces HIGH while counter **24** is producing "10110" to "11110". The signals from these outputs **Ø1**, **Ø2** and **Ø3** are applied to CCD FLM while power supply line VF is supplying power, so that the transmission of analog signal is continuously effected in the transmission gate. By this operation, the accumulated charge remaining in the transmission gate is discharged.

By the reset signal PO2 from power-on reset circuit POR2 produced in response to the power supply, flip-flops FF20 to FF28, FF32, D flip-flops DF20, DF22 and DF24, and counters CO20, CO22 and CO24 are reset. Furthermore, flip-flop FF30 is set to produce HIGH from its Q output **ØR**. By the HIGH from Q output **ØR**, analog switch AS2 turns on to supply output voltage from constant voltage source Vr1 through lead line ANB to CCD FLM. The charge accumulation portion of CCD FLM is set to this voltage.

When microcomputer MC1 produces HIGH from its output O10 to start the integration operation, one-shot circuit OS18 produces a pulse which resets flip-flop FF30. Accordingly, Q output **ØR** produces LOW. Thus, CCD FLM starts to accumulate charge corresponding to the amount of light received by each light receiving element. Also, through inverter IN50, analog switch AS1 conducts to transmit monitor output of CCD FLM from terminal ANB to the inverting input of comparator AC1. In accordance with the accumulated charge, CCD monitor output from terminal ANB drops from constant voltage Vr1, and when it reaches a constant voltage from constant voltage source Vr2, comparator AC1 produces HIGH. In response to this, it is detected that the charge in CCD FLM has completed. By the HIGH from comparator AC1, one-shot circuit OS10 produces HIGH, which is applied through OR gate OR20 to flip-flop FF20. Thus, flip-flop FF20 is set, thereby producing HIGH from its Q output. This HIGH is taken into D flip-flop DF20 in response to the positive edge of HIGH produced from the Q output (output **Ø1**) of flip-flop FF26, thereby producing HIGH from the Q output of D flip-flop DF20. By this HIGH, the reset condition of counter CO20 is released and, AND gates AN60, AN64, AN66 and AN68 are enabled.

When output T0 produced HIGH after the output **Ø1** produces HIGH, flip-flop FF28 is set by the HIGH from output T0, and is reset by the HIGH from output T1. The Q output of flip-flop FF28 is connected through AND gate AN68 to output **ØT**, thereby producing a HIGH pulse to CCD FLM. By this HIGH pulse, the accumulated charge is transmitted to the transfer gate. Furthermore, the signal appearing at the output **ØT** is applied to interruption terminal iT, whereby the microcomputer MC1 carries out the data reading of data from CCD FLM in a manner described above.

When the signal from output **ØT** steps down to LOW, one shot circuit OS16 produces HIGH, thereby setting flip-flop FF32. Thus, flip-flop FF32 produces LOW from its $\overline{Q}$ terminal. Thus, AND gate AN68 is disabled to cut off any further HIGH signal from Q output of flip-flop FF28. Furthermore, through one-shot circuit OS16 and OR gate OR32, flip-flop FF30 is set, thereby again producing HIGH from output **ØR**.

By the transfer signals from outputs **Ø1**, **Ø2** and **Ø3**, the accumulated charges from CCD FLM are sequentially produced from output AOT. The accumulated charges are produced while output **Ø2** is producing HIGH. When D flip-flop DF20 produces HIGH from its Q output and while output **Ø2** is producing HIGH, AND gate AN66 produces output signal **ØS** for the sample/hold in response to HIGH from terminal T4 and AND gate AN64 produces output signal **ØA** for the A-D conversion start in response to HIGH from terminal T5.

The first signal of accumulated charge which is transferred from terminal AOT of CCD FLM is used for off-set adjustment, wherein a charge corresponding to the leakage of light receiving portion is charged. This charge is approximately equal to the voltage Vr1. In this instance, since $\overline{Q}$ output of D flip-flop DF24 is producing HIGH, sample/hold signal **ØS** is applied through AND gate AN70 to sample/hold circuit SH1, thereby storing the voltage for off-set adjustment from CCD FLM, through terminal AOT, in sample/hold circuit SH1. In response to the negative edge of the first sample/hold signal **ØS**, Q output of D flip-flop DF24 produces HIGH. The subsequent sample/hold signals **ØS** are applied through AND gate AN72 to sample/hold circuit SH2, thereby sequentially memorizing in the sample/hold circuit SH2 the voltages corresponding to the amount of light received by light receiving elements thereafter.

When the Q output of D flip-flop DF20 produces HIGH, the signal **Ø3** is applied through AND gate AN60 to one input of AND gate AN62. In response to the first negative edge of the signal **Ø3**, D flip-flop DF22 produces HIGH from its Q output. Accordingly, the pulse signals **Ø3** occurring after the first one are applied to input i10 of microcomputer MC1 through AND gate AN62, thereby commanding the microcomputer MC1 to read in the data through input port IP0. At this moment, the reason for producing HIGH from Q output of D flip-flop DF20 to prevent the first pulse signal **Ø3** from being produced from AND gate AN60 through AND gate AN62 is because that the first data from CCD FLM is for the off-set adjustment, as mentioned above. The pulse signal **Ø3** is also applied to a clock input terminal of counter CO20. Accordingly, after the release of reset condition by the HIGH from Q output of D flip-flop DF20, counter CO20 counts in response to the negative edges of pulse signals **Ø3**. When counter CO20 counts the pulse signals **Ø3** for the number corresponding to the number of light receiving elements in CCD FLM, it produces HIGH from its carry terminal CY.

After the first pulse signal Ø3, output data from CCD FLM are sampled in response to pulse singals Ø3. Then, by a subtraction circuit defined by registers R1 and R2 and operational amplifier OA1, a difference between outputs from sample/hold circuits SH1 and SH2 is calculated. The calculated difference is applied to an analog input of A-D converter AD. The A-D converter AD starts its operation in response to the signal ØA, and in accordance with clock pulses DP1 from counter CO22, it carries out the A-D conversion of the input data. When it is assumed that the voltage from constant voltage source Vr1 is Vr1, the voltage drop caused by the leakage is Vd, and voltage drop by the received light amount is V1, the output from sample/hold circuit SH1 can be given as:

$$Vr1-Vd,$$

and the output from sample/hold circuit SH2 can be given as:

$$Vr1-V1-Vd.$$

Accordingly, the signal produced from the subtraction circuit has only the term V1 representing the received light amount. Preferably, A-D converter AD is capable of carrying out the A-D conversion at a high speed, such as a successive approximation A-D converter.

When all the data from CCD FLM are converted to digital form by A-D converter AD, counter CO20 produces HIGH from its carry terminal CY. Accordingly, the HIGH is transmitted through one-shot circuit OS14 and OR gate OR22, flip-flops FF20 and FF32 and D flip-flops DF20, DF22 and DF24 are reset. Thus, D flip-flop DF20 produces LOW from its Q output, thereby holding counter CO20 in reset condition. Thus, a condition, which is the same as that before producing HIGH from output O10, is established.

Also, when it is detected that a timer in microcomputer MC1 counts a predetermined integration time, output O11 produces a HIGH pulse. In response to the negative edge of this HIGH pulse applied through one-shot circuit OS12 and OR gate OR20, flip-flop FF20 is reset. Accordingly, an operation, which is the same as the case when comparator AC1 produces HIGH, is carried out to A-D convert the output data from CCD FLM, and the converted data are sequentially applied to input port IP0 of microcomputer MC1.

Referring to FIG. 18, a modification of control circuit COT of FIG. 17 is shown. According to the previous embodiment, in the case where output data from CCD is small, it is doubled after it is read in microcomputer MC1 in terms of software (FIG. 11*c*, steps No.78 to No.82) in microcomputer MC1. But, according to this modification, it is doubled in terms of hardware before it is A-D converted.

While output ØR is producing HIGH, a voltage Vr1 determined by constant current source CIS and resistors R10 to R13 is applied to CCD FLM, and while it is producing LOW, monitor output of CCD FLM is applied to inverting inputs of comparators AC10 to AC12. Then, when integration proceeds to cause the monitor output reach voltage Vr2, comparator AC12 produces HIGH, thereby producing a HIGH pulse from one-shot circuit OS10. By this HIGH pulse applied through OR gate OR20, flip-flop FF20 is reset and, thereafter, the same operation as described above is carried out.

Furthermore, this pulse is also applied to the clock terminals of D flip-flops DF32 to DF38. In this case, since comparator AC12 is producing HIGH, Q output of D flip-flop DF38 produces HIGH, thereby turning analog switches AS48 and AS38 on. The resistances of resistors R30 to R40 are as follows:

$$R30 = R40 = R38 = R48 = \frac{R36}{1.5} = \frac{R46}{1.5} = \frac{R34}{2} = \frac{R44}{2} = \frac{R32}{2.5} = \frac{R42}{2.5}.$$

By the turn on of analog switches AS38 and AS48 and since resistors R30, R40, R38 and R48 have the same resistance, operational amplifier OA10 produces a signal V1 without any change.

Contrary, when the object is so dark that comparator AC12 produces no HIGH signal during the maximum integration time, microcomputer MC1 produces HIGH from output O11, which is applied to one-shot circuit OS12 and further to OR gate OR20. In this case, depending on which one of the ranges Vr2-Vr3, Vr3-Vr4 and Vr4-Vr1 does the monitor output falls, one of EXCLUSIVE OR gates EO2 and EO4 and inverter IN52 produces HIGH, thereby producing HIGH from Q output of one of D flip-flops DF32, DF34 and DF36. Accordingly, one pair of analog switch pairs: AS36 and AS46; AS34 and AS44; and AS32 and AS42, is turned on. Thus, the integration operation is forcibly stopped and in accordance with the monitor output level at that moment, operational amplifier OA10 produces either one of 1.5V1, 2V1 or 2.5V1.

Next, a variation of operation flow of microcomputer MC1 described above in connection with FIGS. 11*a* to 13*d* is described. Referring to FIG. 19, only parts of the flow which are different from the above described flow are shown. This variation is directed to a case in which a number of out-of-focus detections are repeated consecutively after a detection of in focus. Between steps No.130 and No.138 (FIG. 12*a*), steps related to flag IFF are inserted. More specifically, when lens is so adjusted as to be shifted to infocus zone, and end flag ENF is carrying "0" (step No.130), it is detected at step No.351 whether flag IFF2 is carrying "1" or not. If it is detected that flag IFF2 is carrying "0", this flag IFF2 is set to carry "1" and, thereafter, the program advances to step No.270 to carry out the measuring operation again for the proof. Contrary, if flag IFF2 is carrying "1", which means that the measuring operation for the proof resulted out-of-focus ($|\Delta L| \geqq ZN1$) for two consecutive times, flags IFF and IFF2 are reset to carry "0", and flag FPF is set to carry "1" and, thereafter, the program advances to step No.135, thereby carrying out the focus adjustment operation again. Between steps No.33 and No.2, and between steps No.240 and No.242, a step (step No.34 or No.241) is provided to reset flag IFF2 to initialize it.

Referring to FIG. 20, a detail of step No.100 shown in FIG. 11*c*, which is for detecting whether the aimed object has a low contrast or not, is shown. At step No.370, the content of register C is made "0". Then, "1" is set in register i (step No.371). Thereafter, an absolute of a difference between output a_i from ith light receiving element and output a_{i+1} from i+1th light receiving element, i.e., $|a_i - a_{i+1}|$ is added to the contents of register C, and the added result is stored in register C (step No.372). Then, "1" is added to the contents of register i (step No.373), and at next step No.374, the contents of register i is compared with n (n is equal to

the total number of light receiving elements.). If $i<n-1$, the program goes to step No.372 so as to add up the absolute differences one after another. Then, when it becomes $i=n-1$, he program goes to step No.375. At step No.375, the contents of register C is equal to:

$$|a_1-a_2|+|a_2-a_3|+|a_3-a_4|+\ldots +|a_{n-2}-a_{n-1}|+|a_{n-1}-a_n|$$

which indicates the contrast of the object, as understood to those skilled in the art. At step No.375, it is detected whether the contents of register C is greater than a predetermined value CD or not. If (C)>CD, which means that the contrast is above a predetermined level, the program goes to step No.101. Contrary, if (C)≦CD, which means that the contrast is below the predetermined level, the program goes to step No.105.

In the case where the focus detection is carried out by the use of light receiving elements arranged in two arrays, the detection of contrast can be done with output signals only from one of the two arrays. Also, in the case where the data representing the contrast is obtained in the process for calculating the defocus amount and the direction of defocus, the contrast data is stored during the calculation. The contrast level is detected by a detection whether or not the stored data is within a predetermined level.

The conversion coefficient data KD produced from an interchangeable lens is read in microcomputer MC1 through microcomputer MC2 at step No.93 and, for example, it is used for the calculation of data N for driving the motor at step No.136. The data can be divided into two parts, in a manner described above in connection with Table 5, first part representing the floating point coefficient and the second part representing the significant digit. The above calculation is carried out by shifting the floating point of the significant digit in the second part in accordance with the floating point coefficient in the first part.

FIGS. **1**, **2** and **3** give a detailed explanation of a prior art optical system for the focus detection. Such an optical system, as it is, is incorporated in the embodiment of the present invention as a part thereof. Therefore, the following description should be considered as an explanation of a part of the embodiment of the present invention, and as an explanation of a problem which the optical system involves by itself.

An optical system for the focus detection employed in the prior art focus detection device includes a focus detection light receptor FLM comprising an array of n-number of light receiving elements, each of said light receiving elements being constituted, as shown in FIG. **1**, by a unitary structure of miniature lens Li and two light receiving elements Ai and Bi positioned rearwardly of the miniature lens Li. (It is to be noted that the character "i" affixed to each alphabetic reference character represents the number 1 to n). FIG. **2** illustrates the relationship between the focus detecting optical system of the light receptor FLM and the photo-taking optical system of an interchangeable lens assembly. In FIG. **2**, the point H depicted on the optical axis X represents the position at which images of the respective light receiving elements are formed by the respective miniature lens Li, and the solid lines HAi and HBi represent respective images corresponding to the images of the light receiving elements Ai and Bi. The position and the size of each of the images HAi and HBi are exclusively determined by the structure of the light receptor FLM. On the other hand, the broken line P represents an exit pupil corresponding to the image of an aperture AP at the smallest f-stop number in the interchangeable lens assembly, and the position and the diameter of the pupil change with the type of interchangeable lens assembly (e.g., a wide-angle, standard or telephoto lens assembly) and/or change in focal length of the lens assembly if the latter is a zoom lens assembly. Accordingly, depending on the type of the lens assembly mounted on the body of a photographic camera, it will happen that the incident beam of light rays falling on any one of the light receiving elements A1 to An will not be uniform with that falling on the associated light receiving elements B1 to Bn because of the vignetting of the lens assembly, as will be described later, and therefore the reliability of the result of the focus detection will be reduced. By way of example, as shown in FIG. **2**, if the point H is located closer to the light receptor FLM than to the position of the pupil and respective portions of the images formed by projecting the images HA and HB on the plane of the exit pupil protrude outwards from the exit pupil (Hereinafter, an aperture corresponding to the outer perimeter of these projected images will be referred to as "critical aperture".), a beam of light rays from a region A1′ and a beam of light rays from a region An′ fall respectively on the light receiving element A1 and the light receiving element An and, as is clear from FIG. **2**, A1′>An′. On the other hand, the light receiving elements B1 and Bn receive a beam of light rays from a region B1′ and that from a region Bn′ and B1′<Bn′. If, for the purpose of simplification, the brightness of a target object to which the distance is desired to be measured is uniform, outputs from the light receiving elements Ai and Bi vary in a manner as shown in FIG. **3**, and therefore it is not possible to determine the accurate correlation in phase difference between these outputs from the light receiving elements. In other words, where the full aperture is smaller than the critical aperture, even if data concerning the amount of deviation of the position, where the image of the target object is formed, relative to the position of an expected focus are obtained from these outputs, the result would be an erroneous detection of the focused condition. A similar description may equally apply even where the point H and the exit pupil are reversed in position with respect to each other.

As has been explained above, the optical system is of a nature that a required focus detection may not be correctly carried out when the fully open aperture size of an attached interchangeable objective lens is smaller than a predetermined size. According to the above explanation, it is believed that the reason why the improvement made by the present invention in adopting the optical system in the embodiment is needed is fully understood.

Although the present invention has been fully described with reference to a preferred embodiment, many modifications and variations thereof will now be apparent to those skilled in the art, and the scope of the present invention is therefore to be limited not by the details of the preferred embodiment described above, but only by the terms of appended claims.

What is claimed is:

1. In a camera system capable of focus detection by means of receiving light through an interchangeable objective lens, a camera body and an interchangeable

objective lens selectively attachable to the camera body comprising:

an opening, located in the camera body for detachably connecting with the interchangeable objective lens;

means, located in the camera body, for receiving light through the opening to produce electric signals;

means, located in the camera body, for processing the electric signals to generate a defocusing information indicative of defocusing degree and defocusing direction relative to an ideal focal plane;

means, located in the camera body, for generating a driving power for automatic focus control, including a first movable member;

means, located in the camera body, for accepting digital data to be transmitted from the interchangeable objective lens, the digital data including a converting information necessary to convert the defocusing degree of the defocusing information into a degree of movement of the first movable member;

means, located in the camera body, for calculating the degree of movement of the first movable member in response to the defocusing degree of the defocusing information and the converting information;

means, located in the camera body, for controlling the generating means to move the first movable member in response to the defocusing direction of the defocusing information and the calculated degree of movement;

means, located in the camera body, for transmitting the driving power of the generating means to the interchangeable objective lens, the transmitting means including a second movable member connectable with the interchangeable objective lens and responsive to the movement of the first movable member;

an optical system, located in the interchangeable objective lens, for forming an image of an object;

means, located in the interchangeable objective lens, for adjusting the focus of the optical system, the adjusting means including a third movable member connectable with the second movable member for a coupled movement therewith;

a read only memory, located in the objective lens, for storing various digital data at a plurality of addresses, the stored digital data including the converting information;

means, located in the interchangeable objective lens, for selectively designating one of the addresses of the read only memory; and

means for sending digital data stored in the designated address to the accepting means,

wherein the converting information is formed as a digital data composed of m-bit of significant digits part and n-bit of floating point coefficient part.

2. The invention of claim 1, further comprising means, located in the interchangeable objective lens, for varying the focal length of the optical system, means, located in the interchangeable objective lens, for classifying the focal length actually determined by the varying means into one of a plurality of prepared focal length zones to indicate a specific focal length zone to which the determined focal length belongs, wherein the designating means is responsive to the classifying means to designate an address corresponding to the indicated focal length zone, and the read only memory includes, in a plurality of respective addresses, a plurality of converting informations corresponding to the plurality of focal length zones, each of the converting informations being representative of focal lengths in each focal length zone with a value of causing an approximately minimum degree of movement in the first movable member within each focal length zone.

3. The invention of claim 1, further comprising means, located in the camera body, for providing a supplemental converting data to convert the degree of movement of the second movable member into that of the first movable member, wherein the converting information stored in the read only memory includes a data for converting the defocusing degree of the defocusing information into the degree of movement of the third movable member which is to be coupled with the second movable member in its movement, and the calculating means is further responsive to supplemental converting data in calculating the degree of movement of the first movable member.

4. The invention of claim 1, wherein the digital data stored in the read only memory includes a direction information indicative of the relation between the defocusing direction and the direction of the movement of the first movable member, and the controlling means includes means for determining the direction of movement of the first movable member in response to the defocusing direction of the defocusing information and the direction information accepted by the accepting means.

5. The invention of claim 1, further comprising means, located in the camera body, for inhibiting the camera body from automatically controlling the focus of the interchangeable objective lens, in response to the accepting means.

6. The invention of claim 5, wherein the receiving means includes a pair of groups of photosensitive elements, the groups being each responsive to light coming through different two parts of exit pupil of the optical system, and the digital data includes a fully open aperture information indicative of a fully open aperture size of the optical system, and wherein the inhibiting means includes means for comparing the fully open aperture information accepted at the accepting means with a reference aperture information indicative of a minimum aperture size allowing the pair of groups of photosensitive elements to properly respond to light coming through the respective two different parts of the exit pupil, the carry out the inhibition with the fully open aperture size less than the minimum aperture size.

7. The invention of claim 6, wherein the digital data includes an auto-focus information indicating that the interchangeable objective lens has the third movable member to be coupled with the second movable member for automatic focus control, wherein the camera body further includes means for indicating the focus condition in response to the processing means, the indicating means being also subject to the comparing means to be disabled when the fully open aperture size is less than the minimum aperture size, and wherein the inhibiting means further includes means for carrying out the inhibition with the function of the indicating means maintained, when the accepting means fails to accept the auto-focus information.

8. The invention of claim 5, wherein the digital data includes a check data for certifying that the interchangeable objective lens is correctly connected to the camera body by means of successful acceptance of the

check data by the accepting means, and wherein the inhibiting means includes means for carrying out the inhibition when the accepting means fails to accept the check data.

9. The invention of claim **5**, wherein the interchangeable objective lens further includes means for bringing the optical system into a macro-photography condition, the designating means being responsive to the bringing means for designating an address relating to the macro-photography condition, and the digital data includes a macro-photography information stored at the address, the macro-photography information indicating that the interchangeable objective lens is in the macro-photography condition, and wherein the camera body further includes means for indicating the focus condition in response to the processing means and the inhibiting means includes means for carrying out the inhibition with the function of the indicating means maintained, when the accepting means accepts the macro-photography information.

10. The invention of claim **1**, further comprising means, located in the camera body, for producing a train of clock pulses, and means located in the interchangeable objective leans, for introducing the clock pulses into the interchangeable objective lens, wherein the designating means includes means for making address data in response to the clock pulses, and the sending means includes means for serially forwarding the digital data under the control of the clock pulses.

11. In a camera system capable of focus detection by means of receiving light through an interchangeable objective lens, an interchangeable objective lens attachable to a camera body, comprising:

an optical system for forming an image of an object;

means for adjusting the focus of the optical system, the adjusting means including a movable member under a control of the camera body;

a read only memory for storing various digital data at a plurality of addresses, the stored digital data including a converting information necessary for the camera body to control the movable member in accordance with a result of the focus detection;

means for selectively designating one of the addresses of the read only memory; and

means for sending data stored in the designated address to the camera body,

wherein the converting information is formed as a digital data composed of m-bit of significant digits part and n-bit of floating point coefficient part.

12. The invention of claim **11** further comprising means for introducing a train of clock pulses from the camera body into the interchangeable objective lens, wherein the designating means includes means for making address data in response to the clock pulses, and the sending means includes means for serially forwarding the digital data under the control of the clock pulses.

13. In a camera system capable of focus detection by means of receiving light through an interchangeable objective lens, an interchangeable objective lens attachable to a camera body, comprising:

an optical system for forming an image of an object;

means for adjusting the focus of the optical system, the adjusting means including a movable member under a control of the camera body;

means for varying the focal length of the optical system;

means for classifying the focal length actually determined by the varying means into one of a plurality of prepared focal length zones to indicate a specific focal length zone to which the determined focal length belongs;

a read only memory for storing various digital data at a plurality of addresses, the stored digital data including, in a plurality of respective addresses, a plurality of converting informations necessary for the camera body to control the movable member in accordance with a result of the focus detection, the plurality of converting informations corresponding to the plurality of focal length zones so that each of the converting informations is representative of focal lengths in each focal length zone with a value of causing an approximately minimum degree of movement of the movable member within each focal length zone;

means for selectively designating one of the addresses of the read only memory corresponding to the indicated focal length zone in response to the classifying means; and

means for sending data stored in the designated address to the camera body.

14. The invention of claim **13** further comprising means for introducing a train of clock pulses from the camera body into the interchangeable objective lens, wherein the designating means includes means for making address data in response to the clock pulses, and the sending means includes means for serially forwarding the digital data under the control of the clock pulses.

15. In a camera system capable of focus detection by means of receiving light through an interchangeable objective lens, an interchangeable objective lens attachable to a camera body, comprising:

an optical system for forming an image of an object;

means for adjusting the focus of the optical system, the adjusting means including a movable member connectable with the camera body to receive a driving power of adjusting focus from the camera body;

a read only memory for storing various digital data at a plurality of addresses, the stored digital data including a converting information for converting a defocusing degree of the optical system into the degree of movement of the movable member;

means for selectively designating one of the addresses of the read only memory; and

means for sending data stored in the designated address to the camera body.

16. The invention of claim **15** further comprising means for introducing a train of clock pulses from the camera body into the interchangeable objective lens, wherein the designating means includes means for making address data in response to the clock pulses, and the sending means includes means for serially forwarding the digital data under the control of the clock pulses.

17. In a camera system capable of focus detection by means of receiving light through an interchangeable objective lens, a camera body connectable with an interchangeable objective lens, comprising:

an opening for detachably connecting with the interchangeable objective lens;

means for receiving light through the opening to produce electric signals;

means for processing the electric signals to generate a defocusing information indicative of defocusing degree and defocusing direction relative to an ideal focal plane;

means for generating a driving power for automatic focus control, including a first movable member;

means for transmitting the driving power of the generating means to the interchangeable objective lens, the transmitting means including a second movable member connectable with the interchangeable objective lens and responsive to the movement of the first movable member;

means for accepting digital data to be transmitted from the interchangeable objective lens, the digital data including a converting information for converting the defocusing degree of the defocusing information into a degree of movement of the second movable member;

means for providing a supplemental converting data to convert the degree of movement of the second movable member into that of the first movable member;

means for calculating the degree of movement of the first movable member in response to the defocusing degree of the defocusing information, the converting information and supplemental converting data; and

means for controlling the generating means to move the first movable member in response to the defocusing direction of the defocusing information and the calculated degree of movement.

18. In a camera system capable of focus detection by means of receiving light through an interchangeable objective lens, an interchangeable objective lens attachable to a camera body, comprising;

an optical system for forming an image of an object;

means for adjusting the focus of the optical system, the adjusting means including a movable member connectable with the camera body to receive a driving power of adjusting focus from the camera body;

a read only memory for storing various digital data at a plurality of addresses, the stored digital data including a converting information necessary for the camera body to control the movable member in accordance with a result of the focusing detection, and a direction information necessary for the camera body to determine the direction to drive the movable member in accordance with a result of the focusing detection;

means for selectively designating one of the addresses of the read only memory; and

means for sending data stored in the designated address to the camera body.

19. The invention of claim **18** further comprising means for introducing a train of clock pulses from the camera body into the interchangeable objective lens, wherein the designating means includes means for making address data in response to the clock pulses, and the sending means includes means for serially forwarding the digital data under the control of the clock pulses.

20. In a camera system capable of focus detection by means of receiving light through an interchangeable objective lens, a camera body connectable with an interchangeable objective lens, comprising:

an opening for detachably connecting with the interchangeable objective lens;

means for receiving light through the opening to produce electric signals;

means for processing the electric signals to generate a defocusing information indicative of defocusing degree and defocusing direction relative to an ideal focal plane;

means for generating a driving power for automatic focus control, including a first movable member;

means for transmitting the driving power of the generating means to the interchangeable objective lens, the transmitting means including a second movable member connectable with the interchangeable objective lens and responsive to the movement of the first movable member;

means for accepting digital data to be transmitted from the interchangeable objective lens, the digital data including a converting information necessary to convert the defocusing degree of the defocusing information into a degree of movement of the first movable member, and a direction information indicative of the relation between the defocusing direction and the direction of the movement of the first movable member;

means for calculating the degree of movement of the first movable member in response to the defocusing degree of the defocusing information and the converting information;

means for determining the direction of movement of the first movable member in response to the defocusing direction of the defocusing information and the direction information; and

means for controlling the generating means to move the first movable member in response to the calculating means and the determining means.

21. In a camera system capable of focus detection by means of receiving light through an interchangeable objective lens, a camera body connectable with an interchangeable objective lens, comprising:

an opening for detachably connecting with the interchangeable objective lens;

means for receiving light through the opening to produce electric signals, including a pair of photosensitive devices, the devices being each responsive to light coming through different two parts of exit pupil of the interchangeable objective lens;

means for processing the electric signals to generate a defocusing information with respect to an ideal focal plane;

means for accepting from the interchangeable objective lens an information of a fully open aperture size thereof;

means for controlling the receiving means and the processing means to inform of the result of focus detection in response to the defocusing information;

means for comparing the informed fully open aperture size of the interchangeable objective lens with a reference aperture size which is the minimum allowing the pair of photosensitive devices to properly respond to light coming through the respective two different parts of the exit pupil; and

means for inhibiting the controlling means from informing of the result of focus detection when the informed fully open aperture size is less than the reference aperture size.

22. The invention of claim **21**, further comprising means responsive to the controlling means for generating a control power to be transmitted to the interchangeable objective lens for automatic focus control, and means responsive to the controlling means for indicating the focus condition, wherein the information of a fully open aperture size is a form of digital data and the

accepting means is further capable of accepting an auto-focus information as a form of digital data from the interchangeable objective lens, the auto-focus information indicating whether or not the interchangeable objective lens is capable of automatic focus adjustment in response to the control power from the camera body, and wherein the camera body further includes means for governing the controlling means to inhibit the generating means from responding to the controlling means with the responsibility of the indicating means to the controlling means maintained, when the accepting means fails to accept the auto-focus information indicating that the interchangeable objective lens is capable of auto-focus adjustment.

23. In a camera system capable of focus detection by means of receiving light through an interchangeable objective lens, an interchangeable objective lens attachable to a camera body, comprising:

an optical system for forming an image of an object;

means for adjusting the focus of the optical system, the adjusting means including a movable member under a control of the camera body;

a read only memory for storing various digital data at a plurality of addresses, the stored digital data including a fully open aperture information indicative of a fully open aperture size of the optical system, and an auto-focus information indicating that the interchangeable objective lens has the movable member for automatic focus adjustment;

means for selectively designating one of the addresses of the read only memory; and

means for sending data stored in the designated address to the camera body.

24. The invention of claim **23** further comprising means for introducing a train of clock pulses from the camera body into the interchangeable objective lens, wherein the designating means includes means for making address data in response to the clock pulses, and the sending means includes means for serially forwarding the digital data under the control of the clock pulses.

25. In a camera system capable of focus detection by means of receiving light through an interchangeable objective lens, an interchangeable objective lens attachable to a camera body, comprising:

an optical system for forming an image of an object;

means for adjusting the focus of the optical system;

a read only memory for storing various digital data at a plurality of addresses, the stored digital data including a fully open aperture information indicative of a fully open aperture size of the optical system, and an auto-focus information indicating that the interchangeable objective lens has no means for automatically adjusting focus under the control of the camera body;

means for selectively designating one of the addresses of the read only memory; and

means for sending data stored in the designated address to the camera body.

26. The invention of claim **25** further comprising means for introducing a train of clock pulses from the camera body into the interchangeable objective lens, wherein the designating means includes means for making address data in response to the clock pulses, and the sending means includes means for serially forwarding the digital data under the control of the clock pulses.

27. In a camera system capable of focus detection by means of receiving light through an interchangeable objective lens, an interchangeable objective lens attachable to a camera body, comprising:

an optical system for forming an image of an object;

means for adjusting the focus of the optical system, the adjusting means including a movable member under a control of the camera body;

means for bringing the optical system into a macro-photography condition;

a read only memory for storing various digital data at a plurality of addresses, the stored digital data including a macro-photography information indicating that the interchangeable objective lens is in the macro-photography condition;

means for selectively designating one of the addresses of the read only memory, the designating means being responsive to the bringing means for designating an address at which the marco-photography information is stored; and

means for sending data stored in the designated addresses to the camera body.

28. The invention of claim **27** further comprising means for introducing train of clock pulses from the camera body into the interchangeable objective lens, wherein the designating means includes means for making address data in response to the clock pulses, and the sending means includes means for serially forwarding the digital data under the control of the clock pulses.

29. In a camera system capable of focus detection by means of receiving light through an interchangeable objective lens, a camera body connectable with an interchangeable objective lens, comprising:

an opening for detachably connecting with the interchangeable objective lens;

means for receiving light through the opening to produce electric signals;

means for processing the electric signals to generate a defocusing information with respect to an ideal focal plane;

means for accepting digital data to be transmitted from the interchangeable objective lens, the digital data including a macro-photography information indicating that the interchangeable objective lens is in a macro-photography condition;

means for controlling the receiving means and the processing means to inform of the result of focus detection in response to the defocusing information;

means responsive to the controlling means for generating a control power to be transmitted to the interchangeable objective lens for automatic focus control;

means responsive to the controlling means for indicating the focus condition; and

means for governing the controlling means to inhibit the generating means from responding to the controlling means with the responsibility of the indicating means to the controlling means maintained, when the accepting means accepts the macro-photography information.

30. In a camera system capable of focus detection by means of receiving light through an interchangeable objective lens, a camera body connectable with an interchangeable objective lens, comprising:

an opening for detachably connecting with the interchangeable objective lens;

means for receiving light through the opening to produce electric signals;

means for processing the electric signals to generate a defocusing information with respect to an ideal focal plane;

means for accepting digital data to be transmitted from the interchangeable objective lens, the digital data including a check data for certifying that the interchangeable objective lens is correctly connected to the camera body by means of successful acceptance of the check data by the accepting means;

means for controlling the receiving means and the processing means to inform of the result of focus detection in response to the defocusing information; and

means for inhibiting the controlling means from informing the result of focus detection when the accepting means fails to accept the check data.

[57] **ABSTRACT**

In a telephoto objective, a positive lens group and a negative lens group closer to the image than the positive lens group move simultaneously in axially opposite directions and relative to a stationary positive lens group which is closer to the image than both movable lens groups while the telephoto objective is being focused on an object. According to one embodiment of the invention, the diaphragm between the movable lens groups is varied in response to focusing so as to control the variation of the diameter of an on-axial light ray bundle.

TELEPHOTO OBJECTIVE

This application is a continuation of application Ser. No. 139,764, filed Apr. 14, 1980, now abandoned.

BACKGROUND OF THE INVENTION

This invention relates to objectives for telephoto lenses and more particularly, to telephoto objectives suitable for close-up photography.

Most photographic objectives are focused by moving their constitutent components as a single unit. However, it is possible to focus an objective by moving either its front component or its rear component. With selective use of proper power distribution, moving the front component to focus offers the advantage of reducing the range of movement for the moving component from the range of movement required when the objective as a whole is moved. However, the front component itself must be properly corrected for aberrations. Otherwise, the overall aberrations would tend to vary substantially during focusing. On the other hand, focusing with the rear member has the advantage of taking place in a space where the height of incidence of on-axial rays is small and facilitates minimization of the weight of the movable focusing component. Moreover, focusing with the rear member prevents variation of the overall length of the objective during focusing and results in little shift of the center of gravity.

The telephoto objective of U.S. Pat. No. 4,045,128 is focused by moving a sub-group within the objective rear group. However, as this sub-group is axially moved to focus down on shorter object distances, the focal length of the entire optical system becomes shorter. For this reason, the image magnification at the same object distance is lowered as compared with the other focusing provision made at the entire system or the front member. It is known to provide a telephoto objective with its rear group having two sub-groups arranged to be axially moved in opposite direction to each other to effect focusing down, as disclosed in U.S. Pat. No. 3,854,797. It is also known to provide a telephoto objective in which either one of the front group or the front sub-group of the rear group is made movable for focusing as disclosed in U.S. Pat. No. 4,113,357. However, these conventional telephoto objectives when assessed from the point of view of a valuable increase in the image magnification, are incapable of satisfying a sufficient picture performance. If focusing is effected down to unduly short object distances, there will be a high possiblity of calling for a great increase in the range of movement of the focusing member, an objectionable lowering of the picture taking quality, or a large increase in the bulk and size of the entire lens system.

We see again that the optical system of the type capable of close-up photography is made axially movable usually as a whole toward the front to effect focusing. In this case, the amount of forward movement of the optical system is related to the image magnification by the following formula (1)

$$\beta = -x'/f \tag{1}$$

and the relationship between the image magnification and the object distance may be expressed by the following formula (2)

$$\hat{g}_1 = -(1-1/\beta)f \tag{2}$$

where

β: the image magnification;

x': the amount of forward movement from the position for an infinitely distant object;

f: the focal length of the entire optical system; and

$\hat{g}_1$: the distance from the front principal plane of the optical system to an object being photographed.

Therefore, to achieve a desirable increase in the image magnification for the same amount of forward movement, the use of smaller values of f is advantageous. On the other hand, for the same image magnification, the object distance may become greater if f is increased. In practice, for example, when photographing a moving object such as an insect or where a great degree of freedom is needed in selecting the position of the main light source, the so-called working distance should be increased. With a 50 mm lens being used for taking a close-up photograph of $\beta = -0.5x$, the required values of forward movement and working distance are 25 mm and 150 mm respectively. With a 200 mm lens, they become 100 mm and 600 mm respectively. However, the increase in the working distance imposes the requirement of imparting a large amount of forward movement to the lens. This makes it necessary to elongate the axial length of the usual helicoid focus control, or to use long bellows. Moreover, as the image mangification is varied by readjusting the position of the lens, the resulting large amount of forward movement adversely affects the ease and speed of handling, and the way the camera is held must be adapted to cope with a large shift in the center of gravity.

SUMMARY OF THE INVENTION

A first object of the present invention is to achieve a valuable increase in the image magnification of a telephoto objective.

A second object is to shorten the minimum object distance.

A third object is to reduce the amounts of movement of two lens groups for focusing down to the shortest object distance.

A fourth object is to provide an image of an object at a short distance which is well corrected for spherical aberration and astigmatism.

A fifth object is to prevent lowering of the luminance at the marginal portions of the area of the picture frame and vignetting which would be otherwise resulted when the frontmost movable lens group is moved to the front.

A sixth object is to facilitate the increase of the image magnification by increasing the synthetic focal length of the entire system as two movable lens groups are moved from a position for an infinitely distant object to effect focusing down to shorter object distances.

A seventh object is to make easy and quick focus adjustment by lowering the sensitivity of a focusing control mechanism as when the lens system is focused on an object at infinity, from that occurring when focused on an object at shorter distances.

An eighth object is to regulate the effective on-axial pencil as its diameter varies with focusing.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1A is a lens block diagram of a first embodiment of a telephoto objective according to the present invention when focused on an infinitely distant object.

FIG. 1B is a similar view of the objective when focused for the unity of image magnification.

FIGS. 2A to 2G are graphic representations of the spherical aberration, sine condition, astigmatism, distortion and lateral aberrations of the objective of FIG. 1 when focused at infinity.

FIGS. 3A to 3G are graphic representations of the spherical aberration, sine condition, astigmatism, distortion, and lateral aberrations of the objective of FIG. 1 when focused for an image magnification of 0.1.

FIGS. 4A to 4G are graphic representations of the spherical aberration, sine condition, astigmatism, distortion and lateral aberrations of the objective of FIG. 1 when focused for an image magnification of 0.5.

FIGS. 5A to 5G are graphic representations of the spherical aberration, sine condition, astigmatism, distortion and lateral aberrations of the objective of FIG. 1 when focused for the magnification of unity.

FIG. 6A is a lens block diagram of a second embodiment of a telephoto objective according to the present invention when focused on an object at infinity.

FIG. 6B is a similar diagram of the objective when focused for an image magnification of 0.5.

FIGS. 7A to 7G are graphic representations of the sherical aberration, sine condition, astigmatism, distortion and lateral aberrations of the objective of FIG. 6 when focused at infinity.

FIGS. 8A to 8G are graphic representations of the spherical aberration, sine condition, astigmatism, distortion and lateral aberrations of the objective of FIG. 6 when focused for an image magnification of 0.1.

FIGS. 9A to 9G are graphic representations of the spherical aberration, sine condition, astigmatism, distortion and lateral aberrations of the objective of FIG. 6 when focused for an image magnification of 0.5.

FIG. 10A is a lens block diagram of a third embodiment of a telephoto objective according to the present invention when focused on an object at infinity.

FIG. 10B is a similar diagram of the objective when focused for an image magnification of 0.5.

FIG. 11A to 11G are graphic representations of the spherical aberration, sine condition, astigmatism, distortion and lateral aberrations of the objective of FIG. 10 when focused at infinity.

FIGS. 12A to 12G are graphic representations of the spherical aberration, sine condition, astigmatism, distortion and lateral aberrations of the objective of FIG. 10 when focused for an image magnification of 0.1.

FIGS. 13A to 13G are graphic representations of the spherical aberration, sine condition, astigmatism, distortion and lateral aberrations of the objective of FIG. 10 when focused for an image magnification of 0.5.

FIGS. 14 to 16 are plan views of cam sleeves for moving the lens groups in a telephoto objective embodying features of the invention.

FIGS. 17 and 18 are lens diagrams illustrating the effect of the groups of lenses on pencil rays entering the lenses.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

FIGS. 1A, 6A and 10A depict three different examples of telephoto objectives in a focusing position for an infinitely distant object. I is a first lens group having a positive refractive power and arranged on the object side to be axially movable for focusing; II is a second lens group having a negative refractive power and arranged in a middle position to be axially moved simultaneously with and in the opposite direction to the first lens group; and III is a stationary lens group having a positive refractive power and arranged on the image side. P indicates the surface of a photo-sensitive material. Again, a rearmost lens element in the movable first lens group I takes a meniscus form convex toward the front and plays a role in preventing the picture taking quality of the telephoto objective having a comparatively long focal length to be lowered during focusing.

On the other hand, FIG. 1B depicts a lens position occurring when focusing is effected down to such an object distance that the image magnification is unity, and FIGS. 6B and 10B depict positions of the respective telephoto objectives where the image magnification is 0.5. As shown in each pair of figures, as the object distance is decreased, the first movable lens group I is moved to the front, while the second movable lens group II is moved to the rear. In this connection it should be noted that it is preferred to make negative the synthetic focal length of the second movable lens group II and stationary lens group III regardless of the movement of the second movable lens group II.

For a long lens covering a range of from an infinitely distant shot to a close-up shot, it is desired that the ratio of the amount of movement S1 of the first movable lens group I to the amount of movement S2 of the second movable lens group satisfies a condition of $0.7<|S1|/|S2|<1.4$, and that a power distribution suited for it is employed.

When the upper limit of this inequality is exceeded, the excess movement of the first movable lens group causes the spherical aberration and astigmatism to be varied to very large extent, and the image quality to be deteriorated when in close-up photography. Further when in close-up photography, as the distance from the diaphragm to the first movable lens group I is increased, there will be a high possibility of occurrence of a large loss of the brightness in the marginal portion of the picture frame and of a mutilation of the pencil which is to reach the corners of the picture frame. On the other hand, when the lower limit of the inequality is exceeded, the excess movement of the second movable lens group II causes the synthetic focal length of the lens to be shortened when in close-up photography so that this contradicts the need of facilitating the close-up photography.

In general, the amount of forward movement of the focusing member is almost proportional to the image magnification. With the objective covering an extended range of image magnifications from an infinitely small value to as large as 0.5 or unity, therefore, if the focusing control mechanism is so constructed that the ratio of the angle of rotation of the focus adjusting ring to the sum of the distances through which the two movable lens groups are displaced is maintained constant throughout the focusing range, the focusing control in the region of ordinary photography will become so far sensitive that upon slight rotation of the focus adjusting ring, the object distance to which focusing is effected is largely changed, thus fine adjustment of focusing is made very difficult to perform.

To compensate this drawback, the cam grooves controlling the movement of the two movable lens groups may be configured so that the amounts of movement of the first and second movable lens groups relative to the angle of rotation of the focus adjusting ring differ be-

tween when in ordinary photography and when in close-up photography.

FIG. **14** depicts a development surface of the cam sleeve for the telephoto objective capable of focusing with the variation of image magnification from an infinitely small value to 0.5. In the figure, **C1** is a cam groove controlling the axial movement of the first movable lens group I, and **C2** is a cam groove controlling the axial movement of the second movable lens group II. Engaged in these cam grooves **C1** and **C2** are cam pins (not shown) radially extending from respective movable lens cells. The cam grooves **C1** and **C2** each have two sections of different gradient so that when in ordinary photography with an object at infinity or down to a moderate distance, the amount of movement of each movable lens goup I, II to a certain angle of rotation of the cam sleeve becomes smaller, and when in focusing to shorter object distances, the relative amount of movement of the movable lens group becomes larger.

Although the cam sleeve of FIG. **14** changes the gradient of the both cam grooves, a telephoto objective having a comparatively short focal length may take a different form of the cam sleeve as shown in FIG. **15** or FIG. **16** where either one of the cam grooves **C1** and **C2** is made to vary the gradient in two sections so that the rate of cam lift is varied therebetween.

According to the foregoing description, the cam grooves and the cam pins are used in combination so as to move the two movable lens groups. However, one of the movable lens groups which does not change in the movement amount may be moved by the inner and outer helicoids. Also in the case where both of the two movable lens groups are not changed in their movement amounts both groups may be moved by a helicoid.

Another subject of the present invention is that the variation with focusing of the effective pencil is made to correlate with the variation of the diaphragm aperture. In this connection it should be explained that since the relative position of the diaphragm to the film plane does not change and the first lens group is moved away from the diaphragm as in the embodiment of the present invention, the effective diameter of the first movable lens goup is required to be large enough to unchange the effective F-number even when closing up. In general, however, the demand for compactness of the lens and like reasons often lead to the impossibility of imparting a sufficiently large effective diameter into the first movable lens group. Although the focusing method of the present invention is less susceptible to that factor because the amount of movement of the first lens group is smaller than when the conventional focusing method of making movable the front member only is employed, as the maximum possible image magnification fication is increased, the additional amount of movement becomes impossible to ignore. As schematically shown in FIG. **17** and particularly FIG. **18**, the effective diameter of the first movable lens group regulates the on-axial maximum pencil so that the effective pencil at the diaphragm plane is smaller than the maximum diameter of the aperture. Therefore, a zone is created where the brightness remains unchanged despite the closing down of the diaphragm from the full aperture, and photographic situations where an inaccurate exposure control is resulted may be encountered. FIG. **17** shows the tracing of a ray of light which is admitted by the full aperture of the diaphragm when the lens system is focused at infinity. FIG. **18** shows the tracing of rays which are admitted by the effective diameter of the first movable lens group when focusing is effected down to a shorter object distance. If the diameter of the first movable lens group is so large that the actually admitted pencil passes along a dashed line, the F-number is not subject to change. When the first lens group is moved to the front, the effect is substantially the same as if the first lens group were edged down to so small a diameter that, as the oblique pencils which the diaphragm allows to pass at points between the dashed and solid lines of FIG. **18** define the limit of the field of view, the closing down of the diaphragm is no longer effective to adjust the brightness due to the on-axial pencil.

To avoid this, it is proposed to provide a mechanism M for adjusting the diameter of the full aperture in response to the focusing ring R. With such mechanism, when focusing is performed, the diaphragm is automatically closed down to a diameter coincident with that of the effective pencil at the position of the diaphragm, thus preventing inconsistency between the actual aperture and the effective pencil when it nears the full one. It is noted that the diaphragm can be closed down to a desired F-number without the recourse to the mechanism M.

The provision of the above-described feature gives rise to an advantage that the compactness is facilitated by the reduction of the diameter of the first movable lens group. Another advantage is that the off-axial pencil can be taken off in portions to improve the picture taking quality.

To further facilitate the improvement of the picture taking quality, besides the diaphragm of regulating the F-number, use may be made of a second diaphragm arranged to be axially movable with focusing in such a manner that when the second lens group is moved to the front, this diaphragm is also moved to the front.

Taking one numerical example, the advantage of the present invention is clarified below. Letting **f1**, **f2** and **f3** denote the focal lengths of the first and second movable lens groups and the stationary lens group respectively, and **e1** and **e2** the intervals between the principal points of the first and second movable lens groups and between those of the movable second and stationary third lens groups, a telephoto objective in question is characterized by:

f1 = 119.33316	e1 = 42.8
f2 = −86.45656	e2 = 55.5
f3 = 143.29756	

We now set forth four different examples of ways in which the objective is focused down to shorter object distances as by (1) moving the first and the second lens groups I and II in opposite direction to each other, (2) bodily moving the entire lens system, (3) moving only the first lens group I to the front, and (4) moving only the second lens group II to the rear. For each of these ways, the focal length, f, object distance, g_1, and image magnification, β, have been evaluated in terms of the amount of movement, d, which are taken at two discrete values, and the results are listed in the following table.

d		1	2	3	4
10 mm	f	189.2	197.4	197.1	192.0
	g_1	−885.3	−4095.6	−1618.6	−1614.3
	β	−0.272	−0.051	−0.139	−0.135
20 mm	f	173.1	197.4	196.7	182.2

-continued

d	1	2	3	4
g_1	−496.0	−2146.5	−906.2	−866.6
β	−0.536	−0.101	−0.277	−0.266

It will be seen from the table that the amount of movement of the focusing lens necessary to effect production of an equivalent image magnification is far smaller in the present invention. Further, the amount of variation of the focal length with the production of an equivalent image magnification when in the focusing method (1) takes an intermediate value between those when in the methods (3) and (4). That is, according to the present invention, an elongation of the focal length and an increase of the image magnification can be achieved by a decreased amount of movement, and the shift of the center of gravity during focusing is made smaller next to the method of moving the second lens group to the rear.

Three examples of specific telephoto objectives may be constructed in accordance with the numerical data given below for the radii of curvature, R, the axial thicknesses and separations, D, along with the Abbe numbers, νd, and the indices of refraction, Nd, for the various lens elements. The focal length is normalized to 100 mm.

What is claimed is:

1. A telephoto objective comprising:
a first axially movable lens group having a positive refractive power;
a second axially movable lens group positioned on the image side of said movable first lens group and having a negative refractive power; and
a fixed lens group positioned on the image side of said movable second lens group and having a positive refractive power;
said first and said second movable lens groups being arranged to be moved simultaneously in opposite axial directions to focus the telephoto objective on an object and when focused at an infinite distance the distance between the first axially movable lens group and the second axially movable lens group being smaller than the distance between the second axially movable lens group and the fixed lens group.

2. A telephoto objective as in claim 1 in that the relationship

$$0.7<|S_1|/|S_2|<1.4$$

is satisfied, wherein S_1 and S_2 are the amounts of movement of said first and second lens group respectively when focusing.

3. A telephoto objective as in claim 1, further including:
a first focusing path for moving said first movable lens group and controlling the amount of movement thereof;
a second focusing path for moving said second movable lens group and controlling the amount of movement thereof; and
drive means for driving said first and said second focusing paths so as to cause the paths to move said first and second movable lens groups;
at least one of said first and said second focusing paths being configured so that the amount of movement of the movable lens group varies as said drive means moves a given amount.

4. A telephoto objective as described in claim 3, wherein each of said first and said second focusing paths is a bent-on-the-way linear focusing groove.

5. A telephoto objective as in claim 1, wherein the objective has a front for facing an object and a rear for facing an image and a plurality of lens elements, and said movable first lens group has a single negative meniscus lens convex toward the front and located separately after at least two lens elements from the front.

6. A telephoto objective according to claim 1, in which the first axially movable lens comprises at least two positive lens elements and one negative lens element as well as a rearmost meniscus lens element with a convex surface directed toward the object.

7. A telephoto objective according to claim 6, in which the meniscus lens element has a weak negative refractive power.

8. A telephoto objective according to claim 6, which when focused at an infinite distance the distance between the first axially movable lens group and the second axially movable lens group is larger than the distance between the meniscus lens element and other lens elements in the first axially movable lens group.

9. A telephoto objective comprising:
a first axially movable lens group having a positive refractive power;
a second axially movable lens group positioned on the image side of said movable first lens group and having a negative refractive power; and
a fixed lens group positioned on the image side of said movable second lens group and having a positive refractive power;
said first and said second movable lens group being arranged to be moved simultaneously in opposite axial directions to focus the telephoto objective on an object and when focused at an infinite distance the distance between the first axially movable lens group and the second axially movable lens group being smaller than the distance between the second axially movable lens group and the fixed lens group;
control means for driving each of said first and said second movable lens group to move said first and second movable lens groups and for controlling the amount of movement thereof; and
a diaphram positioned in a space between said movable second and said fixed lens groups and cooperative with said control means to limit light rays passing therethrough in response to focusing.

10. A telephoto objective comprising:
a first axially movable lens group having a positive refractive power;
a second axially movable lens group positioned on the image side of said movable first lens group and having a negative refractive power; and
a fixed lens group postioned on the image side of said movable second lens group and having a positive refractive power;
said first and said second movable lens group being arranged to be moved simultaneously in opposite axial directions to focus the telephoto objective on the object;
the relationship $0.7<|S_1|/|S_2|<1.4$ being satisfied, where S_1 and S_2 are the amounts of movement of said first and said second lens groups respectively when focusing for photography with a magnification ratio not less than 0.5.

11. A telephoto objective comprising:
a movable first lens group axially movable for focusing and having a positive refractive power;
a movable second lens group on the image side of said first lens group, axially movable for focusing the objective, and having a negative refractive power; and
a fixed lens group on the image side of said second lens group and having a positive refractive power, and satisfying the following data:

Focal Length f = 100 Image Angle 2ω = 12.35°
F-number = 1:4.0 Magnification β = 0.~−1.0X

[57] **ABSTRACT**

An interchangeable objective with a variable lens aperture for a photographic camera has a stationary support member and a diaphragm-operating member that is rotatable about an axis between first and second angular positions relative to the stationary support member. A first spring-loaded locking pin is located in the stationary member in a first plane perpendicular to the axis. A second spring-loaded locking pin is located in the stationary member circumferentially spaced at an angle to the first pin about the axis and in a second plane perpendicular to the axis. The second plane is spaced from the first plane in the direction of the axis. As a result, the distance between locking pins is greater than the angular distance of rotation of the diaphragm-operating member between the end of the M-range and the A-position. A locking groove is formed in the diaphragm-operating member so as alternatively to receive the first and second spring-loaded pins in locking engagement when the diaphragm-operating member is positioned at the first and second angular positions, respectively. An unlocking button is mounted in the diaphragm-operating member over the locking groove to push the respective first and second pins out of engagement with the locking groove upon depression of the unlocking button.

ROTATION CONTROL MECHANISM FOR DIAPHRAM-OPERATING RING IN INTERCHANGEABLE OBJECTIVE FOR PHOTOGRAPHIC CAMERA

CROSS REFERENCE TO RELATED APPLICATIONS

This application is related to application Ser. No. 520,723, filed on even date herewith by Yoshihiro Hama, the disclosure of which is incorporated fully herein by reference.

BACKGROUND OF THE INVENTION

The present invention relates to an interchangeable objective provided with a diaphragm-operating ring which is rotatable between a rotatable range for diaphragm preset and a position for automatic diaphragm regulation and, more particularly, to a rotation control mechanism in such a ring for changeover between the rotatable range for diaphragm preset and the position for automatic diaphragm regulation.

A photographic camera of automatic exposure control type conventionally has a diaphragm priority mode in which a diaphragm value is preset by the user and a shutter speed for appropriate exposure is automatically regulated in the camera body, a shutter speed priority mode in which, inversely, a shutter speed is manually preset by the user and a lens aperture for appropriate exposure is automatically regulated, and a programmed mode in which a combination of diaphragm value and shutter speed is automatically regulated for appropriate exposure.

Interchangeable objectives used with a photographic camera adopting said three modes of automatic exposure control function or different exposure control functions must include a diaphragm-operating ring provided with a rotatable range for manually presetting the diaphragm value (referred to hereinafter as M-range) in said diaphragm priority mode and a position for automatic diaphragm regulation (referred to hereinafter as A-position) in said shutter speed priority mode and said programmed mode. Information as to whether the diaphragm-operating ring occupies the M-range or the A-position must be transferred to the camera body because different exposure control mechanisms are activated in these two cases.

Any unintentional changeover between the M-range and the A-position must be reliably prevented and, in consequence, a suitable changeover locking mechanism and unlocking mechanism are required. However, the structure peculiar to the lens barrel has made it difficult to obtain a large rotation angle for changeover between the end of the M-range and the A-position. This has given rise to various problems with respect not only to the strength of the objectives but also to the degree of freedom for their design.

SUMMARY OF THE INVENTION

According to the invention, a small rotation angle between the end of the M-range and the A-position is achieved comprising the strength of the objective or the degree of design freedom.

Specifically, an interchangeable objective with a variable lens aperture for a photographic camera has a stationary support member and a diaphragm-operating member that is rotatable about an axis between first and second angular positions relative to the stationary support member. A first spring-loaded locking pin is located in the stationary member in a first plane perpendicular to the axis. A second spring-loaded locking pin is located in the stationary member circumferentially spaced at an angle to the first pin about the axis and in a second plane perpendicular to the axis. The second plane is spaced from the first plane in the direction of the axis. As a result, the distance between locking pins is greater than the angular distance of rotation of the diaphragm-operating member between the end of the M-range and the A-position. A locking groove is formed in the diaphragm-operating member so as alternatively to receive the first and second spring-loaded pins in locking engagement when the diaphragm-operating member is positioned at the first and second angular positions, respectively. An unlocking button is mounted in the diaphragm-operating member over the locking groove to push the respective first and second pins out of engagement with the locking groove upon depression of the unlocking button.

BRIEF DESCRIPTION OF THE DRAWINGS

The features of specific embodiments of the best mode contemplated of carrying out the invention are illustrated in the drawings, in which:

FIG. **1** is a rear view of an objective's barrel showing by way of example how the M-range and the A-position of a diaphragm-operating ring are arranged;

FIG. **2** is a section taken along the line II—II in FIG. **1**, showing the objective's barrel of FIG. **1** as mounted onto a camera body;

FIG. **3** is a section showing the pertinent part of the prior art mechanism for changeover between the M-range and the A-position;

FIG. **4** is a section showing the pertinent part of the mechanism in an embodiment of the present invention;

FIG. **5** is a view of part of a diaphragm-operating ring as seen in the direction of an arrow V in FIG. **4**;

FIG. **6** is a front view showing the pertinent part of the diaphragm-operating ring;

FIG. **7** is a view of part of the diaphragm-operating ring as seen in the direction of an arrow VII in FIG. **6**;

FIGS. **8** through **10** show the diaphragm-operating ring in the lens barrel as held at the minimum lens aperture position within the M-range, FIG. **8** being a section of the pertinent part, FIG. **9** being a partial view as seen in the direction of an arrow IX in FIG. **8**, and FIG. **10** being a section taken along the line X—X in FIG. **8**;

FIGS. **11** through **13** show the diaphragm-operating ring in the lens barrel as held at the A-position, FIG. **11** being a section of the pertinent part, FIG. **12** being a partial view as seen in the direction of an arrow XII in FIG. **11** and FIG. **13** being a section taken along the line XIII—XIII in FIG. **11**;

FIG. **14** is a section showing the pertinent part of another embodiment of the present invention;

FIG. **15** is a partial view as seen in the direction of an arrow XV in FIG. **14**; and

FIG. **16** is a section showing the pertinent part of further another embodiment of the present invention.

DETAILED DESCRIPTION OF THE SPECIFIC EMBODIMENTS

In FIGS. **1** through **3**, which describe prior art, a mount ring **2** is integrally connected by screws **3** to a stationary mount support ring so that this mount ring **2** is detachably engaged into a mount ring **4** provided on

the camera body B. A diaphragm-operating ring **5** is rotatably mounted around the outer periphery of the mount support ring **1** and a diaphragm-rotating ring **6** adapted to be rotated integrally with this diaphragm-operating ring **5** is rotatably supported between said mount support ring **1** and the mount ring **2**. The diaphragm-rotating ring **6** is provided with a diaphragm information transferring lever **7** projecting from a part of said diaphragm-rotating ring **6** and this diaphragm information transferring lever **7** extends through a circular arc notch **8** of the mount ring **2** toward the camera body B and engages with a diaphragm information receiving lever **9** provided within the camera body. The diaphragm information receiving lever **9** is operatively associated with a variable resistor (not shown) of an automatic exposure control circuit and generates an electric signal corresponding to the angular position of the diaphragm-operating ring **5**. As represented in FIG. **1**, the following information is given to the camera body: (1) whether diaphragm information transferring lever **7** lies within the M-range, i.e., the diaphragm preset, or on the A-position, and (2) what diaphragm value is assumed by said diaphragm information transferring lever **7** within the M-range.

Referring to FIG. **3** showing by way of example the well known changeover mechanism for changing over between the M-range and the A-position, the mount support ring **1** is provided at a position corresponding to one rotational end in the M-range (e.g., the minimum lens aperture) and at a position corresponding to the A-position with radially extending rotation control pins **10, 11** respectively, which are retractable and outwardly biased by compression coiled springs **10***a*, **11***a*, respectively. The diaphragm-operating ring **5** is provided in the inner surface with a locking groove **12** adapted to receive these rotation control pins **10, 11** and supports an unlocking button **13** adapted for inwardly displacing these pins **10, 11** against the biasing effect of said compression coiled springs **10***a*, **11***a*. Reference numeral **14** designates a tapered flank, i.e., a ramp, allowing rotation of the diaphragm-operating ring **5** within the M-range.

With such prior art changeover mechanism, it has been possible to assure good operation without any problem when the distance l between the rotation control pins **10, 11** (FIG. **1**), i.e., the rotation angle for changeover between the M-range and the A-position is large. However, when the distance l is small, various problems are created such as insufficient strength of the rotation control pins **10, 11** and a restricted degree of freedom for the design.

Accordingly, the present invention provides an interchangeable objective in which the angle for changeover between the M-range and the A-position can be effectively reduced. Specifically, the mount support ring is provided respectively at the position corresponding to the one rotational end within the M-range and at the position corresponding to the A-position with two rotation control pins which are displaceable in the direction of the optical axis. Both rotation control pins can be resiliently biased into the locking groove formed in the diaphragm-operating ring, and said two rotation control pins can be depressed by the single unlocking member out of said locking groove to its initial position.

First, a procedure for determining the rotation angle for changeover between the M-range and the A-position and reasons why this angle should be made relatively small will be explained on the basis of specific numerical data. The rotatable range of the diaphragm information transferring lever **7** is limited by angle θ_k (FIG. **1**) defined by the angle between each pair of adjacent claws **2***a* formed in the mount ring **2**. This angle θ_k depends on factors as following:

(1) number of the claws **2***a* formed in the mount ring **2**

The number of points necessary for definition of a plane is three and the number of the claws also is preferably three. Thus it is assumed here that three claws are formed in this embodiment.

(2) positions of the claws **2***a* in the mount ring **2**

These three claws **2***a* should be positioned at irregular intervals, which permits the mount ring to be received in the mount ring of the camera body at only one angular position. However, putting these claws at irregular intervals tends to bring the optical axes of the objective and the camera body out of mutual alignment. To meet these mutually contradictory requirements, the claws **2***a* are arranged at intervals of 130°, 115°, and 115°.

(3) operating angle for mounting or detaching of objective and angular dimension of the claws

The operating angle, i.e., the amount of rotation required for mounting the objective onto the camera body depends on the intervals at which the claws **2***a* are arranged. When the angular dimension of each claw on the objective corresponds to the angular dimension of each claw on the camera body, the angular dimension of the claw must be less than one half of said 130° or 115°, as the case may be. Accordingly, the operating angle for mounting or detaching the objective will be more than one-half or 130° or 115°, for example, 70° or 60°. The angular dimension of every claw will be 50° with an allowance of 5° for mounting the objective onto the camera body.

(4) angular dimension θ_k of the notch formed between the claws **2***a*

It is preferred that the diaphragm information transferring lever **7** is rotatable within a range as wide as possible. Thus, the notch **8** is formed between the pair of claws **2***a* which are arranged at an interval of 130°. The angle θ_k therefore corresponds to the interval between the claws minus the claw angular dimension, i.e., $130° - 50° = 80°$.

The diaphragm information transferring lever **7** has its rotatable range of 75° with an allowance of 2.5° (circumference length of 1 mm with a radius of 23 mm) toward the maximum lens aperture and the A-position, respectively.

Within such range, the angle θk over which the diaphragm information transferring lever **7** can be rotated from the minimum lens aperture in the M-range to the A-position depends further upon the factor mentioned in the following paragraph.

(5) angle θ_J of the diaphragm information transferring lever **7** itself

The diaphragm information transferring lever must have a sufficient strength for exact transfer of diaphragm information. When such requirement is satisfied by a transferring lever having a circumferential length of 4 mm with a radius of 23 mm, the angle θ_J is obtained by

$$\theta_J = \frac{4 \times 360°}{23 \times 2 \times \pi} = 10°$$

(6) number of steps n from the maximum lens aperture to the minimum lens aperture within the M-range

The exposure control circuit in the camera body receives the diaphragm information within the M-range as the number of steps from the maximum lens aperture to an actually used diaphragm value (five steps when the maximum lens aperture is 1.4 and the actually used diaphragm value is 8). There are 9.5 steps for an objective having a maximum lens aperture of 1.2 and a minimum lens aperture of 32, so that such objective must be able to accommodate 10 steps, i.e., $n=10$.

(7) rotation angle θ_M of the diaphragm information transferring lever 7 per unit diaphragm value

As the minimum unit of diaphragm information, $\frac{1}{3}$ step must be reliably transferred to the exposure control circuit. Assuming that this requirement is satisfied with a circumferential displacement of the variable resistor of 1 mm, said variable resistor having a radius of 28 mm, $\frac{1}{3}\theta_M$, the rotation angle corresponding to $\frac{1}{3}$ step is obtained by

$$\frac{1}{3}\theta_M = \frac{1 \times 360^\circ}{28 \times 2 \times \pi} = 2^\circ$$

Accordingly, the rotation angle θ_M of the diaphragm information transferring lever itself per unit diaphragm value is 6°.

(8) rotation angle θ_A of the diaphragm information transferring lever 7 from the minimum lens aperture to the A-position within the M-range

$\theta_A = 75^\circ - \theta_J - n\theta_M$.

This gives

$\theta_A = 75^\circ - 10^\circ - 10 \times 6^\circ = 5^\circ$.

Thus the rotation angle θ_A is limited to an angle as small as 5°. Assuming that, in the prior art mechanism as shown in FIG. **3**, the rotation control pins **10, 11** are formed with holes **10***b*, **11***b* respectively having diameters of 1.5 mm to receive the compression coiled springs **10***a*, **11***a*, respectively, said pins **10, 11**, must have diameters of at least 2 mm. With the diaphragm-operating **5** having an inner radius of 28 mm, and holes **10***c*, **11***c* adapted to receive the pins **10, 11**, respectively, which are 3 mm deep, the distance l between said holes **10***c* and **11***c* is obtained by

$$l = \frac{(28 - 3) \times 2 \times \pi}{360^\circ} \times 5 - 2 = 0.2 \text{ mm}$$

when θ_A is 5°. If θ_A is so limited to 5°, the distance between the holes **10***c* and **11***c* is 0.2 mm at the narrowest position. In consequence, there is a danger that these holes **10***c*, **11***c* formed in the mount support ring **1** might be destroyed, for example, as the user violently rotates the diaphragm-operating ring **5** when the objective is mounted on the camera body.

According to the present invention, the two rotation control pins **10, 11** are spaced from each other in the direction of the optical axis, as seen in FIGS. **4** and **5**, so as to give the mount support ring **1** sufficient strength, even when the angle θ_A is as small as mentioned above. Specifically, the mount support ring **1** is provided at positions circumferentially spaced from each other by an angular distance corresponding to the rotation angle for changeover between the M-range and the A-position set as above mentioned and by a distance S in the direction of the optical axis also with two radial pin guide holes **10***c*, **11***c* adapted to receive the associated rotation control pins **10, 11** which are, in turn, outwardly biased under action of the compression coiled springs **10***a*, **11***a*, respectively.

The diaphragm-operating ring **5** is provided along its inner peripheral surface with a locking groove **15** extending in the direction of the optical axis to receive said rotation control pins **10, 11**. This locking groove **15** is separated by a circumferential relief groove **16**, which is necessary for machining, into a groove portion **15***a* and a groove portion **15***b* adapted to receive said rotation control pin **10** and said rotation control pin **11**, respectively. There is formed a guide hole **18** radially extending through the diaphragm-operating ring **5** at the intersection of said locking groove **15** and said relief groove **16** for slidably guiding an unlocking button **17**, which is, in turn, provided at the bottom with an extension place **17***a* extending transverse to the unlocking button over the two rotation control pins and lying within the locking groove **15** so that the plate **17***a* may bear against the heads of said two rotation control pins **10, 11**, respectively.

The rotation control pins **10, 11** serve the same function previously mentioned in reference to the well known embodiment, to hold the diaphragm-operating ring **5** against one rotational end (the minimum lens aperture) in the M-range when the pin **10** is received in the locking groove portion **15***a* and to hold said diaphragm-locking operating ring at the A-position when the other pin **11** is received in the locking groove portion **15***b*. Said locking groove portion **15***a* is formed with a tapered flank **19** allowing rotation of the diaphragm-operating ring **5** toward the maximum lens aperture of the M-range.

As shown in FIG. **4**, there is provide a click-stop mechanism **20** between the diaphragm-operating ring **5** and the mount support ring **1**. In this mechanism, the diaphragm-operating ring **5** is provided in the inner peripheral surface with click-grooves **21***a* corresponding to diaphragm value graduations other than the minimum lens aperture, a click-groove **21***b* corresponding to the minimum lens aperture and a click groove **21***c* corresponding to the A-position graduation, while the mount support ring **1** is provided with a click-ball **23** adapted to be received in these click-grooves under a biasing effect of a compression coiled spring **22**. It will be understood that the rotation control pin **10** is received in the locking groove **15** when the click-ball **23** is received in the click-groove **21***b* and the rotation control pin **11** is received in the locking groove **15** when said click-ball **23** is received in the click-groove **21***c*. The mechanism by which the lens aperture is adjusted by rotation of the diaphragm-operating ring **5** is well known and constitutes no part of the present invention. Thus, such mechanism will not be described in detail.

With the interchangeable objective constructed according to the present invention as has been described above, the changeover from the M-range to the A-position can be achieved by depression of the unlocking button **17**. Such changeover from the M-range to the A-position never occurs so long as said unlocking button **17** is not depressed. When the diaphragm-operating ring **5** is rotated to the minimum lens aperture within the M-range, the rotation control pin **10** is received in the locking groove **15** (more specifically, the groove portion **15***a*) as seen in FIGS. **8** through **10**, and thereby

said diaphragm-operating ring **5** is prevented from being further rotated. For rotational adjustment to the A-position, the unlocking button **17** is depressed so as to retract the rotation control pin **10** out of the locking groove **15***a* and then the diaphragm-operating ring may be rotated to the A-position. Then the rotation control pin **11** is received in the locking groove **15** (more specifically, the groove portion **15***b*), and thereby the diaphragm-operating ring **5** is prevented from rotating toward the M-range (as seen in FIGS. **11** through **13**). Changeover from the A-position to the M-range can also be achieved by a similar operation.

The rotation control pins **10, 11** are spaced from each other in the direction of the optical axis according to the present invention, so that the mount support ring **1** maintains the desired strength even when there is available a very small rotation angle for changeover between the M-range and the A-position. Assuming that such rotation angle θ_A for changeover is 5° and the rotation control pins **10, 11** having diameters of 2 mm are spaced from each other by 3 mm center-to-center in the direction of the optical axis, while the diaphragm-operating ring **5** has its inner radius of 28 mm and the pin guide holes **10***c*, **11***c* are 3 mm deep, the minimum aceptable dimension l′ between these guide holes **10***c*, **11***c* is obtained by

$$l' = \sqrt{\left[\frac{(28-3)\times 2\times \pi}{360}\times 5\right]^2 + 3^2} - 2 = 1.7 \text{ mm.}$$

This value is sufficient to maintain the desired strength of the mount support ring **1**.

The embodiment as has been described hereinabove adopts formation of the tapered flank **19** on the diaphragm-operating ring **5**, and, for convenience in machining such tapered flank **19**, there is provided the circumferential relief groove **16**. However, said circumferential relief groove **16** is not necessary, as seen in FIGS. **14** and **15**, when the diaphragm-operating ring **5** including the grooves and flanks comprises a molded synthetic resin or a die cast piece. Biasing of the rotation control pins **10, 11** may be achieved also by, instead of the compression coiled springs, leaf springs **29, 30** fixed at one end by pins **27, 28** respectively, on the inner peripheral surface of the support ring **1** so that the free ends of said leaf springs **29, 30** depress against the lower end surfaces of the rotation control pins **10, 11** inserted into associated through-holes **25, 26** formed in the support ring **1**, as shown in FIG. **16**. It should be noted that the mount support ring **1**, in accordance with the present invention, is a non-rotatable, i.e., stationary, member adapted for support of the diaphragm-operating ring **5**.

The two rotation control pins used for changeover of the diaphragm-operating ring between the M-range and the A-position are speced from each other in the direction of the optical axis in accordance with the present invention. In this way, the supporting member for the diaphragm-operating ring, i.e., the mount support ring **1** can maintain the necessary strength even when the rotation angle for changeover is relatively small. Furthermore, the distance between these two rotation control pins as measured in the direction of the optical axis can be adjusted for every objective in consideration of factors such as the length of the diaphragm-operating ring as measured in the direction of the optical axis. The degree of freedom for design inclusive of dimensioning of the M-range is effectively improved.

What is claimed is:

1. An interchangeable objective with a variable lens aperture for a camera comprising:

a stationary support member;

a diaphragm-operating member rotatable about an axis between first and second angular positions relative to the stationary support member;

a first spring loaded locking pin located in the stationary member in a first plane perpendicular to the axis;

a second spring loaded locking pin located in the stationary member circumferentially spaced at an angle with the first pin about the axis and in a second plane perpendicular to the axis, the second plane being spaced from the first plane in the direction of the axis;

a locking groove formed in the diaphragm-operating member so as alternatively to receive the first and second locking pins in locking engagement when the diaphragm-operating member is positioned at the first and second angular positions, respectively; and

an unlocking button mounted in the diaphragm-operating member over the locking groove to push the respective first and second pins out of engagement with the locking groove upon depression of the unlocking button.

2. The interchangeable objective of claim **1**, in which the first and second locking pins lie retractably in respective first and second bores formed in the stationary member, coil springs biasing the respective locking pins toward the diaphragm-operating member.

3. The interchangeable objective of claim **1**, in which the first and second locking pins retractably lie in respective first and second bores formed in the support member, leaf springs biasing the respective pins toward the diaphragm-operating member.

4. The interchangeable objective of claim **1**, in which the locking groove extends parallel to the axis spanning the distance between the first and second planes and the unlocking button has an extension plate in the locking groove sufficiently long to alternatively engage the first and second pins when the first and second pins lie in the locking groove.

5. The interchangeable objective of claim **4**, in which the locking groove has a tapered flank on one side to permit the diaphragm-operating member to continue to rotate away from the second angular position when the locking groove receives the first locking pin, the first angular position representing one end of an M-range and the second angular position representing an A-position.

6. The interchangeable objective of claim **5**, additionally comprising a plurality of click-grooves on one member and a click-ball on the other member that individually engages the click-grooves in the M-range depending on the lens aperture.

[57] **ABSTRACT**

A compensating mechanism is provided on the leaf guide ring of a photographic objective for single-lens mirror reflex camera which opens to its largest value after a picture is taken in response to the hinge motion of the camera reflex mirror. The mechanism compensates for the advance of the diaphragm control lever on the camera side controlled by the reflex mirror.

6 Claims, 2 Drawing Figures

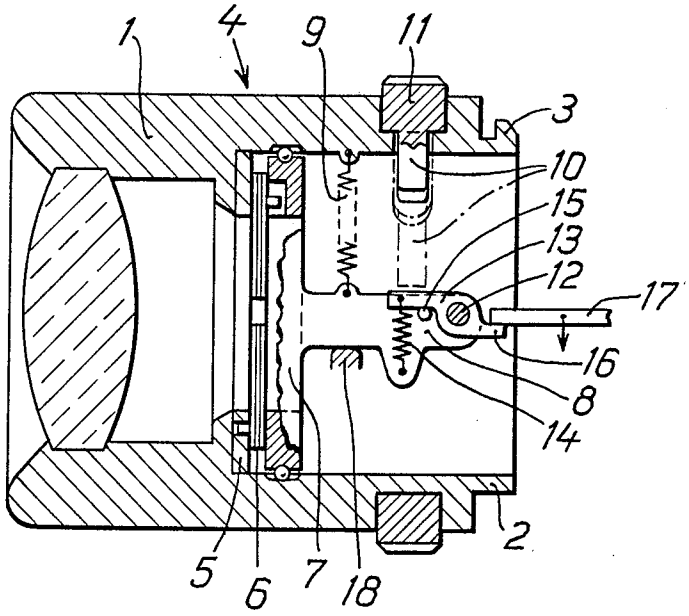

Fig. 1

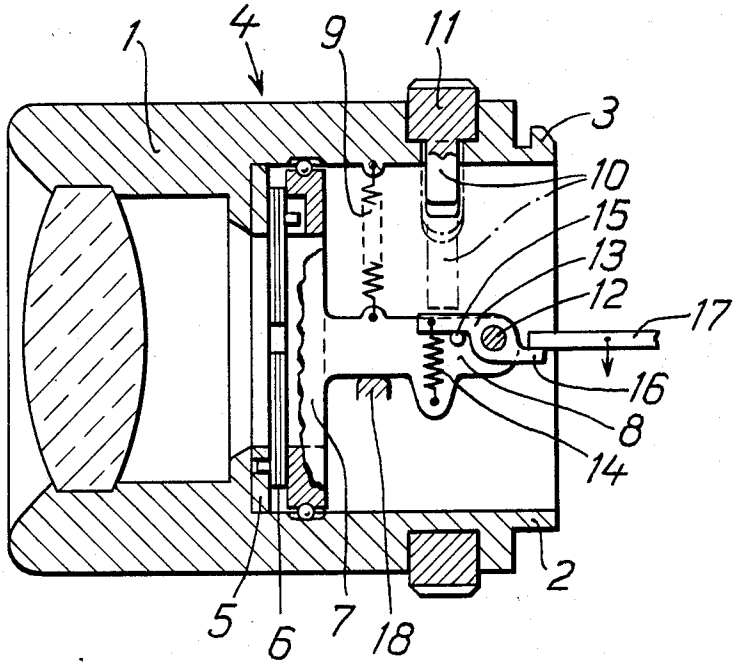

Fig. 2

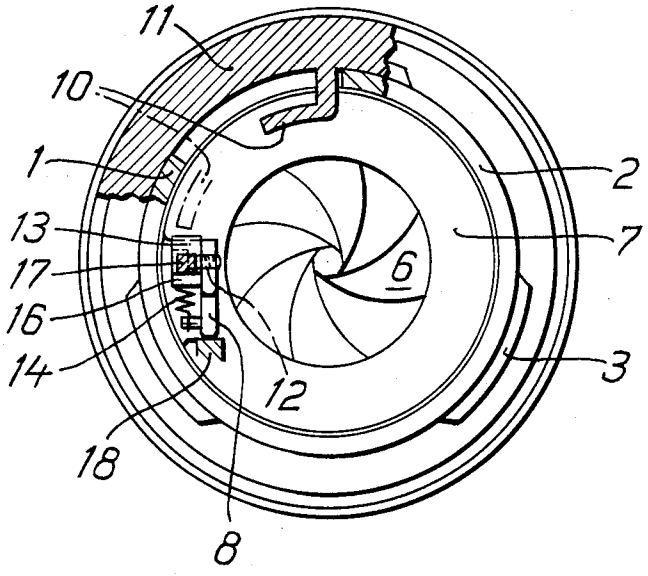

PHOTOGRAPHIC OBJECTIVE WITH AUTOMATIC DIAPHRAGM

BACKGROUND OF THE INVENTION

The present invention relates to a photographic objective for single-lens mirror reflex cameras with a preselector iris system and with an automatic diaphragm comprising a spacially fixed leaf support ring supporting the diaphragm leaves as well as a leaf guide ring rotatable relative to the leaf support ring, and wherein, after a picture is taken, the automatic diaphragm opens to its largest value depending on the hinge motion of the reflex mirror.

After a picture has been taken, the reflex mirror performs an advance, that is a motion larger than required for opening the diaphragm to the full value. The advance assures that the hinge motion of the reflex mirror is sufficient to reach the largest opening value of each objective employed with the mirror reflex camera. The advance has to be compensated for in order to avoid damage occurring in the region of the diaphragm.

In order to compensate for the advance, it is known to provide the guide grooves of the leaf guide ring such that, on one hand, they cause a rapid closing of the diaphragm and, on the other hand, they effect little or no further motion of the diaphragm leaves after the leaves reach the largest opening which could be achieved under control of the diaphragm lever on the side of the camera. Such overflow curves at guide grooves can only be realized with objectives having a short or average focusing length without resulting in disadvantages relative to delays in the closing of the diaphragm. In contrast, objectives with longer focusing lengths and with openings relatively large with respect to this are furnished with leaf guide rings. The guide grooves of the leaf guide rings in fact allow a rapid closing of the diaphragm before the start of the camera shutter operating cycle, but they permit a compensation of the advance of the reflex mirror only under certain technical preconditions.

SUMMARY OF THE INVENTION

An object of the present invention is to provide a photographic objective for a single-lens mirror reflex camera which compensates for the reflex mirror advance.

Another object of the present invention is to provide a photographic objective with compensation for the mirror advance in which the compensation is effected relatively inexpensively and without using overflow curves following the guide grooves.

In accordance with the above and other objects, the present invention is a photographic objective provided with means on the leaf guide ring by way of which the advance of the diaphragm control lever on the camera side controlled by the reflex mirror is compensated.

The photographic objective comprises a diaphragm preset system and an automatic diaphragm. The automatic diaphragm comprises iris blades, a spacially fixed leaf support ring supporting the iris blades and a leaf guide ring rotatable relative to the leaf support ring. The automatic diaphragm is adapted to open to its largest possible value after a picture is taken in response to motion of the reflex mirror transmitted through a diaphragm control lever. A compensating structure is connected to the leaf guide ring for compensating for an advance of the diaphragm control lever whereby after

the diaphragm control lever has moved sufficiently to cause the automatic diaphragm to open to its largest possible value, further motion of the diaphragm control lever does not affect the automatic diaphragm.

In accordance with other aspects of the invention, the diaphragm control lever directly engages the compensating structure.

The compensating structure may comprise a tiltable rocking lever mounted to turn about an axis attached to the leaf guide ring, and a spring attached to bias the rocking lever. The rocking lever is rotated against the spring bias in response to the advance.

The automatic diaphragm includes a spring connected to bias the automatic diaphragm to a closed position. The spring force of the spring connected to said tiltable lever is greater than the spring force of the spring closing the automatic diaphragm.

BRIEF DESCRIPTION OF THE DRAWINGS

The above and other objects will become more readily apparent as the invention becomes more fully understood in connection with the detailed description to follow, reference being had to the accompanying drawings in which like reference numerals represent like parts throughout, and which:

FIG. **1** is a side elevational sectional view of the tube body of a photographic objective; and

FIG. **2** is a rear part fragmentary view of the tube body according to FIG. **1**.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENT

A tube body **1** of a photographic objective, schematically shown in FIG. **1**, can be attached with a bayonet **3** disposed at its rear end **2** to a single-lens mirror reflex camera (not shown).

An automatic diaphragm **4** is disposed in the tube body **1**. The automatic diaphragm comprises a spacially fixed leaf support ring **5**, diaphragm blades **6** supported at the ring **5**, and a leaf guide ring **7** rotatable relative to the leaf support ring **5**. The automatic diaphragm **4** opens and closes in a known manner by tilting the diaphragm blades **6** upon a relative rotation between the leaf support ring **5** and the leaf guide ring **7**.

The automatic diaphragm **4** is maintained at a selected opening diameter by a tension spring **9** attached between the tube body **1** and a diaphragm catch **8**. Catch **8** is formed integrally in a single piece with the leaf guide ring **7**. The size of the opening diameter is determined by a stop **10** of a diaphragm stop ring **11** disposed on the outer circumference of the tube body **1**. At the selected opening, the diaphragm catch **8** is held against the diaphragm stop ring **11** by tension spring **9**.

A rocking lever **13** is tiltable around an axis **12** attached to the diaphragm catch **8**. Rocking lever **13** is positioned at the end of the diaphragm catch **8** disposed closest the mirror reflex camera. The rocking lever **13** is pulled by a tension spring **14** against a stop **15** on the diaphragm catch **8**. As would be apparent to one of ordinary skill in the art, the tension spring **14** can be replaced by other biasing devices, such as a torsion spring acting on the rocking lever **13** and placed around the axis **12**. The force of the spring acting on the rocking lever **13** is designed to be larger than the force of the spring **9** closing the automatic diaphragm **4**.

A diaphragm control lever **17** engages the free end **16** of the rocking lever **13**. The diaphragm control lever **17**

is mechanically linked to the hinge mirror of the mirror reflex camera (not shown) to transmit force from the hinge mirror to the automatic diaphragm **4**. The relative motion between the leaf support ring **5** and the leaf guide ring **7** is effected via the hinge motion of the reflex mirror through diaphragm control lever **17** after a picture has been taken. The diaphragm catch **8** contacts a stop **18** after reaching the largest diaphragm opening. The advance of the diaphragm control lever is now compensated by lifting the rocking lever **13** from the stop **15** against the force of the spring **14** and by turning the rocking lever around the axis **12** while maintaining the force transmitting coupling between the diaphragm control lever **17** and the free end **16** of the rocking lever **13**.

The foregoing description is presented to illustrate the present invention but is not deemed to limit the scope thereof. Clearly, numerous modifications can be made to the invention without departing from the scope thereof as defined in the appended claims.

What is claimed is:

1. Photographic objective for a single-lens mirror reflex camera having a reflex mirror and a diaphragm control lever for transmitting force from said reflex mirror to said objective, said objective comprising:

a diaphragm preset system;

an automatic diaphragm comprising:

iris blades;

a spacially fixed leaf support ring supporting said iris blades; and

a leaf guide ring rotatable relative to the leaf support ring, said automatic diaphragm being adapted to open to its largest possible value after a picture is taken in response to motion of the reflex mirror transmitted through said diaphragm control lever; and

means connected to said leaf guide ring for compensating for an advance of said diaphragm control lever whereby after said diaphragm control lever has moved sufficiently to cause said automatic diaphragm to open to its largest possible value, further motion of said diaphragm control lever does not affect said automatic diaphragm.

2. Photographic objective according to claim **1**, wherein said diaphragm control lever directly engages said compensating means.

3. Photographic objective according to claim **1**, wherein said compensating means comprises a tiltable rocking lever mounted to turn about an axis attached to said leaf guide ring, and a spring attached to bias said rocking lever, said rocking lever being rotated against said spring bias in response to said advance.

4. Photographic objective according to claim **2**, wherein said compensating means comprises a tiltable rocking lever mounted to turn about an axis attached to said leaf guide ring and a spring attached to bias said rocking lever, said rocking lever being rotated against said spring bias in response to said advance.

5. Photographic objective according to claim **3**, wherein said automatic diaphragm includes a spring connected to bias said automatic diaphragm to a closed position, and the spring force of the spring connected to said tiltable lever is greater than the spring force of the spring closing the automatic diaphragm.

6. Photographic objective according to claim **4**, wherein said automatic diaphragm includes a spring connected to bias said automatic diaphragm to a closed position, and the spring force of the spring connected to said tiltable lever is greater than the spring force of the spring closing the automatic diaphragm.

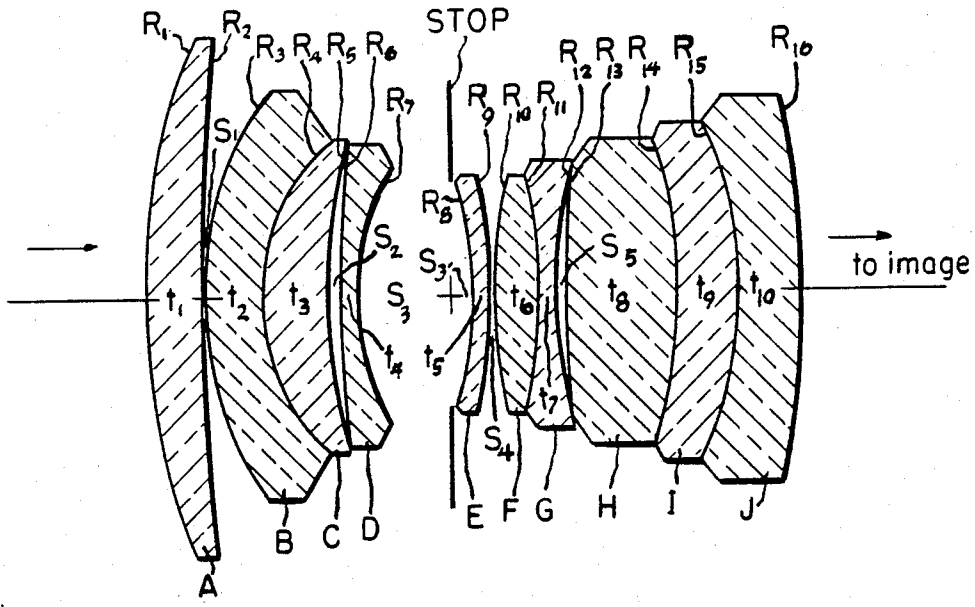
[57] **ABSTRACT**

The invention provides a highly corrected optical system comprising six groups consisting of ten elements, the indicies of refraction of which range from 1.654 to 1.807, the image surface being generally shallowly concave to the object.

2 Claims, 4 Drawing Figures



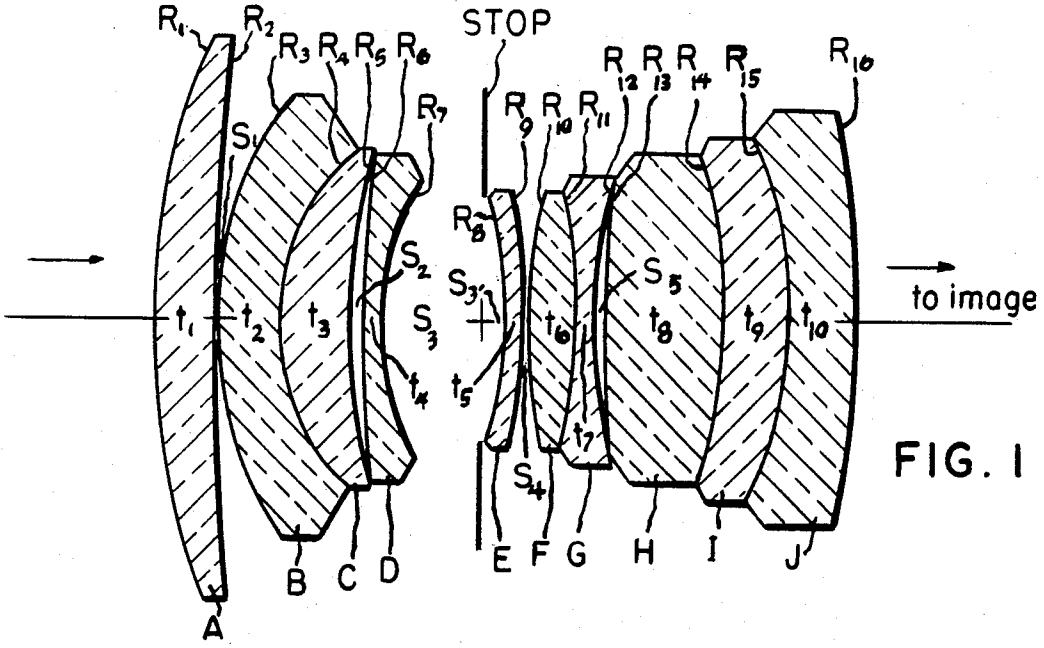


FIG. 1

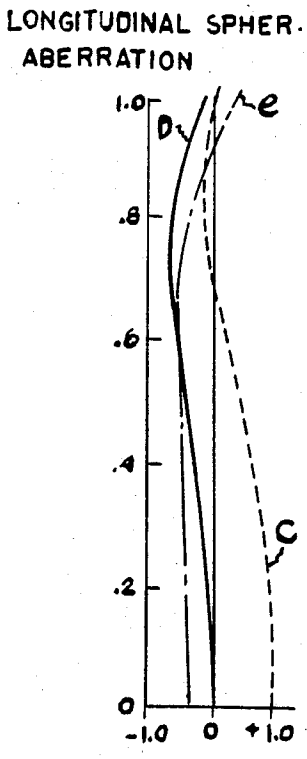

FIG. 2

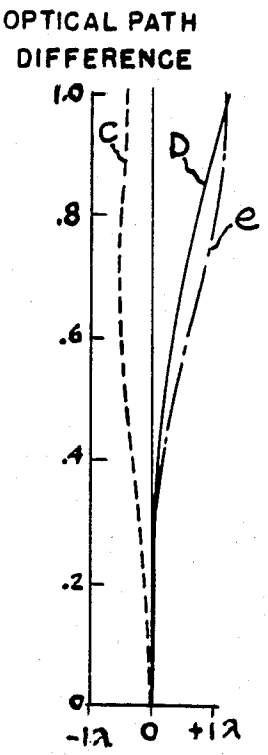

FIG. 3

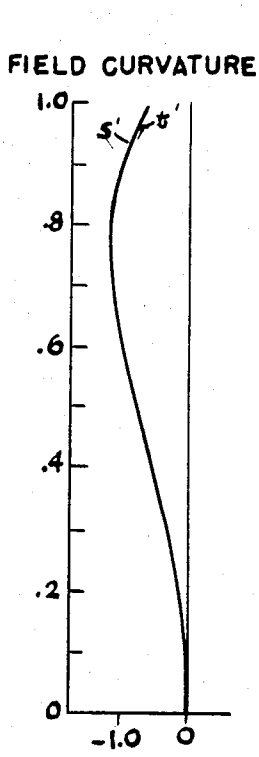

FIG. 4

CURVED FIELD PHOTOGRAPHIC OBJECTIVE

BACKGROUND OF THE INVENTION

The invention relates to photographic objectives of moderate aperture and high correction particularly suitable for aerial photography.

SUMMARY OF THE INVENTION

The improved lens system of the invention consists of four elements in three components forward of the stop and six elements in three components rearwardly of the stop. The elements forward of the stop, in order from the object space, are a positive singlet, a positive cemented doublet and a negative singlet, all surfaces of which are concave to the stop. Rearwardly of the stop are, in order, a negative meniscus concave to the stop, a cemented doublet in the form of a meniscus convex to the stop of comprising a biconvex and a biconcave element, and a biconvex cemented triplet comprising a biconvex element, a positive meniscus and a negative meniscus, the two latter elements being concave to the stop.

This arrangement yields a lens having a relative aperture of f/2.8 and a semi-field of 25.5 degrees producing a substantially astigmatism-free image with extremely low chromatic aberration and low distortion. The very low lateral color achieved herein results from the careful choice of indices and dispersions of the glasses used. Lateral color is less than one Airy disc anywhere in the field. The image surface is quasispherical, the maximum departure from a plane being approximately 1.2 mm at 0.7 field. For a 6 inch focal length lens the theoretical radius of curvature which the film must assume is approximately 1237 mm, an amount readily achieved with a field-curving camera back, and which leaves no residual deformation in the film after exposure. The actual radius of film curvature and the film position are arrived at experimentally to assure that the film intersects the surface of best imagery.

U.S. Pat. Nos. 2,343,627 and 2,771,817 previously issued to this applicant show curved-field lenses but with much more flare surrounding the off-axis images. Astigmatism in the lens of the present invention is virtually zero, the maximum difference between the sagittal and tangential fields of 0.025 mm at 0.9 field, being reduced to zero at 25½ degrees field, and with greatly reduced flare surrounding the off-axis image. Previous attempts to reduce the flare in a curved field lens were unsatisfactory.

A curved field lens and camera has also been described in a paper by Hopkins et al before the Optical Society of America in October 1948, the abstract of which appears in the Journal of the Optical Society of America, Vol. 38, No. 12, Dec. 1948, page 1102.

Other features and additional objectives of the invention will become apparent from the following description of preferred embodiment as illustrated in the accompanying drawing.

BRIEF DESCRIPTION OF THE DRAWING

FIG. 1 is a conventional sectional view of the preferred embodiment of the lens

FIG. 2 shows the longitudinal spherical aberration for the lens for the C, D and e lines

FIG. 3 shows the optical path difference for the C, D and e lines

FIG. 4 shows the field curvature and the absence of astigmatism in the lens

The arrangement of the components as illustrated in FIG. 1 shows the position of the aperture stop in addition to showing all the lens elements. The construction is hybrid, the front groups being derived from the gauss type of lens and the rear groups from the quadruplet type.

The refractive index n_D and the Abbe number ν, together with the radii, thicknesses and spacings are shown in Table 1.

*Edge contact at 26.5 mm semi aperture
**Edge contact at 22.0 mm semi aperture

The unusually high state of correction results from a number of factors including the use of high index glasses, none of the elements having an index lower than 1.654. Most of the glasses have relatively low dispersions for their index of refraction, the highest dispersion glass being Schott SF15 with a V-number of 30.1 used in meniscus element D. Another factor is the use of a majority of surfaces which are concave to the stop. All elements forward of the stop are concave to the stop, while all but two surfaces behind the stop are concave to the stop. Still another factor is the relatively shallow curvature of the surfaces immediately before and behind the stop, r_7 and r_8. In conventional lenses these radii are far steeper, as for example in the conventional double gauss lens in which the ratios of the radii of the forward and rearward surfaces adjacent the stop to the focal length of the objective are almost always between 0.29 and 0.40 respectively. In the present invention the ratios of r_7 and r_8 are 0.303 and 0.514 respectively.

An additional feature is the +, +, − arrangement of the rear cemented triplet in which the biconvex element H has considerably higher index relative to meniscus

element I, but with almost the same dispersion. The triplet can be separated at the last cemented surface with good results, but it has been found equally good or better results are achieved by cementing the last element with the additional advantage of simplifying manufacture. It should also be noted that the axial glass path is usually large; approximately 78% of the distance from the front vertex to the rear vertex is through glass. At the edge of the 25.5 degree semi field the illumination is 31.34%.

It is obvious from the disclosure given above that variations and modifications of the given example will suggest themselves to those skilled in the art.

What is claimed is:

1. In a six-component, ten-element photographic objective, a first lens section forward of the aperture stop comprising a singlet, a doublet and a singlet in order from the long conjugate, and a second lens section rearward of the aperture stop said rearward section consisting, in order from the stop, of a negative singlet concave to the stop, a doublet in the form of a meniscus with its outer surfaces convex to the stop and comprising a biconvex element and a biconcave element with the cemented surface concave to the stop, and a biconvex triplet comprising a biconvex element and two menisci, said biconvex element having a higher index of refraction than said menisci, the cemented surfaces within said biconvex triplet being concave to the stop.

2. A photographic objective as claimed in claim 1, wherein the elements have the following values

EFL = 152.40 REL. APERT. f/2.8 BACK FOCUS = 84.74

Element	radius	thickness & spacing	index n_D	ν

[57] **ABSTRACT**

In a single-lens reflex camera having an objective lens, a focusing screen and a view finder, a photodetector array is arranged to receive a central part of an object image formed by the objective lens and a focusing condition of the objective lens is detected by calculating an evaluation function from image signals supplied from the photodetectors. A presetting dial for selecting given photodetectors whose image signals are used for detecting the focusing condition is provided at such a position that a part of the dial is exposed to the outside through an opening formed in a rear wall of a camera body at a position underneath a film winding lever. A light emitting diode array is provided on the focusing screen so as to be seen by a user through the view finder. Only desired light emitting diodes are lighted on under the control of a signal supplied by the dial to indicate the region of the photodetector array which is used for detecting the focusing condition.
