As can be seen from FIG. **1**, the measuring signal transmitter unit **8** also includes a control receiver unit that is electrically connected to the drives **2**, **3**, **4** for positioning the lens rings **22**, **23**, **24**. The measuring signal receiver unit **30** also includes a control transmitter unit having control actuator elements **17**, **18**, **19**. These control transmitter and receiver units can also be separate from the measuring signal units. In a simpler arrangement, the control units can be combined with the measuring signal units and can be used to adjust the desired state of the lens rings **22**, **23**, **24**. The desired value of the lens ring positions can then be set via the control actuating elements **17**, **18**, **19** which are implemented as rotary control knobs. The desired value is transmitted as a control command via wireless transmission to the drive units **2**, **3**, **4** which drive the respective lens rings **22**, **23**, **24**.

When the set value is changed from one position to the next, the displays **14**, **15**, **16** indicate the actual position of the lens rings **22**, **23**, **24**. The position of the focusing rings **22**, **23**, **24** can be corrected with the control knobs **17**, **18** or **19**, which can be rotated until the desired values on the objective **1** are attained.

Since the actually set position values of the lens rings are accessible, the depth of field can also be precisely determined and displayed. In this way, the cameraman is always kept current of the limiting values for the depth of field of the exposed film. The use of tables can be eliminated by connecting the measuring signal receiver unit **30** to a device for determining and displaying the depth of field **12**. The device can be used in conjunction with the actual position of the lens ring **22**, **23**, **24** to measure and display the useful depth of field that the objective **1** can provide. The depth of field range can then be readily viewed.

While the invention has been illustrated and described as embodied in a control system for an objective of a camera, it is not intended to be limited to the details shown since various modifications and structural changes may be made without departing in any way from the spirit of the present invention.

What is claimed as new and desired to be protected by Letters Patent is set forth in the appended claims:

1. A control system for an objective of a camera, comprising:

at least one lens ring disposed on the objective;

at least one drive unit or automatically adjusting a position of the lens ring to a predetermined desired state; and

at least one position determining means coupled to the lens ring for determining an actual position of the lens ring relative to the objective, said position determining means converting the actual position into a measuring output signal,

wherein the position determining means includes a waveguide extending about the circumference of the objective in the region of the lens ring, a magnet connected to the lens ring at a predetermined location and at least partially movable inside the waveguide, an electromagnetic transmitter element, and an acoustic receiver element arranged in the waveguide, wherein the electromagnetic transmitter element transmits a signal that is received by the acoustic receiver element and wherein a time difference measured between transmission of the signal by the electromagnetic transmitter element and reception of the signal by the acoustic receiver element represents the measuring output signal.

2. A control system for an objective of a camera, comprising:

at least one lens ring disposed on the objective; at least one drive unit for automatically adjusting a position of the lens ring to a predetermined desired state; and

at least one position determining means coupled to the lens ring for determining an actual position of the lens ring relative to the objective, said position determining means converting the actual position into a measuring output signal,

wherein the position determining means includes a first electrode located on the objective and comprised of two sections having areas that increase or decrease in size depending on the position of the lens ring, and a second electrode arranged on the lens ring and capable of rotating without physically contacting the first electrode, the first and second electrode forming a capacitor, wherein the measuring output signal is produced based on a capacitance ratio measured between the two sections of the first electrode and the second electrode.

3. The control system of claim **2** wherein the sections of the first electrode, when arrange on a plane, form a rectangle which is separated along a diagonal of the rectangle.

4. A control system for an objective of a camera, comprising:

at least one lens ring disposed on the objective;

at least one drive unit for automatically adjusting a position of the lens ring to a predetermined desired state;

at least one position determining means coupled to the lens ring for determining an actual position of the lens ring relative to the objective, said position determining means converting the actual position into a measuring output signal; and

a measuring signal transmitter unit receiving as an input signal the measuring output signal of the position determining means and producing an output signal; a measuring signal receiver unit receiving the output signal from the measuring signal transmitter unit; and at least one display device arranged in the measuring signal receiver unit for displaying the actual position of the lens ring.

5. The control system of claim **4** wherein the position determining means is provided in the form of an optical angular encoder which includes an optical encoding element connected to the lens ring, an encoding tracks capable of at least one of reflecting or transmitting optical radiation, a light transmitter for generating the optical radiation, and a light receiver for generating the measuring output signal.

6. The control system of claim **4** wherein the position determining means is provided in the form of a magnetic distance sensor which includes a tape connected to the lens ring and periodically magnetically polarized along at least one track, and a magnetic sensor for sensing the tape without making physical contact with the tape and for generating the measuring output signal.

7. The control system of claim **6** wherein the magnetic sensor is a magneto-resistive magnetic sensor.

8. The control system of claim **4** wherein the measuring signal transmitter unit includes a wireless transmitter section, and the measuring signal receiver unit includes a wireless receiver section, said wireless transmitter section and said wireless receiver section being adapted to transmit the measuring signal data.

9. The control system of claim **4** wherein the measuring signal transmitter unit is attached to the camera.

10. The control system of claim **4** wherein the measuring signal transmitter unit forms a part of the camera.

11. The control system of claim **4** wherein the measuring signal transmitter unit further includes a control receiver unit which is electrically connected to the drive positioning the lens ring, said measuring signal receiver unit further including a control transmitter unit having control actuator elements capable of adjusting the set position of the lens ring.

12. The control system of claim **4** wherein the position of the lens ring defines a focus position of the objective.

13. The control system of claim **4** wherein the position of the lens ring defines a size of an iris diaphragm of the objective.

14. The control system of claim **4** wherein the position of the lens ring defines a focal length of the objective.

15. The control system of claim **6** wherein the tape is filled with magnetic particles.

16. The control system of claim **6** wherein the at least one track is a plurality of tracks that are parallel with respect to each other.

17. The control system of claim **5** wherein the optical encoding element is secured against rotation with respect to the lens ring.

18. A control system for an objective of a camera, comprising:

at least one lens ring disposed on the objective;

at least one drive unit for automatically adjusting a position of the lens ring to a predetermined desired state;

at least one position determining means coupled to the lens ring for determining actual position of the lens ring relative to the objective, said position determining means converting the actual position into a measuring output signal;

a measuring signal receiver unit responsive to the measuring output signal of the position determining means; and

a means connected to the measuring signal receiver unit for determining and optically displaying the depth of

field from the actual positions of the lens ring attainable with the objective.

19. A control system for an objective of a camera, comprising at least one drive unit for automatically adjusting a position of at least one lens ring to thereby impact at least one of a focus position, an iris diaphragm and a focal length, with the drive unit adjusting a predetermined desired state of the lens ring; and at least one device coupled to the lens ring for determining the actual position of the lens ring, wherein the device determines the actual position of the lens ring relative to the objective and converts the actual position into a measuring output signal, wherein the device for determining the actual position of the lens ring includes a waveguide extending around the circumference of the objective in the region of the lens ring and a magnet that is connected to the lens ring at a predetermined location, wherein the magnet is at least partially movable inside the waveguide, wherein an electromagnetic transmitter element and an acoustic receiver element are arranged in the waveguide and wherein the measured time difference between the signal transmitted by the transmitter element and the signal received by the receiver element represents the measuring output signal.

20. A control system for an objective of a camera, comprising at least one drive unit for automatically adjusting a position of at least one lens ring to thereby impact at least one of a focus position, an iris diaphragm and a focal length, with the drive unit adjusting a predetermined desired state of the lens ring; and at least one device coupled to the lens ring for determining the actual position of the lens ring, wherein the device determines the actual position of the lens ring relative to the objective and converts the actual position into a measuring output signal, wherein the device for determining the actual position of the lens ring includes an electrode located on the lens ring, wherein the electrode is rotatable, in a contact-free manner, about a split electrode which is located on the objective and increases or decreases in size depending on the position of the lens ring, wherein the measuring output signal is produced based on the capacitance ratio of the two-piece regions of the electrode with respect to the rotatable electrode.

21. The control system of claim **20** wherein the split electrode in a planar state is represented by a rectangle that is separated along a diagonal.

22. A control system for an objective of a camera, comprising at least one drive unit for automatically adjusting a position of at least one lens ring to thereby impact at least one of a focus position, an iris diaphragm and a focal length, with the drive unit adjusting a predetermined desired state of the lens ring; and at least one device coupled to the lens ring for determining the actual position of the lens ring, wherein the device determines the actual position of the lens ring relative to the objective and converts the actual position into a measuring output signal, wherein the measuring outputs of the device for determining the actual position is connected to a respective input of a measuring signal transmitter unit, and wherein the output of the measuring signal transmitter unit is connected to a measuring signal receiver unit capable of displaying the actual state of the lens ring via one or several displays arranged in the measuring signal receiver unit.

23. The control system of claim **22** wherein the device for determining the actual position of the lens ring includes an optical angular encoder which is formed from an encoding element that is non-rotatably connected to the lens ring and provided with encoding tracks that can be read optically through reflection or transmission of light and a light transmitter and receiver system, wherein the light receiver generates the measuring output signal.

24. The control system of claim **22** wherein the device for determining the actual position of the lens ring includes a magnetic distance sensor in the form of a tape that is preferably placed on the lens ring and filled with magnetic particles, wherein the tape is preferably periodically polarized along several parallel tracks, and a magnetic sensor for sensing the tape without making contact with the tape and generating the measuring output signal.

25. The control system of claim **24** wherein the magnetic sensor is a magneto-resistive magnetic sensor.

26. The control system of claim **22** wherein the measuring signal transmitter unit includes a wireless transmitter section and the measuring signal receiver unit includes a corresponding wireless receiver section which are adapted to transmit the measuring signal data.

27. The control system of claim **22** wherein the measuring signal transmitter unit is attachable to the camera that is associated with the objective, or forms part of the camera.

28. The control system of claim **27** wherein the measuring signal transmitter unit further includes a control receiver unit that is electrically connected with the drive for positioning the lens ring, and wherein the measuring signal receiver unit further includes a control transmitter unit having control actuator elements capable of adjusting the set position of the lens ring.

29. A control system for an objective of a camera, comprising at least one drive unit for automatically adjusting a position of at least one lens ring to thereby impact at least one of a focus position, an iris diaphragm and a focal length, with the drive unit adjusting a predetermined desired state of the lens ring; at least one device coupled to the lens ring for determining the actual position of the lens ring, wherein the device determines the actual position of the lens ring relative to the objective and converts the actual position into a measuring output signal, a measuring signal receiver unit capable of displaying the actual state of the lens ring via one or several displays arranged in the measuring signal receiver unit, wherein the measuring signal receiver unit is connected to a device for determining and optically displaying the depth of field, wherein the device is used to determine from the actual positions of the lens ring the depth of field that can actually be used with the objective.

30. The control system of claim **29** wherein the device for determining the actual position of the lens ring includes an optical angular encoder which is formed from an encoding element that is non-rotatably connected to the lens ring and provided with encoding tracks that can be read optically through reflection or transmission of light and a light transmitter and receiver system, wherein the light receiver generates the measuring output signal.

31. The control system of claim **29** wherein the device for determining the actual position of the lens ring includes a magnetic distance sensor in the form of a tape that is preferably placed on the lens ring and filled with magnetic particles, wherein the tape is preferably periodically polarized along several parallel tracks, and a magnetic sensor for sensing the tape without making contact with the tape and generating the measuring output signal.

32. The control system of claim **31** wherein the magnetic sensor is a magneto-resistive magnetic sensor.

[57] **ABSTRACT**

A retrofocus objective lens system which is conducive for an otoscope includes a first group of optical elements positioned at a distal portion and a second group of optical elements proximally spaced from the first group of optical elements. The first group of optical elements includes at least one negative small diameter lens while the second group of optical elements include a plurality of small diameter lenses having an aggregate optical power which is positive, allowing an image of interest to be transmitted through the system without any intermediate imaging planes, and without the need for rod lenses. The first and second lens groups are retained in a plurality of linearly interconnected lens tubes such that one lens tubes is linearly adjustable in relation to the remaining lens tubes in order to vary the focal length of the lens system.

OBJECTIVE LENS SYSTEM FOR IMAGING INSTRUMENT

CROSS REFERENCE TO RELATED APPLICATIONS

This application is a continuation-in-part of U.S. Ser. No. 09/052,570, filed Mar. 31, 1998, which is based upon provisional applications U.S. Ser. No. 60/043,374, filed Apr. 4, 1997, and U.S. Ser. No. 60/075,406, filed Feb. 20, 1998.

FIELD OF THE INVENTION

This invention relates to the field of imaging instruments, and particularly to a retrofocus objective lens system for use in an imaging instrument such as an otoscope.

BACKGROUND OF THE INVENTION

An otoscope is a portable, direct viewing examination instrument that aids in the observance and study of the inner ear canal, including the tympanic membrane. Many otoscopes are presently known, each typically having a housing including a frusto-conical head portion and specula capable of being placed a predetermined distance within the ear canal of a patient. The interior of the housing includes an optical viewing system, as well as an illumination system for providing light in a coaxial manner with the viewing system. In use, the optics permit viewing using an eyepiece attached to a proximal end of the housing.

With the advent of "telemedicine", videoized versions of medical examination instruments, including otoscopes, have been developed, such as those described in U.S. Pat. No. 5,363,829 issued to Lankford; U.S. Pat. No. 5,239,984, issued to Cane, et al; and U.S. Pat. No. 4,947,245, issued to Ogawa, et al. In each of the above, a miniature video camera, such as a CCD or other electronic sensor, is positioned either within the interior of the instrument or adjacently coupled thereto. The electronic sensor includes a light receiving surface or substrate which receives a focused optical image of a target of interest through the optical viewing system. The sensor then converts the optical signal into an electrical signal and subsequently through processing electronics into a monitor-ready video signal.

In order to provide a complete ear examination of a patient, it is desirable that the otoscope include the capability of producing a stream of air for stimulating the tympanic membrane. This feature is known as insufflation.

To provide insufflation capability, the inner tip housing of the otoscope must be sufficiently large enough to accommodate the illumination system, the optical viewing system, and an air path permitting insufflation.

In addition, and though the ear canal is a relatively small chamber, it is also desirable to provide a sufficient field of view to allow the entirety of the tympanic membrane (approximately 8 mm) to be viewed at one time during an examination. In the past, videoized versions of otoscopes have utilized relay lens systems to achieve this goal.

Several attempts to attach a video camera to a standard otoscope have proved less than successful due to compromises in field size, vignetting (clipping) and lack of video lens interchangeability. In addition, the lens elements must be under three millimeters in diameter in order to fit inside the specula tip of the otoscope.

In order to achieve the relatively long total conjugate length (approximately 99 mm) of a video otoscope, While maintaining the small element diameters (under 3 mm) required, the resulting optical system tends to be complex.

Most of these lens systems **126** are composed of some form of objective means in the distal portion **122** of the otoscope, followed by one or more relay configurations. This type of system has many disadvantages based upon to its overall complexity, therefore producing greater likelihood of manufacturing errors, and requiring a plurality of intermediate imaging planes **138**, as shown in FIG. **1**. The intermediate image planes **138** are necessitated by the relay configurations and are subject to cosmetic issues.

As shown in FIG. **1**, these known lens systems include a number of axially disposed optical elements which transmit the optical signal through a series of intermediate image planes located between the target plane **140** and the image substrate **134** of a miniature video camera along an axis **130**.

For a normally constructed objective lens system, the object and image plane conjugates are essentially in proportion to the system magnification, or more specifically to the ratio of M and 1/M, in which M is the system magnification. By knowing the desired magnification, (1:1), (1:2), etc., it is straight forward to calculate the total conjugate length (the distance from the object to image) for any focal length. Similarly, the focal length required to achieve a desired total conjugate length is also easily calculated.

It is readily known that an objective lens system operating at unit magnification (1:1) is normally located equidistant from the object and image planes. For an objective lens system to operate at a reduction of 0.5 (1:2), the object conjugate must normally be twice that of the image conjugate.

Most often undesirable or unattainable objective positions are produced with the lens systems typically employed in many videoized instruments, including otoscopes. It is desirable to produce a system that allows for the placement of the objective lens at a more favorable location.

SUMMARY OF THE INVENTION

Therefore, it is an object of the present invention to provide a viewing system for an imaging instrument which overcomes the disadvantages of the prior art.

It is another primary object of the present invention to provide an imaging instrument having an optical viewing system that does not include any intermediate imaging planes.

Another object of the invention is to provide an optical system for a diagnostic instrument such as an otoscope which provides adequate spacing to allow viewing while still allowing permitting incorporation of insufflation or other features.

It is yet another object of the invention to provide an improved objective lens system for an imaging instrument, particularly an instrument requiring small diameter lenses.

Therefore, and according to a preferred aspect of the present invention, there is provided a retrofocus objective lens system for an imaging instrument, comprising;

a first group of optical elements positioned at a distal portion of said system;

a second group of optical elements proximally spaced from said first optical element and aligned along an optical axis; and

a single imaging plane disposed along said optical axis proximal to said first optical element and said plurality of intermediate optical elements, wherein said first group of optical elements includes at least one lens component, said at least one lens component having negative optical power, and said second group of

optical elements including a plurality of elements having an aggregate optical power which is positive and wherein an image of a target viewed by said system is focused only at the imaging plane.

Preferably, the first group of optical elements is defined by a single small diameter negative lens, the diameter in fact being smaller than its corresponding focal length. The second group of optical elements includes a combination of positive and negative lens having an overall or aggregate positive optical power which allows an image transferred through the system to be focused only at the single image plane, preferably onto the imaging substrate of a suitably positioned electronic sensor.

According to a preferred embodiment, the second group of optical elements includes a plurality of lenses including respective second, third, and fourth lens components. Preferably, the second lens and fourth lenses are positive, and the third lens is a doublet containing a negative lens contiguous with a positive lens and having an overall or aggregate optical power which is negative. An aperture stop of convenient size is suitably positioned between the first and second lenses according to this design.

In an alternative embodiment, the second optical group includes a second positive lens, a third lens proximally spaced relative to the second lens, a fourth lens proximally spaced relative to the third lens, and a fifth lens proximally spaced relative to the fourth lens. In this system design, the second and fifth lenses are positive, and the fourth lens element is a doublet containing a negative lens contiguous with a positive lens such that the aggregate optical power of the doublet is negative. The aperture stop, according to this system design, is positioned between the second and third lenses.

According to another preferred aspect of the present invention, there is provided an otoscope having a retrofocus objective lens system for reducing an object onto a single image plane, said lens system comprising:

- a first group of optical elements positioned at a distal portion of said system;
- a second group of optical elements proximally spaced from said first group of optical elements and aligned along an optical axis;
- a single imaging plane disposed proximally from said second group wherein an image of a target of interest is transmitted through said system without intermediate imaging planes.

In a preferred embodiment, each group of optical elements is disposed in a lens tube or cell retained within an instrument housing. More preferably, the elements used in the objective lens system are sized such that coaxial illumination and insufflation features can be included in an otoscope without interfering with the viewing of an object through the objective lens system.

According to yet another embodiment there is described an otoscope comprising a housing including a distal tip opening, an imaging element disposed in relation to a proximal end of said housing; and an optical system disposed within said housing and aligned between said distal tip opening and said imaging element, wherein said optical system contains focussing means for focussing an optical image of a target of interest at said imaging element without any intermediate imaging planes between said target and said imaging element. Preferably, the otoscope includes illumination means for illuminating the target of interest through the distal tip opening and insufflation means for stimulating the tympanic membrane, each being disposed in the housing without interfering with the functions of the optical system.

An advantageous feature of the present invention is that a retrofocus lens system, as described, produces desirable objective positions and includes a long overall length using small diameter lens elements, yet produces minimal distortion and minimal vignetting, making this system ideal for an imaging instrument such as an otoscope.

A further advantage is that the above optical system can be suitably arranged in an instrument housing of compact size without compromising the ability to provide other needed instrument features, such as insufflation in the case of an otoscope.

These and other objects, advantages, and features will be described in the following Detailed Description of the Invention which should be read in conjunction with the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a partial sectional view of an otoscope having an optical viewing system according to the prior art, including a partial ray trace of a target object as transmitted through the system;

FIG. **2** is a diagrammatic view of an optical viewing system in accordance with a preferred embodiment of the present invention illustrating the transmission of a chief ray relative to the optical axis of the system;

FIG. **3** is the ray trace diagram of FIG. **2**, illustrating a bundle of rays through the optical viewing system relative to the optical axis;

FIG. **4** is a sectional view of the optical viewing system of FIGS. **2** and **3** as contained within a lens cell in accordance with a preferred embodiment of the invention;

FIG. **5** is an enlarged partial sectional view of an otoscope having the contained optical viewing system of FIG. **4**;

FIG. **6** is a sectional view of FIG. **5**, further indicating the combination of insufflation and illumination with the optical viewing system of FIGS. **2–5**;

FIG. **7** is a partial front perspective view of an otoscopic head including a modified insufflation feature; and

FIG. **8** is a side partial view of a compact otoscopic head having the optical system of FIGS. **2–6** as used in combination with a hand-held multimedia instrument.

DETAILED DESCRIPTION OF THE INVENTION

The following discussion describes an optical viewing system according to a specific embodiment for use with a specific medical examination instrument, i.e.: an otoscope. As will be apparent from the following discussion, however, there are other suitable applications for an optical viewing system embodying the concepts described herein. That is, the described objective lens system can be used in other medical (endoscopic) and/or non-medical (such as borescopic) applications involving the examination of cavities having narrow or shaped openings.

Reference is now made to FIGS. **2–6** which relates to an optical viewing system **12** in accordance with the present invention. Referring first to FIGS. **2** and **3**, the viewing system **12** is shown diagrammatically. A first lens **40** is disposed at the distal end of the system **12**. A key feature of the present invention is that the first lens **40** is a negative lens of suitable power which is aligned along a system viewing axis **32**. An aperture stop **50** is disposed proximally from the first lens **40** and is aligned therewith along the viewing axis **104**. A second lens **52** is disposed somewhat adjacently and proximally from the aperture stop **50**. According to the

present embodiment, the second lens **52** is a positive lens. A third lens **58** in the form of a doublet is disposed proximally from the previously described elements **40**, **52** at a predetermined distance followed by a fourth positive lens **60**, each also aligned with the viewing axis **32**.

As shown in FIGS. **2** and **3**, a chief ray **25**, FIG. **2** or bundle of rays **27**, FIG. **3**, entering the system from a target plane **29** are first directed through the negative lens **40** which diverges the light and fills the aperture stop **50**. Light emerging the aperture stop **50** passes through the second lens **52** having sufficient power to partially converge the light which then passes to the doublet **58** having an aggregate negative power which further diverges the light transmitted to the fourth positive lens **60** which essentially collimates the light until the light is focused at the imager **106**. There are no intermediate imaging planes. In use, an optical signal is channeled through each of the above disposed optical elements and is ultimately focused at the imaging substrate of the imager **106**.

Referring to FIGS. **4–6**, the objective system **12** of the invention is shown in use within an otoscopic instrument head **10**. Referring to FIG. **5**, the illustrated otoscopic instrument head **10** includes a substantially cylindrically shaped proximal housing portion **14**, an intermediate housing portion **16**, and a frusto-conical distal insertion portion **18**. The distal insertion portion **18** has a defined interior which includes overlapping and conically shaped inner and outer tip housings **20**, **22**, each tip housing having a respective distal tip opening **24**, **26** coaxially arranged along a defined optical axis **32**. The inner tip housing **20** extends distally from the tip opening **26** of the outer tip housing **22**. A hollow safety speculum **28**, preferably made from a plastic material and having a distal tip opening **30**, is mounted onto the conical periphery of the distal insertion portion **18**, also in overlapping relation. Each of the distal tip openings **24**, **26**, **30** are coaxial with one another along the optical axis **32**, the tip openings of the mounted speculum **28** and the distal insertion portion **18** being slightly displaced from the tip opening **24** of the inner tip housing **20**.

An illumination assembly **63** includes a miniature halogen lamp **64** which is disposed within the proximal housing portion **14**. Light from the halogen lamp **64** is directed to one end of a bundle of optical fibers **82** (partially shown), the fibers being fanned out into a first annular space **84** formed between the exterior portion of a series of interconnected lens tubes **34**, **36**, **38** supporting the viewing system **12** and the interior wall of the inner tip housing **20** so as not to interfere with the transmission of optical data through the lens tubes. The bundle of fibers **82** terminate at the distal tip opening **24** of the inner tip housing **20**, preferably as a polished light emitting end **110** which is coterminous with a first lens tube **34**, as described below.

As noted, the safety speculum **28** is releasably attached to the exterior of the front insertion portion **18**. A preferred attaching arrangement is described in commonly owned U.S. Pat. No. 4,380,998 issued to Kieffer, et al, the entire contents of which are herein incorporated by reference. The instrument head **10** is locked into engagement with the front interface **170** of the instrument, as shown in FIG. **8**.

As noted above, the above lens system **12** is disposed within the series of interconnected lens tubes **34**, **36**, **38**, each coaxially arranged within the interior of the instrument head **10** along an optical axis **32**. The first lens **40** is disposed in a first lens tube **34** adjacent the distal opening **24** of the inner tip housing **20** along with a plano glass section **42**, preferably disposed directly in front of the first lens **40**.

Preferably, the interior wall of the first lens tube **34** defines a shoulder **44** for supporting and positioning the adjacent elements **40**, **42**. The proximal end **46** of the first lens tube **34** is wider than that of the remainder of the tube and is sized for receiving the distal end **48** of an attached second lens tube **36**. The aperture stop **50** and the second lens **52** are each retained within the widened proximal end **46** of the first lens tube **34** prior to the distal end **48** of the second lens tube **36**. The aperture stop **50** provides the proper direction of the image through the objective, limits the distortion of the image, and limits vignetting at the full field position. The second lens **52** is a positive lens of sufficient power. A proximal end of the second lens tube **36** is retained within a cavity **54** of the distal end **56** of a third lens tube **38**, wherein a third lens **58** is attached at the proximal end of the second lens tube **36**. According to this embodiment, the third lens **58** is a doublet containing respective concave and convex lenses of an appropriate size. The third lens **58**, preferably having an overall or aggregate negative optical power provides a large dispersion and is used to provide color correction to the image.

Finally, and according to this particular system design, the fourth lens **60** is provided and disposed in a cavity **62** at approximately the midpoint of the length of the third lens tube **38**. As noted above, the fourth lens **60** is preferably of positive optical power and functionally takes collimated parallel light arriving from the third lens **58** and focuses the light down to the imager **106**, providing for correction of the direction of the image.

It should be readily evident that the fourth lens **60** could alternately be disposed within a pilot section (not shown) of the instrument **174**.

As should be apparent from the design of the above system, there are no intermedia image planes thereby defining a retrofocus objective lens system. The lens system has an overall fixed length, a fixed focal length, and a fixed magnification.

The defining characteristics of the lens system, such as the focal length, are adjustable by changing the position of the first lens tube **34** in relation to the second lens tube **36**.

Specifics for the design of the above system **12** are provided in Table I and the parameters of the lens elements are provided in Table II.

TABLE I

Overall length of lens system (TCL)	82.78 mm
Focal Length of lens system (EFL)	10.076 mm
Back focal length of lens system (BFL)	36.432 mm
Lens diameters (distal end)	less than 3 mm
Total conjugate distance (distance from target plane to image plane)	98.78 mm
Distortion	less than 5%
Vignetting (at full field position)	less than 20%
Magnification	0.5
Field of view	8.3 mm
Target distance	16 mm

TABLE II

Optical Element	Radius	Material	Thickness
Plano Glass	Plano	BK7	1.0000
First Lens Element	−3.101	BK7	0.7500
	3.101		
	Concave		

TABLE II-continued

Optical Element	Radius	Material	Thickness
Second Lens Element	19.7350 −7.226 Convex	BK7	1.0000
Third Lens Element Doublet	−8.7590 Concave	BK7	1.0000
	−2.9700 −7.4700 Convex	F2	0.7500
Fourth Lens Element	−13.332 Concave −8.3670 Convex	BK7	1.0000

The aperture stop **50** limits the distortion to under 5% and vignetting to under 20% at the full field position. The lens system achieves a magnification of 0.5 reduction for an object having a diameter (field of view) of 8.3 mm and positioned at an object or target distance of 16 mm from the piano glass section **42**.

It should be readily apparent to one of sufficient skill in the field that it is possible to vary the position of at least some of the lens elements or alternately add lens elements to the above retrofocus objective lens system design and achieve the desired results.

For example, and as shown in phantom in FIG. **4**, a fifth lens **49** can be added to the above system and positioned between the first lens **40** and the aperture stop **50** in the first lens tube **34**. Moreover, it is also possible to selectively vary the position of certain elements in the described system depending on the optical distance. For example, by adjusting the separation between lenses **40** and **52**, by up to approximately 0.35 mm, the optical working distance can be varied from 16 mm to infinity.

Referring to FIG. **6**, an insufflation port **88** is provided in the intermediate housing portion **16**, the port being adequately sized to receive a fitting (not shown). The insufflation port **88** defines one end of a passageway extending into the interior of the distal insertion portion **18**. The fitting allows a known depressible pneumatic bulb (not shown) to be connected thereto for directing air (or creating a vacuum) through the path **92** which is defined through an opening of an interior wall **94** into a second annular space **96** between the inner and outer tip housings **20**, **22**. The air passes through the annular space and exits the distal tip opening **26** of the outer tip housing **22** into a third annular space **98** defined between the inner tip housing **20** and the interior of the safety speculum **28**. The directed air exits through the distal tip opening **30** of the safety speculum **28**. A rear wall **100** according to this embodiment acts to seal the assembly, to prevent air from passing through the rear portion of the instrument head, while the mounted safety speculum **28** assists in preventing air leakage other than through the distal tip opening **30**.

In use, the target of interest (e.g., the interior of the ear canal) is viewed by the instrument by placing the front insertion portion **18** into an ear canal (not shown) of interest, placing the tympanic membrane (not shown) approximately 16 mm away from the negative lens **40**. The retrofocus objective lens assembly **12** through the aligned tip opening **30**, **24** projects an optical image of the target (approximately 8 mm in size) along the optical viewing axis **32**, FIG. **2**, ultimately focusing the image onto the imager **106**, FIG. **2**.

Insufflation can be further achieved in the manner shown in FIG. **8**, wherein the outer tip housing **22** includes a predetermined number of flattened areas **80** provided on the outer periphery thereof. Other variations can easily be imagined.

While the foregoing description and drawings represent the preferred embodiments of the present invention, it will be understood that various changes and modifications may be made without departing from the spirit and scope of the present invention.

We claim:

1. An otological imaging instrument for viewing an ear interior, said instrument comprising:

an instrument housing including a frusto-conical insertion portion at a distal end thereof;

an electronic imager disposed in a proximal end of said instrument housing opposite said distal end;

illumination means disposed within said insertion portion for illuminating the interior of the ear for viewing; and

a retrofocusing lens system for reducing an object onto said proximally disposed imager at a single imaging plane located at said proximally disposed imager without the need of intermediate imaging planes and rod lenses, said retrofocusing lens system including a plurality of optical elements housed within a plurality of linearly interconnected lens tubes retained within said instrument housing, at least one of said lens tubes being linearly adjustable in relation to the remaining lens tubes in order to vary the focal length of the lens system, said plurality of optical elements including a first group of optical elements positioned within the frusto-conical insertion portion of said instrument housing opposite from said proximal end and a second group of optical elements disposed proximally from said first group, said first and second groups being aligned along an optical axis and in which said first group includes at least one first negative lens and said second group includes a plurality of lenses having an aggregate positive optical power.

2. The instrument as recited in claim **1**, wherein said illumination means includes a plurality of optical fibers having distal light-emitting ends which are substantially coterminous with said first group of optical elements.

3. The instrument as recited in claim **2**, wherein at least one lens tube and an interior wall of said insertion portion define a first annular space.

4. The instrument as recited in claim **3**, wherein said plurality of optical fibers extends through said first annular space.

5. The instrument as recited in claim **1**, wherein said second group of optical elements includes a second lens, a third lens spaced proximally relative to said second lens, and a fourth lens spaced proximally relative to said third lens, each of said second and said fourth lenses being positive lenses.

6. The instrument as recited in claim **5**, wherein said third lens is a doublet containing a negative lens contiguous with a positive lens, said doublet having a negative aggregate optical power.

7. The instrument as recited in claim **1**, wherein said first group of optical elements is retained within a first lens tube of said interconnected lens tubes.

8. The instrument as recited in claim **7**, wherein said first lens tube is linearly adjustable relative to an adjacent second lens tube so as to adjust the relative focal length of said retrofocusing lens system.

9. The instrument as recited in claim **8**, wherein said first lens tube includes a widened proximal end which is sized to receive a distal end of said second lens tube in overlapping engagement therewith and allowing relative linear adjustment of each of said first and second lens tubes so as to adjust the relative focal length of said retrofocusing lens system.

10. An instrument as recited in claim **9**, wherein said plurality of interconnected lens tubes includes a third lens tube, said third lens tube having a cavity for receiving a proximal end of said second lens tube in overlapping engagement therewith.

11. An instrument as recited in claim **8**, wherein said plurality of interconnected lens tubes includes a third lens tube, said third lens tube having a cavity for receiving a proximal end of said second lens tube in overlapping engagement therewith.

12. The instrument as recited in claim **1**, including an aperture stop disposed between said first and second groups of optical elements.

13. The instrument as recited in claim **1**, wherein said second group of optical elements includes a second lens, a third lens spaced proximally relative to said second lens, a fourth lens spaced proximally relative to said third lens, and a fifth lens spaced proximally relative to said fourth lens said fifth lens being a positive lens.

14. The instrument as recited in claim **13**, wherein said fourth lens is a doublet containing a negative lens contiguous with a positive lens such that the aggregate sum of optical power of said fourth lens is negative.

15. The instrument as recited in claim **13**, including an aperture stop disposed between said second and said third lenses.

16. The instrument as recited in claim **1**, wherein said distal insertion portion includes an inner tip housing and an outer tip housing, each of said inner tip housing and said outer tip housing being coaxial with said optical axis wherein the interior of said outer tip housing and the exterior of said inner tip housing define a second annular space.

17. The instrument as recited in claim **16**, including insufflation means for stimulating the tympanic membrane, said insufflation means including an insufflation path provided by said second annular space.

18. The instrument as recited in claim **1**, including means for varying the linear distance between the first and second groups of optical elements along said optical axis.

19. The instrument as recited in claim **1**, including insufflation means for stimulating the tympanic membrane through said insertion portion, said retrofocusing lens system being retained within said insertion portion so as not to interfere with the operation of said illumination means and said insufflation means.

20. An otological imaging instrument for viewing an ear interior, said instrument comprising:

an instrument housing including a frusto-conical insertion portion at a distal end thereof;

an electronic imager disposed in a proximal end of said instrument housing opposite said distal end;

illumination means disposed within said insertion portion for illuminating the interior of the ear for viewing; and

a retrofocusing lens system for reducing an object onto said proximally disposed imager;

wherein said retrofocusing lens system includes a first group of optical elements positioned within the frusto-conical insertion portion of said instrument housing opposite from said proximal end and a second group of optical elements disposed proximally from said first group of elements and aligned therewith along an optical axis, said first group of optical elements including at least one negative lens and said second group of optical elements including a plurality of lenses having an aggregate positive optical power,

whereby an optical image is imaged at a single imaging plane located at said proximally disposed imager using said retrofocusing lens system without the need of intermediate imaging planes wherein said distal insertion portion includes an inner tip housing and an outer tip housing, each of said inner tip housing and said outer tip housing being coaxial with said optical axis wherein the interior of said outer tip housing and the exterior of said inner tip housing define a second annular space, said instrument further including insufflation means for stimulating the tympanic membrane, said insufflation means including an insufflation path provided by said second annular space wherein said inner tip housing includes a plurality of circumferentially disposed flattened sections to provide vents for said insufflation means.

[57] **ABSTRACT**

An optical filter, such as a low-pass filter, which is disposed between a photo-taking lens mounted on a mount part of the camera body having an image sensor disposed on an image forming plane and a main mirror disposed within the camera body, is held in position jointly by a holding member fixed to the lower end of a front aperture part of the camera body and an elastic member fixed to the rear side of the holding member with a resilient force applied to the optical filter. In mounting the photo-taking lens on the camera body, when an end part of the photo-taking lens comes to touch the optical filter, the optical filter is allowed to temporarily move to escape from the photo-taking lens and to come back to its original position upon completion of the lens mounting operation.

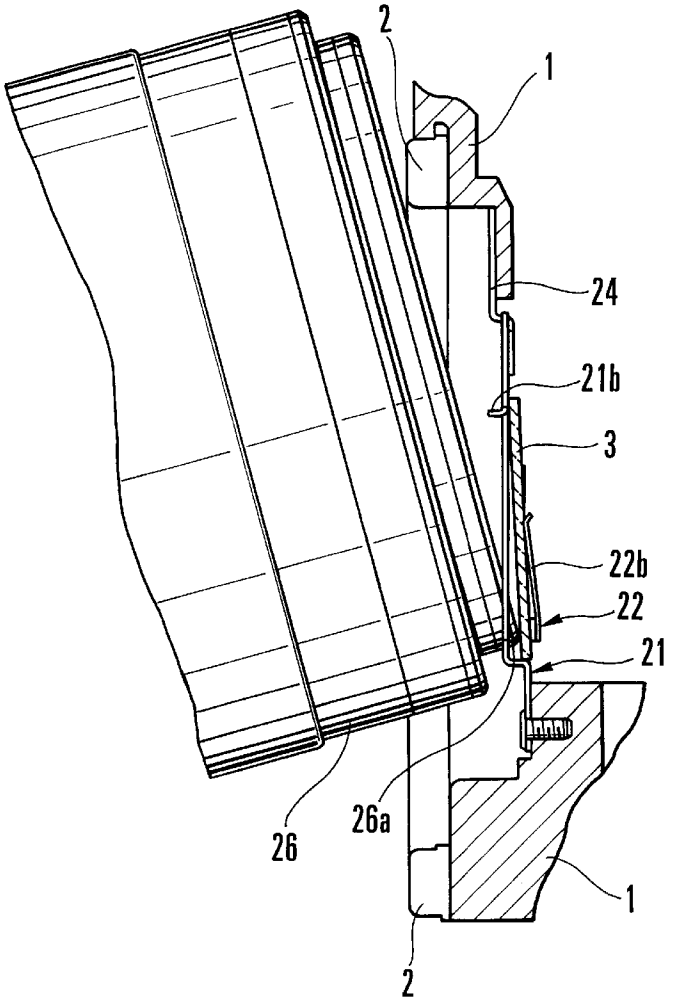

FIG. 1

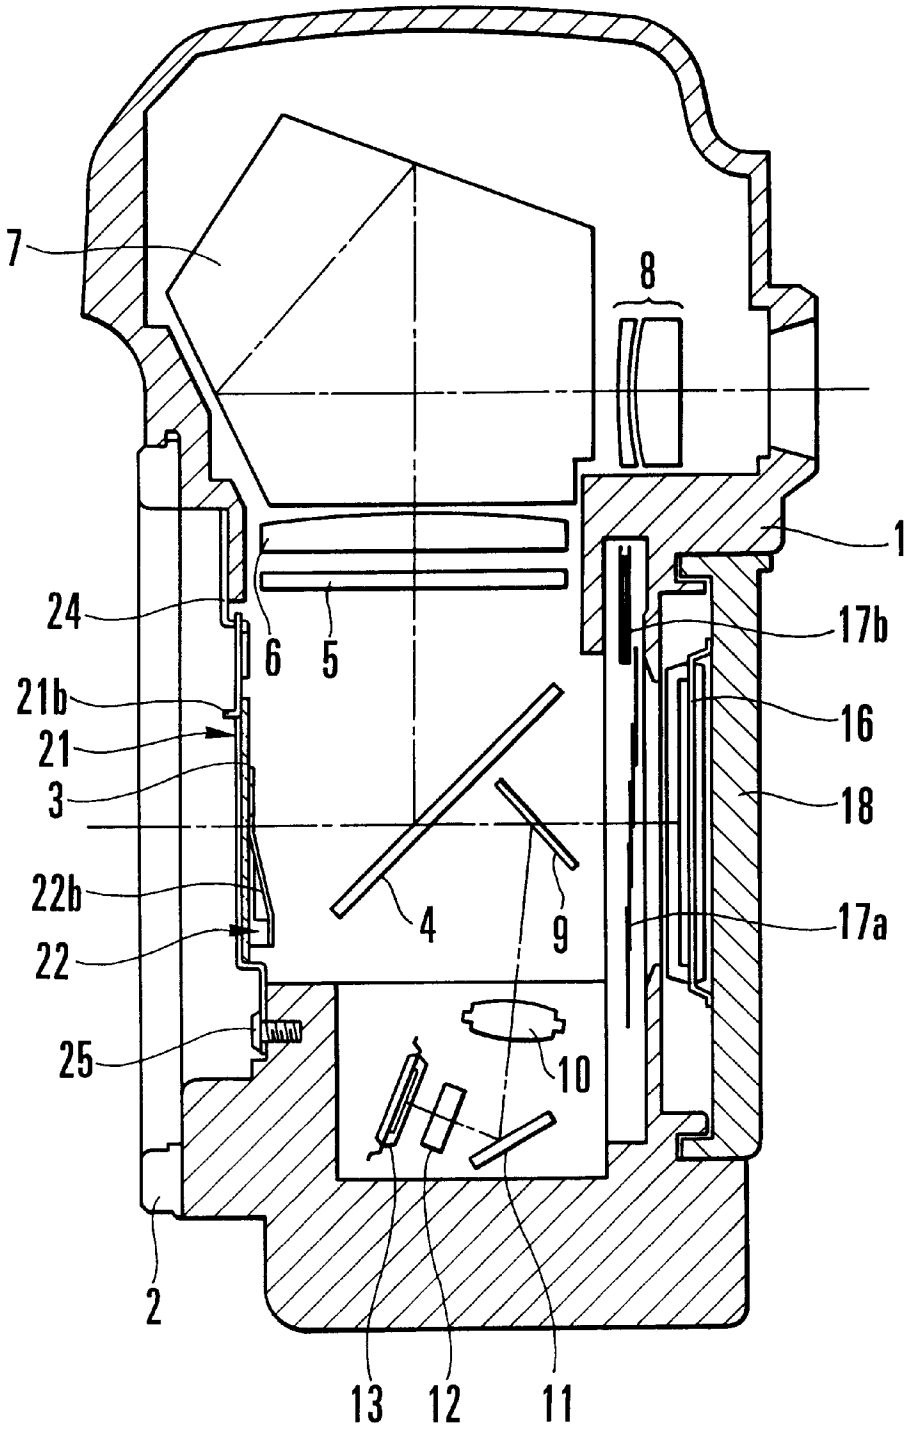

FIG. 2

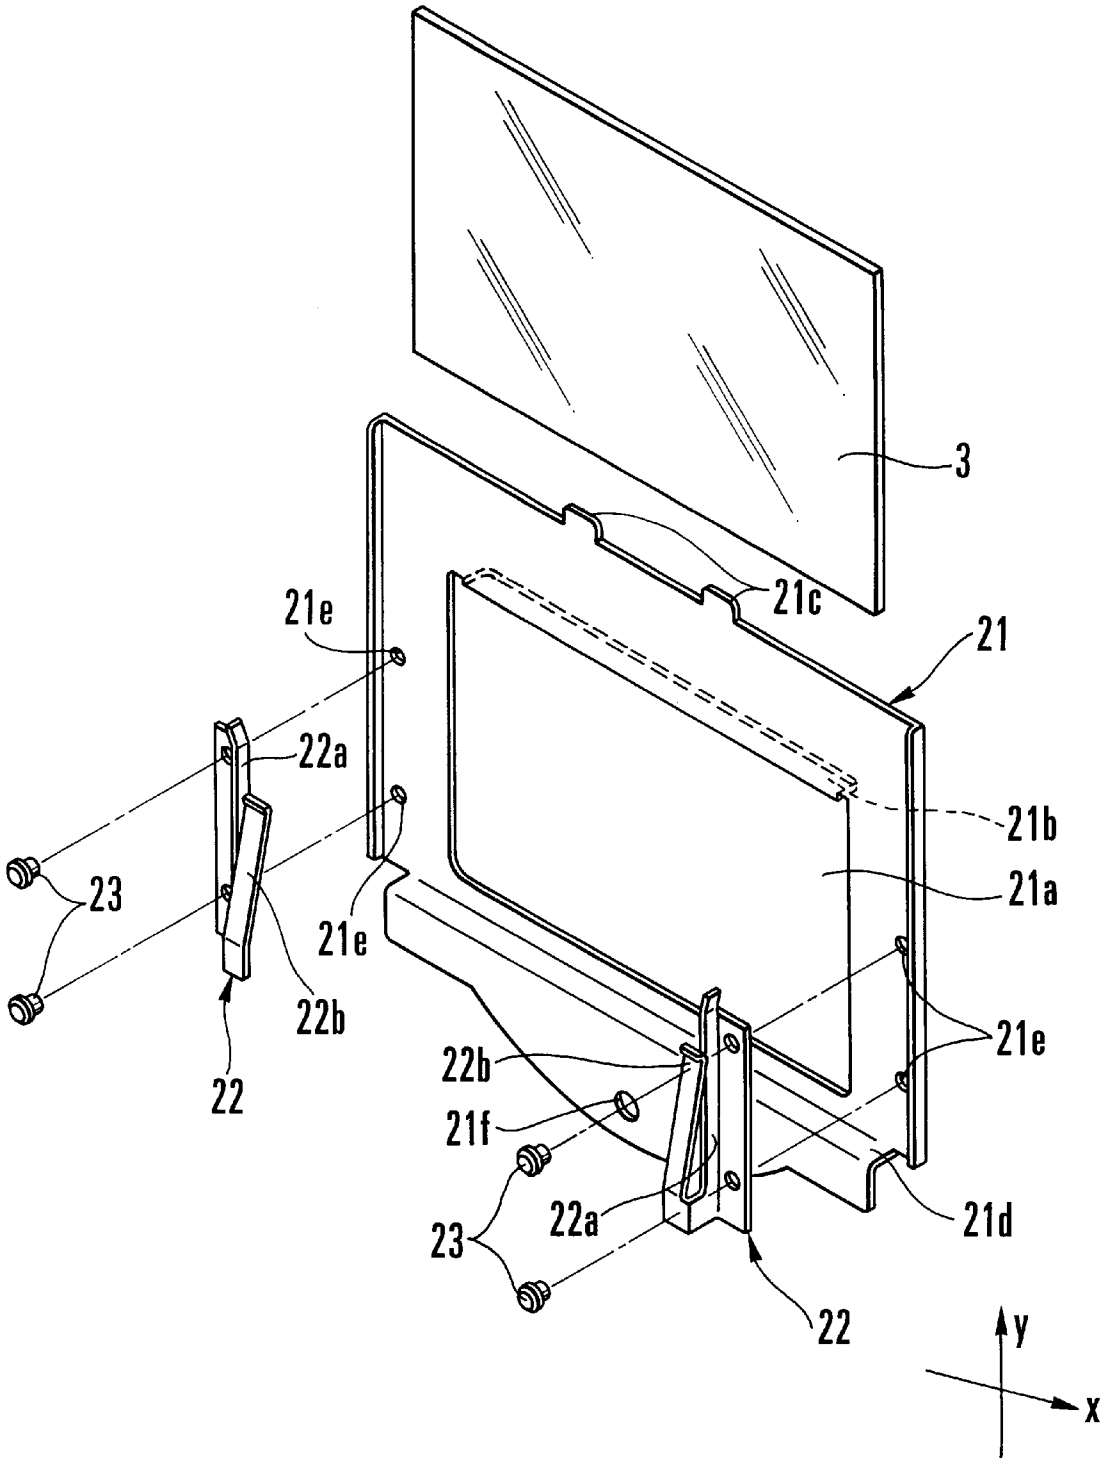

FIG. 3

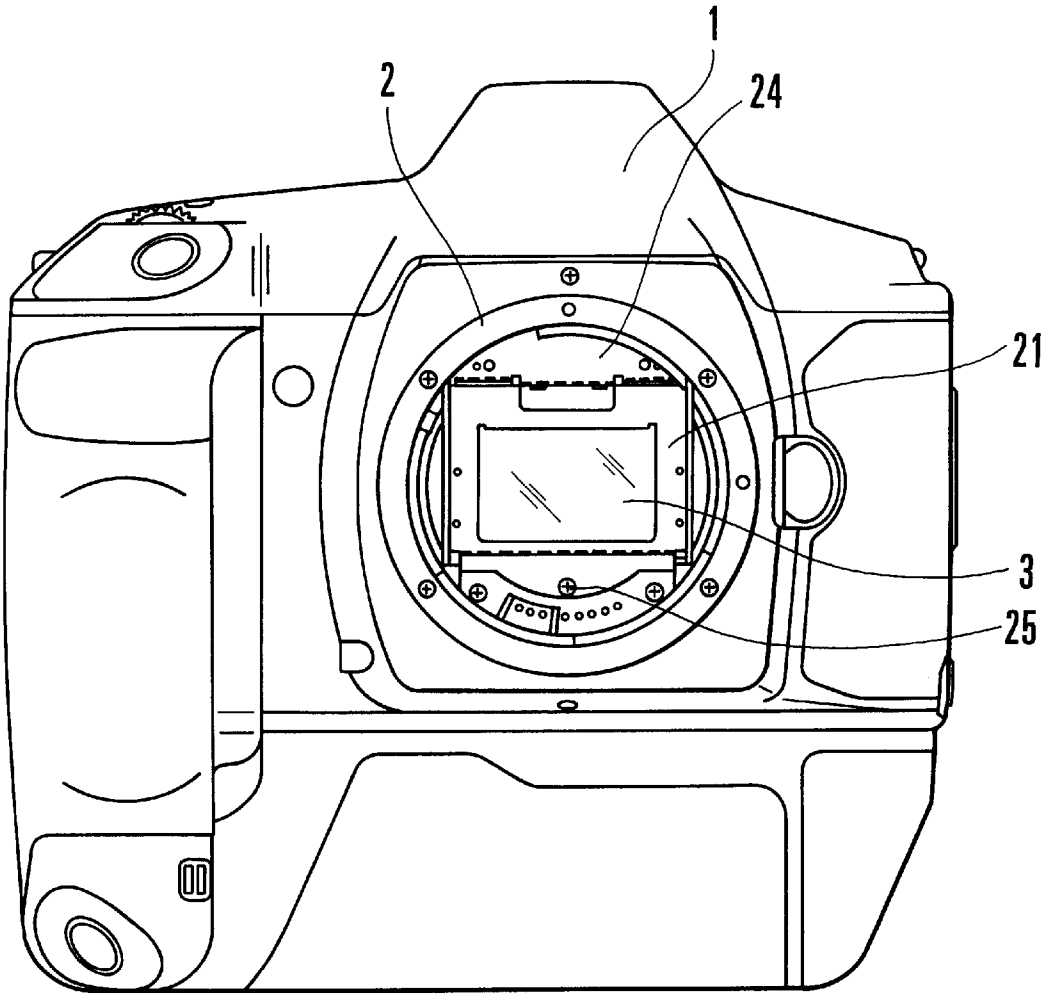

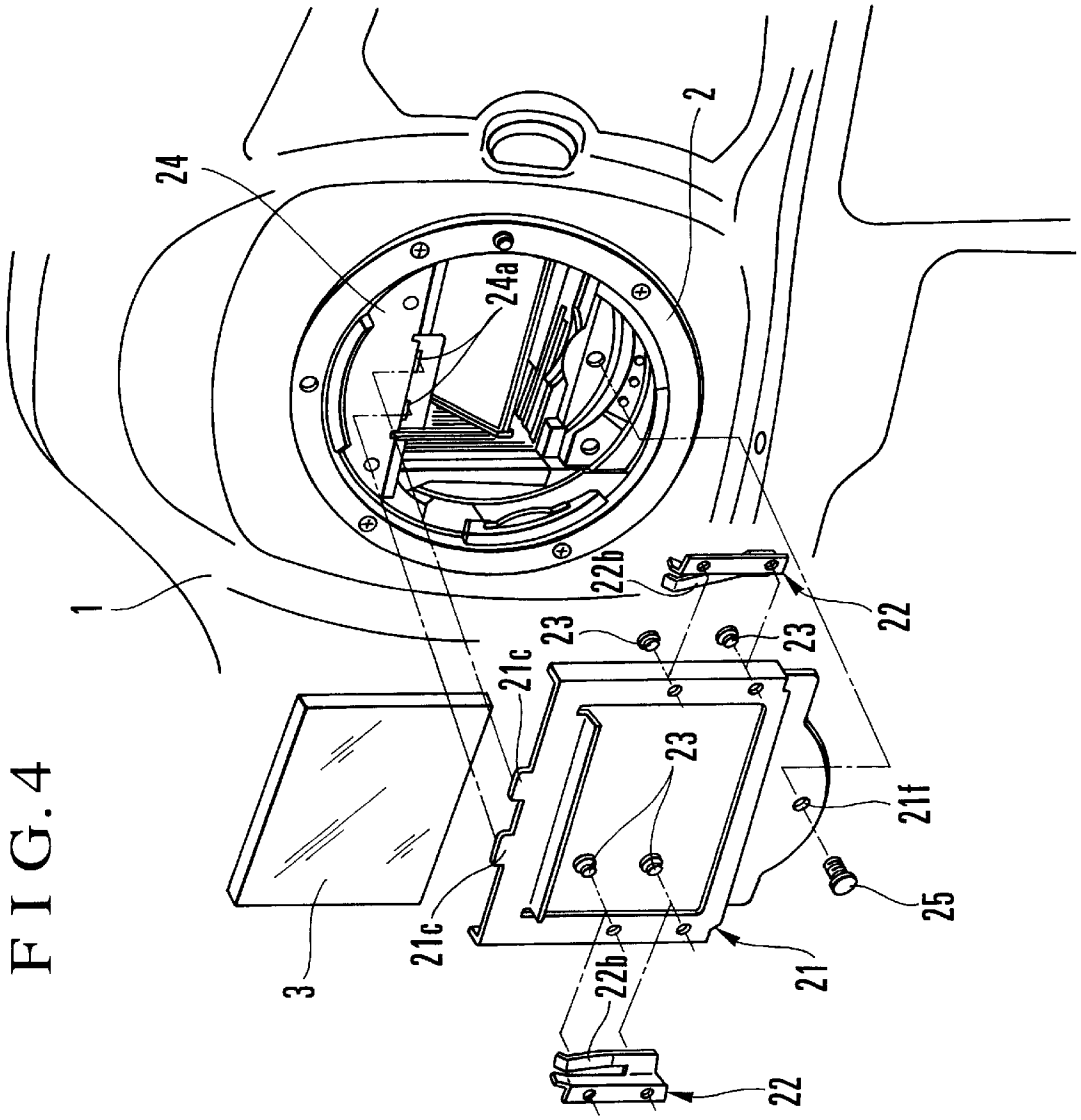

FIG. 4

FIG. 5

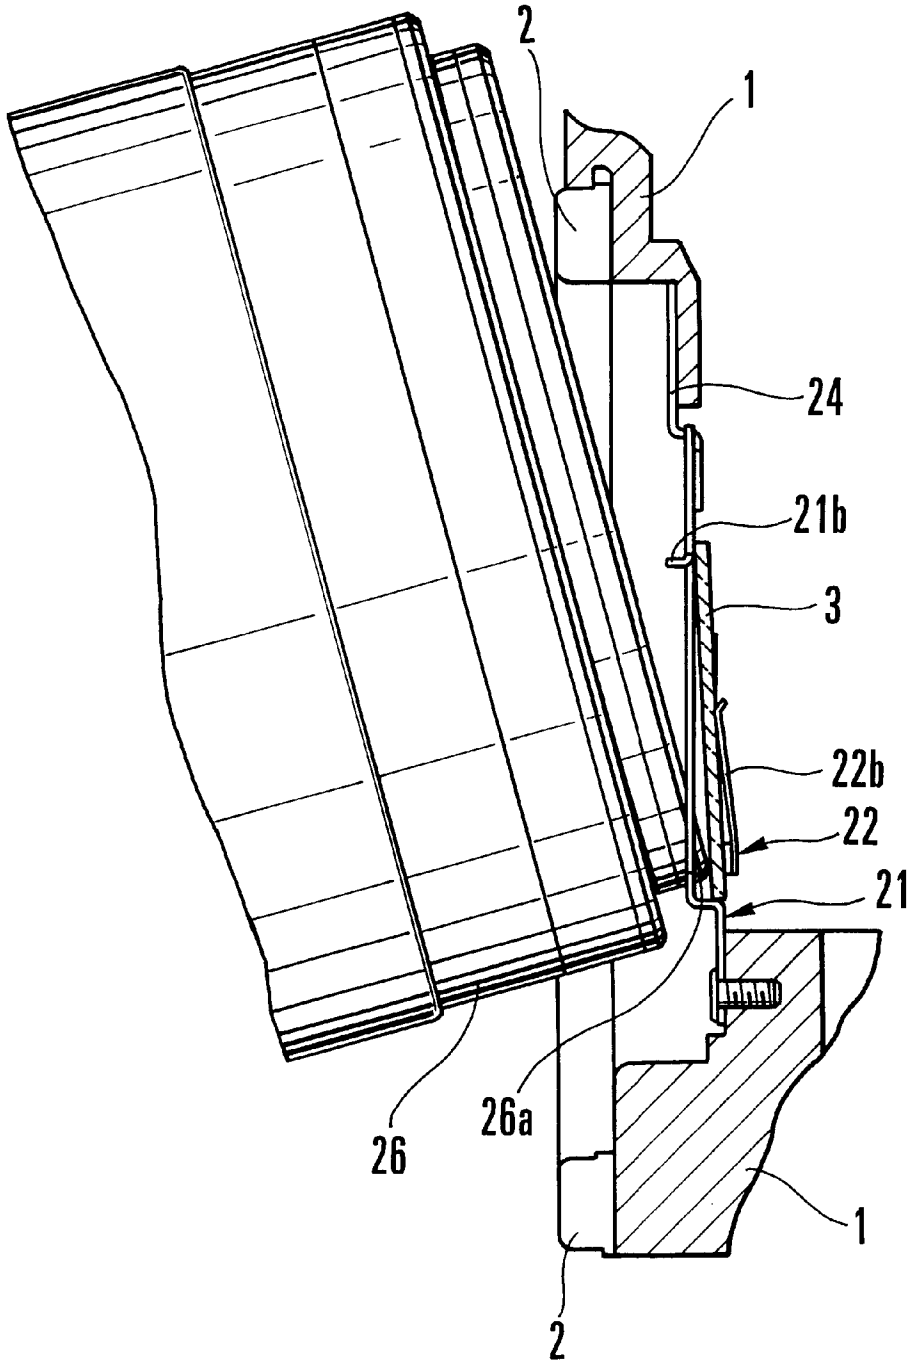

FIG. 6

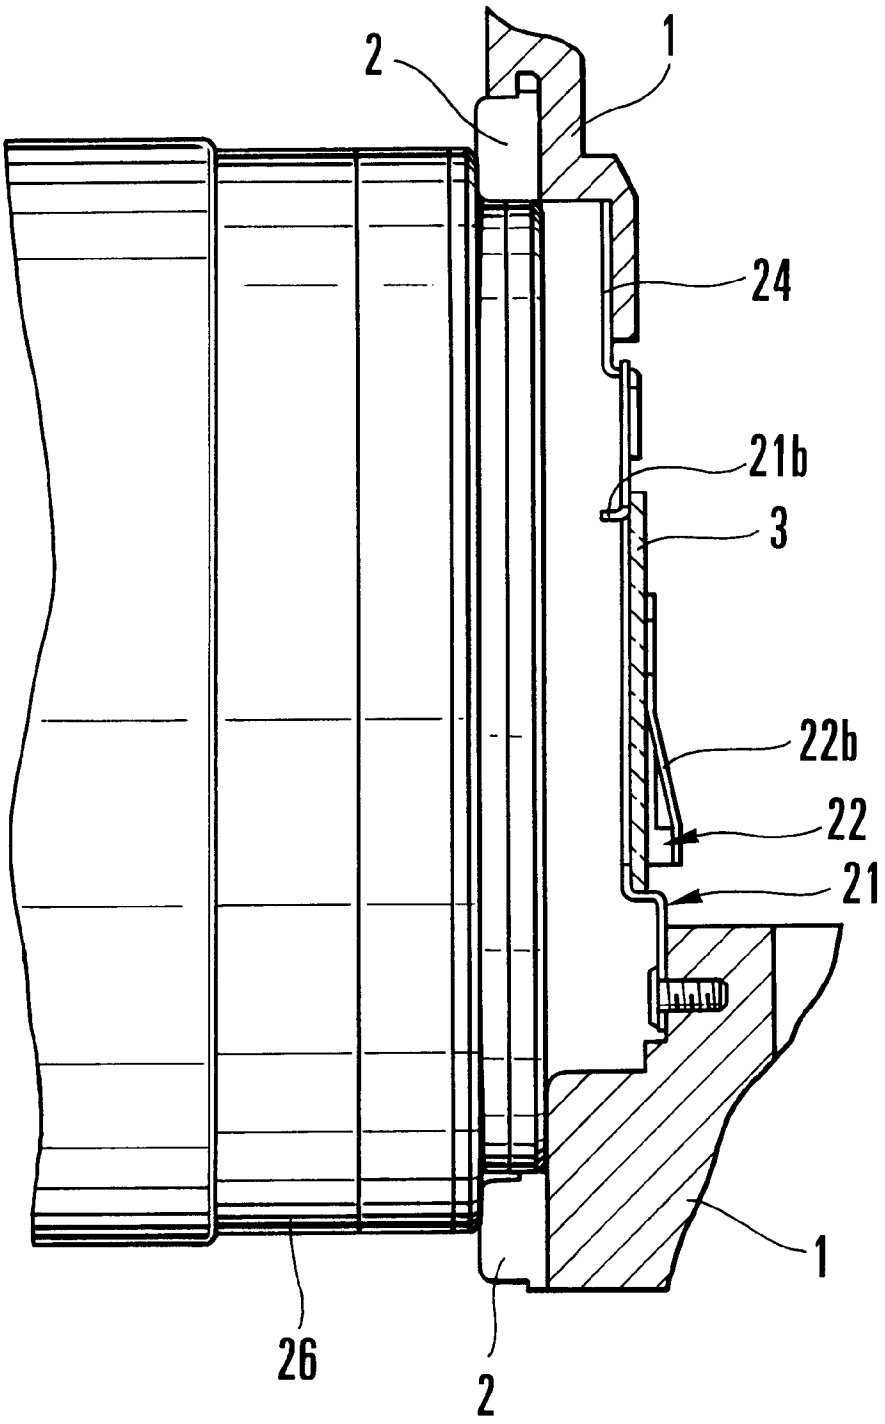

FIG. 7

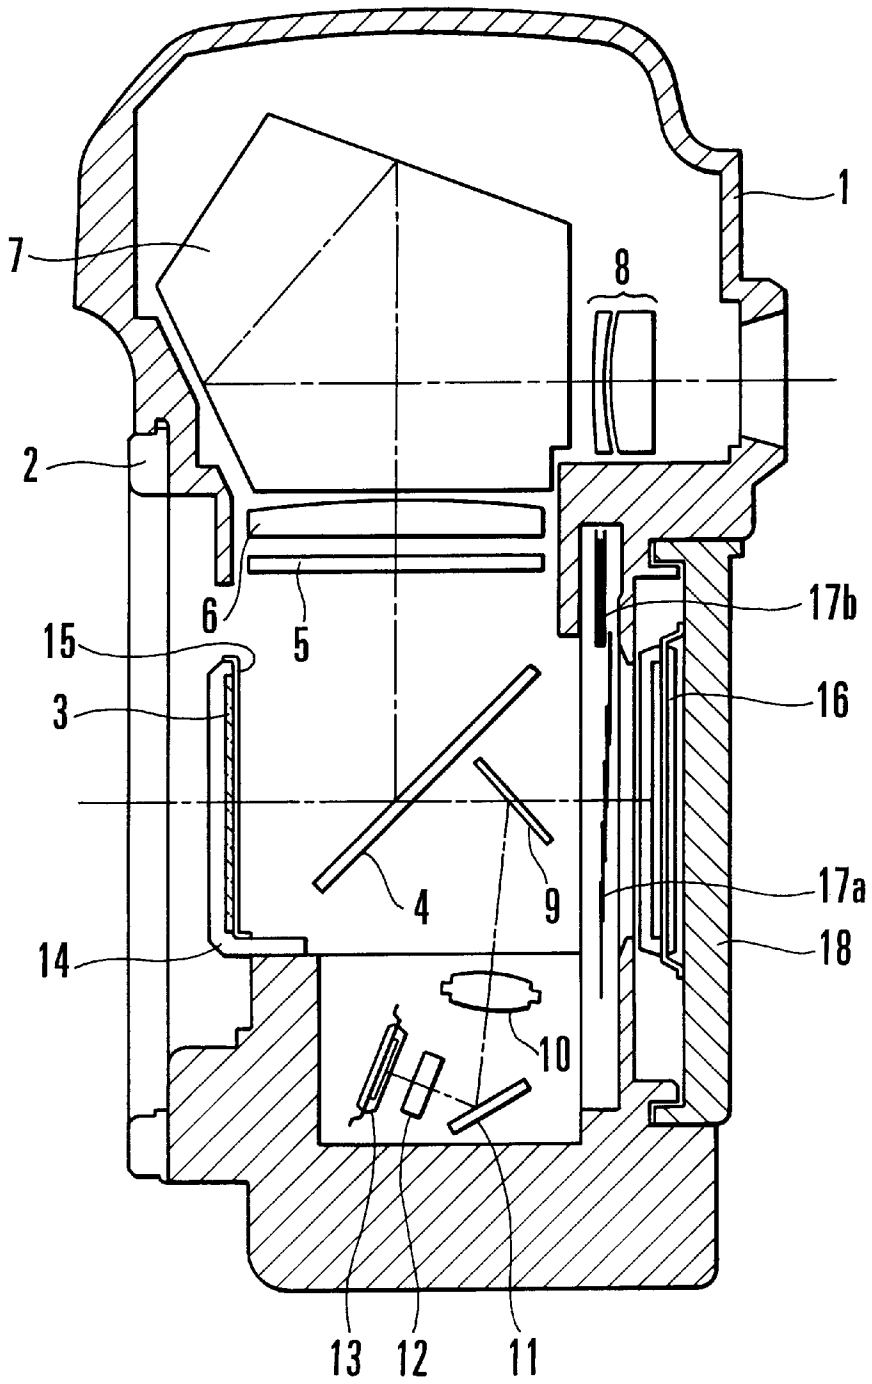

CAMERA HAVING INTERCHANGEABLE OBJECTIVE LENS

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to a single-lens reflex type camera having a solid-state image sensor and arranged to be capable of recording information by using the solid-state image sensor and to permit use of an interchangeable photo-taking lens.

2. Description of Related Art

A number of cameras of the single-lens reflex type having a light flux obtained through a photo-taking lens used both by a viewfinder optical system for observing a photo-taking object and by an image forming system for taking a picture of the object have been developed to use a solid-state image sensor in place of a silver-halide film at an image recording part. However, if accessories used for the conventional single-lens reflex cameras, such as interchangeable lenses, external electronic flash devices, etc., are not usable for the cameras having the solid-state image sensors, it is greatly disadvantageous not only to the users of conventional single-lens reflex cameras but also to the providers of the cameras.

Accordingly, a number of cameras have been variously proposed in which, to provide a camera having a solid-state image sensor without varying the system interchangeability of single-lens reflex cameras, the solid-state image sensor is placed at a focal image forming portion corresponding to the position of the silver-halide film on the base of the conventional silver-halide-film-using single-lens reflex camera.

In the case of such a camera having a solid-state image sensor, a CCD image sensor or the like is used in general. However, such an image sensor has a spectral sensitivity characteristic which requires some correction. To meet this requirement, some optical filters are used in general. These filters include a low-pass filter which is used for avoiding a moire pattern resulting from a relation between the number of pixels of the image sensor and the high spatial frequency of the photo-taking object and for avoiding a spurious color obtained in the case of a color image sensor, and an infrared cut filter for cutting off an infrared component. As disclosed in Japanese Patent Publication No. HEI 4-435, the optical filter can be disposed in a space immediately before a shutter.

However, such a disposition of the optical filter in that space brings about the following two problems.

Firstly, unlike the conventional single-lens reflex camera, the camera of the kind having a solid-state image sensor requires no film replacing action and thus requires no back lid (back cover) arranged to be opened and closed for replacing a film. Therefore, if it is taken into consideration that the work of removing dust attached to the optical filter or replacing the optical filter with another optical filter is performed through a lens-mount opening part of the camera, the existence of a main mirror makes it very difficult to perform that working.

Secondly, since a light flux coming from a photo-taking object is split by the main mirror into light fluxes which are directed respectively toward a viewfinder system and a photo-taking system and, then, only the light flux directed to the photo-taking system passes through the optical filter, a change in optical path length caused by the optical filter takes place only in the photo-taking system. Hence, the optical path length of the viewfinder system must be made

to be equal to that of the photo-taking system either by providing the viewfinder system also with an optical filter or by modifying the design of optical path length of the viewfinder or that of the total optical path length of the photo-taking system. However, such a modification not only necessitates redesign work but also results in an increase in size of the camera.

To solve the above-stated two problems, it has been considered to change the installing position of the optical filter to a position immediately before the main mirror, i.e., immediately behind the photo-taking lens.

Such a change in the installing position of the optical filter solves the above first problem to facilitate the above-stated optical filter cleaning and replacing work, because the optical filter is located immediately behind the lens-mount opening part.

As for the above second problem, since the object light flux is split by the main mirror to the viewfinder system and the photo-taking system after passing through the optical filter, the change in optical path length is equally caused by the optical filter both in the viewfinder system and the photo-taking system. Therefore, a change in the focal image forming position resulting from an increase of the optical path length due to the optical filter can be corrected by just changing the thickness of the mount.

FIG. **7** shows by way of example the arrangement of the conventional single-lens reflex type camera having a solid-state image sensor in which an optical filter is installed immediately before a main mirror. Referring to FIG. **7**, a bayonet mount part **2** is provided at the front surface of a camera body **1**. A photo-taking lens (not shown) is detachably mounted on the mount part **2**. An optical filter **3** which is a low-pass filter or an infrared cut filter is disposed between the mount part **2** and the main mirror **4**. When the user of the camera observes an object image, an object light flux coming through the photo-taking lens passes through the optical filter, so that a spectral sensitivity characteristic of the object light flux is corrected there. After the correction, a part of the object light flux is reflected upward almost at a right angle by the main mirror **4**, which is a half-mirror. The reflected object light flux passes through a focusing screen **5** and a condenser lens **6** to be converted into an erecting image by a vertical and lateral inverting action of an erecting image forming element **7**. The light flux of the erecting image thus obtained is led to the user through an eyepiece lens group **8**. In addition, another part of the object light flux passes through the main mirror **4** and is then totally reflected by a total-reflection submirror **9**. The light flux reflected by the submirror **9** is led to an automatic focusing sensor **13** through an automatic focusing optical system (**10**, **11** and **12**) so as to detect a focusing state of the photo-taking lens.

The optical filter **3** is interposed in between a support member **14** and a fixing plate **15** to be fixed in position perpendicularly to an optical axis and not to become aslant. The support member **14** is mounted, integrally with the optical filter **3**, on the camera body **1** with a screw (not shown).

In taking a shot at an object, the main mirror **4** and the submirror **9** required for the above-stated observation and focus detection are beforehand retracted from the path of the object light flux between an objective lens group of the photo-taking lens and a CCD image sensor **16** serving as a focal plane.

Next, a photo-taking light flux having passed through the objective lens group of the photo-taking lens passes through

the optical filter **3** to have a spectral sensitivity characteristic thereof corrected there. When a fully-open state of shutter leading blades (front curtain) **17***a* is obtained, an image of the photo-taking object is formed on the CCD image sensor **16**, which is mounted from the side of a back lid **18** in a focal image forming position that is about the same as the position of a silver-halide film in a single-lens reflex camera. After the CCD image sensor is exposed to the light of the object image to accumulate it for a predetermined period of time, the light flux of the photo-taking object image is cut off by a closing action of shutter trailing blades (rear curtain) **17***b*. After that, information on the image thus picked up is transferred to be recorded as an image signal on a storage device disposed either within the camera body or outside of the camera body.

The single-lens reflex type camera arranged to have the optical filter mounted immediately before the main mirror as described above, however, has the following problem. Since the main mirror **4** is arranged to be retracted upward at the time of an exposure, the size of a flange back part must be increased for the purpose of preventing the main mirror **4** from interfering with the optical filter **3**. This increase causes an increase in size of the camera.

This problem may be solved by arranging the main mirror **4** in a smaller size to prevent the main mirror **4** from interfering with the optical filter **3**.

However, in mounting a photo-taking lens on the above-stated camera having a solid-state image sensor, the base of which is the conventional single-lens reflex camera using a silver-halide film, an end part of the photo-taking lens tends to damage, or might break, the surface of the optical filter if the end part of the photo-taking lens comes to touch the optical filter. This problem still remains to be solved.

BRIEF SUMMARY OF THE INVENTION

The invention is directed to the solution of the above-stated problem. It is, therefore, an object of the invention to provide a camera having a solid-state image sensor, in which an optical filter is prevented from being damaged by a mounting or demounting operation on a photo-taking lens and is easy for maintenance work.

To attain the above object, in accordance with an aspect of the invention, there is provided a camera having a solid-state image sensor, in which an optical filter is disposed between a photo-taking lens and a main mirror and the optical filter is held by a support member which supports the optical filter and an elastic member which pushes the optical filter against the support member.

The above and other objects and features of the invention will become apparent from the following detailed description of a preferred embodiment thereof taken in connection with the accompanying drawings.

BRIEF DESCRIPTION OF THE SEVERAL VIEWS OF THE DRAWING

FIG. **1** is a vertical section view of a camera having a solid-state image sensor according to an embodiment of the invention.

FIG. **2** is an exploded perspective view showing an optical filter unit of the camera.

FIG. **3** is a front view of the camera with a photo-taking lens demounted.

FIG. **4** is a perspective view showing the manner of fixing the optical filter unit to the camera body.

FIG. **5** is a sectional view showing essential parts of the camera during the process of mounting the photo-taking lens on the camera body.

FIG. **6** is a sectional view showing essential parts of the camera at the time of completion of mounting the photo-taking lens on the camera body.

FIG. **7** is a vertical section view of the conventional camera having a solid-state image sensor.

DETAILED DESCRIPTION OF THE INVENTION

Hereinafter, a preferred embodiment of the invention will be described in detail with reference to the drawings.

FIG. **1** is a vertical section view of a camera having a solid-state image sensor according to the embodiment of the invention. FIG. **2** is an exploded perspective view of an optical filter unit of the camera. FIG. **3** is a front view of the camera with a photo-taking lens demounted. FIG. **4** is an exploded perspective view showing the manner of fixing the optical filter unit to the camera body.

The structural arrangement of the camera having a solid-state image sensor shown in FIG. **1** is the same as that of the conventional camera shown in FIG. **7**, except for the support structure for the optical filter unit. Therefore, the parts of the camera shown in FIG. **1** which are the same as those shown in FIG. **7** are denoted by the same reference numerals as in FIG. **7**, and the details of them are omitted from the following description.

Referring to FIGS. **1** and **2**, a support member **21** is arranged to support an optical filter **3**. The support member **21** is provided with an aperture part **21***a* for restricting the amount of an object light flux coming through the photo-taking lens, and a picking part **21***b* which is formed along the upper edge of the aperture part **21***a* to serve as a knob in mounting and removing the optical filter unit on and from the camera body **1**. Further, the support member **21** is provided with a pair of projections **21***c* and an L-shaped bent part **21***d*, which are formed respectively on the upper and lower edges of the support member **21**. Furthermore, a pair of pin holes **21***e* for receiving caulking pins **23** are formed in the edge part of each of two sides of the support member **21**, and the L-shaped bent part **21***d* is provided with a hole **21***f* for a stop screw **25** which will be described later herein.

Referring to FIGS. **2** and **4**, a pair of elastic members **22** are arranged to push the optical filter **3** against the support member **21** so as to ensure that the optical filter **3** never moves nor comes off when the camera is moved. Each of the elastic members **22** is composed of a restricting part **22***a* and an elastic part **22***b*. The restricting part **22***a* has two faces. One face of the restricting part **22***a* defines the position of the optical filter **3** in the direction of "x" on a plane orthogonally intersecting the direction of an optical axis, while the other face thereof slants outward at the upper end of the restricting part **22***a*. The restricting part **22***a* is thus arranged to guide the optical filter **3** when the optical filter **3** is inserted. The elastic part **22***b* exerts a resilient force to push the optical filter **3** against the support member **21**. The caulking pins **23** are inserted into the pin holes **21***e* of the support member **21** to have the elastic member **22** secured there by caulking.

Referring to FIGS. **3** and **4**, a shield member **24** is fixedly secured to the upper edge side of a front aperture part of the camera body **1**. The shield member **24** has a pair of open parts **24***a* formed in its lower edge part to insert therein the projections **21***c* of the support member **21**. The stop screw **25** is arranged to secure the support member **21** to the lower edge side of the front aperture part of the camera body **1** through the hole part **21***f* provided in the support member **21**.

The optical filter unit having the above structure is assembled and fixed to the camera body **1**, as described below with reference to FIGS. **2** and **4**.

With the elastic member **22** in a state of having been fixed to the support member **21** with the caulking pins **23**, the optical filter **3** is first slid from above in between the support member **21** and the elastic parts **22***b* of the elastic member **22**. The optical filter **3** is thus inserted until the lower end face of the optical filter **3** abuts on the bent part **21***d* of the support member **21**. Thus, the optical filter unit is assembled in the above manner.

Next, the projections **21***c* provided at the upper part of the support member **21** are inserted into the pair of open parts **24***a* of the shield member **24** fixed to the front aperture side of the camera body **1**. Then, the optical filter unit is fixedly secured to the camera body **1** with the stop screw **25** inserted into the lower hole part **21***f* of the support member **21**.

With the optical filter unit thus fixed to the camera body **1**, in mounting a photo-taking lens **26** on the camera body **1** at the bayonet mount part **2**, the optical filter unit acts as follows, as shown in FIGS. **5** and **6**.

As shown in FIG. **5**, in mounting the photo-taking lens **26** on the bayonet mount part **2**, an end part **26***a* of the photo-taking lens **26** comes to touch the surface of the optical filter **3**. Therefore, there arises some force of pushing the optical filter **3** with the photo-taking lens **26**. When this pushing force comes to exceed a certain amount of force, the resilient force of the elastic part **22***b* of the elastic member **22**, which keeps the optical filter **3** in contact with the support member **21**, yields to the pushing force, so that the optical filter **3** slants as shown in FIG. **5**. Accordingly, since the optical filter **3** moves in the direction of escaping from the photo-taking lens **26**, the optical filter **3** is effectively saved from receiving any force that exceeds a predetermined value.

The optical filter **3** thus can be prevented from being damaged or broken by the photo-taking lens **26**.

In this instance, the picking part **21***b* of the support member **21** is located closer to the photo-taking lens **26** than the aperture part **21***a* in the direction of the optical axis and serves to prevent the end part **26***a* of the photo-taking lens **26** from touching the upper half of the surface of the optical filter **3** which extends perpendicular to the optical axis.

Next, the end part **26***a* of the photo-taking lens **26** no longer touches the optical filter **3** after completion of mounting the photo-taking lens on the bayonet mount part **2**. As a result, the optical filter **3** is pushed only by the resilient force of the elastic part **22***b* of the elastic member **22** and is thus allowed to resume its state of abutting on the support member **21**, as shown in FIG. **6**.

As described above, in accordance with the invention, in a camera of the kind having a solid-state image sensor and an interchangeable photo-taking lens with an optical filter disposed between the photo-taking lens and the main mirror, a fixing member for the optical filter is composed of a support member which supports the optical filter and an elastic member which causes the optical filter to abut on the support member with its elastic part. This arrangement allows the optical filter to move in the direction of escaping from the photo-taking lens when the photo-taking lens comes to touch the optical filter in mounting the photo-taking lens on the camera body. Therefore, the photo-taking lens can be mounted on the camera body without damaging or breaking the optical filter. Besides, the arrangement facilitates maintenance work on the optical filter.

Further, according to the arrangement of the embodiment disclosed, the elastic member causes the optical filter to abut on the support member by exerting its resilient force on the side of the second surface of the optical filter located opposite to its first surface which faces the end part of the photo-taking lens in mounting the photo-taking lens. That arrangement ensures that the photo-taking lens can be mounted and demounted without damaging the optical filter, and the optical filter can be promptly set in its predetermined position after the photo-taking lens is mounted.

Further, according to the invention, the optical filter is composed of a low-pass filter or an infrared cut filter. Therefore, the use of the optical filter enables the camera having a solid-state image sensor to take pictures with an excellent picture quality.

What is claimed is:

1. A camera body on which an interchangeable objective lens is mountable, comprising:

a solid-state image sensor disposed in a position where said objective lens forms an image; and

an optical filter disposed within said camera body in facing relation with said objective lens,

wherein said optical filter is mounted so as to be displaceable, as a result of contact with said objective lens during mounting of said objective lens, away from a position where said objective lens is mountable, and so as to move toward said position where said objective lens is mountable during the releasing of said contact.

2. A camera body according to claim **1**, further comprising a mirror arranged between said optical filter and said solid-state image sensor to reflect a light flux coming through said objective lens toward a viewfinder unit.

3. A camera body according to claim **1**, wherein said optical filter is an optical low-pass filter.

4. A camera body according to claim **1**, wherein said optical filter is an infrared cut filter.

5. A camera body according to claim **1**, further comprising a holding member which holds said optical filter, said holding member being fixed to said camera body and being provided with an elastic member for urging said optical filter toward said holding member.

6. A camera body on which an interchangeable objective lens is mountable, comprising:

a solid-state image sensor disposed in a position where said objective lens forms an image; and

an optical filter mounted within said camera body so as to be displaceable, as a result of contact with said objective lens in the course of mounting of said objective lens, away from a position where said objective lens is mountable, and so as to move toward said position where said objective lens is mountable during releasing of said contact.

7. A camera body according to claim **6**, further comprising a holding member which holds said optical filter, said holding member being fixed to said camera body and supporting said holding member for said displacement by said objective lens.

8. A camera body according to claim **7**, wherein said holding member includes an elastic member for returning said optical filter to undisplaced disposition following displacement of said optical filter by said objective lens.

9. A camera body according to claim **6**, wherein said displacement of said optical filter is a slanting movement along an optical axis.

10. A camera body comprising:

a mount for an interchangeable objective lens; and

an optical filter disposed within said camera body in facing relation with said objective lens mount,

wherein said optical filter is mounted so as to be displaceable, as a result of contact with said objective lens during mounting of said objective lens on said objective lens mount, away from said objective lens mount, and so as to move toward said objective lens mount during the releasing of said contact.

11. A camera body comprising:

a mount for an interchangeable objective lens; and

an optical filter mounted within said camera body so as to be displaceable, as a result of contact with said objective lens in the course of mounting of said objective lens on said objective lens mount, and so as to move toward said objective lens mount during release of said contact.

CYLINDRICAL MOUNT FOR OPTICAL COMPONENTS OF A VARIABLE-POWER OBJECTIVE

BACKGROUND OF THE INVENTION

1. Field of the Invention

The invention relates to a cylindrical mount for optical components of a variable-power objective.

2. Related Art

Many versions of mounts for variable-power objectives, such as zoom lenses, are known. In them, a plurality of lenses or lens groups are held in different carriers and are displaced relative to one another along the optical axis of the objective in order to change the focal length. Thus, in variable-power (or zoom) objectives, a change in focal length of the objective results in variable magnification of the object in the image plane.

In addition, it is often necessary to displace individual lenses or lens groups in order to set the focus of the objective, which is independent of changing the focal length. A zoom objective in a position of a selected focal length setting should be adjusted or focussed to the correct distance of the object for sharp imaging in the image plane.

As may be gathered, for example, from U.S. Pat. No. 5,675,444, the displacement of the lenses or lens groups relative to one another normally takes place via a cam control which is driven by an outer rotary ring. In this case, the carrier of the lenses or lens groups engages via a pin into the cam track of a rotatably mounted cam carrier and is simultaneously guided in the axial direction in a straight-line guide. U.S. Pat. No. 5,748,390 discloses rod systems for guidance in a straight line, on which the lens carriers run and which are fastened to the mount. Further rod systems may also be fastened to one of the adjustable lens carriers. This ensures that, in the event of displacement, the lenses are not rotated, so as to avoid optical imaging errors due to decentering. It is also known to separate the cam control and the straight-line guide from one another, in which case separate straight-line guide elements for the carriers of the lenses are provided in the mount cylinder.

In the known mounts, the focus setting movement is transmitted via a helical gearing, in which the mount of the lenses or lens components to be displaced is rotated. Depending on the pitch of the driving worm, the angle of rotation is generally not too great, so that any possible imaging errors due to the rotation of the optical surfaces relative to the fixed lens surfaces are often acceptable. However, for example, some sluggishness in the movement of the worm is unavoidable.

Front lens groups, onto which filters and diaphragms are also attached, are frequently used for focussing. In order to use polarizing filters and noncircular diaphragms, it is then necessary to choose a different type of fastening, so that their orientation can be maintained when the focus is being set.

SUMMARY OF THE INVENTION

An object on which the invention is based is, therefore, to provide a device for focus setting, which allows axial adjustment of the lens components without rotation. The focus setting is not to change in the event of a subsequent focal length setting and nevertheless is to be very smooth.

In a cylindrical mount, this object can be achieved, according to one aspect of the present invention, by an inner straight-line guide, with a cam control which is capable of being actuated via a rotary ring arranged on the outside of the mount and which is intended for the adjustment of carriers, for lenses or lens groups relative to one another in order to change the focal length. A further rotary ring is provided for adjusting a holder for lenses or lens groups for setting the focus of the objective. The holder is arranged on a linear guide which is adjustable in the direction of the optical axis and which is fastened to a carrier displaceable with the change in focal length. The further rotary ring has, on its inner cylindrical surface, a cam carrier which is held displaceably in the direction of the optical axis on the cylindrical surface. The holder has a transmission element which is in engagement with the cam carrier, and the cam carrier possesses a guide element which points inward in the radial direction and which is in engagement with a guide slot arranged perpendicularly to the optical axis of the objective on the outer cylindrical surface of the carrier.

Further features of the invention form the subject matter of the claims and will be explained in more detail, in conjunction with further advantages of the invention, with reference to an exemplary embodiment.

BRIEF DESCRIPTION OF THE DRAWINGS

Embodiments of the invention, serving as an examples, are illustrated schematically in the drawings, in which:

FIG. **1** shows a longitudinal section through the mount, and

FIG. **2** shows a cross section through the mount.

DETAILED DESCRIPTION OF THE EXEMPLARY EMBODIMENTS

FIG. **1** illustrates a cylindrical mount **1**, for example, for a camera, which has an inner straight-line guide. The straight-line guide comprises a rail **2**, on which ball-mounted slides **3** slide. Fastened to the slides **3** are carriers **4**,**4'**, into which lenses or lens groups, not illustrated, are inserted. A further carrier **5** is displaceably mounted, via ball bearings not illustrated, on the carrier **4** on two rod guides **6**, **7**. For setting the focus, a holder **10** for lenses or lens groups, likewise not illustrated, is displaceably mounted on the carrier **4'** via further rod guides **8**, **9** and ball bearings. The rod guides, located diametrically opposite one another, bring about play-free and extremely smooth straight-line guidance to the carrier **5** and the holder **10**.

The carriers **4**, **4'**, **5** engage, with the pins **11** fastened to them, into cam guides **12** which are milled into a cylinder **13**. The cylinder **13** is connected via a pin **14** to a rotary ring **15** which is rotatably mounted on the mount **1**. When the rotary ring **15** is actuated, the cylinder **13** is co-rotated and, by virtue of the gradient of the milled-in cam guides **12**, transmits said gradient to the carriers **4**, **4'**, **5** as an axial displacement along the rail **2** or the rod guides **6**, **7**, **8**, **9**. Each of the carriers **4**, **4'**, **5** may be provided with its own form of the cam guide **12**, so that each executes its own displacement movement.

Fastened to the outer cylindrical part of the carrier **4'** is a guide slot **16**. Into this engages a guide element which is designed as a flat web **17** and which is fastened to a cam carrier **18**. The cam carrier **18** is held displaceably in the axial direction on the inner cylindrical surface of a further rotary ring **19**. The holder **10** has a pin **20** which is in engagement with a cam track **21** in the cam carrier **18**.

During axial adjustment of the carrier **4'**, via the cam guide **12** assigned to it, in order to change the focal length, carrier **4'** also displaces the holder **10** in the same way by virtue of the axially rigid coupling of the guide slot **16** to the

web **17**, cam carrier **18** and pin **20**. When the rotary ring **19** is actuated only the cam carrier **18** is co-rotated and via the gradient of the cam guide **21** and the pin **20** exerts an axial adjusting force on the holder **10**. In this case, the axial position of the cam carrier **18** is maintained via the web **17** and the guide slot **16**. Rotation of the holder **10** about the optical axis **24** is ruled out by the rod guides **8**, **9**. On account of the smooth movement of the axially adjustable focussing component, a motor drive (not shown) may also be used, instead of the manually actuable rotary ring **19**, so that the solution according to the invention can also be used, in particular, for auto-focus objectives.

FIG. **2** illustrates how the cam carrier **18** is held on the inner cylindrical surface of the rotary ring **19** in two dovetail guides **22**, **23** which extend in the axial direction. Flat web **17**, which slides in the guide slot **16**, is integrally formed on the cam carrier **18**. The guide slot **16** is fastened to the carrier **4'**.

Although the invention has been described above by reference to certain embodiments of the invention, the invention is not limited to the embodiments described above. Modifications and variations of the embodiments described above will occur to those skilled in the art, in light of the above teachings.

German Patent Application No. 198 40 775.0, filed Sep. 7, 1998, including the specification, the drawings, the claims, and the abstract, upon which this application is based, is incorporated herein by reference in its entirety.

What is claimed is:

1. A cylindrical mount for optical components of a variable-power objective, comprising:

an inner straight-line guide having a cam control actuatable using a first rotary ring arranged on an outside of the mount;

a first adjustable carrier for carrying a first optical element; and

a second rotary ring for adjusting a holder of a second optical element for setting a focus of the variable-power objective, wherein said holder is coupled to a linear guide that is adjustable in the direction of an optical axis and which is coupled to a second adjustable carrier for carrying an additional optical element that is displaceable with a change in focal length, wherein said second rotary ring further includes, on its inner cylindrical surface, a cam carrier that is held displaceably in the direction of said optical axis on a cylindrical surface, wherein said holder includes a transmission element in engagement with said cam carrier, and wherein said cam carrier includes a guide element that points inward in a radial direction and which is in engagement with a guide slot arranged perpendicularly to said optical axis on an outer cylindrical surface of said second adjustable carrier.

2. The cylindrical mount according to claim **1**, wherein said first adjustable carrier comprises a plurality of carriers of lenses or lens groups adjustable relative to one another in order to change said focal length.

3. The cylindrical mount according to claim **1**, wherein said guide element is a flat web.

4. The cylindrical mount according to claim **1**, wherein said cam carrier is held in a dovetail guide.

5. The cylindrical mount according to claim **1**, wherein an axial adjustment of said carriers is accomplished without a rotation of said optical elements.

6. A cylindrical mount for optical components of a variable-power objective, comprising:

an inner straight-line guide;

a cam control which is actuatable via a first rotary ring arranged on the outside of the mount and which is intended for the adjustment of first, second and third carriers for lenses or lens groups relative to one another in order to change the focal length; and

a second rotary ring for adjusting a holder for lenses or lens groups for setting the focus of the objective, wherein the holder is arranged on a linear guide which is adjustable in the direction of the optical axis and which is fastened to the second carrier displaceable with the change in focal length, the second rotary ring has, on its inner cylindrical surface, a cam carrier which is held displaceably in the direction of the optical axis on the cylindrical surface, the holder has a transmission element which is in engagement with the cam carrier, and the cam carrier possesses a guide element which points inward in the radial direction and which is in engagement with a guide slot arranged perpendicularly to the optical axis of the objective on the outer cylindrical surface of the second carrier.

7. The cylindrical mount as claimed in claim **6**, wherein the guide element arranged on the cam carrier is a flat web.

8. The cylindrical mount as claimed in claim **6**, wherein the cam carrier displaceable in the direction of the optical axis is held in a dovetail guide.

[57] **ABSTRACT**

There is disclosed a compact lens system having four injection-molded singlet lens elements with one of the singlet lens elements having a diffractive optical surface to control axial chromatic aberrations and another of the singlet lens elements having a flint-like plastic material to control lateral chromatic aberration. The lens system includes interdigitated flange features which provides interdigitated alignment between the lens elements. A plurality of light suppression elements are used to suppress stray light paths from reaching a detector array of the lens system. Moreover, the lens system includes an anti-aliasing surface on one of the lens elements for controlling aliasing effects.

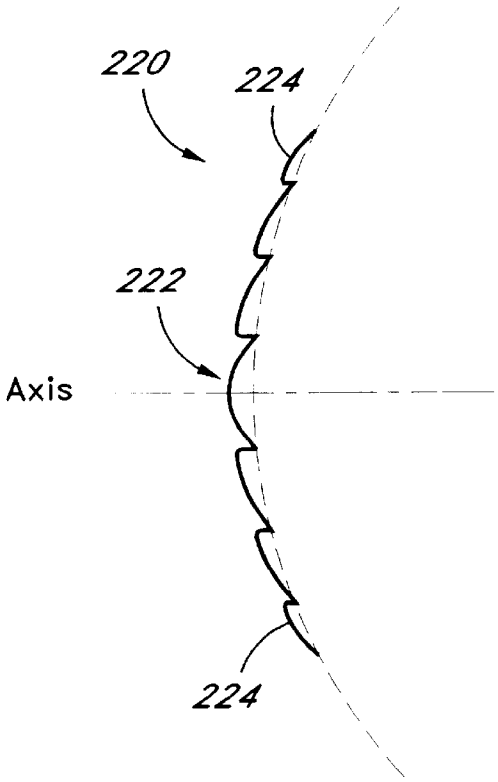

Fig. 3

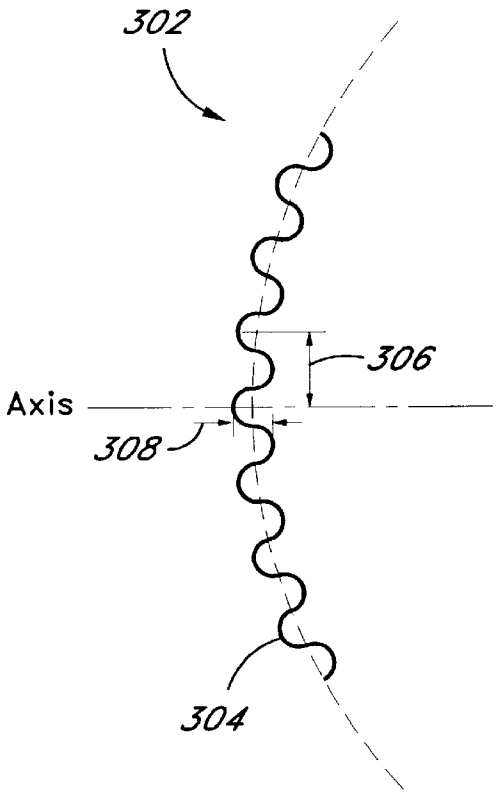

COMPACT DIGITAL CAMERA OBJECTIVE WITH INTERDIGITATED ELEMENT ALIGNMENT, STRAY LIGHT SUPPRESSION, AND ANTI-ALIASING FEATURES

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates generally to the field of lens systems, and specifically, to a compact digital camera objective having interdigitated element alignment, stray light suppression, and anti-aliasing features.

2. Background Information

Prior art complex lens systems with a f/2.0 relative aperture and a 50 degrees field of view that cover color applications (e.g., white light applications, visual applications, film applications, etc.) typically require six lens elements in high index optical glasses with doublet construction in at least two groups of lens elements to provide control of (axial and lateral) chromatic aberrations. Chromatic aberrations are typically severe for plastic lenses and there are only a limited number of materials to choose from. The doublet construction typically includes a positive lens element that has a low dispersion material (e.g., crown) and a negative lens element that has a high dispersion material (e.g., flint) coupled together. However, the disadvantage with prior art lens systems is that the doublet construction in the two groups of lens elements requires two extra lens elements which is very expensive to produce. Moreover, a lens system with six lens elements cannot be made as compact as a lens system with four lens elements.

Accordingly, there is a need in the art for a method and apparatus to provide a complex lens system that is compact and inexpensive while correcting chromatic and all other optical aberrations.

In addition, complex lens systems that operate in the f/2.0 relative aperture, 50 degree full field diagonal and have a small imaging device format (e.g., less than an 8.0 mm diagonal) require very sensitive fabrication and assembly tolerances for acceptable "as-built", image quality. The prior art lens systems typically align lens elements by using spacers. The disadvantage with using spacers is that they add to the cost of the lens system and require a high degree of accuracy in assembly of the lens system.

Therefore, there is a further need in the technology to provide interdigitated alignment between lens elements without the need for extra parts while facilitating construction of the lens system. There is also a need to suppress stray light from reaching a detector array in a lens system that includes interdigitated single piece lens elements having an optical portion and a non-optical mechanical flange portion.

A further problem with optical systems that form images on detector arrays (e.g., a charge-coupled detector, "CCD") and discretely sample images is that they produce aliasing effects in the displayed image. An example of aliasing effects is Moiré effects which occur when objects move, change patterns, and/or change color relative to the detector array and have dimensions commensurate with the pixel dimensions of the detector array. One solution for eliminating or minimizing aliasing effects is to add a quartz plate in front of the detector array. The quartz plate blurs and reduces the sharpness of the image just the right amount to minimize such aliasing effects. However, quartz plates are very expensive, virtually costing as much as the lens system.

It is therefore desirable to provide an optical lens system that eliminates aliasing effects while maintaining a low cost.

SUMMARY OF THE INVENTION

In one embodiment, the present invention is a lens system. The lens system includes a first lens element having a diffractive surface disposed on one surface to correct axial chromatic aberrations of light passing therethrough. The lens system further includes a second lens element having a flint-like material to correct lateral chromatic aberrations of light passing therethrough.

BRIEF DESCRIPTION OF THE DRAWINGS

The features and advantages of the present invention will become apparent from the following detailed description of the present invention in which:

FIG. **1** illustrates a cross section of a lens system of the present invention.

FIG. **2**A illustrates a front view of the diffractive surface of the present invention.

FIG. **2**B illustrates a side view of the diffractive surface of the present invention.

FIG. **3** illustrates an expanded side view of a lens element anti-alias surface of the present invention.

DESCRIPTION OF THE PREFERRED EMBODIMENT

In the preferred embodiment, the present invention is a method and apparatus for providing a compact digital camera objective having, at most, four lens elements with one lens element having a diffractive surface and another lens element made out of flint-like material to correct axial and lateral chromatic aberrations. The present invention further provides interdigitated lens element alignment, stray light suppression, and anti-aliasing features. The compact digital camera objective may be used with any imaging system (e.g., cameras, camcorders, video conferencing imagers, etc.) that have isolated pixelated detectors such as, but not limited or restricted to, a charge coupled device ("CCD"), a charge injection device ("CID"), or a complementary metal oxide semiconductor ("CMOS") device.

In the following description, for purposes of explanation, numerous details are set forth in order to provide a thorough understanding of the present invention. However, it will be apparent to one skilled in the art that these specific details are not required in order to practice the present invention.

FIG. **1** illustrates a cross section of a lens system **100** of the present invention. Referring to FIG. **1**, the lens system **100** includes a first lens element **102** (also referred to as an objective lens element) having first and second surfaces **110** and **112**, a second lens element **104** having first and second surfaces **114** and **116**, a third lens element **106** having first and second surfaces **118** and **120**, and a fourth lens element **108** having first and second surfaces **122** and **124**. The lens elements are enclosed in a housing **164** (or lens cell). The first lens element **102** is closest to the object side while the fourth lens element **108** is closest to an imaging device. The first lens element **102** is a negative lens element and is used to increase (or modify) the field of view of the lens system **100**. The second lens element **104** is a positive lens element having an aspheric first surface **114** (e.g., an eighth order asphere). The third lens element **106** is a positive lens element and adds focusing power to the lens system **100**. The fourth lens element **108** is a negative lens element and has an aspheric first surface **122** (e.g., a sixth order asphere). All of the lens elements **102**, **104**, **106**, and **108** are injection molded plastic singlet lens elements.

To correct axial chromatic aberrations, one of the lens elements of the lens system **100** has a diffractive surface. In

a preferred embodiment, the diffractive surface is on the second surface **116** of the second lens element **104**. However, it is contemplated that the diffractive surface may be placed on another surface such as, but not limited or restricted to, the first surface **118** of the third lens element **106**.

FIG. **2**A illustrates a front view of the diffractive surface of the present invention. Referring to FIG. **2**A, the diffractive surface includes a plurality of rings **210** that are concentric from the center of an aperture. The rings **210** at the center of the surface are widely spaced apart and as the surface is traversed from the center, the rings are more and more closely spaced together.

FIG. **2**B illustrates a side view of the diffractive surface **220**. As shown in FIG. **2**B, the diffractive surface **220** includes a center zone **222** and successive annular zones **224**. In the embodiment shown, the diffractive surface **220** adds strong negative axial chromatic aberration which offsets the positive axial chromatic aberration of the remainder of the optical surfaces. That is, with the diffractive surface, flint elements used in a doublet construction of the prior art lens systems are no longer required.

Referring back to FIG. **1**, since the diffractive surface **116** is close to an aperture stop **152**, it only operates on the axial chromatic aberrations. In order to correct lateral chromatic aberrations, the lens system **100** uses a flint-like lens element. Typically, the flint-like lens element is placed close to the image or close to the object.

In the preferred embodiment, the fourth lens element **108** is made out of flint-like material (e.g., SAN, NAS, polycarbonate, styrene, etc.) and the first, second, and third lens elements **102**, **104**, and **106** are made out of crown-like material (e.g., acrylic, cyclic olefin co-polymer "COC", etc.). The specific configuration of the lens system **100** of FIG. **1**, i.e., the combination of the diffractive optical surface **116** and the flint-like fourth lens element **108**, corrects chromatic (axial and lateral) aberrations. In another embodiment, the first lens element **102** is made out of flint-like material and the second, third, and fourth lens elements **104**, **106**, and **108** are made out of crown-like material. The compact form of the lens system **100** is a direct result of the reduction of the six lens element (or more) configuration of the prior art lens systems to a four lens element configuration of the present invention.

On the object side of the first lens element **102** is an opening **166** that provides the optical pathway to the lens system **100**. The diameter of the opening **166** is shown by distance d**1**, and in one embodiment, is 14.5 millimeters ("mm"). Moreover, in one embodiment, the lens system **100** has a relative aperture of f/2.0 with a 50 degrees full field diagonal. However, it is to be appreciated that the lens system of the present invention may be designed to have a different relative aperture (e.g., f/1.6) and a different size field of view (e.g., 35 degrees). A glass window **142** is incorporated within the lens cell **164** on the object side of the first lens element **102** to protect the lens system **100** from the environment.

On the second side **124** of the fourth lens element **108** is an imaging device **156** having an image plane **158** (hereinafter referred to as a detector array). The diameter of the detector array **158** is shown by distance d**2** and, in one embodiment, is 8 mm. The imaging device **156** may be a CCD, CID, or CMOS detector array, to name a few. In front of the detector array **158** is a glass plate **160**. The detector array **158** and the glass plate **160** are incorporated in a case **162**. Light rays, such as light ray bundles **168** and **170** enter the lens system **100** through the opening **166**, propagate through the four lens elements, and onto the detector array **158**. The detector array **158** generates signals that represent an image formed by the light rays.

The four lens elements **102**, **104**, **106**, and **108** have minimal airspace between them in order to force a compact design and also to permit alignment between the lens elements. Because the imaging device **156** is small, the focal length of the lens system **100** is short, and all four lens elements are small. Small lens elements require very small fabrication and assembly tolerances to maintain the "as-built" image quality. By way of example, if two lens elements are each four inches in diameter, a centration error of approximately 0.005 inches represents a small tolerance error and the impact on the image quality is negligible. On the other hand, if two lens elements are each approximately 0.20 inches in diameter (typical values for this invention), a centration error of approximately 0.005 inches is a substantial tolerance error, yielding a totally unacceptable image quality. The latter example has at least twenty times the affect on image quality that would be present using four inch diameter lens elements. In one embodiment, the tolerances for the lens system **100** of the present invention are approximately on the order of 0.0005 to 0.0008 inches. Accordingly, it is critical to force alignment between the lens elements.

Continuing to refer to FIG. **1**, each of the lens elements is injection molded into a single part. During fabrication of the mold, the entire surface of each lens element is diamond turned in one setup. Each lens element has an optical portion designated by numerals **102**, **104**, **106**, and **108** and a mechanical flange portion (also referred to as an alignment finger) designated as numerals **126**, **128**, **130**, and **132**, respectively, which serves as the mechanical alignment function of the lens element. The mechanical flanges of adjacent lens elements interdigitate, i.e., form a substantially perfect fit or alignment, in order to capture each lens element and its neighbor with one or more alignment surfaces. That is, each pair of adjacent lens elements are pushed together until they come into intimate contact and there is no clearance in-between.

In the embodiment of FIG. **1**, the mechanical flange **132** of the fourth lens element **108** interdigitates with the mechanical flange **130** of the third lens element **106** at only two surfaces, as shown by numerals **140** and **176**. The first surface **140** sets the separation between the third and fourth lens elements **106** and **108**. The second surface **176** sets the centration of the two lens elements. The other two surfaces, designated by numerals **178** and **180**, are clear and do not touch. If any of these surfaces touch, it can cause an over-constrained condition which stresses the lens elements, causing the optical surfaces to distort images.

Similarly, the mechanical flange **130** of the third lens element **106** interdigitates with the mechanical flange **128** of the second lens element **104** at surfaces **138** and **182**. The mechanical flanges **128** and **130** of the second and third lens elements interdigitate with an aperture stop **152**. As will be apparent by the description below, the first and second lens elements **102** and **104** are not directly interdigitated together. Rather, the mechanical flanges **128** of the second lens element **104** interdigitates with an opaque spacer **150** at surfaces **136** and **184**. Similarly, the mechanical flange **126** of the first lens element **102** interdigitates with the opaque separator **150** at surfaces **134** and **186**. Surfaces **134** and **136** set the separation between the first and second lens elements **102** and **104** and the opaque separator **150**. Moreover, the surfaces **184** and **186** set the centration of the first and second lens elements **102** and **104**. The opaque spacer **150**

serves as a stray light suppression element. As discussed above, each pair of adjacent lens elements or a lens element and the adjacent opaque spacer **150** interdigitate at only two surfaces, as designated.

The mechanical flange **126** of the first lens element **102** has the property of allowing light that enters it to propagate in an uncontrolled manner through the mechanical flanges of the other lens elements and eventually become dispersed across the detector array **158**. This uncontrolled stray light on the detector array **158** causes unwanted bright artifacts localized at various points in the detector array which in turn causes a general loss of contrast across the entire detector array. This effect is dramatic and makes the lens system useless if the stray light is not effectively suppressed.

Accordingly, the lens system **100** of the present invention comprises a plurality of light suppression elements for suppressing stray light that may propagate through the mechanical flanges of the lens elements and onto the detector array **158**. The first light suppression element is a lens shroud **144** which is coupled to and projects forward from the front of the lens cell **164** and limits the field of view. In the preferred embodiment, the lens shroud **144** limits the full field of view to 50 degrees diagonal. Moreover, in one embodiment, the lens shroud **144** is a conical baffle which serves the function of preventing sun light, when it is outside the used field of view, from illuminating the glass window **142** or the first lens element **102**. If these optical surfaces are illuminated and have micro-scratches or dust, they will scatter sun light onto the detector array **158**. The lens shroud **144** may be made as long as the cosmetic requirements of the objective lens permits. The internal surface of the lens shroud **144** (not shown) is typically a cone with slightly greater included angle than the full field diagonal of the lens field of view.

The second light suppression element is a light baffle surface **146** located on the front of the lens system **100** and projects over most of the mechanical flange **126** (i.e., the non-optical portion) of the first lens element **102**. The third light suppression element is a compressible foam seal **148** which projects over the remaining exposed portion of the mechanical flange **126** of the first lens element **102**. The compressible foam seal **148** also serves to seal the lens system from the environment while forcing the four lens elements (**102**, **104**, **106**, **108** including opaque spacer **150**) into intimate contact.

The fourth light suppression element is the opaque black spacer **150** which is interdigitated between the mechanical flanges **126** and **128** of the first and second lens elements **102** and **104**, respectively. The opaque black spacer **150** absorbs stray light which may enter the lens system **100** through the mechanical flange **126** of the first lens element **102** and subsequently propagate through the mechanical flange **128** of the second lens element **104**. In one embodiment, the internal surface of the opaque black spacer **150** is either diffused or has micro grooves to prevent specular reflection of light into the rest of the lens system **100**.

The fifth light suppression element is an aperture stop **152**. The aperture stop **152** is placed near the second surface **116** of the second lens element **104** and defines the optical pathway of the bundle of light rays. It is made of opaque black material to suppress much of the stray light. The aperture stop **152** structure prevents light that enters from the front of the lens system from reaching the mechanical flanges (i.e., the non-optical portions) **130** and **132** of the third and fourth lens elements **106** and **108**. In the preferred embodiment, the front surface **172** of the aperture stop **152** is in a rough diffused condition. The aperture stop **152** includes an inner surface **174** which is also left in a diffused condition. In the preferred embodiment, the inner surface **174** is a V-blade cross-section to eliminate flat specular surfaces that could reflect light toward the detector array **158**. The sixth light suppression element is an opaque black baffle **154** which is placed adjacent to the mechanical flange **132** of the fourth lens element **108**. The baffle **154** prevents stray light, which has been diffusely or multiply scattered by other structures, from reaching the detector array **158**.

The lens system **100** of the present invention further includes an antialiasing feature for eliminating aliasing effects that occur when an object moves relative to the detector array **158** and has dimensions commensurate with the pixel dimensions of the detector array **158**. FIG. **3** illustrates an expanded side view of a lens element anti-alias surface **302** of the present invention. Referring to FIG. **3**, the lens element surface **302** includes a radially-symmetric periodic "cosine-like" surface **304** molded on the lens element surface **302**. The periodic surface **302** (or microscopic ripple) causes the image of a point to be spread in a controlled manner.

In the preferred embodiment, the lens element surface **302** is the first surface **118** of the third lens element **106** of FIG. **1**. The period **306** and depth **308** of the rippled surface are carefully selected and optimized to control the size of the blur and the rate at which energy is distributed. In one embodiment, the radially-symmetric cosine ripple has a constant amplitude and at least two periods across the semi-diameter of the aperture stop **152** of FIG. **1**. In a second embodiment, the cosine ripple has a monotonically decreasing amplitude across the aperture. In a third embodiment, the cosine ripple has a monotonically changing period across the aperture. In yet a fourth embodiment, the cosine ripple has both a monotonically decreasing amplitude and changing period across the aperture. The cosine ripple is created on a tool, typically made out of stainless steel. The lens element is then injection molded with hot plastic which forms the ripple on the surface. In another embodiment, the lens element surface **302** includes a "puckered" structure that has a two-dimensional array of elevated "bumps" which cause the image to become blurred in a controlled manner. These type of anti-aliasing features are insensitive to the relative aperture and the object distance.

In the preferred embodiment, the lens system of the present invention achieves a fast relative aperture (f/2.0) and a moderately large field of view of 50 degrees using four lens elements in a very compact form. Prior art lens systems with the same relative aperture and field of view require six lens elements using high index optical glasses which are very expensive to produce. The lens elements are each injection molded into single pieces and are interdigitated to provide optical alignment of the lens system. A plurality of light suppression features are provided to suppress and prevent stray light from entering the mechanical flange portions of the lens elements and dispersing onto the detector array. In addition, a cosine-like structure or a "puckered" structure is molded on a lens element surface to minimize aliasing effects (e.g., Moiré effects).

While certain exemplary embodiments have been described and shown in the accompanying drawings, it is to be understood that such embodiments are merely illustrative of and not restrictive on the broad invention, and that this invention not be limited to the specific constructions and arrangements shown and described, since various other modifications may occur to those ordinarily skilled in the art.

What is claimed is:

1. A lens system comprising:

a detector array;

a first lens element made of crown-like material and located in front of the detector array, the first lens element including a diffractive surface;

a second lens element made of a flint-like material and located in front of the detector array; and

third and fourth lens elements made of crown-like material and located in front of the detector array,

said first through fourth lens elements to correct axial and lateral chromatic aberration of light passing through the lens elements and falling on the detector array.

2. The lens system of claim 1 wherein the second lens element is located between the first lens element and the detector array.

3. The lens system of claim 1 wherein the first lens element is located between the second lens element and the detector array.

4. The lens system of claim 3 wherein each of the first, second, third, and fourth lens elements includes a mechanical flange, wherein the mechanical flanges of the first and fourth lens elements interdigitate and the mechanical flanges of the second and fourth lens elements interdigitate.

5. The lens system of claim 4 further comprising an opaque spacer that interdigitates with the mechanical flanges of the first and third lens element.

6. The lens system of claim 1 wherein the flint-like material comprises one of the following: SAN, NAS, polycarbonate, and styrene; and wherein the crown-like material comprises one of the following: acrylic and cyclic olefin copolymer.

7. The lens system of claim 1 further comprising an aperture stop proximate to the diffractive surface of the first lens element.

8. The lens system of claim 7 wherein the lens system has a relative aperture ranging between approximately f/1.6 approximately to f/2.0.

9. The lens system of claim 1 wherein the detector array and the first, second, third, and fourth lens elements are incorporated into a housing having an opening.

10. The lens system of claim 9 further comprising a light baffle surface placed in front of the housing to prevent stray light from entering the mechanical flange of the third lens element.

11. The lens system of claim 9 further comprising a lens shroud placed proximate to the opening of the housing to limit the field of view of the lens system.

12. The lens system of claim 1 wherein the detector array is a complementary metal oxide semiconductor device.

13. The lens system of claim 1 further comprising a baffle placed behind the second lens element, said baffle to prevent stray light from falling on the detector array.

14. The lens system of claim 1 wherein each of the first and second lens elements has an aspheric surface on one of the surfaces.

15. The lens system of claim 1 wherein the fourth lens element includes a periodic surface molded thereon to reduce aliasing effects.

16. The lens system of claim 15 wherein an amount of aliasing is controlled by varying a period and depth of the periodic surface.

17. The lens system of claim 1 wherein each of the first, second, third, and fourth lens elements is injection molded into a single piece having an optical portion and a mechanical alignment portion.

18. The lens system of claim 1 wherein the fourth lens element includes an array of elevated bumps on one surface for controlling aliasing effects.

19. A lens system comprising:

a housing having an opening, the housing including,

(a) a first lens element including a first mechanical flange;

(b) a second lens element including a second mechanical flange;

(c) an opaque spacer that interdigitates with the first and second mechanical flanges of the first and second lens elements;

(d) a third lens element including a third mechanical flange that interdigitates with the second mechanical flange of the second lens element; and

(e) a fourth lens element including a fourth mechanical flange that interdigitates with the third mechanical flange of the third lens element.

20. The lens system of claim 19 wherein each of the first, second, third, and fourth lens elements is injection molded into a single piece having an optical portion and a mechanical alignment portion.

21. The lens system of claim 19 wherein said second lens element includes a diffractive surface disposed on one surface, said first through third lens elements are made from crown-like material, and said fourth lens element is made from flint-like material to correct axial and lateral chromatic aberrations of light passing therethrough.

22. The lens system of claim 19 wherein said third lens element includes a diffractive surface disposed on one surface, said first through third lens elements are made from crown-like material, and said fourth lens element is made from flint-like material to correct axial and lateral chromatic aberrations of light passing therethrough.

23. The lens system of claim 19 wherein the housing further includes an aperture stop between the second and third lens elements.

24. The lens system of claim 19 wherein the housing further includes a glass window and a compressible foam seal placed between the first lens element and the glass window, said compressible foam seal to reduce an amount of stray light from entering the first mechanical flange of the first lens element and alternatively to force alignment between the lens elements.

25. The lens system of claim 19 wherein each of the second and fourth lens elements has an aspheric surface on one of the surfaces.

26. The lens system of claim 19 wherein the housing further includes a detector array placed behind the first, second, third, and fourth lens elements.

27. The lens system of claim 26 wherein the detector array comprises one of the following devices; a complementary metal oxide semiconductor device, a charge coupled device, and a charge injection device.

28. The lens system of claim 26 wherein the third lens element includes a periodic surface molded thereon to reduce aliasing effects.

29. The lens system of claim 28 wherein an amount of aliasing is controlled by varying a period and depth of the periodic surface.

30. The lens system of claim 26 wherein the third lens element includes an array of elevated bumps on one surface for controlling aliasing effects.

31. A camera system having an optical axis, comprising:

a lens system including,

a first lens element on the optical axis, the first lens element including a diffractive surface disposed on one surface and made of crown-like material,

an aperture stop,

a second lens element on the optical axis, the second lens element made of a flint-like material,

a third lens element on the optical axis, and made of crown-like material, and

a fourth lens element on the optical axis, and made of crown-like material; and

a detector array on the optical axis behind the first through fourth lens elements.

32. The camera system of claim **31** wherein said the first through fourth lens elements to correct axial and lateral chromatic aberrations of light passing therethrough.

33. The camera system of claim **31** wherein the first lens element is in front of the second lens element.

34. The camera system of claim **33** wherein the third lens element is in front of the first lens element and the fourth lens element is between the first and second lens elements.

35. The camera system of claim **33** wherein each of the first, second, third, and fourth lens elements include a mechanical flange, wherein the mechanical flanges of the first and fourth lens elements interdigitate and the mechanical flanges of the second and fourth lens elements interdigitate.

36. The camera system of claim **31** wherein the second lens element is in front of the first lens element.

37. The camera system of claim **36** wherein the first lens element is in front of the third and fourth lens elements.

38. The camera system of claim **31** wherein the diffractive surface includes a plurality of concentric rings.

39. The camera system of claim **35** further comprising an opaque spacer that interdigitates with the mechanical flanges of the first and third lens elements.

40. The camera system of claim **31** wherein the lens system has a relative aperture ranging between approximately f/1.6 to approximately f/2.0.

41. The camera system of claim **31** wherein the detector array comprises one of the following devices: a complementary metal oxide semiconductor device, a charge coupled device, and a charge injection device.

42. The camera system of claim **31** wherein the fourth lens element includes a periodic surface molded thereon to reduce aliasing effects.

43. The camera system of claim **31** wherein the fourth lens element includes an array of elevated bumps on one surface for reducing aliasing effects.

[57] **ABSTRACT**

A lens system having a reduced number of injection-molded singlet lens elements with at least one diffractive surface to control axial and lateral chromatic aberrations is disclosed. In one embodiment, the diffractive surface is placed on the first surface of the third lens, which is closest to the image plane. An opaque spacer provides suppression of stray light from reaching the image plane.

FIG. 3

DIGITAL CAMERA OBJECTIVE WITH DIFFRACTIVE OPTICAL SURFACE

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates generally to the field of lens systems, and, more particularly, to a digital camera objective having stray light suppression features.

2. Description of Related Art

Prior art complex lens systems with a relative aperture of F/2 and 50 degree field of view for color applications typically require numerous lens elements such as five or six lens elements in high index optical glass. These utilize doublet construction in at least two groups of lens elements to provide control of lateral and axial chromatic aberrations. The doublet construction typically consists of a positive lens of a low dispersion material and a negative lens of a high dispersion material. The disadvantage of the doublet construction is that it requires an extra element, which increases the cost of the lens system. Also, the overall length, weight, and cost of the lens system that utilizes numerous lens elements is increased.

There is a need to provide a lens system with a reduced number of elements, while still maintaining correction of chromatic aberrations.

SUMMARY OF THE INVENTION

In accordance with the present invention, a lens system for forming an image of an object is provided which comprises a reduced number of elements, while still maintaining correction of chromatic aberrations. This is achieved by using an appropriately defined and positioned diffractive surface. If the diffractive surface is positioned at (or near) the aperture stop, it will affect the axial aberration. The remaining lateral color may be corrected by using a high dispersion material for one of the lenses. However, if the diffractive surface is appropriately defined and positioned away from the aperture stop, it will affect both the axial and lateral color, and will eliminate the need for the high dispersion material. In any event, the number of lenses is reduced from the prior art five or six and the need for multiple materials.

Other objects, features, and advantages of the present invention will become apparent upon consideration of the following detailed description and accompanying drawings, in which like reference designations represent like features throughout the FIGURES.

BRIEF DESCRIPTION OF THE DRAWINGS

The drawings referred to in this description should be understood as not being drawn to scale except if specifically noted.

FIG. **1**, in cross-section, illustrates a lens system of the present invention;

FIG. **2**, also in cross-section, is a view of the diffractive surface employed in the practice of the present invention; and

FIG. **3**, on coordinates of relative modulation and frequency (in cycles per millimeter), is a plot depicting the modulation transfer function of a specific lens system of the present invention.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

Reference is now made in detail to a specific embodiment of the present invention, which illustrates the best mode presently contemplated by the inventor for practicing the invention. Alternative embodiments are also briefly described as applicable.

In the preferred embodiment, the present invention is a digital camera objective having no more than five lens elements, preferably no more than four lens elements, and most preferably no more than three lens elements. Alternatively, the digital camera objective may have no more than two lens elements. In any event, each of the lens elements has a first surface and a second surface and at least one of the surfaces of the lens elements comprises a diffractive surface to correct axial and lateral chromatic aberrations. The digital camera objective may be used with any imaging system (e.g., cameras, camcorders, video conferencing imagers, scanners, etc.), employing detectors such as, but not limited or restricted to, charge coupled devices ("CCD"), charge injection devices ("CID"), or complementary metal oxide semiconductor ("CMOS") devices.

In the following description, details are given to provide an understanding of the present invention. It will be apparent to one skilled in the art that these specific details are not required in order to practice the present invention.

The lens system of the present invention forms an image of an object on an image plane. The object is located on the object side of the lens system, which comprises no more than five lens elements. Each of the lens elements has a first surface and a second surface, with at least one of the surfaces comprising a diffractive surface, which provides correction of axial and lateral chromatic aberrations of light passing through the lens system. In appropriate situations, the object and the image plane of the lens system may be interchanged.

FIG. **1** is a cross-sectional view of a three element lens system **10** of the invention. The lens system **10** comprises a first lens **12**, with a first surface **12***a* and a second surface **12***b*, a second lens **14** having a first surface **14***a* and a second surface **14***b*, and a third lens **16** having a first surface **16***a* and a second surface **16***b*. The lenses **12**, **14**, **16** are enclosed in a housing **18**. The first lens **12** is closest to the object side, generally denoted at **20**, while the third lens **16** is closest to the image side, generally denoted at **22**. In a specific application, such as a camera, there may be a detector **24** located on the image side **22**, with a window **26** between the third lens **16** and the detector **24**.

Preferably, all of the lenses **12**, **14**, **16** may be injection-molded plastic singlet lenses, most preferably of a conventional crown-like material. Examples of suitable crown-like materials that may be employed in the practice of the present invention include acrylates and methacrylates.

To correct axial and lateral chromatic aberrations, one of the lens elements has a diffractive surface. It is preferred that this diffractive surface be on the first surface **16***a* of the third element **16**, although it may be placed on another surface such as, but not restricted to, the second surface **14***b* of the second element **14**.

The first element **12** is a negative lens, which serves to increase the field of view. The second element **14** is a power lens. The surfaces of the first lens **12**, the second lens **14**, and the third lens **16** may be provided with aspheric surfaces.

An aperture stop **28** is placed between the first lens **12** and the second lens **14**. Alternatively, but less preferred, the aperture stop **28** may be placed between the second lens **14** and the third lens **16**, as shown in phantom. In any event, the aperture stop is an opaque spacer and serves to limit a bundle of rays passing through the first element **12**. To further reduce stray light, the aperture stop **28** may be placed at both locations.

FIG. **2** shows a cross-sectional view of the diffractive surface, here, **16***a*. With this diffractive surface, the doublet construction of the prior art lens systems is no longer required. Since the diffractive surface **16***a* (or **14***b*) is away from the aperture stop **28** in the preferred case, it operates on both axial and lateral chromatic aberrations.

Turning now to the nature of the diffractive surface **16***a* (or **14***b*), it is well-known that a major difference between a refractive optical surface and a diffractive optical surface in ray tracing analysis is that a refractive surface is governed by Snell's law:

$$n_1 \sin\Theta_1 = n_2 \sin\Theta_2$$

where n is the refractive index of the material.

On the other hand, a diffractive optical surface is, in scalar terms, subject to the grating equation:

$$m\lambda = d \sin\Theta,$$

where

m=diffractive order;

λ=the wavelength of the incident light beam;

d=grating periodicity; and

Θ=diffractive angle.

The grating height h is determined according to the formula

$$h = \frac{\lambda}{(n-1)}.$$

Depending upon the particular effect desired, the feature size will be some multiple of h, where the multiple will determine the phase shift in units of wave-length. In practice, this multiple will generally be between 1/20 and 200 times the wavelength of light. Typical values include ¼, ½, ¾, 1, 2, 3, etc. In general, for plastic materials with visible light, this translates into feature heights on the order of micrometers.

The lateral dimensions of spacing of the features, as well as the periodicity, is determined differently for different diffractive patterns, as will be discussed in more detail below. Typically, the lateral dimensions will range from a fraction to about a thousand times the wavelength of light. For plastic materials with visible light, the range is generally between about one-half to about one hundred micrometers. It should be noted that the present invention applies equally as well to light outside the visible spectrum, i.e., infrared and ultraviolet light.

In refractive analysis, when a collimated beam of light impinges on a curved surface of a lens, the plane wavefront is transformed according to Snell's law into a spherical wavefront. Using a diffractive structure, the wavefront is transformed as determined by the grating equation.

The design of the diffraction grating itself depends upon its desired effect. For example, the diffractive surface may be designed to cooperate with the remaining refractive power to achieve the desired correction of chromatic aberration. Other uses include, but are not limited to, athermalization, replacement of refractive power, aspheric correction, or color filtration.

The design of the diffractive optical surface can be achieved through mathematical modeling, using any of several techniques depending upon the level of sophistication required. These techniques include scalar analysis, rigorous coupled wave theory, parabasal ray tracing, vector analysis, and the beam propagation method. Commercially available codes can be employed to carry out the diffractive design analysis. Some of these codes include "Code V" or "Light Tools", both from Optical Research Associates (Pasadena, Calif.), "ASAP" from Breault Research Organization (Tucson, Ariz.), "Diffract" from MM Research (Tucson, Ariz.), or "Grating Solver" from Grating Solver Development Corporation (Allen, Tex.). Examples of this mathematical analysis are discussed in more depth in U.S. Pat. No. 5,218,471 to Swanson et al., which is incorporated herein by reference. U.S. Pat. No. 5,538,674 to Nisper et al, which is incorporated herein by reference, discloses techniques for fabricating diffractive optical elements.

One example of such a lens system as depicted in FIG. **1** comprises:

- a first lens **12** having a first surface **12***a* with a radius of 3 mm, and a second surface **12***b* having a radius of 1.6 mm,
- a second lens **14**, having a first surface **14***a* with a radius of 166 mm, and a second surface **14***b* having a radius of −3.5 mm, and
- a third lens **16**, having a first surface **16***a* with a diffractive optical element defined by the phase coefficient -6×10^{-3}, and a second surface **16***b* having a radius of 800 mm.

Another example of such a lens system as depicted in FIG. **1** comprises:

- a first lens **12** having a first surface **12***a* with a radius of 6.9 mm, and a second surface **12***b* having a radius of 1.9 mm,
- a second lens **14**, having a first surface **14***a* with a radius of 12.4 mm, and second surface **14***b* having a radius of −6.7 mm, and
- a third lens **16**, having a first surface **16***a* with radius 7.8 mm and with a diffractive optical element defined by the phase coefficient -7.2×10^{-3}, and a second surface **16***b* having a radius of 8.3 mm.

The modulation transfer function of one such lens system is depicted in FIG. **3**, in which Curve **30** is the predicted result and Curve **32** is the measured result, indicating the high degree of correction of the system.

INDUSTRIAL APPLICABILITY

The digital camera objective of the present invention is expected to find use in still and video camera applications.

Thus, there has been disclosed a digital camera objective, which includes a lens having a diffractive surface. It will be readily apparent to those skilled in this art that various changes and modifications of an obvious nature may be made, and all such changes and modifications are considered to fall within the scope of the present invention, as defined by the appended claims.

What is claimed is:

1. A lens system for forming an image of an object on an image plane, said lens system comprising a first negative lens closest to an object side, a third lens closest to an image side, and a second power lens disposed between said first lens and said third lens, with each lens having first and second surfaces, at least one of said surfaces of said lenses comprising a diffractive surface, said lens system further comprising an opaque spacer between said second lens and said third lens, to prevent stray light from reaching said image side, said lens system comprising no more than three lens elements and being corrected for axial and lateral chromatic aberrations of light passing therethrough.

2. The lens system of claim **1** having an opaque spacer between said first lens and said second lens, creating an aperture stop to limit a bundle of rays passing through said first lens.

3. The lens system of claim 1 wherein at least one of said first surface and said second surface of said third lens comprises a diffractive surface.

4. The lens system of claim 3 wherein said first surface comprises said diffractive surface, said first surface being closer to said object side.

5. The lens system of claim 1 wherein at least one of said first surface and said second surface of the second lens comprises a diffractive surface.

6. The lens system of claim 5 wherein said second surface of said second lens comprises said diffractive surface, said second surface being closer to said image side.

7. The lens system of claim 1 wherein a detector is located on said image side at said image plane.

8. The lens system of claim 1 wherein each of said lens elements comprises a crown-like material.

9. The lens system of claim 1 in which at least one of said lens elements comprises a plastic material.

10. The lens system of claim 9 in which at least one of said lens elements comprises an injection-molded plastic material.

11. The lens system of claim 1 wherein at least one of said surfaces of said lens elements comprises a spheric surface.

12. The lens system of claim 1 wherein at least one of said surfaces of said lens elements comprises an aspheric surface.

13. A lens system for forming an image of an object on an image plane, comprising no more than three lens elements, each of said lens elements having a first surface and a second surface, said lens system comprising a first lens closest to an object side, a third lens closest to an image side, and a second lens disposed between said first lens and said third lens, wherein said third lens has a diffractive surface, wherein each of said lens elements comprises a crown-like material, and wherein at least one of said surfaces of said lens elements comprises an aspheric surface, said lens system being corrected for axial and lateral chromatic aberrations of light passing therethrough.

14. The lens system of claim 13 in which at least one of said lens elements comprises a plastic material.

15. The lens system of claim 14 in which at least one of said lens elements comprises an injection-molded plastic material.

16. The lens system of claim 13 wherein at least one of said surfaces of said lens elements comprises a spheric surface.

17. The lens system of claim 13 having an opaque spacer between said first lens and said second lens, creating an aperture stop to limit a bundle of rays passing through said first lens.

18. The lens system of claim 13 having an opaque spacer between said second lens and said third lens, to prevent stray light from reaching said image surface.

19. The lens system of claim 13 wherein said first surface of said third lens comprises said diffractive surface, said first surface being closer to said object side.

20. The lens system of claim 13 wherein a detector is located on said image side at said image plane.

21. A lens system for forming an image of an object on an image plane, said lens system comprising no more than three elements, each of said lens elements having a first surface and a second surface and comprising a crown-like material, said lens system being corrected for axial and lateral chromatic aberrations of light passing therethrough, said lens system comprising:

(a) a first negative lens closest to an object side,

(b) a second power lens,

(c) a third lens closest to said image plane, wherein said third lens has a diffractive surface on a surface away from said image plane; and

(d) an opaque spacer between said first lens and said second lens, creating an aperture stop to limit a bundle of rays passing through said first lens.

22. The lens system of claim 21 wherein each of said first and second lenses has an aspheric surface.

23. The lens system of claim 21 wherein a detector is located at said image plane.

24. A lens system for forming an image of an object on an image plane, said lens system comprising a first negative lens closest to an object side, a third lens closest to an image side, and a second power lens disposed between said first lens and said third lens, with each lens having first and second surfaces, said first surface of said third lens comprising a diffractive surface, said first surface being closer to said object side, said lens system comprising no more than three lens elements and being corrected for axial and lateral chromatic aberrations of light passing therethrough.

25. The lens system of claim 24 having an opaque spacer between said first lens and said second lens, creating an aperture stop to limit a bundle of rays passing through said first lens.

26. The lens system of claim 24 having an opaque spacer between said second lens and said third lens, to prevent stray light from reaching said image side.

27. The lens system of claim 24 wherein a detector is located on said image side at said image plane.

28. The lens system of claim 24 wherein each of said three elements comprises a crown-like material.

29. The lens system of claim 24 wherein at least one of said lens elements comprises a plastic material.

30. The lens system of claim 29 wherein at least one of said lens elements comprises an injection-molded plastic material.

31. The lens system of claim 24 wherein at least one of said surfaces of said lens elements comprises a spheric surface.

32. The lens system of claim 24 wherein at least one of said surfaces of said lens elements comprises an aspheric surface.

33. A lens system for forming an image of an object on an image plane, said lens system comprising a first negative lens closest to an object side, a third lens closest to an image side, and a second power lens disposed between said first lens and said third lens, with each lens having first and second surfaces, said second surface of said second lens comprising a diffractive surface, said second surface being closer to said image side, said lens system comprising no more than three lens elements and being corrected for axial and lateral chromatic aberrations of light passing therethrough, wherein said lens elements each comprise a crown-like material.

34. The lens system of claim 33 having an opaque spacer between said first lens and said second lens, creating an aperture stop to limit a bundle of rays passing through said first lens.

35. The lens system of claim 33 having an opaque spacer between said second lens and said third lens, to prevent stray light from reaching said image side.

36. The lens system of claim 33 wherein a detector is located on said image side at said image plane.

37. The lens system of claim 33 wherein at least one of said lens elements comprises a plastic material.

38. The lens system of claim 37 wherein at least one of said lens elements comprises an injection-molded plastic material.

39. The lens system of claim 33 wherein at least one of said surfaces of said lens elements comprises a spheric surface.

40. The lens system of claim 33 wherein at least one of said surfaces of said lens elements comprises an aspheric surface.

[57] **ABSTRACT**

Objective lenses for endoscopes are made substantially of sapphire. The high refractive index of sapphire results in optical components with shallower curvatures, leading to smaller geometric aberrations, and consequently, fewer components are required to correct for these aberrations. Chromatic aberrations are less severe because of sapphire's low dispersion. The objectives may be either of the landscape or retrofocus type, and are compact with moderate field of view, low f-number, and less distortion than most conventional designs.

SAPPHIRE OBJECTIVE SYSTEM

BACKGROUND OF THE INVENTION

1. Field of the Invention

The invention relates generally to an objective lens system ("objective") for use in endoscopes and the like, and more specifically to landscape and retrofocus type objectives for endoscopes.

2. Description of the Prior Art

Endoscopy is a technique that allows the examination of an area of a body by means of an endoscope, which is a tube like instrument with lenses and a light source attached. The endoscope provides a visual examination of the interior of a body through a natural body opening such as the throat, or through a small incision into the body. Because an endoscope can be inserted through a very small opening, it is a less invasive method than other surgical techniques, causing less scaring and quicker recovery time. A camera or video recorder is often used during an endoscopic procedure to provide long term records of internal organs which can be used for later reference. The increasing use of endoscopes for both diagnostic and therapeutic uses has substantially reduced the need for invasive surgical procedures such as gynecological and reproductive disorders, biopsies, gastrointestinal track inspection, knee and other joint surgery and the like.

In basic structure, the endoscope typically includes an ocular at its proximal end and an objective assembly at its distal end. Between the ocular and the objective assembly, a typical endoscope will include elongated relay optics of relatively small cross-section. The relay optics can be rigid and include rod lenses spaced along a sheath. Alternatively, the relay optics can be flexible and include optical fibers.

The smaller the cross-section of the distal end of the endoscope, the less invasive the procedure. For medical applications, these optics have to be relatively good and without visible distortion. There is a tension between reducing the cross-section of the endoscope distal end and improving its optical quality. The resulting conventional optical systems used in endoscopes are generally complex and employ various combinations of lenses within the elongated tube or sheath, typically including the objective lens, the relay lens system, and the ocular or eyepiece. The objective lens forms an image at the inner distal end of the tube which is then picked up and transmitted by the relay lens system to the proximal end of the tube where it is viewed with the ocular.

The objective lens is generally a wide angle lens having a short focal length and is physically separated from its environment by a rugged, transparent optical material. In order to correct for the various chromatic as well as geometric aberrations inherent in lenses, it is generally necessary to employ several different lenses, each of which corrects or partially corrects for aberrations in the optical train. Geometric aberrations are typically reduced by increasing the number of lenses or aspherizing one or more surfaces, whereas chromatic aberration can be corrected for by the proper choice of low and high dispersion glasses. Typical prior art endoscope designs include retrofocus lens systems made of glass having one or more aspheric surfaces. (See, for example, U.S. Pat. Nos. 4,403,837 to Nakahasi and 4,867,546 to Nishioka et al.) Unfortunately, these systems are relatively complicated, employing aspheric lenses, and typically have relatively long total tracks and higher than desirable distortion.

The use of sapphire as a material in endoscopic systems has been largely limited to that of a protective covering or window at the distal end of the endoscope. A sapphire barrier at the distal end of an endoscope is said to have enhanced resistance to the higher temperatures and pressures associated with sterilization procedures, such as found in an autoclave. U.S. Pat. No. 5,377,669 to Schulz discloses a sapphire protective covering whose proximal end is so constructed that the sapphire also functions as a negative lens. Although this sapphire negative lens increases the field of view of the objective, following nonsapphire optics are used to correct for geometric and chromatic aberrations. U.S. Pat. No. 5,555,131 to Horton describes an objective that employs a sapphire positive lens/plastic negative lens combination immediately following a virtual image of the stop. The other elements in the optical train are plastic with low indices of refraction and moderate dispersion. Since the refractive index of plastic is relatively low, an endoscope in accordance with the Horton patent has a relatively small field of view and a high f-number. To compensate for plastic's low index of refraction, aspheric surfaces are required, but they do not have enough bending power to limit the lenses to a small diameter, which results in the endoscopic procedure being more invasive in a surgical procedure. U.S. Pat. No. 5,424,877 to Tsuyuki et al. discloses an observation optical system for endoscopes in which the objective lens system may include a sapphire negative lens element for obtaining a wide angle visual field. Sapphire is also used in rod form in fiber optic probe systems (U.S. Pat. No. 5,166,756 to McGee et al. and U.S. Pat. No. 5,351,322 to VonBargen) and as a contact member in a surgical laser probe (U.S. Pat. No. 4,592,353 to Daikuzono).

There is still a need, however, for endoscopic systems, and in particular objective lens systems for endoscopes and the like, that are compact, small in diameter, simple, and offer the user high optical performance.

SUMMARY OF THE INVENTION

The invention relates to landscape and retrofocus type objectives for endoscopes whose objectives are made substantially or entirely from sapphire optical components. The resulting objectives have good fields of view, are rugged enough to withstand high temperatures such as found in an autoclave, of a same diameter, provide fast (i.e., low) f-numbers, and good optical quality with low distortion.

In one embodiment of the invention, there is provided an objective lens system for forming an image at the distal end of an endoscope that is to be transmitted to the proximal end of the endoscope. The objective lens system has a first optical group of a net positive optical power that includes a plurality of optical components, more than one of which comprise sapphire, or alternatively, an all sapphire, first optical group of positive optical power having at least one optical component. The objective lens system also includes an aperture stop on the object side of said first optical group. In one embodiment, the objective lens system further comprises a second optical group on the object side of the first optical group. The second optical group may comprise an optical window such that the objective lens system is of the landscape type, or alternatively, the second optical group may be of negative optical power with the objective lens system being of the retrofocus type.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1***a* shows an embodiment of an endoscopic landscape-type objective lens system along with ray paths through the system.

FIG. **1***b* shows ray trace information in the form of spot diagrams for the embodiment of FIG. **1***a*.

FIG. **1***c* shows polychromatic diffraction modulation transfer functions for the embodiment of FIG. **1***a*.

FIG. **1***d* shows field curvature and distortion plots for the embodiment of FIG. **1***a*.

FIGS. **2–7** show additional embodiments of endoscopic landscape-type objective lens systems along with respective ray paths through the systems.

FIG. **8** shows an embodiment of an endoscopic retrofocus-type objective lens system along with ray paths through the system.

FIGS. **9–11** show additional embodiments of endoscopic retrofocus-type objective lens systems.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENT

The numerical information and descriptions given below are surface specifications for preferred embodiments of the endoscope objectives according to the present invention, in which Embodiments 1–7 are landscape-type objectives and Embodiments 8–11 are retrofocus-type objectives. Herein "retrofocus" refers to a lens or lens system consisting of an ordinary objective and a negative component near its front focal point. Thus, the back focus is large, relative to its focal length, and the field angle is relatively large. Retrofocus lenses are sometimes referred to as reversed telephoto lens systems. A (rear) landscape-type objective is composed of a stop followed by a positive lens group. In its simplest form, it is a single positive meniscus lens with a stop that is positioned between the lens and the object to minimize coma and tangential field curvature. Other geometric aberrations are either tolerated or minimized by reducing the aperture diameter. It is possible to have a front landscape lens (i.e., a lens with the positive group before the stop), although its aberration residuals are generally much worse than the rear landscape lens. In the embodiments disclosed herein, generally the stop is shifted to the front focal point of the lens group to make the lens telecentric in image space, although this position may be somewhat shifted depending on the numerical aperture of the relay optics to favorably correct aberrations. Spherical aberration is well corrected by the second lens and high refractive index of the sapphire, and therefore faster (i.e., lower) f-numbers are possible. Lateral color is held to negligible levels because of sapphire's low dispersion.

In accordance with the present invention, the objective lens system includes optical elements made of sapphire. Sapphire has a high index of refraction (i.e., n_d=1.768), as well as low dispersion, and these optical properties are utilized to produce favorable designs for objective lens systems. In particular, less curvature is required in the optical elements that constitute the objective, so that geometric aberrations are reduced, and the low dispersion leads to less severe chromatic aberration.

The following abbreviations and notation are used throughout: "FOV" is the field of view in degrees, "ROC" is the radius of curvature of the optical element (indicated as infinity in the case of a plano surface), "Thickness" is the center thickness of the optical element (or the distance between elements in the case of a space between elements), and "Diameter" is the diameter at the given surface. All lengths are in millimeters (corresponding to the preferred embodiments). The conic constant defines the curvature of the conic section, in which a conic constant of 0 corresponds to a spherical surface, a conic constant less than −1 to a hyperboloid, a conic constant=−1 to a paraboloid, a conic constant between −1 and 0 to a prolate ellipsoid, and a conic constant greater than 0 to an oblate ellipsoid.

The invention relates to landscape and retrofocus type objectives for endoscopes and the like, in which the objectives are comprised substantially or entirely of sapphire optical components or another material having a high index of refraction (on the order of 1.7 or greater) and a high Abbe number (on the order of 65 or greater). Because sapphire has a high index of refraction (n_d=1.768), there is effectively more bending power per surface, and therefore less curvature is required to bring an image to a focus, so that geometric aberrations are reduced. Furthermore, sapphire has low dispersion (i.e., an Abbe number of 72.2), so that chromatic aberrations are intrinsically less severe. Because of these favorable optical properties, the lens objectives of the present invention are compact and have excellent optical properties, such as moderately wide field of view (up to about 80° or less) and relatively fast f-numbers (e.g., down to about 1.7), which makes them advantageous for endoscopic use. Additionally, sapphire is a highly durable material that may be fabricated more precisely and to higher optical quality than conventional glasses or plastics. Further, because of sapphire's high index of refraction, an antireflection coating may consist of only a single layer of magnesium fluoride, instead of the multiple layers generally required for glass optics.

FIG. **1***a* shows a first preferred embodiment of the present invention. The surface specifications of Embodiment 1 appear in Table 1. This embodiment is advantageous due to the low number of lenses and the simplicity of their design, but edge performance is better in other embodiments. At the object side of an objective **20** within an endoscopic sheath **22**, there is preferably a window **24** followed by two plano-convex sapphire elements **26** and **28**. The window **24** in this and the other embodiments physically separates the objective **20** from the surrounding environment. The window is preferably made of sapphire but alternatively can be polycarbonate, fused silica or another transparent optical material.

8	28	Infinity	4.273E − 001		1.350E + 000	0
IMAGE	34	Infinity			1.029E + 000	0

The window **24** and sapphire element **26** are preferably separated by an aperture stop **30**, although in all the embodiments discussed herein, the aperture stop can alternatively be located on the object side of the most distal optical component or within the objective. In this and the other embodiments, if a window is not used, then the aperture stop is preferably placed in direct contact with the outside of the most distal of the sapphire elements so as to avoid clogging the aperture. Elements **26** and **28** are preferably in contact with each other so that ancillary spacers are not required. The objective **20** images an object onto a focal plane **34** on the image side of the objective at the distal end of the endoscope, with the image being transmitted to the proximal end of the endoscope, generally through relay optics **36** (shown schematically) that may include a fiber optic followed by an eyepiece **38**.

The spot diagram information of FIG. **1***b* corresponds to Embodiment 1 and illustrates the extent of chromatic aberrations in the focal plane **34** at the wavelengths 0.486, 0.587, and 0.656 microns, as determined for five different angles of inclination designated (i)–(v): 0 degrees (the on-axis case), 11, 19, 26.3, and 38.5 degrees (the marginal ray case, representing the maximum possible inclination). These angles correspond to the field points (i)–(v) shown in FIG. **1***a* as well as in FIGS. **2–11** below (except that in FIGS. **8–11** the maximum possible inclination is 37.5 degrees, corresponding to a maximum field of view of 75 degrees). Even for the marginal rays, the extent of chromatic aberration is quite limited, as can be seen in FIG. **1***b*. FIG. **1***c* illustrates the polychromatic diffraction modulation transfer functions for the same 5 field points and indicates that performance is quite good. The field curvature and distortion plots for the objective **20** shown in FIG. **1***d* likewise illustrate that the optical performance is good. The weighting factors used for these calculations are 1.0, 0.3, and 0.3 for 0.587, 0.486, and 0.656 microns, respectively. The apparent resolution as perceived by an observer may actually be higher than what is shown in FIG. **1***c*, since barrel distortion (cf. FIG. **1***d*) causes compression of the image at the edge of the field, an effect that may be partially deconvolved by the observer.

FIG. **2** shows a more optically optimized configuration corresponding to Embodiment 2, in which performance at the edge of the field is improved at the expense of design simplicity and distortion. The lens data for the second embodiment appear in Table 2, below. In this embodiment, a window **50** is followed by an aperture stop **52** and two sapphire elements **54** and **56** that are preferably noncontacting. The sapphire elements **54** and **56** have curvature on both of their respective sides, leading to improved performance of the objective. The image is focused onto a focal plane **58**.

TABLE 2

EMBODIMENT 2
Image space F/# = 2.5
Effective focal length = 8.533E − 001
Maximum FOV = 7.700E + 001

FIG. **3** shows a third embodiment, in which the image "plane" is curved to better compensate for field curvature, which is especially important at the edge of the field. The lens data for the third embodiment appear in Table 3, below. This embodiment comprises a window **60**, an aperture stop **62**, and sapphire elements **64** and **66**, which focus the image to a curved image surface **68**. The objective shown here results in acceptable distortion with excellent resolution over the full extent of the field and is pixel-limited (i.e., the resolution of the optical system is better than pixel resolution) across the entire field, given state of the art pixel technology.

TABLE 3

EMBODIMENT 3
Image space F/# = 2.5

Alternative landscape-type objectives (Embodiments 4–7) are shown in FIGS. **4–7**, respectively. FIG. **4** shows an objective comprising a window **70**, aperture stop **72**, and sapphire elements **74** and **76**. The lens data for the fourth embodiment appear in Table 4, below. The image surface **78** is embedded in sapphire element **76** and is preferably aligned with the sapphire element's proximal surface, thereby facilitating direct coupling of the image into a fiber optic cable, for example. Embodiment 4 has resolution similar to Embodiment 2 with distortion performance similar to Embodiment 1.

FIG. **5** illustrates an objective composed of, in addition to a window **80** and aperture stop **82**, three sapphire elements **84**, **85**, and **86**. The lens data for the fifth embodiment appear in Table 5, below. Embodiment 5 has an increased complexity to yield optical performance similar to Embodiment 3, but in a flat focal plane **88**.

FIG. **6** shows an objective comprising a window **90**, an aperture stop **92**, and a single sapphire element **94** with two aspheric surfaces leading to a flat image plane **96**. The lens data for the sixth embodiment appear in Table 6, below. This embodiment is easy to assemble and has a higher per lens fabrication cost due to the aspheric surfaces. It yields an objective having resolution about the same as Embodiment 1, but with improved distortion.

FIG. **7** shows another single sapphire lens embodiment comprising a window **100**, an aperture stop **102**, and a sapphire element **104** having two aspheric surfaces leading to a curved image surface **106**. The lens data for the seventh embodiment appear in Table 7, below. Embodiment 7 has excellent resolution over the entire field with low distortion. Like Embodiment 3, it is pixel-limited across the entire field, in view of state of the art pixel technology.

FIGS. **8–11** show retrofocus-type objectives corresponding to Embodiments 8–11. In FIG. **8**, a plano-convex element **110** that is preferably made of sapphire acts simultaneously as a window and as a negative lens, due to the curvature of its proximal surface. The objective further comprises an aperture stop **112** proximal to the element **110** and two sapphire elements **114** and **116**, leading to a focal plane **118**. The performance is about the same as in Embodiment 2.

Respective pairs of optical elements **124** and **126**, **134** and **136**, and **144** and **146** focus light on respective image planes **128**, **138**, and **148**. The optical elements of Embodiments 9–11 are all preferably sapphire. The focal plane **128** of Embodiment 9 is embedded in optical element **126**. Embodiment 9 has about the same performance as Embodiment 8 but with improved distortion. The image plane **138** of Embodiment 10 is likewise embedded in optical element **136**. As in Embodiment 3, the field curvature in Embodiment 10 is corrected, providing resolution that is pixel-limited given state of the art fiber image bundles. Embodiment 11 employs an aspheric surface as the proximal surface of the plano-convex element **140** to provide performance similar to that of Embodiment 10,

TABLE 8

Although the present invention is described herein with respect to endoscopic objective lens systems, it will be understood by those in the art that the principles disclosed herein can be used to design other optical systems, e.g., microscope objectives, optical systems for photocopier machines and the like, which use a wide field of view with low dispersion in perhaps a rugged environment with a broad temperature range. While sapphire has been emphasized, it should be noted that other, future materials having the same optical characteristics as sapphire would be within the spirit and scope of the present invention.

What is claimed is:

1. An objective lens system for forming an image at the distal end of an endoscope to be transmitted to the proximal end of the endoscope, comprising:

a first optical group, said first optical group having positive optical power and including a plurality of optical components, more than one of which comprises sapphire to reduce optical aberrations;

an aperture stop on the object side of said first optical group; and

a second optical group, in which said second optical group is on the object side of said first optical group

in which said second optical group comprises an optical window and said objective lens system is of the landscape type.

2. The objective lens system of claim **1**, said first optical group comprising two sapphire elements that contact each other.

3. The objective lens system of claim **1**, said first optical group comprising two noncontacting sapphire elements.

4. The objective lens system of claim **1**, in which the image at the distal end of the endoscope is nonplanar at its focus.

5. The objective lens system of claim **4**, in which the image at the distal end of the endoscope is at a focus near the proximal surface of an optical element.

6. The objective lens system of claim **1**, said first optical group comprising three sapphire elements.

7. The objective lens system of claim **1**, further comprising relay optics and an eyepiece to form an endoscope.

8. An objective lens system for forming an image at the distal end of an endoscope to be transmitted to the proximal end of the endoscope, comprising:

a first optical group, said first optical group having positive optical power and including a plurality of optical components, more than one of which comprises sapphire to reduce optical aberrations,

an aperture stop on the object side of said first optical group; and

a second optical group, in which said second optical group is on the object side of said first optical group, and

in which said aperture stop is located between said first and said second optical groups.

9. The objective lens system of claim **8**, further comprising relay optics and an eyepiece to form an endoscope.

10. An objective lens system for forming an image at the distal end of an endoscope to be transmitted to the proximal end of the endoscope, comprising:

a first optical group, said first optical group having positive optical power and including a plurality of optical components, more than one of which comprises sapphire to reduce optical aberrations;

an aperture stop on the object side of said first optical group; and

a second optical group, in which said second optical group is on the object side of said first optical group,

in which said second optical group is of negative optical power and said objective lens system is of the retrofocus type.

11. The objective lens system of claim **10**, in which said first optical group comprises two noncontacting sapphire elements and the image at the distal end of the endoscope is at a planar focus.

12. The objective lens system of claim **11**, in which the planar focus is near the proximal surface of an optical element.

13. The objective lens system of claim **10**, in which said first optical group comprises two contacting sapphire elements and the image at the distal end of the endoscope is at a nonplanar focus.

14. The objective lens system of claim **10**, further comprising relay optics and an eyepiece to form an endoscope.

15. An objective lens system for forming an image at the distal end of an endoscope to be transmitted to the proximal end of the endoscope, comprising:

an all sapphire, first optical group, said first optical group having positive optical power and including at least one optical component, said first optical group comprising sapphire to reduce optical aberrations;

an aperture stop on the object side of said first optical group; and

a second optical group, in which said second optical group is on the object side of said first optical group, and

in which said first optical group is a single sapphire element and the image at the distal end of the endoscope is non-planar at its focus.

16. The objective lens system of claim **15**, further comprising relay optics and an eyepiece to form an endoscope.

17. An objective lens system for forming an image at the distal end of an endoscope to be transmitted to the proximal end of the endoscope, comprising:

an all sapphire, first optical group, said first optical group having positive optical power and including at least one optical component, said first optical group comprising sapphire to reduce optical aberrations;

an aperture stop on the object side of said first optical group; and

a second optical group, in which said second optical group is on the object side of said first optical group, and

in which said second optical group comprises an optical window and said objective lens system is of the landscape type.

18. The objective lens system of claim **17**, in which said first optical group is a single sapphire element that focuses the image at the distal end of the endoscope to an image plane.

19. The objective lens system of claim **17**, further comprising relay optics and an eyepiece to form an endoscope.

20. An objective lens system having an object side and an image side, comprising:

a first optical group, said first optical group having positive optical power and including a plurality of optical components, more than one of which has an index of refraction greater than 1.7 and an Abbe number of at least 65 to reduce optical aberrations; and

an aperture stop on the object side of said first optical group.

21. The objective lens system of claim **20**, comprising:

a second optical group, in which said second optical group is on the object side of said first optical group and includes an optical window, and

in which said objective lens system is of the landscape type.

22. The objective lens system of claim **21**, said first optical group comprising two sapphire elements that contact each other.

23. The objective lens system of claim **21**, said first optical group comprising two non-contacting sapphire elements.

24. The objective lens system of claim **21**, in which the image at the distal end of the endoscope is non-planar at its focus.

25. The objective lens system of claim **24**, in which the image at the distal end of the endoscope is at a focus near the proximal surface of an optical element.

26. The objective lens system of claim **21**, said first optical group comprising three sapphire elements.

27. The objective lens system of claim **21**, further comprising relay optics and an eyepiece to form an endoscope.

28. The objective lens system of claim **20**, further comprising a second optical group, in which said second optical group is on the object side of said first optical group, and in which said aperture stop is located between said first and said second optical groups.

29. The objective lens system of claim **28**, further comprising relay optics and an eyepiece to form an endoscope.

30. The objective lens system of claim **20**, further comprising a second optical group, in which said second optical group is on the object side of said first optical group, and in which said second optical group is of negative optical power and said objective lens system is of the retrofocus type.

31. The objective lens system of claim **30**, in which said first optical group comprises two non-contacting sapphire elements and the image at the distal end of the endoscope is at a planar focus.

32. The objective lens system of claim **31**, in which the planar focus is near the proximal surface of an optical element.

33. The objective lens system of claim **30**, in which said first optical group comprises two contacting sapphire elements and the image at the distal end of the endoscope is at a non-planar focus.

34. The objective lens system of claim **30**, further comprising relay optics and an eyepiece to form an endoscope.

35. An objective lens system having an object side and an image side, comprising:

a first optical group having positive optical power and including at least one optical component, said first optical group consisting essentially of optical material having an index of refraction greater than 1.7 and an Abbe number of at least 65 to reduce optical aberrations; and

an aperture stop on the object side of said first optical group.

36. The objective lens system of claim **35**, further comprising:

a second optical group, in which said second optical group is on the object side of said first optical group, and

in which said first optical group is a single sapphire element and the image at the distal end of the endoscope is non-planar at its focus.

37. The objective lens system of claim **36**, further comprising relay optics and an eyepiece to form an endoscope.

38. The objective lens system of claim 35, further comprising:

a second optical group, in which said second optical group is on the object side of said first optical group and comprises an optical window, and

in which said objective lens system is of the landscape type.

39. The objective lens system of claim 38, further comprising relay optics and an eyepiece to form an endoscope.

40. The objective lens system of claim 38, in which said first optical group is a single sapphire element that focuses the image at the distal end of the endoscope to an image plane.

41. A method of forming an image of an object, comprising:

imaging light through an objective, the objective including a first optical group having positive optical power and further including an aperture stop on the object side of the first optical group, the first optical group including a plurality of optical components of which more than one includes sapphire to reduce optical aberrations of the light imaged through the objective;

forming an image at the distal end of the objective; and

transmitting the image to the proximal end of an endoscope.

42. A method of forming an image of an object, comprising:

imaging light through an objective, the objective including a first optical group having positive optical power and further including an aperture stop on the object side of the first optical group, the first optical group consisting essentially of sapphire to reduce optical aberrations of the light imaged through the objective;

forming an image at the distal end of the objective; and

transmitting the image to the proximal end of an endoscope.

43. An objective lens system for forming an image at the distal end of an endoscope to be transmitted to the proximal end of the endoscope, comprising:

a first optical group, said first optical group having positive optical power and including a plurality of optical components, more than one of which comprises sapphire; and

an aperture stop on the object side of said first optical group, said aperture stop being conjugate with both an entrance pupil and an exit pupil of said lens system.

44. An objective lens system for forming an image at the distal end of an endoscope to be transmitted to the proximal end of the endoscope, comprising:

an all sapphire, first optical group, said first optical group having positive optical power and including at least one optical component; and

an aperture stop on the object side of said first optical group, said aperture stop being conjugate with both an entrance pupil and an exit pupil of said lens system.

45. An objective lens system for forming an image at the distal end of an endoscope to be transmitted to the proximal end of the endoscope, comprising:

a first optical group, said first optical group having positive optical power and including a plurality of optical components, more than one of which comprises sapphire;

an aperture stop on the object side of said first optical group; and

a second optical group of non-negative optical power, in which said second optical group is on the object side of said first optical group, said first optical group, said aperture stop, and said second optical group forming an objective lens system.

46. An objective lens system for forming an image at the distal end of an endoscope to be transmitted to the proximal end of the endoscope, comprising:

a first optical group, said first optical group having positive optical power and including a plurality of optical components, more than one of which comprises sapphire;

an aperture stop on the object side of said first optical group; and

a second optical group, in which said second optical group is on the object side of said aperture stop, wherein said first optical group, said aperture stop, and said second optical group form an objective lens system.

47. An objective lens system for forming an image at the distal end of an endoscope to be transmitted to the proximal end of the endoscope, comprising:

an all sapphire, first optical group, said first optical group having positive optical power and including at least one optical component;

an aperture stop on the object side of said first optical group; and

a second optical group, in which said second optical group is on the object side of said aperture stop, wherein said first optical group, said aperture stop, and said second optical group form an objective lens system.

48. An objective lens system for forming an image at the distal end of an endoscope to be transmitted to the proximal end of the endoscope, comprising:

a first optical group, said first optical group having positive optical power and including a plurality of optical components, more than one of which comprises sapphire;

an aperture stop on the object side of said first optical group; and

a second optical group, in which said second optical group is on the object side of said first optical group, said first optical group, said aperture stop, and said second optical group forming an objective lens system capable of imaging a field of view of up to 80 degrees.

49. The objective lens system of claim 48, in which said second optical group comprises an optical window and said objective lens system is of the landscape type.

50. The objective lens system of claim 49, said first optical group comprising two sapphire elements that contact each other.

51. The objective lens system of claim 49, said first optical group comprising two non-contacting sapphire elements.

52. The objective lens system of claim 49, in which the image at the distal end of the endoscope is non-planar at its focus.

53. The objective lens system of claim 52, in which the image at the distal end of the endoscope is at a focus near the proximal surface of an optical element.

54. The objective lens system of claim 49, said first optical group comprising three sapphire elements.

55. The objective lens system of claim 48, in which said aperture stop is located between said first and said second optical groups.

56. The objective lens system of claim 48, in which said second optical group is of negative optical power and said objective lens system is of the retrofocus type.

57. The objective lens system of claim 56, in which said first optical group comprises two non-contacting sapphire elements and the image at the distal end of the endoscope is at a planar focus.

58. The objective lens system of claim 57, in which the planar focus is near the proximal surface of an optical element.

59. The objective lens system of claim 56, in which said first optical group comprises two contacting sapphire elements and the image at the distal end of the endoscope is at a non-planar focus.

60. The objective lens system of claim 48, further comprising relay optics and an eyepiece to form an endoscope.

[57] **ABSTRACT**

An apparatus for aligning an actuator lens within a baseplate using a beam of radiant energy. The actuator lens has an actuator optical axis and an actuator optical center and the apparatus includes a frame, a cradle, a tower assembly, a lever assembly, and a gripper assembly. The cradle assembly is employed to hold the baseplate and is mounted to the frame with at least one degree of freedom of motion. The tower assembly defines a tower axis and is also mounted to the frame. The cradle and tower assemblies are positioned to receive the beam of radiant energy along the tower axis and analyze a spot profile of the beam. The lever assembly is rotatably mounted to the frame and the gripper assembly is mounted to the lever assembly.

METHOD AND APPARATUS FOR ALIGNING AN OBJECTIVE LENS

CROSS REFERENCE TO RELATED APLICATIONS

This application is a divisional application of U.S. application Ser. No. 08/474,831, filed Jun. 7, 1995, now U.S. Pat. No. 5,790,325, which is a divisional application of U.S. application Ser. No. 08/418,698, filed Apr. 7, 1995, now U.S. Pat. No. 5,742,441.

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to manufacturing of optical systems, and, in particular, to the manipulation and alignment of an objective lens during manufacture of an optical system.

2. Description of the Related Art

In the manufacture of prior optical systems, specific alignment of the objective lens with respect to a storage medium was not critical. In those systems, a spindle which holds the storage medium is aligned with respect to guide rails. A carriage rides along the guide rails, and the objective lens is placed within the carriage. Because the information storage densities used in such optical systems were sufficiently low, and because manufacturing tolerances of the spindle, rails, and objective lens were sufficiently high, specific alignment of the objective lens was not necessary. The objective lens was placed, then tested for alignment within tolerable limits.

Another example of a prior art optical system does perform active alignment of the objective lens. However, the objective lens is fixedly mounted to an actuator, and the objective lens/actuator combination is aligned with respect to a carriage assembly. Once aligned with respect to the carriage assembly, the actuator is mounted to the carriage assembly, which is aligned with respect to the storage medium. This prior art optical system requires that the actuator be alignable with respect to the carriage assembly. Additionally, the actuator/carriage assembly combination is quite large relative to such assemblies in other optical systems.

SUMMARY OF THE INVENTION

As information storage densities increase, the alignment between the objective lens and the storage medium becomes more critical. As a result, either stricter manufacturing tolerances or improved alignment of the objective lens is necessary. Because stricter manufacturing tolerances increase manufacturing cost significantly, improved alignment of the objective lens allows higher information storage densities at an economically feasible cost.

An apparatus is described which aligns such an objective lens. The apparatus comprises a frame, a cradle assembly mounted to the frame with at least one degree of freedom of motion, a tower assembly mounted to the frame, a lever assembly rotatably mounted to the frame, and a gripper assembly mounted to the lever assembly. The cradle assembly includes a baseplate alignment assembly comprising a source of radiant energy for projecting a beam of radiant energy, means for determining the tilt alignment of the beam with respect to the tower assembly, and a plurality of tilt actuators for aligning the tilt of the beam with respect to the tower assembly. The baseplate alignment assembly may further comprise means for determining the lateral alignment of the beam with respect to the tower assembly and a plurality of lateral actuators for aligning the beam laterally with respect to the tower assembly. The tower assembly comprises a video camera having a camera lens, a tower magnifying lens, and a monitor for displaying a representation of a beam of radiant energy passing through the tower magnifying lens and into the video camera.

The gripper assembly comprises an objective lens assembly, a gripper objective lens mounted to the objective lens assembly, an objective lens alignment assembly for aligning the gripper objective lens with respect to the tower assembly and the cradle assembly, and an actuator lens tilt assembly for aligning the objective lens with respect to the tower assembly and the cradle assembly. The objective lens assembly further comprises a housing having an opening at one end for receiving an objective lens and a bellows structure on its surface to allow bending of the housing, a gripper objective lens, a non-opaque substrate mounted within the housing, and a pneumatic tube attached to the housing for creating a pressure differential between the interior and the exterior of the housing sufficient to hold the actuator lens against the opening. The objective lens alignment assembly further comprises an assembly support, a first lateral alignment support slidably mounted to the assembly support, a first lateral actuator for positioning the first lateral alignment support, a second lateral alignment support slidably mounted to the first lateral alignment support, a second lateral actuator for positioning the second lateral alignment support, a support frame having a frame base and a frame extension, mounted to the second lateral actuator, a support leaf spring mounted to the support frame and biasing the housing against the frame extension, and a focus actuator for positioning the frame extension with respect to the frame base. The actuator lens tilt assembly further comprises a flexure support ring; two flexure support plates; four flexure plates mounted at equal intervals around the flexure support ring, two of which are mounted to the housing and two of which are mounted to the flexure support plates; a first lever disposed against a flexure plate; a first tilt actuator mounted against the first lever for imparting motion on the first lever which is translated into rotational motion by the flexure support ring, the flexure support plates, and the flexure plates; a second lever disposed against a flexure plate; and a second tilt actuator mounted against the second lever for imparting motion on the second lever which is translated into rotational motion by the flexure support ring, the flexure support plates, and the flexure plates.

A method for aligning an actuator lens is described comprising the steps of moving a baseplate assembly with respect to the tower assembly, moving the objective lens assembly with respect to the tower assembly, and moving the actuator lens with respect to the tower assembly. The step of moving the baseplate assembly further comprises moving the baseplate assembly laterally with respect to the tower assembly and rotating the baseplate assembly with respect to the tower assembly. The step of moving the actuator lens further comprises moving the actuator lens laterally with respect to the tower assembly and rotating the actuator lens with respect to the tower assembly. Such a method may be used with the above-described apparatus.

For a better understanding of these and other objects of the present invention, reference is made to the detailed description of the invention which is to be read in conjunction with the following drawings, wnerein:

BRIEF DESCRIPTION OF THE DRAWING

FIG. **1** is a generalized side view of one embodiment of the invention, showing the gripper assembly in a closed position.

FIG. **2** is a generalized side view of one embodiment of the invention, showing the gripper assembly in an open position.

FIG. **3** is a cross-sectional view of the tower assembly, including an embodiment of the analysis assembly.

FIG. **4** is a cross-section view of the vacuum chuck and the microscope objective lens assembly.

FIG. **5** is a view of the microscope objective lens alignment assembly.

FIG. **6** is a side view of the actuator lens tilt assembly.

FIG. **7** is a front view of the actuator lens tilt assembly.

FIG. **8** is a view of an alignment actuator.

FIG. **9** is a top view of one embodiment of the cradle assembly.

FIG. **10** is a cross-sectional view of one embodiment of the cradle assembly, taken along line **10**—**10** of FIG. **9**.

FIG. **11** is a cross-sectional view of one embodiment of a vacuum clamp in the open position, taken along line **11**—**11** of FIG. **9**.

FIG. **12** is a cross-sectional view of one embodiment of a vacuum clamp in the closed position, taken along line **11**—**11** of FIG. **9**.

FIG. **13** is a top view of a baseplate assembly.

FIG. **14** is a pictorial representation illustrating the focusing of an objective lens according to the methods of the present invention.

DESCRIPTION OF THE PREFERRED EMBODIMENT

Referring to exemplary FIGS. **1** and **2**, according to one aspect of the invention, the apparatus comprises a tower assembly **1**, a gripper assembly **2**, and a cradle assembly **3**. The tower assembly **1** is fixedly mounted to a frame **4**. The tower assembly **1** defines a tower axis. The gripper assembly **2** is fixedly mounted to a lever assembly **5**, which is rotatably mounted to the frame **4**. The cradle assembly **3** is mounted to the frame **4** with at least one degree of freedom of motion. A line (not shown) between the tower assembly **1** and the cradle assembly **3** is referred to as an assembly axis. In the closed position, as shown in FIG. **1**, the gripper assembly **2** is between the tower assembly **1** and the cradle assembly **3** along the assembly axis. In the open position, as shown in FIG. **2**, the gripper assembly **2** is not along the assembly axis.

Referring to exemplary FIG. **3**, a cross-section of the tower assembly **1** is shown in more detail. The tower assembly **1** comprises a tower magnifying lens **6** and a video camera **7** having a camera lens **8**. The optical axes of the camera lens **8** of the video camera **7** and the tower magnifying lens **6** are the same, and are referred to collectively as the tower optical axis. The output from the video camera **7** is connected to an analysis assembly **9**. The analysis assembly **9** may be any assembly suitable for analyzing the characteristics of a radiant beam of energy. In the embodiment shown in exemplary FIG. **3**, the analysis assembly **9** comprises a processor **10** and a monitor **11**.

Referring to exemplary FIGS. **4**, **5**, **6** and **7**, the gripper assembly **2** comprises a vacuum chuck **12**, a microscope objective lens assembly **13**, a microscope objective lens alignment assembly **14**, and an actuator lens tilt assembly **15**. FIG. **4** shows a cross-sectional view of one embodiment of the vacuum chuck **12** and the microscope objective lens assembly **13**. FIG. **5** shows a view of one embodiment of the microscope objective lens alignment assembly **14**. FIGS. **6** and **7** show two views of the actuator lens tilt assembly **15**.

Referring to exemplary FIG. **4**, the vacuum chuck **12** comprises a housing **16**, a bellows structure **17**, and an actuator lens receiving opening **18**. A pneumatic tube **37** is connected to the housing **16**. In operation, an actuator lens (not shown) is placed within the actuator lens receiving opening **18** such that the actuator lens receiving opening **18** is completely covered. The actuator lens may be an objective lens. Air is then evacuated from the housing **16** through the pneumatic tube **37** to create a pressure differential between the interior and the exterior of the housing **16**. This pressure differential operates to hold the actuator lens against the actuator lens receiving opening **18** when the gripper assembly **2** moves. The housing **16** contains the bellows structure **17** to allow the housing **16** to bend while maintaining a pressure differential.

The microscope objective lens assembly **13** comprises a microscope objective lens **19** and a substrate **20**. In operation, a beam of radiant energy will enter the housing **16** through the actuator lens receiving opening **18** and, if present, through the actuator lens. The beam will pass through the substrate **20** and through the microscope objective lens **19**. The beam then passes through the housing **16** and into the tower assembly **1**, where it passes through the tower magnifying lens **6** and is received by the video camera **7**. Together, the microscope objective lens **19** and the tower magnifying lens **6** magnify the beam and focus the beam in the video camera **7**. The tower magnifying lens **6** may be a tube lens. The substrate **20** simulates the optical properties of an information-bearing disk, and the effects of those properties on the beam. The substrate **20** is mounted such that, when the gripper assembly **2** is in the closed position, the substrate **20** is orthogonal to the tower optical axis.

Referring to exemplary FIG. **5**, the microscope objective lens alignment assembly **14** comprises an X-axis lateral alignment actuator **21**, a Y-axis lateral alignment actuator **22**, and a focus actuator **23**. Referring to exemplary FIG. **5**, there is shown a reference coordinate system **24**. This reference coordinate system **24** is chosen for purposes of explanation only, and it will be obvious to one skilled in the art that any convenient coordinate system could be chosen without departing from the spirit and scope of the present invention.

In the embodiment particularly shown in FIG. **5**, a microscope support frame **25** having a frame extension **28** supports the housing **16** by a support leaf spring **26**. The support leaf spring **26** biases the housing **16** against a cylindrical bearing **27** located between the housing **16** and the frame extension **28**. The focus actuator **23** is mounted to the frame extension **28**, and maintains a distance between the frame extension **28** and the microscope support frame **25** along the Z-axis, as indicated by the reference coordinate system **24**. Motion of the housing **16** along the Z-axis adjusts the focus of the microscope objective lens **19** in combination with the tower magnifying lens **6**.

The microscope support frame **25** is mounted on a Y-axis lateral alignment support **29** such that the microscope support frame **25** may slide relative to the Y-axis lateral alignment support **29** along the Y-axis, as indicated by the reference coordinate system **24**. The Y-axis lateral alignment actuator **22** is mounted to the microscope support frame **25**, and will actuate the relative sliding motion along the Y-axis.

The Y-axis lateral alignment support **29** is mounted on an X-axis lateral alignment support **30** such that the Y-axis lateral alignment support **29** may slide relative to the X-axis lateral alignment support **30** along the X-axis, as indicated by the reference coordinate system **24**. The X-axis lateral alignment actuator **21** is mounted to the Y-axis lateral

alignment support **29**, and will actuate the relative sliding motion along the X-axis.

The X-axis lateral alignment support **30** is mounted to a lateral alignment assembly support **31**. The lateral alignment assembly support **31** is mounted to the lever assembly **5**. It will be apparent to one skilled in the art that the mountings between the microscope support frame **25**, the Y-axis lateral alignment support **29**, the X-axis lateral alignment support **30**, and the lateral alignment assembly support **31** may be rearranged from the above description without departing from the spirit and scope of the present invention.

Referring to exemplary FIGS. **6** and **7**, there are shown two views of the actuator lens tilt assembly **15**. FIG. **6** represents a left side view of the actuator lens tilt assembly **15** according to one aspect of the invention. FIG. **7** represents a front view of the same actuator lens tilt assembly **15**. The actuator lens tilt assembly **15** comprises an X-axis tilt actuator **32**, a Y-axis tilt actuator **33**, and a flexure assembly **34**. The X-axis tilt actuator **32** is mounted to the lever assembly **5** and against an X-axis lever **35**. The X-axis lever **35**, at the end nearest the X-axis tilt actuator **32**, is biased against the lever assembly **5**, and at the other end is mounted to the flexure assembly **34**. The Y-axis tilt actuator **33** is mounted to the lever assembly **5** and against a Y-axis lever **36**. The Y-axis lever **36**, at the end nearest the Y-axis tilt actuator **33**, is biased against the lever assembly **5**, and at the other end is mounted to the flexure assembly **34**.

The flexure assembly **34** comprises a plurality of flexure plates **71**, **72**, **73**, **74**, a flexure support ring **38**, and a plurality of flexure support plates **39**. Flexure plate **71** is mounted at one end to the flexure support ring **38**, and mounted at its other end to the X-axis lever **35** and the housing **16**. Flexure plate **73** is mounted opposite flexure plate **71** to the flexure support ring **38** and to the housing **16**. Flexure plate **74** is mounted at one end to the Y-axis lever **36** and the flexure support ring **38**, and mounted at its other end to a flexure support plate **39**. Flexure plate **74** is mounted at a 90 degree interval from both flexure plate **71** and flexure plate **73**. Flexure plate **72** is mounted opposite flexure plate **74** to the flexure support ring **38** and to a flexure support plate **39**. The flexure support plates **39** are mounted to the lever assembly **5**.

Flexure plates **71**, **72**, **73**, **74** each lie in a separate plane. The planes in which flexure plates **71** and **73** lie intersect along a line through an intersection point **40**. The planes in which flexure plates **71** and **73** lie intersection along a line through the intersection point **40**. The lines may be orthogonal to each other.

The operation of the actuator lens tilt assembly **15** will be described with respect to a downward motion imparted on each of the tilt actuators, the X-axis tilt actuator **32** and the Y-axis tilt actuator **33**.

A downward motion of the X-axis tilt actuator **32** imparts a downward motion on the X-axis lever **35**. This downward force produces a counterclockwise rotational force on flexure plate **71** about the point where flexure plate **71** is mounted to the flexure support ring **38**. The downward force also translates into a counterclockwise rotational force on flexure plate **73** about the point where flexure plate **73** is mounted to the flexure support ring **38**. These two rotational forces cause rotation about the intersection of the two planes in which the flexure plates **71**, **73** lie. This intersection occurs at intersection point **40**.

A downward motion of the Y-axis tilt actuator **33** imparts a downward force on the Y-axis lever **36**. This downward force produces a clockwise rotational force on flexure plate **74** about the point where flexure plate **74** is mounted to the flexure support plate **39**. Because of the rigidity of the flexure support ring **38**, this rotational force translates into a clockwise rotational force on flexure plate **72** about the point where flexure plate **72** is mounted to the flexure support plate **39**. These two rotational forces cause rotation about the intersection of the two planes in which the flexure plates **72** and **74** lie. This intersection occurs at intersection point **40**.

Referring to exemplary FIG. **8**, there is shown one embodiment of an alignment actuator **41**. The alignment actuator **41** may be a tilt actuator or a lateral alignment actuator, as described above. The alignment actuator **41** contains a handle **42** and a threaded body **43**. The threaded body **43** is threadably mounted through a fixed surface **44** and against a movable surface **45**. The movable surface **45** is biased toward the fixed surface **44** by a spring **46** or other suitable biasing means. The mounting of the movable surface **45** determines whether the force by the alignment actuator **41** or the biasing by the spring **46** produces a lateral or rotational force. The alignment actuator **41** may include what is commonly referred to as a micrometer stage.

Referring to exemplary FIG. **9**, there is shown a top view of the cradle assembly **3**. Referring to exemplary FIG. **10**, there is shown a cross-sectional view of the cradle assembly **3**, taken along line **10**—**10** of FIG. **9**. The cradle assembly **3** comprises a cradle **47** having a surface **48** and a side **49**, a plurality of vacuum clamps **50**, and a baseplate alignment assembly (not shown). The cradle includes side walls **52** and end wails **53** for securing a baseplate assembly (not shown) in the cradle **47**. In the embodiment particularly shown in exemplary FIGS. **9** and **10**, the baseplate alignment assembly (not shown) comprises a source of radiant energy **54**, a Y-axis source lateral actuator **55**, a Z-axis source lateral actuator **56**, an X-axis cradle assembly tilt actuator **57**, a Y-axis cradle assembly tilt actuator **58**, a mirror **59**, and an alignment analyzer **60**. In another embodiment, the baseplate alignment assembly (not shown) comprises a source of radiant energy **54**, an X-axis cradle assembly tilt actuator **57**, a Y-axis cradle assembly tilt actuator **58**, a mirror **59**, and an alignment analyzer **60**. In both embodiments, the mirror **59** is aligned below a hole **61** in the surface **48** of the cradle **47**. Additionally, the source of radiant energy **54** and the alignment analyzer **60** may be combined in an auto-collimator or an auto-collimator/telescope.

Referring to exemplary FIG. **11**, a cross-sectional view of a vacuum clamp **50** is shown in the open position. Exemplary FIG. **12** shows a cross-sectional view of a vacuum clamp **50** in the closed position. The surface **48** of the cradle **47** extends laterally beyond the side **49** of the cradle **47**. The vacuum clamp **50**, having with a U-shaped cross-section, is placed over the extension **51** of the cradle **47**, with one leg of the "U" on each side of the extension **51**. A pivot pin **62** is placed through each leg of the U-shape and through the extension of the cradle **47**. In the open position, a baseplate assembly can be placed on the cradle **47**. Once in place, a pneumatic tube **81** biases the vacuum clamp **50** to the closed position, securing the baseplate against movement.

In operation, as shown in exemplary FIG. **13**, a baseplate assembly **63** is provided. The baseplate assembly **63** contains a spindle **64** and a spindle motor **65** for rotating an information-bearing disk, and a spindle servo (not shown) for controlling the speed of the spindle motor **65**. The baseplate assembly **63** further contains an optics module assembly **66**. The baseplate assembly. **63** also contains a carriage motor (not shown) and a carriage assembly **67** for directing a beam of radiant energy from the optics module assembly **66** toward a position on the information-bearing

disk, and a carriage control servo (not shown) for controlling the position of the carriage assembly. At this point, the carriage assembly **67** does not contain an actuator lens for focussing the beam of radiant energy on the information-bearing disk. The carriage assembly **67** may be held in place relative to the spindle **64** by a carriage stop (not shown).

The baseplate assembly **63** is placed on the surface **48** of the cradle **47** and secured with the vacuum clamps **50**. A test disk of glass or other suitable material (not shown) is placed on the spindle of the baseplate assembly **63**. The gripper assembly **2** is then lowered into the closed position.

The source of radiant energy **54** radiates two cradle alignment beams of radiant energy toward the mirror **59**. The first cradle alignment beam is reflected from the mirror **59**, then passes through the hole **61** in the cradle **47** and through the baseplate assembly **63**. The first cradle alignment beam reflects off the test disk and is received by the alignment analyzer **60**. The second cradle alignment beam is reflected from the mirror **59**, then passes through the hole **61** in the cradle **47** and through the baseplate assembly **63**. The second cradle alignment beam reflects off the substrate **20** and is received by the alignment analyzer **60**. By analyzing the relative positions of the first and second cradle alignment beams, the alignment analyzer **60** determines the tilt of the test disk with respect to the substrate **20**. It will be obvious that the mirror **59** may comprise two parallel mirrors, each reflecting one of the cradle alignment beams.

Tilt between the test disk and the substrate **20** is corrected in the following manner. The X-axis cradle assembly tilt actuator **57** tilts the cradle assembly **3** about the X-axis. The Y-axis cradle assembly tilt actuator **58** tilts the cradle assembly **3** about the Y-axis. Acting together, the cradle assembly tilt actuators **57**, **58** tilt the cradle assembly **3**, including the test disk, with respect to the substrate **20**. Because the substrate **20** is orthogonal to the tower optical axis, this action tilts the cradle assembly **3** with respect to the tower optical axis. Each of the actuators **57**, **58** may be an alignment actuator **41** as shown in exemplary FIG. **8**.

In one embodiment, lateral alignment of the cradle assembly **3** with respect to the tower optical axis is done mechanically, and is not tested or measured. In another embodiment, if the cradle alignment beam is not received by the alignment analyzer **60**, or is off-center when received by the alignment analyzer **60**, the position of the source of radiant energy **54** can be moved using the Y-axis source lateral actuator **55** and the Z-axis source lateral actuator **56**. As shown best in FIG. **9**, the mirror **59** is situated such that a change in the position of the source of radiant energy **54** along the Y-axis is translated into a change in the position of the cradle alignment beam along the Y-axis as it is received by the alignment analyzer **60**. The Y-axis source lateral actuator **55** effects this change in position. Similarly, a change in the position of the source of radiant energy **54** along the Z-axis is translated into a change in the position of the cradle alignment beam along the X-axis as it is received by the alignment analyzer **60**. The Z-axis source lateral actuator **56** effects this change in position. Each of the actuators **55**, **56** may be an alignment actuator **41** as shown in exemplary FIG. **8**.

In the embodiment particularly described below, all references to a coordinate system are made in accordance with reference coordinate system **24** shown in exemplary FIG. **5**. This reference coordinate system **24** is chosen for purposes of explanation only, and it will be obvious to one skilled in the art that any convenient coordinate system could be chosen without departing from the spirit and scope of the present invention.

Once aligned, the source of radiant energy **54** is turned off and the test disk is removed. If not previously aligned, the carriage assembly of the baseplate assembly **63** is moved in approximate alignment with the assembly axis, and an actuator lens (not shown) is placed within the carriage assembly of the baseplate assembly **63** and is allowed to assume a natural rest position. The lever assembly **5** is lowered to the closed position.

A pressure differential is then created between the vacuum chuck **12** and the atmosphere. This pressure differential operates to hold the actuator lens against the vacuum chuck **12**, while maintaining the orientation of the actuator lens. Additionally, the optical center of the actuator lens is maintained at the intersection point **40**. This optical center may also be substantially at the center of mass of the actuator lens.

An adjustable power supply is attached to the radiant energy source within the optics module assembly **66**. The radiant energy source projects a lens alignment beam of radiant energy into the carriage assembly. Within the carriage assembly, the lens alignment beam passes through pentaprism (not shown) and through the actuator lens. The lens alignment beam then passes through the substrate **20**, through the microscope objective lens **19**, and into the tower assembly **1**, where the lens alignment beam passes through the tower magnifying lens **6** and is received by the video camera **7**. The analysis assembly **9** then displays and analyzes the spot profile of the lens alignment beam.

If the lens alignment beam is not received by the video camera **7** and passed to the analysis assembly **9**, the X-axis lateral alignment actuator **21** and the Y-axis lateral alignment actuator **22** are used to move the microscope objective lens **19** laterally with respect to the tower assembly **1**. The X-axis lateral alignment actuator **21** and the Y-axis lateral alignment actuator **22** may be alignment actuators **41** as shown in exemplary FIG. **8**.

If the lens alignment beam is not focussed properly in the video camera **7** and analysis assembly **9**, the focus actuator **23** is used to move the microscope objective lens **19** toward or away from the tower assembly **1** until the lens alignment beam is in proper focus within the video camera **7** and analysis assembly **9**. The focus actuator **23** may be an alignment actuator **41** as shown in exemplary FIG. **8**.

Once focussed properly, the analysis assembly **9** analyzes the profile of the beam for coma and astigmatism, as the cradle alignment beam was previously analyzed. If these optical aberrations occur, the actuator lens tilt assembly **15** operates to minimize these aberrations by aligning the actuator lens. As described above, the X-axis tilt actuator **32** rotates the actuator lens about the X-axis. Likewise, the Y-axis tilt actuator **33** rotates the actuator lens about the Y-axis. Together, the actuator lens tilt assembly **15** can rotate the actuator lens in any direction with respect to the lens alignment beam, while maintaining the optical center or the center of mass of the actuator lens at the intersection point **40**.

Once the misalignment is corrected to within an acceptable tolerance, the gripper assembly **2**, including the vacuum chuck **12** and the actuator lens, is raised to the open position. A fastening agent is placed on the pedestals of the carriage assembly, and the gripper assembly **2** is again lowered to the closed position. The actuator lens is secured by the fastening agent to the carriage assembly, without changing the orientation of the actuator lens established by the actuator lens tilt assembly **15**. The fastening agent may be a selectably curable adhesive, such as ultraviolet radiation curable adhesive.

Once the fastening agent has cured, the actuator lens is tested for alignment. As above, a lens alignment beam is radiated through the actuator lens, the substrate **20**, the microscope objective lens **19**, the tower magnifying lens **6**, and into the video camera **7**. The analysis assembly **9** then analyzes the spot profile of the lens alignment beam. Each of the alignments described above may need to be adjusted for this testing process. Depending on its configuration, the vacuum chuck **12** may need to be retracted or removed to avoid contacting and damaging the carriage assembly.

In another embodiment of the invention, the cradle assembly **3** may comprise a plurality of cradles **47**, a plurality of vacuum clamps **50**, and a baseplate alignment assembly (not shown). The cradles **47** may be movable with respect to the tower assembly **1**, and there may be either one baseplate alignment assembly (not shown) for each cradle **47**, or a single baseplate alignment assembly (not shown) which aligns only the cradle **47** presently in position with respect to the tower assembly **1**. Further, there may be a single source of radiant energy **54** and set of actuators **55**, **56**, **57**, **58** regardless of the number of cradles **47**, with one mirror **59** associated with each cradle **47**.

According to this embodiment, there may be a second tower assembly **1** identical to the first tower assembly **1** described above. In addition, there may be a second gripper assembly **2** associated with the second tower assembly **1** as described above. The second gripper assembly **2** will not contain a vacuum chuck **12**.

In operation, the first tower assembly **1** and first gripper assembly **2** operate as described in the previous embodiment. After fastening the actuator lens to the carriage assembly with the fastening agent, the cradle **47** containing the baseplate assembly **63** is moved beneath the second tower assembly **1** and second gripper assembly **2**. Again, a lens alignment beam of radiant energy is projected by the optics module assembly **66** through the same path in the second tower assembly **1** and second gripper assembly **2** as described with respect to the first tower assembly **1** and first gripper assembly **2**. The analysis assembly **9** associated with the second tower assembly **1** analyzes the spot profile of the lens alignment beam after the actuator lens is fastened to the baseplate assembly **63**. It will be obvious to one skilled in the art that, by allowing the vacuum chuck **12** to be removable or retractable, the first tower assembly **1** and first gripper assembly **2** may function as the second tower assembly **1** and second gripper assembly **2**, respectively.

With reference now to FIG. **14**, there is shown a method of focusing a beam of radiant energy **76** onto an optical disc **78**. The beam of radiant energy **76** may be provided by the source of radiant energy **54** shown in FIG. **9**. The method of focusing the beam of radiant energy **76** onto the optical disc **78** includes the step of directing the beam of radiant energy **76** through an objective lens **80** onto the optical disc **78**. The objective lens **80** may be held in position by the actuator lens receiving opening **18** of the microscope objective lens assembly shown in FIG. **4**. As indicated above, the actuator lens may be an objective lens. The present method further includes the step of aligning the beam of radiant energy **76** with respect to the optical disc **78** with the alignment assembly **14**, FIG. **5**, while maintaining the optical center of the objective lens **80** at a predetermined intersection point relative to the reference coordinate system **24**. The alignment assembly **14** may advantageously include the alignment actuator **41** shown in FIG. **8**. The present method also includes receiving a return beam of radiant energy **76***a* reflected from the optical disc **78**, and analyzing the spot profile of the return beam **76***a* with the analyzer assembly **9** which includes the processor **10** and monitor **11**. While viewing the monitor **11**, the objective lens **23** may be moved toward and away from the optical disc **78** using the focus actuator **23**, FIG. **5**, until the analyzer assembly **9** indicates that the beam **76** is in proper focus. This method may be alternatively performed after placing the objective lens **80** in the carriage assembly **67** shown in FIG. **13**.

While this invention has been described in detail with reference to certain preferred embodiments, it should be appreciated that the present invention is not limited to those precise embodiments. Rather, in view of the present disclosure which describes the current best mode for practicing the invention, many modifications and variations would present themselves to those of skill in the art without departing from the scope and spirit of this invention. The scope of the invention is, therefore, indicated by the following claims rather than by the foregoing description. All changes, modifications, and variations coming within the meaning and range of equivalency of the claims are to be considered within their scope.

What is claimed is:

1. An apparatus for aligning an actuator lens within a baseplate using a beam of radiant energy, the actuator lens having an actuator optical axis and an actuator optical center, said apparatus comprising:

a frame;

a cradle assembly for holding the baseplate, said cradle assembly mounted to said frame with at least one degree of freedom of motion;

a tower assembly defining a tower axis and mounted to said frame, said cradle assembly and said tower assembly defining an assembly axis, for receiving the beam of radiant energy along said tower axis and analyzing a spot profile of said beam of radiant energy;

a lever assembly rotatably mounted to said frame; and

a gripper assembly mounted to said lever assembly.

[57] **ABSTRACT**

An objective lens system consisting of a first lens unit having a negative refractive power and a second lens unit having a positive refractive power wherein the first lens unit or the second lens unit comprises at least one radial type gradient index lens element which has a refractive index distribution in a radial direction from an optical axis. This objective lens system favorably corrects chromatic aberration and other aberrations by adequately selecting a value expressing an Abbe's number and a refractive power of medium for the radial type gradient index lens element.

OBJECTIVE LENS SYSTEM

BACKGROUND OF THE INVENTION

a) Field of the Invention

The present invention relates to an objective lens system which uses a radial type gradient index lens element.

b) Description of the Prior Art

As conventional examples of lens systems having relatively wide field angles and high optical performance which are used, for example, as objective lens systems for endoscopes, there are known many lens systems such as a lens system disclosed by Japanese Patent Kokoku Publication No. Sho 60-46410 shown in FIG. **1**. A conventional example shown in FIG. **1** is a lens system of the so-called retrofocus type which is composed, in order from the object side, of a front lens unit having negative refractive power, a stop and a rear lens unit having a positive refractive power. In this lens system, the front lens unit has a function to widen a field angle and another function to correct curvature of field by reducing a Petzval's sum of the lens system as a whole, the rear lens unit serves for suppressing production of spherical aberration and coma by distributing refractive powers among three positive lens elements and a cemented lens component, and the cemented lens component corrects lateral chromatic aberration which poses a problem, in particular, in a lens system which has a wide field angle. Though this conventional example favorably corrects aberrations, it is composed of lens elements in a number as large as six, thereby posing a problem of low producibility or a high manufacturing cost. Accordingly, it is expected to develop a retrofocus type objective lens system for endoscopes which is composed of an extremely small number of lens elements and has a high producibility. However, a lens system which favorably corrects aberrations and has high optical performance can hardly be composed of two homogenous spherical lens elements.

Further, an endoscope is generally equipped with a system for illuminating a location to be observed since it is used frequently for observing and photographing dark locations such as interiors of human bodies, aircraft engines, pipings and so on. In addition, an objective lens system for endoscopes has an NA which is not so large for obtaining a large depth of field. Accordingly, axial aberrations do not pose a serious problem, but a wide field angle and a negative-positive asymmetrical composition as shown in FIG. **1** make it difficult to correct offaxial aberrations. When an objective lens system is to be composed of two negative and positive lens elements, it is impossible to use a cemented lens component as in the objective lens system disclosed by Japanese Patent Kokoku Publication No. Sho 60-46410 mentioned above as the conventional example, whereby lateral chromatic aberration can hardly be corrected and offaxial imaging performance is remarkably degraded. It is therefore difficult to favorably correct offaxial aberrations with two homogenous lens elements so as to obtain favorable offaxial imaging performance.

It is therefore conceivable to use a radial type gradient index lens element which is characterized in that it corrects chromatic aberration in particular more favorably than a homogenous lens element. As a conventional example of an objective lens system for endoscopes which uses a radial type gradient index lens element and is composed of two lens elements, there is known a lens system disclosed by Japanese Patent Kokai Publication No. Sho 52-29238. However, this conventional example has a field angle as narrow as 72° which is insufficient for use as an objective lens system for endoscopes.

Further, a lens system disclosed by Japanese Patent Kokai Publication No. Hei 5-107471,for example, is known as a conventional example of an objective lens system having a wide field angle obtained with two lens elements. Though this example uses a radial type gradient index lens element, it does not effectively make use of the chromatic aberration correcting capability of the radial type gradient index lens element and does not sufficiently correct lateral chromatic aberration which poses a problem in a lens system having a wide field angle in particular.

SUMMARY OF THE INVENTION

A primary object of the present invention is to provide an objective lens system which is composed of lens elements in a number on the order of 2, that favorably corrects aberrations and has a wide field angle.

The objective lens system according to the present invention is characterized in that it comprises, in order from the object side, a first lens unit having a negative refractive power and a second lens unit having a positive refractive power; that at least the first lens unit comprises a radial gradient index lens element which has a refractive index distribution in a radial direction of the lens element; and that the first lens unit satisfies the following condition (1):

$$1/V_{10}<1/V_{00} \tag{1}$$

wherein the reference symbols V_{00} and V_{10} represent parameters expressing a dispersing power of the radial type gradient index lens element which are given by the following formulae (b) and (c) respectively:

$$V_{10}=(N_{00d}-1)/(N_{00F}-N_{00C}) \tag{b}$$

$$V_{10}=N_{10d}/(N_{10F}-N_{10C}) \tag{c}$$

wherein the reference symbols N_{00d}, N_{00F} and N_{00C} represent refractive indices of the radial type gradient index lens element for the d-line, F-line and C-line respectively, and the reference symbols N_{10d}, N_{10F} and N_{10C} designate values of a coefficient of a term r^2 for the d-line, F-line and C-line respectively when a refractive indices of the radial type gradient index lens element is expressed in a form of a polynominal. In embodiments of the present invention which are to be described later, refractive indices of radial type gradient index lens elements are given by the following formula (a):

$$n(r)=N_{00}+N_{10}r^2+N_{20}r^4+ \tag{a}$$

wherein the reference symbol r represents a distance as measured from an optical axis in a radial direction of the radial type gradient index element and the reference symbol n(r) designates a refractive index of a portion of the radial type gradient index lens element located at the distance r. Further, the objective lens system according to the present invention is characterized in: that it is composed, in order from the object side, of a first lens unit having a negative refractive power, and a second lens unit having a positive refractive power, that at least the second lens unit comprises a radial type gradient index lens element having a refractive index distribution in a radial direction of the lens element, and that the second lens unit satisfies the following conditions (1) and (3):

$$1/V_{10}<1/V_{00} \tag{1}$$

$$0.05<\phi_{2m}/\phi<1.0 \tag{3}$$

wherein the reference symbol ϕ_{2m} represents a refractive index of a medium of the radial type gradient lens element used in the second lens unit.

Further, it is desirable that the objective lens system according to the present invention described above satisfies the following condition (2):

$$-0.5<\phi_{1m}/\phi<-0.02 \quad (2)$$

wherein the reference symbol ϕ_{1m} represents a refractive power of a medium of the radial type gradient index lens element used in the first lens unit and the reference symbol ϕ designates a refractive power of the objective lens system as a whole.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** shows a sectional view illustrating a composition of a conventional objective lens system;

FIG. **2** shows a diagram schematically showing a fundamental composition of the objective lens system according to the present invention;

FIG. **3** shows a diagram schematically showing the fundamental composition of the objective lens system according to the present invention wherein an image surface is positioned in parallel with an optical axis;

FIGS. **4** through **15** show sectional views illustrating compositions of first through twelfth embodiments of the objective lens system according to the present invention;

FIGS. **16**A and **16**B show views illustrating a composition of a thirteenth embodiment of the objective lens system according to the present invention;

FIGS. **17** through **21** show sectional views illustrating composition of fourteenth through eighteenth embodiments of the objective lens system according to the present invention;

FIGS. **22**A, **22**B and **22**C show diagrams exemplifying a shape, before working, of a lens element which is to be used in the objective lens system according to the present invention;

FIGS. **23**A, **23**B and **23**C show diagrams exemplifying a shape, after working, of the lens system which is to be used in the objective lens system according to the present invention;

FIG. **24** is a diagram showing an example of a stop which is to be disposed in the objective lens system according to the present invention;

FIG. **25** is a diagram showing another example of a stop which is to be disposed in the objective lens system according to the present invention;

FIGS. **26** through **31** show sectional views illustrating compositions of nineteenth through twenty-fourth embodiments of the objective lens system according to the present invention;

FIG. **32** shows a perspective view illustrating an endoscope which uses the objective lens system according to the present invention;

FIG. **33** shows a side view of a non-flexible endoscope which uses the objective lens system according to the present invention;

FIG. **34** shows a perspective view illustrating a video camera which uses the objective lens system according to the present invention;

FIG. **35** shows a perspective view illustrating a portable TV telephone which uses the objective lens system according to the present invention; and FIG. **36** shows a perspective view illustrating a portable data input unit which uses the objective lens system according to the present invention.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

It is desirable that an objective lens system which has a relatively wide field angle for use in endoscopes, for example, is configured as the so-called retrofocus type composed, in order from the object side, of a first lens unit having a negative refractive power and a second lens unit having a positive refractive power.

Further, it is desirable that endoscopes, for example, which are inserted into human bodies and pipings for observing interiors thereof use objective lens systems having small diameters. When the lens system according to the present invention is to be used as an objective lens system for endoscopes, it is desirable for reducing a diameter of the lens system to compose it by disposing a stop between a negative lens unit and a positive lens unit. By selecting such a composition, it is possible to lower heights of rays passing through a first lens unit or a second lens unit, thereby reducing the diameter of the lens system. When the lens system has an asymmetrical composition, or is composed of a positive lens unit and a negative lens unit disposed on both sides of a stop, however, off-axial aberrations are apt to be produced in large amounts in the lens system as a whole, or it is difficult to favorably correct lateral chromatic aberration in particular. For favorably correcting lateral chromatic aberration, it is desirable to use a radial type gradient index lens element which has a more excellent characteristic for correcting chromatic aberration than a homogenous lens element.

It is known that lateral chromatic aberration LTC produced by a thin radial type gradient index lens element is expressed by the following formula (d):

$$LTC=K(\phi_s/V_{00}+\phi_m/V_{10}) \quad (d)$$

wherein the reference symbol K represents a constant determined dependently on a height of an offaxial ray and an angle of a final axial ray, the reference symbol ϕ_s designates a refractive power of a surface of the radial type gradient index lens element and the reference symbol ϕ_m denotes a refractive power of a medium of the radial type gradient index lens element which is known to be approximated by the following formula (e):

$$\phi_m \approx -2N_{10}d_G \quad (e)$$

wherein the reference symbol d_G represents thickness of the radial type gradient index lens element.

As is apparent from the formula (d), it is possible to control an amount of chromatic aberration to a desired value by varying V_{10} in the second term of the formula.

Since the objective lens system according to the present invention has an asymmetrical composition, like the model of thin lens elements shown in FIG. **2**, wherein a first negative lens unit L_1 and a second positive lens unit L_2 are disposed in that order from the object side and on both side of a stop S, each of the lens units refracts a ray RO coming from an offaxial object point, unlike a ray RA coming from an axial object point, in a direction which is the same as a refracted direction (downward in FIG. **2**) of an incident light bundle. Accordingly, lateral chromatic aberration is produced in a very large amount in the objective lens system according to the present invention, thereby making it difficult to compose the objective lens system, in order from the object side, of a negative lens unit and a positive lens unit which consist of two homogenous lens elements.

For solving this problem or favorably correcting lateral chromatic aberration by adopting a radial type gradient index lens element, it is conceivable to select either of two cases: one where the radial index lens element is used in the first negative lens unit and the other where the radial gradient lens element is used in the second positive lens unit.

Description will be made of a first composition of the objective lens system according to the present invention where a radial gradient index element is used in the first negative lens unit.

For allowing a radial type gradient index lens element to produce chromatic aberration in an amount smaller than that of chromatic aberration produced by a homogenous lens element which has the same refractive power as that of the radial type gradient index lens element, it is necessary from the formula (d) to satisfy the following relationship:

$$\phi_s/V_{00}+\phi_m/V_{10}<\phi_t/V_{00}$$

wherein the reference symbol ϕ_t represents a refractive power of the homogenous lens element on an assumption that it has an Abbe's number which is equal to that on the optical axis of the radial type gradient index lens element.

Since the radial type gradient index lens element and the homogenous lens element which are compared with each other have the same refractive power, we obtain:

$$\phi_t=\phi_s+\phi_m$$

From the two formulae mentioned above, there establishes the following relationship:

$$\phi_s/V_{00}+\phi_m/V_{10}<\phi_s/V_{00}+\phi_m/V_{00}$$

The above-mentioned condition (1) is obtained from this formula.

For favorably correcting lateral chromatic aberration in the objective lens system according to the present invention, it is desirable to use a radial type gradient index lens element satisfying the condition (1) as the first lens unit which has the negative refractive power as described above. The condition (1) is required for allowing a radial type gradient index lens element to produce chromatic aberration in an amount smaller than that of chromatic aberration produced by a homogenous lens element which has the same refractive power as that of the radial type gradient index lens element. If the condition (1) is not satisfied, a radial type gradient index lens element cannot correct lateral chromatic aberration more favorably than a homogenous lens element which has the same refractive power as that of the radial type gradient index lens element.

When a radial type gradient index lens element is to be used for correcting lateral chromatic aberration, it is necessary, as apparent from the formula (d), to take into sufficient consideration not only a value of V_{10} but also refractive powers of a surface and a medium. For reducing an amount of lateral chromatic aberration to be produced by the first lens unit in the objective lens system according to the present invention, it is desirable from the formula (d) to meet the following equation:

$$\phi_s/V_{00}+\phi_m/V_{10}\approx 0$$

By using a total refractive power of a surface and a medium $\phi_G(=\phi_s+\phi_m)$ in this formula and developing it, we obtain:

$$\phi_m\approx\phi_G\times V_{10}/(V_{10}-V_{00})$$

Since the Abbe's number V_{00} of a radial type gradient index lens element ordinarily has a value on the order of 30 to 80 on an optical axis and the first lens unit has the negative refractive power, the condition (1) required for correcting chromatic aberration can be transformed as follows:

$$\phi_G\times V_{10}/(V_{10}-V_{00})<0$$

It is desirable as understood from this formula that a medium has a negative refractive power. Taking into consideration this fact and the requirement to correct lateral chromatic aberration favorably in the objective lens system as a whole, it is desirable that a radial type gradient index lens element which is to be used in the objective optical system according to the present invention is made of a medium having a refractive power ϕ_{1m} satisfying the above-mentioned condition (2).

When a ratio of a refractive power of a medium of the first lens unit relative to a refractive power of the objective lens system satisfies the condition (2), it is possible to correct lateral chromatic aberration favorably in the objective lens system as a whole. If the upper limit of −0.02 of the condition (2) is exceeded, a medium of the radial type gradient index lens element will have a weak refractive power, thereby undesirably making it difficult to correct lateral chromatic aberration favorably in the objective lens system as a whole. If the lower limit of −0.5 of the condition (2) is not satisfied, in contrast, a medium will have too strong a refractive power, thereby overcorrecting lateral chromatic aberration.

The objective lens system according to the present invention which has a second composition is composed of a first lens unit having a negative refractive power and a second lens unit having a positive refractive power; a radial type gradient index lens element being used in the second lens unit having the positive refractive power; and the radial type gradient index lens element used in the second lens unit having a refractive index expressed by the above-mentioned formula (a) and satisfying the following conditions (1) and (3):

$$1/V_{10}<1/V_{00} \quad (1)$$

$$0.05<\phi_{2m}/\phi<1.0 \quad (3)$$

wherein the reference symbol ϕ_{2m} represents a refractive power of the gradient index lens element which is used in the second lens unit and the reference symbol ϕ designates a refractive power of the objective lens system as a whole.

Since lateral chromatic aberration is produced in a very large amount in the objective lens system as a whole as described above, it is difficult to compose the lens system, in order from the object side, of two negative and positive homogenous lens elements. When a radial type gradient index lens element is to be used in the second lens lens unit for solving this problem or favorably correcting lateral chromatic aberration, it is desirable to configure this lens element so as to satisfy the condition (1) mentioned above.

The condition (1) is required for allowing the radial type gradient index lens element to produce chromatic aberration in an amount smaller than that of chromatic aberration produced by a homogenous lens element which has the same refractive power as that of the radial type gradient index lens element.

If the condition (1) is not satisfied, the radial type gradient index lens element cannot correct chromatic aberration more favorably than the homogenous lens element having the same refractive power as that of the radial type gradient index lens element.

When a radial type gradient index lens element is to be used for correcting lateral chromatic aberration, it is necessary to take into consideration not only a value of V_{10} but also refractive powers of a surface and a medium as described above. When lateral chromatic aberration produced by the second lens unit is to be reduced in the objective lens system according to the present invention, the

formula (d) is transformed, as in the case where a radial type gradient index lens element is used in the first lens unit, into the following formula:

$$\phi_m \approx \phi_G \times V_{10}/(V_{10}-V_{00})$$

Since the second lens unit has a positive refractive power, it is desirable that ϕ_m has a positive value. When a radial type gradient index lens element is to be used in the second lens unit for correcting lateral chromatic aberration favorably in the objective lens system as a whole, it is desirable that the refractive power ϕ_m of a medium satisfies the above-mentioned condition (3).

When a ratio of a refractive power of medium relative to a refractive power of the objective lens system as a whole satisfies the condition (3), it is possible to correct lateral chromatic aberration favorably in the objective lens system as a whole.

If the lower limit of 0.05 of the condition (3) is not satisfied, a medium of the radial type gradient index lens element will have a weak refractive power, thereby undesirably making it difficult to correct lateral chromatic aberration favorably in the objective lens system as a whole. If the upper limit of 1.0 of the condition (3) is not satisfied, in contrast, a refractive power of medium will be too strong, thereby undesirably overcorrecting lateral chromatic aberration.

The condition (3) is required also for favorably correcting not only chromatic aberration but also the other aberrations.

The objective optical system according to the present invention which has a wide field angle produces a positive Petzval's sum in the lens system as a whole, thereby tending to tilt an image surface toward the object side. For favorably correcting this Petzval's sum, it is desirable to use a radial type gradient index lens element in the second lens unit which has a large positive Petzval's sum.

A Petzval's sum PTZ of a radial type gradient index lens element is expressed by the following formula (f):

$$PTZ=\phi_s/N_{00}+\phi_m/N_{00}^2 \quad (f)$$

As is apparent from the formula (f) in which the denominator of the second term on the right side is squared, it is possible to configure a radial type gradient index lens element so as to have a Petzval's sum which is smaller than that of a homogenous lens element having the same refractive power as that of the radial type gradient index lens element.

For reducing a Petzval's sum of the objective lens system with a radial type gradient index lens element, it is desirable from the formula (f) that the radial type gradient index lens element satisfies the following formula:

$$\phi_s/N_{00}+\phi_m/N_{00}^2 \approx 0$$

The formula shown below can be derived by using a total refractive power of surface and medium. $\phi_G(=\phi_2+\phi_m)$ in the above formula and developing it.

$$\phi_m \approx \phi_G \times N_{00}/(N_{00}-1)$$

Since refractive indices N_{00} on an optical axis of radial gradient index lens elements ordinarily have values larger than 1, or on the order of 1.45 to 1.85, it is desirable for favorably correcting a Petzval's sum to use a radial type gradient index lens element which has a positive refractive power of medium when it is to be used in the second lens unit having the positive refractive power. If a radial type gradient index lens element which has a negative refractive power of medium is used in the second lens unit, the positive Petzval's sum will be further enlarged, hereby undesirably tilting an image surface toward the object side.

For correcting the Petzval's sum in the objective lens system according to the present invention, it is desirable from the formula (f) that a refractive power of medium is strong to a certain degree or refractive power of medium ϕ_m satisfies the condition (3). When a ratio of the refractive power of medium relative to a refractive power of the objective lens system as a whole satisfies the condition (3), it is possible to favorably correct the Petzval's sum in the objective lens system as a whole. If the lower limit of 0.05 of the condition (3) is not satisfied, a refractive power of medium will be weak, thereby making it difficult to correct the Petzval's sum favorably in the objective lens system as a whole. If the upper limit of 1.0 of the condition (3) is exceeded, in contrast, a refractive power of medium will be too strong and the Petzval's sum will be overcorrected, thereby undesirably tilting an image surface in a direction away from the object side.

As understood from the foregoing description, the condition (3) is required for favorably correcting lateral chromatic aberration and Petzval's sum at the same time in the objective lens system according to the present invention (which has the second composition).

Further, an objective lens system for endoscopes is generally used in combination with a solid-state image pickup device such as CCD or an end surface of the so-called image guide composed of an optical fiber bundle which is disposed on an image surface. When an objective lens system is to be combined not with a silver salt photographic film but with a solid-state image pickup device or an image guide, it is desirable for enhancing a light condensing efficiency to configure the objective lens system so as to be telecentric on the image side so that incident rays are as perpendicular as possible to an image surface. For configuring the objective lens system according to the present invention so as to meet this requirement, the second lens unit having the positive refractive power must have an image side surface which has a positive refractive power stronger than that of an object side surface thereof. When the image side surface of the second lens unit on which offaxial rays are relatively high has a strengthened refractive power in the objective lens system according to the present invention having a wide field angle, however, this surface will produce coma in a large amount and it will be difficult to correct this coma favorably with a homogenous lens element.

Accordingly, it was conceived to correct coma favoraly in the objective lens system according to the present invention with a radial type gradient index lens element used in the second lens unit. For correcting this aberration, it is desirable that the radial type gradient index lens element has such a refractive index distribution as to progressively lower refractive indices from the optical axis toward a marginal portion. An amount of coma to be produced by the image side surface of the second lens unit can be reduced by configuring the radial type gradient index lens element to be used in the second lens unit so as to have such a refractive index distribution. Therefore, the condition (3) serves for favorable correction of coma in addition to favorable correction of lateral chromatic aberration. When the condition (3) is satisfied, the radial type gradient index lens element has a refractive index distribution wherein refractive indices are progressively lowered from the optical axis toward the marginal portion, thereby being capable of favorably correcting coma. If the lower limit of 0.05 of the condition (3) is not satisfied, it will be difficult to favorably correct coma

with the radial type gradient index lens element. If the upper limit of 1.0 of the condition (3) is exceeded, in contrast, coma will undesirably be overcorrected.

Since the objective lens system according to the present invention has a wide field angle and the asymmetrical composition which is negative-positive in order from the object side, it tends to produce remarkable barrel form distortion which can hardly be corrected favorably with two homogenous lens elements. For correcting the barrel form distortion favorably in the objective lens system according to the present invention, it is desirable to use, in the second lens unit having the positive refractive power, a radial type gradient index lens element which has a refractive index distribution wherein refractive indices are progressively lowered from the optical axis toward the marginal portion. Distortion to be produced by the second lens unit can be reduced by using a radial type gradient index lens element having such a refractive index distribution. Accordingly, the condition (3) serves for favorable correction of distortion in addition to favorable correction of lateral chromatic aberration. When the contition (3) is satisfied, refractive indices are progressively lowered from the optical axis toward the marginal portion, thereby enabling to favorably correct distortion. If the lower limit of 0.05 of the condition (3) is not satisfied, it will be difficult to favorably correct distortion with a radial type gradient index lens element. If the upper limit of 1.0 of the condition (3) is exceeded, in contrast, aberrations other than distortion will undesirably be overcorrected.

The objective lens system according to the present invention which has a third composition is characterized in: that it is composed, in order from the object side, of a first lens unit having a negative refractive power and a second lens unit having a positive refractive power; that it uses at least one radial type gradient index lens element having a refractive index distribution in a radial direction from an optical axis which is expressed by the formula (a); and that at least one of the surfaces of lens elements including the radial type gradient index lens element composing the lens system is configured as an aspherical surface which has such a shape as to weaken a refractive power of the lens element having the aspherical surface from the optical axis toward the marginal portion.

Since the objective lens system according to the present invention has a wide field angle and an asymmetrical composition which is negative-positive in order from the object side, it tends to produce remarkable distortion in addition to lateral chromatic aberration. Though distortion can be corrected to a certain degree by using a radial type gradient index lens element in the second lens unit as described above, it is desirable for correcting distortion more favorably to configure the objective optical system according to the present invention so as to comprise at least one surface of at least one lens element which is configured as an aspherical surface having such a shape as to weaken a refractive power of the lens element having the aspherical surface from the optical axis toward the marginal portion. In the objective lens system according to the present invention, barrel form distortion is produced by both the first lens unit having the negative refractive power and the second lens unit having the positive refractive power. When an aspherical surface is to be used in either of the lens units in the objective lens system, it is therefore desirable to configure the aspherical surface so as to have such a shape as to weaken a refractive power from the optical axis toward the marginal portion of the lens element using the aspherical surface. When the second lens unit uses a radial type gradient index lens element, for example, it is desirable to use an aspherical surface in the first lens unit having the negative refractive power and configure the aspherical surface so as to have such a shape as to weaken the negative refractive power from the optical axis toward the marginal portion. Though distortion produced by the second lens unit can be corrected to a certain degree by using a radial type gradient index lens element in the second lens unit as described above, distortion can be corrected more favorably by using an aspherical surface in the first lens unit.

When a radial type gradient index lens element is used in the first lens unit, it is desirable to use, in the second lens unit having a positive refractive power, an aspherical surface which has such a shape as to weaken the positive refractive power toward the optical axis to a marginal portion.

If an aspherical surface has such a shape as to strengthen the refractive power of a lens unit which comprises this aspherical surface, it will undesirably make barrel form distortion more remarkable in the objective lens system as a whole.

It is needless to say that an effect similar to that described above can be obtained by configuring a surface of a radial type gradient index lens element as an aspherical surface.

For correcting lateral chromatic aberration in the objective lens system according to the present invention which has the third composition, it is desirable to configure the radial type gradient index lens element so as to satisfy the condition (1). If the condition (1) is not satisfied, lateral chromatic aberration will undesirably be more remarkable in the objective lens system according to the present invention.

It is needless to say that lateral chromatic aberration can be corrected more favorably by using two radial type gradient index lens elements when the objective lens system according to the present invention is to be composed of two negative and positive lens elements.

It is also needless to say that distortion can be corrected more favorably by using an aspherical surface on each of the lens elements when the objective lens system is to be composed of two negative and positive lens elements.

The objective lens system according to the present invention which has a fourth composition is characterized in that it is composed, in order from the object side, of a first lens unit having a negative refractive power and a second lens unit having a positive refractive power. The second lens unit comprises at least one radial type gradient index lens element which has a refractive index distribution in a radial direction expressed by the formula (a), or wherein refractive indices are progressively lowered from an optical axis toward a marginal portion. The radial type gradient index lens element has a shape of a positive lens element. The radial type gradient index lens element satisfies the condition (1).

When a radial type gradient index lens element is to be used in the second lens unit, it is desirable for correcting lateral chromatic aberration to configure it so as to satisfy the condition (1) as described above, and it is desirable for correcting a Petzval's sum, coma or distortion that this lens element has a refractive index distribution wherein refractive indices are lowered from the optical axis toward the marginal portion. When not only correction of aberrations but also manufacturing facility are taken into consideration, it is desirable that the radial type gradient index lens element has a shape of a positive lens element.

Since the objective lens system according to the present invention has a wide field angle, it is necessary that the second lens unit has a strong positive refractive power. When a radial type gradient index lens element is to be used

in the second lens unit, it is therefore desirable that the radial type gradient index lens element also has a strongly positive refractive power. However, it is undesirable that the radial type gradient index lens element has an extremely strong positive refractive power of medium for a reason described below. As apparent from the formula (e), it is sufficient for strengthening a refractive power of medium of a radial type gradient index lens element to enlarge an absolute value of the refractive index distribution coefficient of the second order N_{10} or thickness d_G of the radial type gradient index lens element. However, an absolute value of the refractive index distribution coefficient of the second order can be enlarged only within a range limited by preparation of materials and enlargement of thickness d_G makes it difficult to configure the objective lens system compactly, thereby making it unusable as an objective lens system for endoscopes, for example, which are desired to be compact. Accordingly, it is desirable not to impart an extremely strong positive refractive power to a medium but to impart refractive powers to both the medium and surfaces, or configure the radial type gradient index lens element so as to have a shape of a positive lens element.

The objective lens system according to the present invention, which has a fifth composition, is characterized in that it is composed, in order from the object side, of a first lens unit having a negative refractive power and a second lens unit having a positive refractive power; that it uses at least one lens element which is configured as a radial type gradient index lens element having a refractive index distribution in the radial direction from an optical axis expressed by the formula (a); and that a lens unit comprising the radial type gradient index lens element or at least one optical element disposed in the objective lens system has a function to shield components having specific wavelengths.

By using a radial type gradient index lens element, it is possible to obtain an objective lens system which favorably corrects chromatic aberration in particular and has high imaging performance. An objective lens system for endoscopes which comprises a solid-state image pickup device such as a CCD, for example, may use an infrared cut filter for cutting off rays in the infrared region since the image pickup device has high sensitivity at wavelengths in the infrared region. Further, such an optical system may use a low pass filter made, for example, of quartz for eliminating noise components produced due to moiré. Furthermore, such an objective lens system may use a band cut filter for cutting off components having specific wavelengths since endoscopes may be used not only for observing interiors of human bodies but also for cutting off diseased portions of patients with laser knives. It is therefore desirable that the objective lens system according to the present invention uses not only a radial type gradient index lens element but also filters of the kinds mentioned above so that it can exhibit high imaging performance when it is used in optical systems for endoscopes which use, for example, solid-state image pickup devices such as CCD's.

It is desirable that these filters are disposed at locations between a lens element disposed on the image side and an image surface at which offaxial rays, in particular, are nearly in parallel with the optical axis. By disposing the filters as described above, it is possible to prepare approximately equal optical path lengths for axial and offaxial rays, thereby allowing the filters to exhibit their effects uniformly over the entire image pickup surface.

Endoscopes which are to be inserted into human bodies must be compact and require compacter optical systems. When importance is laid on compactness rather than optical performance, it is effective to dispose filters between the first lens unit and the second lens unit. Further, for obtaining an objective lens system which is compact and can be manufactured at a low cost, it is effective to impart filter functions to at least one of the lens elements including a radial type gradient index lens element.

The objective lens system according to the present invention which has a sixth embodiment is characterized in that it is composed, in order from the object side, of a first lens unit having a negative refractive power and a second lens unit having a positive refractive power; that it uses at least one radial type gradient index lens element which has a refractive index distribution in a radial direction expressed by the formula (a); and that it uses a reflecting surface for at least a single reflection disposed on the image side of the second lens unit.

Resolution of an optical system for endoscopes which uses a solid-state image pickup device such as CCD, for example, can be enhanced by reducing the size of picture elements and arranging these picture elements in a larger number at a higher density on the image pickup device. However, the size of a picture element can be reduced only within a certain manufacturing limit and it is therefore conceivable to enhance resolution by enlarging an image pickup surface. However, it is desirable that endoscopes which may be inserted into human bodies have smaller diameters, or it is undesirable to enlarge image pickup surfaces, thereby enlarging diameters of endoscopes.

For allowing solid-state image pickup devices having larger image pickup surfaces to be used without enlarging diameters of endoscopes, the objective lens system according to the present invention uses a reflecting surface for at least one reflection on the image side of the second lens unit which makes it possible to dispose a solid-state image pickup device, not in parallel with a radial direction of the endoscope, but in a position inclined with regard thereto. FIG. **3** shows a conceptional diagram of the objective lens system according to the present invention which has the sixth composition. In FIG. **3**, the reference symbol L_1 represents the first negative lens unit, the reference symbol L_2 designates the second positive lens unit, the reference symbol RA denotes an axial ray, the reference symbol RO represents an offaxial ray, the reference symbol R designates the reflecting surface and the reference numeral **10** denotes the image pickup device disposed on an image pickup plane. The reflecting surface R disposed on the image side of the second lens unit makes it possible to arrange the solid-state image pickup device which has a large image pickup surface nearly parallel to the optical axis. Though a system for a single reflection is illustrated in FIG. **3**, it is possible, needless to say, to obtain a similar effect by using a larger number of reflecting surfaces for a plurality of reflections.

When a solid-state image pickup device having a large image pickup surface is used, an image height can be enhanced in a lens system for obtaining a lens system having a wide field angle. However, it is desired for an objective lens system to correct aberrations more favorably over a range from a center to a marginal portion of an image plane. For an objective lens system having a wide field angle in particular, it is desired to favorably correct lateral chromatic aberration.

An objective lens system which has high imaging performance for axial and offaxial rays can therefore be obtained by using a radial gradient index lens element which has high capability to correct chromatic aberration in particular. It is possible to obtain an objective lens system having higher performance by combining an objective lens system which

uses a radial type gradient index lens element with a reflection system shown in FIG. **3** which permits enlarging an image pickup surface.

When a radial type gradient index lens element is used in the second lens unit in each of the compositions (first through sixth compositions) of the objective lens system according to the present invention, it is desirable for more favorable correction of lateral chromatic aberration, coma and distortion to satisfy the following condition (4):

$$-0.5<N_{10p}\cdot f^2<-0.01 \quad (4)$$

wherein the reference symbol N_{10p} represents a refractive index distribution coefficient of the second order when a radial type gradient index lens element is used in the second lens unit and the reference symbol f designates a focal length of the objective lens system as a whole.

When the condition (4) is satisfied, a refractive power of medium of the radial type gradient index lens element has a sufficiently large value, thereby making it possible to correct lateral chromatic aberration favorably. Further, refractive indices are progressively lowered from the optical axis toward a marginal portion and a difference in refractive index (Δn) is large between the optical axis and the marginal portion, thereby making it possible to favorably correct coma produced by an image side surface of the second lens unit and barrel form distortion which poses a problem in the objective lens system as a whole.

If the upper limit of −0.01 of the condition (4) is exceeded, the radial type gradient index lens element will have a weak refractive power of medium, thereby making it difficult to correct lateral chromatic aberration favorably in the objective lens system as a whole, and the difference in refractive indices will be small between the optical axis and the marginal portion, thereby making it difficult to correct coma and distortion. If the lower limit of −0.5 of the condition (4) is not satisfied, in contrast, the radial type gradient index lens element will have a large refractive index difference Δn, thereby undesirably making it difficult to prepare a material for the radial type gradient index lens element.

When a radial type gradient index lens element is used in the first lens unit in the objective lens system according to the present invention which has one of the compositions described above, it is desirable for correcting lateral chromatic aberration more favorably to satisfy the following condition (5):

$$0.01<N_{10n}\cdot f^2<0.6$$

wherein the reference symbol N_{10n} represents the refractive index distribution coefficient of the second order of a gradient index lens element when the radial type gradient index lens element is used in the first lens unit and the reference symbol f designates a focal length of the objective lens system as a whole.

When the condition (5) is satisfied, a refractive power of medium of the radial type gradient index lens element has a sufficiently large value, thereby making it possible to correct lateral chromatic aberration favorably.

If the lower limit of 0.01 of the condition (5) is not satisfied, the radial type gradient index lens element will have a weak refractive power of medium, thereby making it difficult to correct lateral chromatic aberration favorably in the objective lens system as a whole. If the upper limit of 0.6 of the condition (5) is exceeded, the radial type gradient index lens element will have a large refractive index difference Δn, thereby making it difficult to prepare a material for the radial type gradient index lens element.

When the radial type gradient index lens element is used in the first lens unit or the second lens unit of the objective lens system according to the present invention, it is desirable for correcting lateral chromatic aberration more favorably in the lens system to satisfy the following condition (6):

$$1/V_{10}<0.01 \quad (6)$$

The objective lens system which satisfies the condition (6) can favorably correct lateral chromatic aberration. Since radial type gradient index lens elements have Abbe's numbers on the order of 30 to 80 as described above, it is desirable from the formula (d), for allowing a radial type gradient index lens element to exhibit a sufficient function for correcting chromatic aberration to satisfy the condition (6). If the condition (6) is not satisfied, it will undesirably be impossible to sufficiently correct lateral chromatic aberration.

When a radial type gradient index lens element is used in the first lens unit of the objective lens system according to the present invention which has any one of the first through sixth compositions, it is desirable for correcting lateral chromatic aberration more favorably to satisfy the following condition (7):

$$0.05<d_{Gn}/f_{Gn}<1.2 \quad (7)$$

wherein the reference symbol d_{Gn} represents thickness of the radial type gradient index lens element used in the first lens unit and the reference symbol f_{Gn} designates a focal length of the radial type gradient index lens element used in the first lens unit.

A radial type gradient index lens element can exhibit its effect to correct chromatic aberration when it has refractive power of medium ϕ_m having a value which is large to a certain degree as described above. When a radial type gradient index lens element has extremely small thickness, for example, the refractive power of medium ϕ_m is weak as judged from the formula (e), thereby making it difficult to favorably correct chromatic aberration. It is therefore desirable that the objective lens system according to the present invention satisfies the condition (7) when a radial type gradient index lens element is used in the first lens unit.

If the lower limit of 0.05 of the condition (7) is not satisfied, the refractive power of medium will be weak, thereby undesirably making it difficult to favorably correct lateral chromatic aberration. If the upper limit of 1.2 of the condition (7) is exceeded, in contrast, the radial type gradient index lens element will have a large thickness, thereby undesirably prolonging a total length of the objective lens system.

When a radial type gradient index lens element is used in the second lens unit of the objective lens system according to the present invention which has any one of the composition described above, it is desirable for correcting lateral chromatic aberration more favorably to satisfy the following condition (8):

$$0.3<d_{Gp}/f_{Gp}<4.0 \quad (8)$$

wherein the reference symbol d_{Gp} represents the thickness of the radial type gradient index lens element used in the second lens unit and the reference symbol f_{Gp} designates a focal length of the radial type gradient index lens element used in the second lens unit.

When a radial type gradient index lens element has extremely small thickness as described above, for example, the refractive power of medium ϕ_m is weak, thereby making it difficult to correct chromatic aberration favorably. When a

radial type gradient index lens element is to be used in the second lens unit of the objective lens system according to the present invention, the lens system is therefore configured so as to satisfy the condition (8).

If the lower limit of 0.3 of the condition (8) is exceeded, a refractive power of medium will be weak, thereby undesirably making it difficult to favorably correct lateral chromatic aberration. If the upper limit of 4.0 of the condition (8) is exceeded, a radial type gradient index lens element will have large thickness, thereby undesirably enlarging the objective lens system.

When the first lens unit is to be composed of a single negative lens element in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable for favorably correcting aberrations to satisfy the following condition (9):

$$0.1<1H/r_2<1.7 \tag{9}$$

wherein the reference symbol 1H represents an image height and the reference symbol r_2 designates a radius of curvature on an image side surface of the first lens unit having the negative refractive power.

If the lower limit of 0.1 of the condition (9) is not satisfied, the image side surface of the first lens unit will have a weak refractive power and it will be necessary to strengthen a negative refractive power of an object side surface of the first lens unit on which offaxial rays are relatively high, whereby the object side surface will undesirably produce distortion, astigmatism, etc. in larger amounts. If the upper limit of 1.7 of the condition (9) is exceeded, in contrast, the image side surface of the first lens unit will have a strong negative refractive power, thereby undesirably overcorrecting spherical aberration in the objective lens system as a whole.

When the second lens unit is to be composed of a single positive lens element in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable for favorably correcting aberrations to satisfy the following condition (10):

$$-1.5<IH/r_3<0.8 \tag{10}$$

wherein the reference symbol IH represents an image height and the reference symbol r_3 designates a radius of curvature on an object side surface of the second lens unit having the positive refractive power.

If the lower limit of −1.5 of the condition (10) is not satisfied, the object side surface of the second lens unit will have a strong negative refractive power, thereby undesirably overcorrecting spherical aberration in the objective lens system as a whole. If the upper limit of 0.8 of the condition (10) is exceeded, in contrast, the object side surface will undesirably produce spherical aberration, etc. in larger amounts.

When the second lens unit is to be composed of a single positive lens element in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable for favorably correcting aberrations to satisfy the following condition (11):

$$-1.0<IH/r_4<-0.1 \tag{11}$$

wherein the reference symbol IH represents an image height and the reference symbol r_4 designates a radius of curvature on an image side surface of the second lens unit having the positive refractive power.

If the lower limit of −1.0 of the condition (11) is not satisfied, the image side surface of the second lens unit will have a strong positive refractive power, thereby undesirably aggravating astigmatism and distortion in the objective lens system as a whole. If the upper limit of −0.1 of the condition (11) is exceeded, in contrast, it will be necessary to strengthen a positive refractive power of the object side surface of the second lens unit, whereby the object side surface will undesirably produce astigmatism and distortion in large amounts.

When a radial type gradient index element is to be used in the first lens unit in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable for correcting lateral chromatic aberration more favorably to satisfy the following condition (12):

$$0.05<N_{10n}\cdot f_{Gn}{}^2<1.2 \tag{12}$$

wherein the reference symbol f_{Gn} represents a focal length of the radial type gradient index lens element to be used in the first lens unit.

When the condition (12) is satisfied, the refractive power of medium of the radial type gradient index lens element will have a value which is sufficiently large relative to its total refractive power and can favorably correct lateral chromatic aberration. If the lower limit of 0.05 of the condition (12) is not satisfied, the refractive power of medium will be weak, thereby undesirably making it difficult to correct lateral chromatic aberration favorably with the radial type gradient index lens element. If the upper limit of 1.2 of the condition (12) is exceeded, refractive index difference Δn will be large, thereby undesirably making it difficult to prepare a material for the radial type gradient index lens element.

When a radial type gradient index lens element is to be used in the second lens element in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable for correcting lateral chromatic aberration, a Petzval's sum, coma or distortion more favorably to satisfy the following condition (13):

$$-0.8<N_{10p}\cdot f_{Gp}{}^2<-0.05 \tag{13}$$

wherein the reference symbol f_{Gp} represents a focal length of the radial type gradient index lens element to be used in the second lens unit.

When the condition (13) is satisfied, the refractive power of medium of the radial type gradient index lens will have a value which is sufficiently large relative to its total refractive power and can favorably correct lateral chromatic aberration. If the upper limit of −0.05 of the condition (13) is exceeded, the refractive power of medium will be weak, thereby undesirably making it difficult to correct lateral chromatic aberration favorably with the radial type gradient index lens element. If the lower limit of −0.8 of the condition (13) is not satisfied, in contrast, refractive index difference Δn will be large, thereby undesirably making it difficult to prepare a material for the radial type gradient index lens element.

When a radial type gradient index lens element is to be used in the second lens unit in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable, for facilitating preparation of a material in addition to correction of lateral chromatic aberration, to satisfy the following condition (14):

$$0.1<\phi_{2m}/\phi<0.8 \tag{14} (14)$$

When the condition (14) is satisfied, the radial type gradient index lens element will have a strong refractive

power of medium and can correct lateral chromatic aberration favorably. If the lower limit of 0.1 of the condition (14) is not satisfied, the radial type gradient index lens element will have a weak refractive power of medium and can hardly correct lateral chromatic aberration favorably in the objective lens system as a whole, and a difference in refractive indices will be small between a portion of the radial type gradient index lens element located on the optical axis and a marginal portion thereof, thereby making it difficult to correct coma and distortion. If the upper limit of 0.8 of the condition (14) is exceeded, in contrast, the radial type gradient index lens element will have a large refractive index difference Δn or large thickness, thereby undesirably making it difficult to prepare a material for the radial type gradient index lens element in the former case or undesirably enhancing a manufacturing cost and prolonging a total length of the objective lens system in the latter case.

When a radial type index lens element is to be used in the first lens unit in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable, for facilitating manufacturing of the radial type gradient index lens element in addition to correction of lateral chromatic aberration, to satisfy the following condition (15):

$$-0.25<\phi_{1m}/\phi<-0.05 \tag{15}$$

When the condition (15) is satisfied, the radial type gradient index lens element will have a strong refractive power of medium and can favorably correct lateral chromatic aberration. If the upper limit of −0.05 of the condition (15) is exceeded, the radial type gradient index lens element will undesirably have a weak refractive power of medium and can hardly correct lateral chromatic aberration favorably. If the lower limit of −0.25 of the condition (15) is not reached, the radial type gradient index lens element will undesirably have a large refractive index difference Δn, whereby it can hardly be manufactured or it will be thicker and more expensive to manufacture.

When a radial type gradient index lens element is to be used in the first lens unit in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable, for facilitating manufacturing of the radial type gradient index lens element in addition to correction of lateral chromatic aberration, to satisfy the following condition (16):

$$0.02<N_{10n}\cdot f^2<0.4 \tag{16}$$

When the condition (16) is satisfied, a marginal portion of the radial type gradient index lens element used in the first lens unit may have a refractive index higher than that of a portion thereof on the optical axis, whereby the radial type gradient index lens element has a sufficiently strong refractive power of medium and can correct lateral chromatic aberration favorably.

If the lower limit of 0.02 of the condition (16) is not satisfied, the radial type gradient index lens element will have a weak refractive power of medium, thereby making it difficult to correct lateral chromatic aberration favorably in the objective lens system as a whole. If the upper limit of 0.4 of the condition (16) is exceeded, the radial type gradient index lens element will have a large refractive index difference Δn, thereby undesirable making it difficult to prepare a material therefor.

When a radial type gradient index lens element is to be used in the second lens unit of the objective lens system according to the present invention which has any one of the compositions described above, it is desirable, for facilitating manufacturing of the radial type gradient index lens element in addition to correction of lateral chromatic aberration, to satisfy the following condition (17):

$$-0.25<N_{10p}\cdot f^2<-0.04 \tag{17}$$

When the condition (17) is satisfied, the radial type gradient index lens element has a sufficiently strong refractive power of medium and can favorably correct lateral chromatic aberration.

If the upper limit of −0.04 of the condition (17) is exceeded, the radial type gradient index lens element will have a weak refractive power of medium, thereby making it difficult to correct lateral chromatic aberration favorably in the objective lens system as a whole. If the lower limit of −0.25 of the condition (17) is not satisfied, in contrast, the radial type gradient index lens element will have a large refractive index difference Δn, thereby making it difficult to prepare a material therefor.

For correcting lateral chromatic aberration more favorably in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable to configure a radial type gradient index lens element so as to satisfy the following condition (18):

$$1/V_{10}<0 \tag{18}$$

When the condition (18) is satisfied, the radial type gradient index lens element produces chromatic aberration in a direction opposite to that of chromatic aberration produced by a homogenous lens element having a refractive power which is the same as that of the radial type gradient index lens element. That is to say, when a radial type gradient index lens element which is used in the first lens unit or the second lens unit of the objective lens system according to the present invention satisfies the condition (18), lateral chromatic aberration is overcorrected independently by the radial type gradient index lens element, but this overcorrected chromatic aberration cancels lateral chromatic aberration produced by the other lens element, thereby correcting chromatic aberration favorably in the objective lens system as a whole.

When a radial type gradient index lens element is to be used in the first lens unit of the objective lens system according to the present invention which has any one of the compositions described above, it is desirable, for facilitating manufacturing of the radial type gradient index lens element in addition to correction of lateral chromatic aberration, to satisfy the following condition (19):

$$0.1<d_{Gn}/f_{Gn}<0.9 \tag{19}$$

If the lower limit of 0.1 of the condition (19) is exceeded, the radial type gradient index lens element will undesirably have a weak refractive power of medium, thereby undesirably making it difficult to correct lateral chromatic aberration favorably. If the upper limit of 0.9 of the condition (19) is exceeded, in contrast, the radial type gradient index lens element will be thick, thereby undesirably increasing the manufacturing cost of the objective lens system.

When a radial type gradient index lens element is to be used in the first lens unit of the objective lens system according to the present invention which has any one of the composition described above, it is desirable, for facilitating manufacturing of the radial type gradient index lens element in addition to correction of lateral chromatic aberration, to satisfy the following condition (20):

$$0.7<d_{Gp}/f_{Gp}<2.8 \tag{20}$$

When a radial type gradient index lens element has extremely small thickness, for example, it has a weak refractive power of medium ϕ_m and can hardly correct chromatic aberration favorably. When a radial type gradient index lens element is to be used in the second lens unit of the objective lens system according to the present invention, it is therefore desirable to configure the radial type gradient index lens element so as to satisfy the condition (20).

If the lower limit of 0.7 of the condition (20) is exceeded, the radial type gradient index lens element will undesirably have a weak refractive power of medium, thereby undesirably making it difficult to correct lateral chromatic aberration favorably. If the upper limit of 2.8 of the condition (20) is exceeded, in contrast, the radial type gradient index lens element will have large thickness, thereby undesirably increasing the manufacturing cost of the objective lens system.

When the first lens unit is to be composed of a single negative lens element in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable for more favorable correction of aberrations to configure it so as to satisfy the following condition (21):

$$0.25<IH/r_2<1.4 \tag{21}$$

If the lower limit of 0.25 of the condition (21) is not satisfied, an image side surface of the first lens unit will have a weak negative refractive power and it will be necessary to strengthen a negative refractive power of an object side surface of the first lens unit on which offaxial rays are relatively high, whereby the object side surface will undesirably produce distortion, astigmatism, etc. in large amounts. If the upper limit of 1.4 of the condition (21) is exceeded, in contrast, the image side surface of the first lens unit will have a strong negative refractive power, thereby undesirably overcorrecting spherical aberration in the objective lens system as a whole.

When the second lens unit is to be composed of a single positive lens element in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable for favorably correcting aberrations to satisfy the following condition (22):

$$-0.9<IH/r_3<0.6 \tag{22}$$

If the lower limit of −0.9 of the condition (22) is not reached, an object side surface of the second lens unit will have a strong negative refractive power, thereby undesirably overcorrecting spherical aberration in the objective lens system as a whole. If the upper limit of 0.6 of the condition (22) is exceeded, in contrast, the object side surface will undesirably produce astigmatism, distortion, etc. in large amounts.

When the second lens unit is to be composed of a single positive lens element in the objective lens system according to the present invention which has any one of the compositions described above, it is desirable for favorable correction of aberrations to satisfy the following condition (23):

$$-0.8<IH/r_4<-0.2 \tag{23}$$

If the lower limit of −0.8 of the condition (23) is not reached, the image side surface of the second lens unit will have a strong negative refractive power, thereby undesirably aggravating astigmatism and distortion in the objective lens system as a whole. If the upper limit of −0.2 of the condition (23) is exceeded, in contrast, it will be necessary to strengthen the positive refractive power of the object side surface of the second lens unit, whereby the object side surface will undesirably produce spherical aberrations, etc. in large amounts.

When a radial type gradient index lens element is to be used as the first lens unit of the objective lens system according to the present invention which has any one of the compositions described above, it is desirable, for facilitating manufacturing of the radial type gradient index lens element in addition to correction of lateral chromatic aberration, to satisfy the following condition (24):

$$0.1N_{10n}{f_{Gn}}^2<0.85 \tag{24}$$

When the condition (24) is satisfied, a refractive power of medium of the radial type gradient index lens element has a value sufficiently large relative to a total refractive power thereof, thereby making it possible to correct lateral chromatic aberration favorably. If the lower limit of 0.1 of the condition (24) is not satisfied, the radial type gradient index lens element will undesirably have a weak refractive power of medium and can hardly correct lateral chromatic aberration favorably. If the upper limit of 0.85 of the condition (24) is exceeded, in contrast, a refractive index difference Δn will undesirably be large, thereby making it difficult to prepare a material for the radial type gradient index lens element.

When a radial type gradient index lens element is to be used as the second lens element of the objective lens system according to the present invention which has any one of the compositions described above, it is desirable, for facilitating manufacturing of the radial type gradient index lens element in addition to correction of lateral chromatic aberration, to satisfy the following condition (25):

$$-0.3<N_{10p}{f_{Gp}}^2<-0.1 \tag{25}$$

When the condition (25) is satisfied, a refractive power of medium of the radial type gradient index lens element has a value sufficiently large relative to a total refractive power thereof, whereby the radial type gradient index lens element can correct lateral chromatic aberration favorably. If the upper limit of −0.1 of the condition (25) is exceeded, the refractive power of medium will undesirably be weakened, thereby undesirably making it difficult to correct lateral chromatic aberration with the radial type gradient index lens element. If the lower limit of −0.3 of the condition (25) is not reached, in contrast, the refractive index difference Δn will undesirably be large, thereby making it difficult to prepare a material for the radial type gradient index lens element.

Though it is desirable to satisfy the condition (18) for correcting lateral chromatic aberration more favorably in the objective lens system according to the present invention which has any one of the compositions described above, lateral chromatic aberration is overcorrected when $1/V_{10}$ has a negative value which is too large. Therefore, it is further desirable to satisfy the following condition (26):

$$-0.5<1/V_{10}<0 \tag{26}$$

When the condition (26) is satisfied, it is possible to correct lateral chromatic aberration favorably. If the upper limit of 0 of the condition (26) is exceeded, lateral chromatic aberration will undesirably be undercorrected. If the lower limit of −0.5 of the condition (26) is not satisfied, lateral chromatic aberration will undesirably be overcorrected.

From a viewpoint of reducing a manufacturing cost of the objective lens system according to the present invention, it is desirable that a radial type gradient index lens element has a planar surface on one side or planar surfaces on both sides.

The objective lens system according to the present invention which has a seventh composition uses a diffraction type

optical element as an optical element which is disposed in the lens system.

The objective lens system according to the present invention which has the seventh composition is composed, for example, of a first lens unit having a negative refractive power, a stop and a second lens unit having a positive refractive power: the first lens unit being composed of a diffractive optical element and the second lens unit being composed of a refractive optical element (lens).

Further, an objective lens system which can accomplish the object of the present invention can be obtained by composing a lens system of a positive lens unit and a positive lens unit: the positive lens unit disposed on the object side being composed of a radial type gradient index lens element and the lens unit disposed on the image side being composed of a diffractive optical element.

The objective lens system which has each of the compositions described above is composed of a small number of optical elements, has a compact size and exhibits favorable optical performance. It is therefore suited for use as an objective lens system for endoscopes, non-flexible endoscopes and video cameras.

Accordingly, endoscopes, non-flexible endoscopes, video cameras, portable TV telephones, portable data input units, etc. which use the objective lens system according to the present invention having the compositions described above are included within the scope of the present invention.

Now, embodiments of the objective lens system according to the present invention will be described below:

Embodiment 1

focal length = 1.07 mm, object distance = 11.8 mm,
image height = 0.97 mm, NA = 0.0115, 2ω = 113.1°

$r_1 = \infty$

$d_1 = 0.3000$ $n_1 = 1.48749$ $\nu_1 = 70.21$

$r_2 = 1.2764$

$d_2 = 1.2646$

$r_3 = \infty$ (stop)

$d_3 = 0.5196$

$r_4 = -11.2580$

$d_4 = 1.8811$ n_2 (radial type gradient index lens)

$r_5 = -1.6678$

wherein the reference symbols r_1, r_2, . . . represent radii of curvature on surfaces of respective lens elements, the reference symbols d_1, d_2, . . . designate thicknesses of the respective lens elements and air-spaces reserved therebetween, the reference symbols n_1, n_2, . . . denote refractive indices of the respective lens elements, and the reference symbols ν_1, ν_2, . . . represent Abbe's numbers of the respective lens elements.

The first embodiment of the objective lens system according to the present invention has a composition illustrated in FIG. **4**. Speaking concretely, it is composed of two lens units, i.e., in order from the object side, a first lens unit consisting of a negative lens element, a stop and a second lens unit consisting of a positive lens element. The second lens unit having the positive refractive power is configured as a radial type gradient index lens element. The first lens unit is composed of a homogenous lens element which has a planar surface on the object side and a concave surface on the image side, whereas the second lens unit is composed of a radial type gradient index lens element having a meniscus shape which has a concave surface on the object side.

Though it is ordinarily difficult to favorably correct lateral chromatic aberration in particular with two lens elements, the lens system preferred as the first embodiment is capable of favorably correcting lateral chromatic aberration by using the radial type gradient index lens element as the second lens unit.

Further, distortion and coma produced by the second lens unit are favorably corrected by the radial type gradient index lens element used as the second lens unit which has a refractive index distribution wherein refractive indices are progressively lowered from an optical axis toward a marginal portion.

In the first embodiment, lateral chromatic aberration in particular is corrected favorably by configuring the radial type gradient index lens element used as the second lens unit so as to satisfy the condition (18).

Furthermore, the object side planar surface of the first lens unit is effective for lowering a cost required for polishing the lens element.

Though the first embodiment is composed only of the two lens elements, it favorably corrects aberrations and has high optical performance.

The second embodiment of the present invention is an objective lens system which has a composition illustrated in FIG. **5**. Speaking concretely, it is composed of two lens elements, i.e., in order from the object side, a first lens unit

composed of a negative lens element, a stop and a second lens unit composed of a positive lens element. The second lens unit having the positive refractive power is configured as a radial type gradient index lens element.

The second embodiment is an example in which the objective lens system is configured so as to have a total length that is shorter than that of the first embodiment. In the second embodiment also, lateral chromatic aberration in particular is favorably corrected by using the radial type gradient index lens element as the second lens unit.

The radial type gradient index lens element has a meniscus shape which has a concave surface on the object side. When a radial type gradient index lens element has such a meniscus shape, its refractive power of surface and refractive power of medium which are weaker and stronger respectively than a refractive power of surface and a refractive power of medium of a radial type gradient index lens element having a biconvex shape and a refractive power which is the same as that of the radial type gradient index lens element. When a radial type gradient index lens element has a strong refractive power of medium, its effect for correcting chromatic aberration can be effectively utilized as seen from the formula (d). For effectively utilizing the effect of a radial type gradient index lens element, the second embodiment adopts the radial type gradient index lens element which has the meniscus shape. The meniscus shape which has the concave surface on the object side is effective in particular for preventing offaxial aberrations from being aggravated.

In the second embodiment, the outer circumferential portion located outside an effective diameter of the first lens unit and the second lens unit is configured as a nearly planar surfaces on which both the lens units are cemented or kept in contact with each other. By cementing these two lens units into an integrated part, it is possible to simplify a structure of a lens barrel and facilitate assembly of the objective lens system.

The second embodiment also has high optical performance though it is composed only of the two lens elements.

The third embodiment of the present invention is an objective lens system which has a composition illustrated in FIG. **6**. That is to say, the objective lens system is composed of two lens units, in order from the object side, of a first lens unit composed of a negative lens element, a stop, and a second lens unit composed of a positive lens element. The second lens unit having the positive refractive power is configured as a radial type gradient index lens element. The first lens unit is composed of a homogenous lens element having a biconcave shape, whereas the second lens unit is composed of a radial type gradient index lens element having a meniscus shape which has a concave surface on the object side.

Though it is ordinarily difficult to favorably correct lateral chromatic aberration with two lens elements, the objective lens system according to the present invention is capable of favorably correcting lateral chromatic aberration by using the radial type gradient index lens element as the second lens unit.

The third embodiment is an example wherein amounts of aberrations to be produced by the first lens unit are reduced by selecting the biconcave surface for the first lens unit so that a power of this lens unit is shared between the surfaces.

Though $1/V_{10}$ of the radial type gradient index lens element has a positive value, lateral chromatic aberration is favorably corrected by satisfying the condition (1).

The objective lens system preferred as the third embodiment also has high optical performance though it is composed only of the two lens elements.

The fourth embodiment of the present invention is an objective lens system which has a composition shown in FIG. **7**. Concretely, it is composed of two lens units, in order from the object side, a first lens unit composed of a negative lens element, a stop and a second lens unit composed of a positive lens element. The second lens unit having the positive refractive power is configured as a radial type gradient index lens element. The first lens unit has a planar surface on the object side and a concave surface on the image side configured as an aspherical surface which weakens a negative refractive power as portions of the aspherical surface are farther from an optical axis toward a marginal portion. The second lens unit is composed of a radial type gradient index lens element which has a biconvex shape.

The aspherical surface used in this embodiment has a shape expressed by the following formula:

$$x = \frac{y^2/r}{1+\sqrt{1-p(y/r)^2}} + \sum A_{2i}y^{2i}$$

wherein a direction along the optical axis is taken as the x axis, a direction perpendicular to the optical axis is taken as the y axis, the reference symbol r represents a radius of curvature on the optical axis, the reference symbol p designates a conical constant and the reference symbol A_{2i} denotes an aspherical surface coefficient.

In the fourth embodiment, the aspherical surface used in the first lens unit is capable of favorably correcting mainly barrel form distortion produced in the lens system as a whole.

Though the first lens unit has the planar surface on the object side in the fourth embodiment, a similar effect can be obtained by using an aspherical surface as the object side surface of the first lens unit.

The fourth embodiment is an example wherein the second lens unit is configured as the biconvex radial type gradient index lens element which has a weakened refractive power of medium and a strengthened refractive power of surface. Accordingly, the radial type gradient index lens element can have a small refractive index difference Δn contributing to a refractive power of medium, thereby enhancing productibility or shortening a time required for imparting a refractive index distribution at a stage to prepare a material for the radial type gradient index lens element.

In spite of the fact that the fourth embodiment is composed only of the two lens elements, it has high optical performance.

It is possible to obtain a similar effect by using, in place of the aspherical surface disposed in the first lens unit, an axial type gradient index lens element having a refractive index continuously varying in the direction along the optical axis.

The fifth embodiment of the present invention is an objective lens system which has a composition illustrated in FIG. **8**. That is to say, it is composed of two lens elements, in order from the object side, a first lens unit composed of a negative lens element, a stop and a second lens unit composed of a positive lens element configured as a radial type gradient index lens element. The first lens unit has a planar surface on the object side and a concave surface on the image side which is configured as an aspherical surface which has such a shape as tc weaken a negative refractive power as portions of the aspherical surface are farther from the optical axis toward a marginal portion, whereas the second lens unit is configured as a radial type gradient index lens element having a biconvex shape. The aspherical sur-

face used in the first lens unit is capable of favorably correcting barrel form distortion which is produced in the objective lens system as a whole as in the fourth embodiment.

For configuring compactly a tip of an endoscope which is to comprise the objective lens system according to the present invention, an outer circumferential portion of the radial type gradient index lens element used as the second lens unit is cut off as shown in FIG. **8**. A tip of the objective lens system can be made thinner since a lens barrel or the like can be disposed, for example, as the slashed location **3** on the cut portion **2**.

The fifth embodiment is an example wherein the objective lens system has a total length that is shorter than that of the fourth embodiment. Though the fifth embodiment is composed only of the two lens elements, it has high optical performance.

The sixth embodiment of the present invention has a composition shown in FIG. **9**. Speaking concretely, it is composed of two lens units, in order from the object side, a first lens unit composed of a negative lens element, a stop and a second lens unit composed of a positive lens element. The first lens unit having the negative refractive power is configured as a radial type gradient index lens element. The first lens unit is a radial type gradient index lens element which has a planar surface on the object side and a concave surface on the image side, whereas the second lens unit is a biconvex homogenous lens element.

Unlike the first through fifth embodiments, the sixth embodiment uses the radial type gradient index lens element as the first lens unit for favorably correcting lateral chromatic aberration which poses a problem in particular in the objective lens system according to the present invention.

The planar surface adopted as the object side surface of the first lens unit makes it possible to reduce the cost for polishing the lens element.

Further, aberrations are reduced by selecting the biconvex shape for the second lens unit so that its power is shared between the two surfaces.

Furthermore, the image side surface of the second lens unit has a refractive power of surface which is stronger than that of the object side surface thereof so that offaxial rays are incident on an image surface nearly at telecentric angles.

The sixth embodiment also has high optical performance though it is composed only of the two lens elements.

The seventh embodiment of the present invention has a composition illustrated in FIG. **10**. That is to say, an objective lens system preferred as the seventh embodiment is composed of two lens units, in order from the object side, a first lens unit composed of a negative lens element, stop and a second lens unit composed of a positive lens element. The first lens unit having the positive refractive power is configured as a radial type gradient index lens element. The first lens unit is a radial type gradient index lens element which has a planar surface on the object side and a concave surface on the image side, whereas the second lens unit is a homogenous lens element which has a biconvex shape

This embodiment also has high optical performance though it is composed only of the two lens elements

The eighth embodiment of the present invention is an objective lens system which has a composition shown in FIG. **11**. This lens system is composed of two lens units, in order from the object side, a first lens unit composed of a negative lens element, a stop and a second lens unit composed of a positive lens element. The first lens unit having the positive refractive power is configured as a radial type gradient index lens element. The first lens unit is a radial type gradient index lens element having a meniscus shape which has a concave surface on the image side, whereas the second lens unit is a homogenous lens element which has a biconvex shape.

The composition of the eighth embodiment, in which the radial type gradient index lens element has the meniscus shape which has a concave surface on the image side is advantageous for correcting offaxial aberrations in particular.

The eighth embodiment also has high optical performance in spite of the fact that it is composed only of the two lens elements.

The ninth embodiment of the present invention is an objective lens system which has a composition illustrated in FIG. **12**. Speaking concretely, this lens system is composed of two lens elements, in order from the object side, a first lens unit composed of a negative lens units, a stop and a second lens unit composed of a positive lens element. The first lens unit having the negative refractive power is configured as a radial type gradient index lens element. The first lens unit is a radial type gradient index lens element having a meniscus shape which has a planar surface on the object side and a concave surface on the image side, whereas the second lens unit has aspherical surfaces on both sides.

Owing to a fact that an image side surface of the second lens unit on which offaxial rays are relatively high is configured as an aspherical surface having such a shape as to weaken a positive refractive power as portions of the aspherical surface are farther from an optical axis toward a marginal portion, the ninth embodiment is capable of favorably correcting barrel form distortion produced in the lens system as a whole.

Though the ninth embodiment uses the aspherical surfaces on both sides of the second lens unit, a similar effect can be obtained by using an aspherical surface only on one side.

The ninth embodiment also exhibits high optical performance though it consists only of the two lens elements.

Further, a similar effect can be obtained by adopting, in place of the aspherical surfaces used in the second lens unit, an axial type gradient index lens element which continuously varies a refractive index in a direction along the optical axis.

The tenth embodiment of the present invention is an objective lens system which has a composition shown in FIG. **13**. This lens system consists of two lens units, in order from the object side, a first lens unit composed of a negative lens element, a stop and a second lens unit composed of a positive lens element. The first lens unit having the negative refractive power and the second lens unit having the positive refractive power are configured as radial type gradient index lens elements. The first lens unit is a radial type gradient index lens element which has a planar surface on the object side and a concave surface on the image side, whereas the second lens unit is a radial type gradient index lens element which has a biconvex shape.

The tenth embodiment is an example wherein lateral chromatic aberration produced in the lens system as a whole is favorably corrected by using radial type gradient index lens elements in both the lens units. In other words, lateral chromatic aberration is favorably corrected by configuring the radial type gradient index lens element used in the first lens unit to satisfy the condition (1) and the condition (2), and designing the radial type gradient index lens element used in the second embodiment to satisfy the condition (1) and the condition (3).

Though the tenth embodiment consists only of the two lens elements, it has high optical performance.

Preferred as an eleventh embodiment of the present invention is an objective lens system which has a composition illustrated in FIG. **14**. This lens system comprises two lens units, or is composed, in order from the object side, a first lens unit composed of a negative lens element, a stop, a second lens unit composed of a positive lens element and filters F disposed on the image side of the second positive lens unit. The first lens unit is configured as a homogenous lens element which has a planar surface on the object side and a concave surface on the image side, whereas the second lens unit is configured as a biconcave radial type gradient index lens element which has an object side surface having a weak positive refractive power.

When the objective lens system according to the present invention is used in a video scope or the like which uses a solid-state image pickup device such as a CCD, a low pass filter and an infrared cut filter composed, for example, of quartz or diffraction gratings may be disposed on the object side of an image surface as exemplified in FIG. **14**. The eleventh embodiment is an example comprising such filters. In the objective lens system according to the present invention, the above-mentioned filters can be disposed between the negative lens element and the positive lens element.

Preferred as the twelfth embodiment of the present invention is an objective lens system which has a composition shown in FIG. **15**. Like the eleventh embodiment, the twelfth embodiment comprises two lens units, or is composed, in order from the object side, of a first lens unit composed of a negative lens element, a stop, a second lens unit composed of a positive lens element, and filters which are disposed between the two lens elements and on the image side of the positive lens element. The first lens unit is configured as a homogenous lens element which has a planar surface on the object side and a concave surface on the image side, whereas the second lens unit is configured as a radial type gradient index lens element which has a biconvex shape.

The thirteenth embodiment of the present invention has a composition illustrated in FIGS. **16**A and **16**E: FIG. **16**A being a sectional view showing the thirteenth embodiment as a whole and FIG. **16**B being a diagram illustrating only a portion B on an enlarged scale. The thirteenth embodiment is composed, in order from the object side, of a first lens unit composed of a negative lens element, a stop and a second lens unit composed of a positive lens element. A radial type gradient index lens element is used as the second lens unit. The first lens unit has a planar surface on the object side and a concave surface on the image side, whereas the second lens unit has a planar surface on the object side and a convex surface on the image side.

The thirteen embodiment is an example wherein aberrations are favorably corrected by using a racial type gradient index lens element and a large number of planar surfaces are adopted for reducing a cost required for polishing lens elements, or the object side surface of the first lens unit and the object side surface of the second lens unit are configured the planar.

Further, for preventing eccentricities of lens elements, in directions along an optical axis and perpendicular thereto in particular, which pose a problem at a stage of assembly, an outer circumferential portion **4** is obliquely chamfered as shown in FIG. **16**B so that a chamfered portion **4** is limited at a location **6** of a lens barrel **5**. Since a radial type gradient index lens element which has a refractive power of medium requires a manufacturing precision stricter than that for a homogenous lens element, the thirteenth embodiment provides effective assembling convenience. A similar effect can, needless to say, be obtained by assembling the first lens unit having the negative refractive power in similar manner.

Though the thirteenth embodiment uses a large number of planar surfaces, it has high optical performance.

The fourteenth embodiment of the present invention is an objective lens system which has a composition illustrated in FIG. **17**. That is to say, the fourteenth embodiment is composed, in order from the object side, of a first lens unit consisting of a negative lens element, a stop and a second lens unit consisting of a positive lens element which is configured as a radial type gradient index lens element. The first lens unit has a planar surface on the object side and a concave surface on the image side, whereas the second lens unit has a meniscus shape which has a concave surface on the object side.

When a radial type gradient index lens element is used as the second lens unit, it is desirable for correcting aberrations such as spherical aberration that the term of the fourth order N_{20} of a refractive index distribution has a positive value.

The fifteenth embodiment of the present invention has a composition shown in FIG. **18**. Speaking concretely, the fifteenth embodiment is composed, in order from the object side, of a first lens unit consisting of a negative lens element, a second lens unit consisting of a positive lens element and a reflecting optical element. A radial type gradient index lens element is used as the second lens unit. In this embodiment, a light bundle emerging from the second lens unit is reflected by a reflecting surface **7** of a reflecting optical element P made, for example, of a mirror or a prism so that it is imaged onto a solid-state image pickup device **10** which is disposed nearly parallel to the optical axis. This reflecting surface makes it possible to dispose a solid-state image pickup device such as a CCD that is not parallel to a radial direction of the lens elements, but oblique. Though a solid-state image pickup device **10** is disposed nearly parallel to the optical axis in the fifteenth embodiment, the image pickup device can be disposed more obliquely by selecting an adequate inclination angle for the reflecting surface **7** relative to the optical axis. Though the fifteenth embodiment is configured to reflect the light bundle only once, it is possible to reflect the light bundle twice, three times or more times by adopting a larger number of reflecting surfaces.

The sixteenth embodiment of the present invention is an objective lens system which has a composition shown in FIG. **19**. That is to say, the sixteenth embodiment is composed, in order from the object side, of a first lens unit composed of a negative lens element, a second lens unit composed of a positive lens element and a solid-state image pickup device. A radial type gradient index lens element is used as the second lens unit. In this embodiment, the radial type gradient index lens element has a nearly planar image side surface which is cemented or kept in close contact to or with a solid-state image pickup device **10** such as a CCD. Further, disposed in the second lens unit, is a member which extends from an outer circumference toward an optical axis for shielding a light bundle passing through the lens unit or functioning as an aperture stop of the objective lens system. Such a shielding member can be constituted, for example, by forming a cut **8** from the outer circumference toward the optical axis. For preventing the cut from producing flare, it is desirable to color the cut **8**. Further, it is possible to cut the second lens unit along a dashed line **9** shown in FIG. **25** into a front portion La and a rear portion Lb, attach a stop S to a cut surface of the front portion La and cementing the two portions to each other or bringing them into close contact with each other. A similar effect can be obtained by attaching

the stop S to the rear portion Lb in place of the front portion La. As means for attaching the stop, it is conceivable to utilize deposition, printing or bonding a stop plate. This means can be utilized for manufacturing not only an aperture stop but also a flare stop.

In the sixteenth embodiment, the aperture stop is disposed at a location 1 mm apart from an object side surface of the second lens unit toward an image surface.

It is needless to say that an aperture stop, a flare stop or the like can be manufactured by the means described above in each of the embodiments.

The seventeenth embodiment of the present invention has a composition illustrated in FIG. **20**. That is to say, the seventeenth embodiment is composed, in order from the object side, of a first lens unit composed of a negative lens element, a second lens unit composed of a positive lens element, an optical filter F and a solid-state image pickup device **10**. A radial type gradient index lens element is used as the second lens unit. In the seventeenth embodiment, the second lens unit has planar surfaces on both sides for reducing the cost for polishing the lens unit. The seventeenth embodiment is an example wherein the second lens unit is cemented to the optical filter F for simplifying a structure of a lens barrel and assembly of the objective lens system. Further, the optical filter F is cemented or kept in close contact to or with the solid-state image pickup device **10**. Furthermore, the first lens unit and the second lens unit are cemented or kept in close contact to or with each other on outer circumferences thereof outside an effective diameter thereof.

In the seventeenth embodiment, an aperture stop is disposed at a location 1 mm apart from an object side surface of the second lens unit toward an image surface.

The eighteenth embodiment of the present invention has a composition shown in FIG. **21**. That is to say, the eighteenth embodiment is composed, in order from the object side, of a first lens unit composed of a negative lens element, a regularly reflecting optical element and a second lens unit composed of a positive lens element. The second lens unit which is disposed on the image side is configured as a radial type gradient index lens element.

Certain endoscopes are specified for oblique observation in directions inclined relative to the optical axis. When the objective lens system according to the present invention is used in an endoscope for oblique observation, a reflecting optical element P composed of a mirror or a prism is disposed between the first lens unit and the second lens unit as shown in FIG. **21** SO that a light bundle emerging from the first lens unit is reflected by a reflecting surface **7** of the reflecting optical element and led to the second lens unit.

Though a lens element ordinarily has a circular sectional shape, it may have a different sectional shape. FIGS. **22**A, **22**B, **22**C, **23**A, **23**B and **23**C exemplify lens elements which have external shapes cut or worked in accordance with shapes of image pickup devices for configuring objective lens systems compactly. FIGS. **22**A, **22**B and **22**C schematically show the second lens unit which is used in the first through eighteenth embodiments before being shaped. FIG. **22**A shows a sectional view taken in a direction from an object, FIG. **22**B is a sectional view taken in a direction in parallel with the optical axis, and FIG. **22**C illustrates an image circle **11** of the objective lens system and an image pickup surface **12** of an image pickup device. FIGS. **23**A, **23**B and **23**C schematically show the lens element illustrated in FIGS. **22**A, **22**B and **22**C in another condition after it is shaped. Since a solid-state image pickup device such as a CCD may have a rectangular shape and a lens element ordinarily has a circular shape as shown in FIG. **22**A, there is produced, as slashed in FIG. **22**C, a region which serves for image formation but is not used for image pickup. Since it is desired to configure an objective lens system for endoscopes compacter, it is conceivable to cut off the region of the lens element which is not used for image pickup. The eithteenth embodiment is an example wherein lens portions through which rays to be condensed outside an image pickup surface of an image pickup device are cut off as exemplified by FIGS. **23**A and **23**B so that an image formation range of the lens element is nearly coincident with the image pickup surface of the image pickup device. It is possible to obtain a compacter objective lens system or endoscopes by configuring a lens element so as to occupy a narrower space.

Though the second lens unit is worked for narrowing a lens space in the example described above, it is needless to say that a similar effect can be obtained by working other lens element or optical element, for example, the first lens unit or the reflecting optical element.

The nineteenth embodiment has a composition illustrated in FIG. **26**. Speaking concretely, the nineteenth embodiment is a retrofocus type objective lens system which is composed, in order from the object side, of a first negative lens unit, a second positive lens unit and a third positive lens unit. A stop is disposed between the second lens unit and the third lens unit. The nineteenth embodiment is an objective lens system which has a wide field angle and is usable for endoscopes, video cameras, etc. Though the nineteenth embodiment has a wide field angle which makes it rather hard to correct lateral chromatic aberration, it corrects lateral chromatic aberration with a radial type gradient index lens element. In the nineteenth embodiment, the first lens unit has a plano-concave shape and a function to widen a field angle, the second lens unit has a plano-convex shape and a function to correct mainly lateral chromatic aberration produced by the first lens unit, and the third lens unit has a biconvex shape and a main imaging function, and is configured as a radial type gradient index lens element.

Though it is rather hard in the nineteenth embodiment to correct coma which is produced by the third lens unit disposed on the image side of a stop, coma is corrected by configuring the third lens unit as a radial type gradient index lens element which has such a characteristic as to progressively lower a refractive index in a radial direction from an optical axis. In other words, coma is corrected by imparting a positive refractive power to a medium of the radial type gradient index lens element. The composition described above is capable of correcting not only coma but also distortion.

For correcting coma with a medium of a radial type gradient index lens element, it is desirable that terms of high orders of a refractive index distribution satisfy the following condition (27):

$$-0.05 < \sum_{i=2}^{n} N_{iod} e^{2i} < 0.2 \tag{27}$$

wherein the reference symbol e represents an effective diameter of the lens element.

If the lower limit of −0.05 of the condition (27) is not satisfied, coma will be undercorrected. If the upper limit of 0.2 of the condition (27) is exceeded, in contrast, coma will be overcorrected.

It is desirable for more favorable correction of coma to satisfy the following condition (28):

$$0 < \sum_{i=2}^{n} N_{iod} e^{2i} < 0.1 \quad (28)$$

If the lower limit of 0 of the condition (28) is not satisfied, coma will be undercorrected. If the upper limit of 0.1 of the condition (28) is exceeded, in contrast, coma will be overcorrected. Either of these cases is undesirable for more favorable correction of coma.

Further, a planar surface used as an object side surface of the lens element disposed on the image side in the nineteenth embodiment has an effect for preventing adhesion of foreign matter such as dust.

In this embodiment, at least one lens element can have a function to cut off components having specific wavelengths, or a radial type gradient index lens element can have such a function.

When an image pickup device such as a CCD which has high sensitivity in the infrared wavelength region is to be disposed on an image pickup surface, for example, it is desirable to provide a function to cut off components having wavelengths in the infrared region. Accordingly, it is desirable that at least one lens element has a function to cut off components having specific wavelengths such as those in the infrared region.

The function to cut off components having specific wavelengths can be obtained by forming, on a flat portion of a lens element or a flat plate, an interference film which cuts off the components having specific wavelengths.

A stop can be manufactured from a thin plate.

Further, amounts of aberrations produced can be reduced by configuring a radial type gradient index lens element so as to have a biconvex shape, thereby sharing a refractive power between the two surfaces.

Use of a radial type gradient index lens element makes it possible to obtain an optical system which is compact and composed of a small number of lens elements, and has a wide field angle and favorably corrected aberrations such as chromatic aberration and coma. Accordingly, it is effective to use an optical system such as an optical system for image input units for portable TV telephones and portable data input units such as those shown in FIGS. **35** and **36**.

The twentieth embodiment is an optical system which has a composition illustrated in FIG. **27**. It is a retrofocus type optical system which is composed, in order from the object side, of a first lens unit having a negative refractive power, a second lens unit having a positive refractive power and a third lens unit having a positive refractive power. A stop is disposed between the second lens unit and the third lens unit.

The twentieth embodiment is an optical system which has a wide field angle and is usable as an objective lens system for endoscopes or a lens system for video cameras, etc. Though the twentieth embodiment also has a wide field angle and hardly allows correction of lateral chromatic aberration in particular, aberrations are favorably corrected in this embodiment by using a radial type gradient index lens element.

In the twentieth embodiment, the first lens unit is a plano-concave lens element having a function to widen a field angle, the second lens unit is a radial type gradient index lens element having planar surfaces on both sides and a function to correct lateral chromatic aberration produced by the first lens unit, and the third lens unit has a biconvex shape and a main imaging function. The twentieth embodiment favorably corrects lateral chromatic aberration in particular by using, as the second lens unit disposed on the object side of the stop, a radial type gradient index lens element made of a medium which has a positive refractive power and a relatively strong dispersing power. The medium having the positive refractive power favorably corrects a Petzval's sum.

For correcting lateral chromatic aberration by disposing a radial type gradient index lens element on a stop, it is desirable to satisfy the following condition (29):

$$0.01 < 1/V_{10} < 0.5 \quad (29)$$

If the lower limit of 0.01 of the condition (29) is not satisfied, lateral chromatic aberration will be undercorrected. If the upper limit of 0.5 of the condition (29) is exceeded, in contrast, lateral chromatic aberration will be overcorrected.

For correcting lateral chromatic aberration more favorably by disposing a radial type gradient index lens element on the object side of the stop, it is desirable to satisfy the following condition (30):

$$0.015 < 1/V_{10} < 0.1 \quad (30)$$

If the lower limit of 0.015 of the condition (30) is not satisfied, lateral chromatic aberration will be undercorrected. If the upper limit of 0.1 of the condition (30) is exceeded, lateral chromatic aberration will be overcorrected. Either of these cases is undesirable for correcting lateral chromatic aberration extremely favorably.

When preparation of a material for a radial type gradient index lens element is taken into consideration, it is desirable that $1/V_{10}$ has a value not exceeding 0.05. From viewpoints of manufacturing convenience and cost, it is desirable to configure a radial type gradient index lens element so as to have planar surfaces on both sides. When durability of a radial type gradient index lens element is taken into consideration, it is desirable to make it entirely of a glass material.

The twenty-first embodiment has a composition illustrated in FIG. **28**, or is a retrofocus type optical system which is composed, in order from the object side, of a first lens unit having a negative refractive power and a second lens unit having a positive refractive power. A stop is disposed between the first lens unit and the second lens unit. The twenty-first embodiment which is an optical system having a wide field angle is usable as an objective lens system for endoscopes or video cameras and so on. Though this optical system also has a wide field angle and hardly allows correction of lateral chromatic aberration in particular, lateral chromatic aberration is favorably corrected by using a radial type gradient index lens element.

In the optical system preferred as the twenty-first embodiment, the first lens unit has a negative meniscus shape which has a concave surface on the image side, and the second lens unit has a biconvex shape and a main imaging function. A radial type gradient index lens element is used as the first lens unit.

Offaxial aberrations can be corrected favorably by configuring the radial type gradient index lens element used as the first lens unit so as to have the meniscus shape which has the concave surface on the side of the stop. Lateral chromatic aberration is favorably corrected in particular owing to a fact that the radial type gradient index lens element has a positive refractive power of medium and is configured so as to satisfy the condition (29).

Further, coma is corrected favorably by using an aspherical surface on the lens element disposed on the object side of the stop. This aspherical surface has such a shape as to

weaken a positive refractive power as portions of the aspherical surface are farther from an optical axis toward a marginal portion. Owing to this aspherical surface, the twenty-first embodiment is configured as an optical system which is compact and composed of a small number of lens elements, has a wide field angle and favorably corrects aberrations such as coma. It is therefore effective to apply the twenty-first embodiment as an optical system for image intake devices for portable TV telephones and portable date input units.

The twenty-second embodiment has a composition shown in FIG. **29**, or is an optical system composed of a single radial type gradient index lens element. The radial type gradient index lens element has a meniscus shape which has a concave surface on the object side and a positive power of medium. A stop is disposed at a location 0.9471 mm apart from an object side surface of the lens element toward the image side.

The twenty-second embodiment has a wide field angle, and is usable as an objective lens system for endoscopes or a lens system for video cameras and so on. Though the twenty-second embodiment which has the wide field angle hardly allows correction of chromatic aberration, it is corrected with the radial type gradient index lens element. A flat glass plate is disposed on the object side as a cover glass plate. A stop is disposed in the radial type gradient index lens element for obtaining highly symmetrical refractive power of medium, thereby favorably correcting offaxial aberrations. The radial type gradient index lens element satisfies the condition (29) for correcting lateral chromatic aberration produced by an object side concave or convex surface with a medium located on the object side of the stop.

For reducing chromatic aberration to be produced by surfaces of the radial type gradient index lens element, it is desirable that V_{00} has a value of at least 30, or more desirably, at least 40. For reducing aberrations to be produced by the surfaces of the radial type gradient index lens element, it is desirable that N_{00} has a value of at least 1.55, or more desirably, at least 1.6.

The twenty-third embodiment has a composition shown in FIG. **30**, or is composed of two lens units, in order from the object side, a first positive lens unit and a second positive lens unit. The twenty-third embodiment is an example wherein aberrations are corrected favorably by composing an optical system of a radial type gradient index lens element and a diffraction type optical element(DOE) Speaking more concretely, the twenty-third embodiment is composed, in order from the object side, of a first lens unit composed of a radial type gradient index lens element and a second lens unit composed of a diffraction type optical element.

A diffraction type optical element is equivalent to a lens element which has a very high imaginary refractive index as described in literature SPIE, Vol. 126, P46 (1997). For this reason, the diffractive optical element is assumed to be a lens element which is optically equivalent to the optical element including aberrations to be produced thereby, and radii of curvature, thickness, a refractive index, an Abbe's number and aspherical surface coefficients of the lens element are described in the numerical data of the twenty-third embodiment. In the twenty-third embodiment, a stop is disposed on the object side of the optical system (the first lens unit).

In the twenty-third embodiment, the first lens unit composed of the radial type gradient index lens element has a main imaging function and the second lens unit composed of the diffraction type optical element favorably corrects lateral chromatic aberration. The twenty-third embodiment is an example of an optical system which is composed of a small number of optical elements and has a wide field angle, and favorably corrects lateral chromatic aberration with a diffractive optical element disposed on the image since of a stop. The diffraction type optical element has a positive refractive power, is disposed on the image side of the radial type gradient index lens element and has a function to favorably correct lateral chromatic aberration produced by a convex surface of the radial type gradient index lens element. Further, the radial type gradient index lens element has another function to favorably correct a Petzval's sum.

The twenty-third embodiment is usable, as described above, as an objective lens system for endoscopes or an optical system for video cameras and so on. Since the twenty-third embodiment is an optical system which is compact and is composed of a small number of lens elements, and favorably corrects aberrations such as chromatic aberration owing to the fact that it uses the diffraction type optical element, it is effective to apply it as an optical system for image intake devices for portable TV telephones and portable data input units.

The twenty-fourth embodiment has a composition illustrated in FIG. **31**, or is composed, in order from the object side, of a first lens unit having a negative refractive power and a second lens unit having a positive refractive power. A stop is disposed between the first lens unit and the second lens unit. In the twenty-fourth embodiment, the first lens unit having the negative refractive power serves mainly for widening a field angle and the second lens unit having the positive refractive power functions mainly for imaging.

The twenty-fourth embodiment favorably corrects aberrations by using the diffraction type optical element in place of the radial type gradient index lens element adopted for the twenty-first embodiment.

The twenty-fourth embodiment hardly allows correction of offaxial aberrations since it has an asymmetrical refractive power distribution wherein a negative refractive power is disposed on the object side of the stop and a positive refractive power is disposed on the image side of the stop. For this reason, lateral chromatic aberration is corrected favorably by disposing the diffraction type optical element on the object side of the stop and imparting a negative refractive power to this optical element. Coma and distortion in particular can be corrected favorably by using an aspherical surface on a positive lens unit disposed on the image side of the stop and configuring this aspherical surface so as to have such a shape as to weaken a positive refractive power in a radial direction from an optical axis. The negative lens unit has a meniscus shape which has a concave surface on the side of the stop for reducing amounts of offaxial aberrations in particular. Further, the positive lens unit has a biconvex shape so that amounts of aberrations are reduced by sharing a refractive power between two surfaces. Furthermore, the diffraction type optical element is disposed on a surface which is concave toward the stop so that differences between angles of incidence of paraxial rays and offaxial rays are reduced, thereby enhancing a diffraction efficiency.

FIG. **32** is a perspective view illustrating an endoscope according to the present invention which uses an objective lens system such as the embodiment described above. The reference numeral **21** represents the objective lens system.

FIG. **33** is a side view of a non-flexible endoscope according to the present invention which uses an objective lens system such as the embodiment described above. The reference numeral **21** represents the objective lens system.

FIG. **34** shows a video camera according to the present invention which uses an objective lens system such as the

embodiment describes above. The reference numeral **21** represents the objective lens system.

FIG. **35** shows a perspective view illustrating a portable TV telephone according to the present invention which uses an objective lens system such as the embodiment described above. The reference numeral **21** represents the objective lens system, the reference numeral **22** designates an antenna for transmission and reception, the reference numeral **23** denotes a display, and the reference numeral **24** represents switches.

Further, FIG. **36** shows a perspective view illustrating a portable data input unit according to the present invention which uses an objective lens system such as the embodiment described above. The reference numeral **21** represents the objective lens system, the reference numeral **22** designates an antenna for transmission and reception, the reference numeral **23** denotes a display, and the reference numeral **24** represents switches.

As understood from the foregoing description, the objective lens system for endoscopes according to the present invention is composed of lens elements in a number on the order of 2, and is nevertheless an optical system which favorably corrects aberrations, lateral chromatic aberration in particular, and has high optical performance.

I claim:

1. An objective lens system comprising, in order from the object side:

a first lens unit consisting of a lens element having a homogeneous lens medium and having a negative refracting power, said first lens unit being the most object-side lens unit of said objective system; and

a second lens unit consisting of a lens element having a radial type gradient refractive index and having a positive refractive power, said second lens unit being the second most object-side lens unit of said objective system,

wherein only one radial type gradient index lens element, which has a refractive index distribution in a radial direction from an optical axis, is disposed in said second lens unit and in the lens system as a whole,

wherein said radial type gradient index lens element has a planar surface on at least one side, and

wherein said radial type gradient index lens element satisfies the following condition (6):

$$1/V_{10}<0.01 \quad (6)$$

wherein the reference symbol V_{10} represents a dispersing power of said radial type gradient index lens element which is given by the formula (c) shown below:

$$V_{10}=N_{10d}/(N_{10F}-N_{10C})$$

wherein the reference symbols N_{10d}, N_{10F} and N_{10C} designate values of a coefficient of a term r^2 for the d-line, F-line and C-line, respectively, when a refractive index of said radial type gradient index lens element is expressed as a polynomial of r.

2. An objective lens system according to claim **1** wherein said radial type gradient index lens element has planar surfaces on both sides.

3. An objective lens system according to claim **1**, wherein said first lens unit and said second lens unit are cemented to each other outside an effective diameter thereof, thereby forming a cemented lens unit.

4. An objective lens system according to claim **1** wherein a term of the fourth order N_{20} of a refractive index distribution coefficient of said radial type gradient index lens element has a positive value.

5. An objective lens system according to claim **1** satisfying the following condition (3):

$$0.05<\phi_{2m}/\phi<1.0 \quad (3)$$

wherein the reference symbol ϕ_{2m} represents a refractive power of said radial type gradient index lens element used in the second lens unit and the reference symbol ϕ designates a refractive power of said objective lens system as a whole.

6. An objective lens system according to claim **1** satisfying the following condition (4):

$$-0.5<N_{10P}\cdot f^2<-0.01 \quad (4)$$

wherein the reference symbol N_{10P} represents a refractive index distribution coefficient of the second order when the radial type gradient index lens element is used in said second lens unit and the reference symbol f designates a focal length of said objective lens system as a whole.

7. An image pickup apparatus comprising an objective lens system according to claim **1**.

[57] **ABSTRACT**

The invention provides a high-performance yet low-cost phototaking optical system using a diffractive optical element. The optical system comprises, in order from an object side thereof, a first positive lens in a meniscus form convex toward the object side, an aperture stop, and a second positive lens in a double-convex form, with a diffractive surface formed on the object side of the first lens. The system comprising an aperture stop, at least two lenses and at least one diffractive surface satisfies the condition $0<d_{DOE}/f<0.24$ where f is a focal length of the overall system and d_{DOE} is a distance on an optical axis thereof from the aperture stop to the diffractive surface. This condition is provided to locate the diffractive surface in the vicinity of the aperture stop to lower ray height, thereby placing chromatic aberration in a well-balanced state.

HYBRID PHOTOGRAPHIC OBJECTIVE

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to a phototaking optical system using a diffractive optical element (DOE for short). More particularly, this invention is directed to a phototaking optical system designed for use on cameras such as silver halide or electronic cameras.

2. Discussion of Related Art

For phototaking optical systems designed for use on silver halide or electronic cameras, it has so far been proposed to improve their performance and cut down their cost. In regard to a general phototaking optical system, it is difficult to achieve cost reductions because many lenses are needed for achieving high performance by correcting aberrations. In recent years, therefore, cost reductions have been accomplished by reducing the number of lenses while keeping performance acceptable by the use of aspheric surfaces. However, aspheric surfaces have a grave disadvantage of being incapable of correcting for chromatic aberrations although they may correct monochromatic aberrations such as spherical aberrations, and coma. Therefore, an extreme reduction in the number of lenses for the purpose of achieving cost reductions often results in performance loss because chromatic aberrations become worse. To correct chromatic aberrations, there is thus no choice but to use suitable combinations of lenses of varying powers, but this inevitably incurs an increase in the number of lenses. That is, it is difficult to arrive at a sensible tradeoff between high performance and low cost.

Attention is now directed to a diffractive optical element (or DOE) having diffractive action to bend light rays. Unlike a general vitreous material, the DOE is characterized by having reciprocal dispersion, i.e., an Abbe number of −3.45, so that achromatization is achievable by a combination of positive power and positive power, unlike a conventional refractive system. Such a characteristic feature is believed to enable the DOE to be used with a phototaking optical system.

An account is here given of a DOE in general. The DOE is interpreted at great length in "Optics", Vol. 22, pp. 635–642, and pp. 730–737, for instance.

A conventional lens is based on refracting action at an interface of the medium, whereas the DOE is based on the diffraction of light. Now assume that light is incident on such a diffraction grating as depicted in FIG. **1**. In general, the light leaving the grating upon diffraction then satisfies the following relation:

$$\sin\theta-\sin\theta'=m\lambda/d \tag{a}$$

where θ is the angle of incidence, θ' is the exit angle, λ is the wavelength of light, d is the pitch of the diffraction grating, and m is the order of diffraction.

Therefore, if a ring form of diffraction grating is designed to have a proper pitch according to equation (a), it is then possible to focus light upon one point. In other words, the diffraction grating is allowed to have lens action. Here, let r_j and f represent the radius of a j-th grating ring and the focal length of a diffractive surface, respectively. If an optical path difference between a light ray diffracted by the j-th grating and a light ray passing through the center of the diffraction grating is designed to be integral multiples of wavelength, both light rays interact with each other to increase their intensity. That is, the following relation holds:

$$\sqrt{(r_j^2+f^2)}-f=j\lambda \tag{b-1}$$

Also, if r_j is not very large with respect to the focal length, the radius r_j of the grating ring is then given by

$$r_j=\sqrt{(2j\lambda f)} \tag{b-2}$$

For the diffraction grating, several types are proposed, for instance, an amplitude modulation type made up of a bright-and-dark ring, and a phase modulation type with a variable refractive index or optical path length. In the amplitude type DOE, the ratio between the quantity of incident light and the quantity of light subject to first-order diffraction (hereinafter called diffraction efficiency), for instance, is at most about 6% because light of plural orders of diffraction is generated. The amplitude modulation type DOE, even when bleached or otherwise treated for diffraction efficiency improvements, has a diffraction efficiency of at most about 34%. However, the same phase modulation type DOE, if it is of a sawtoothed shape in section as depicted in FIG. **2**, can have a diffraction efficiency increased to 100%. Such a DOE is called a kinoform. Here the height of each sawtooth is given by

$$h=m\lambda/(n-1) \tag{c}$$

where h is the height of the sawtooth, m is the order of diffraction (hereinafter called the design order of diffraction), and n is the index of refraction of an optical member forming the diffractive surface.

As can be expected from equation (c) depending on wavelength, however, the diffraction efficiency of 100% is achievable for only one wavelength. Thus, the diffraction efficiency $D_M(\lambda)$ depends on wavelength, and so is given by:

$$D_M(\lambda)=\mathrm{sinc}^2[\pi\{M-m\{(1-n)/(1-n_{DOE})\}(\lambda_{DOE}/\lambda)] \tag{d}$$

where M is the order of diffraction at which the DOE is used, m is the design order of diffraction, λ is the wavelength at which the DOE is used, λ_{DOE} is the design wavelength, and n and n_{DOE} are the indices of refraction of an optical member forming the diffractive surface at the wavelengths λ and λ_{DOE}.

A kinoform element, if it is to step approximation as depicted in FIG. **3**, is often called a binary optical element, and can be relatively easily fabricated by lithographic techniques. The binary optical element is known to have a diffraction efficiency of 81%, 95%, and 99% according to 4-, 8-, and 16-step approximation, respectively.

Examples of such a DOE applied to phototaking optical systems are disclosed in the following publications.

WO95/18393 shows a phototaking optical system comprising a single lens and a diffractive surface for making correction for aberrations. JP-A 4-181908 discloses an easy-to-manufacture radial type inhomogeneous lens wherein the chromatic aberrations produced are set off and corrected by a diffractive lens. This inhomogeneous lens is made up of one to three lens elements. JP-A's 6-324262 and 6-331887 teach that a diffractive surface is formed on front lenses of telescopic systems to make correction for chromatic aberrations. The former system is made up of six lens elements, and the latter system is made up of 10 or 11 lens elements.

However, all these phototaking optical systems using DOEs are found to be still less than satisfactory in terms of performance and cost. The system disclosed in WO95/18393 is somewhat more inexpensive because of being a single lens, but its performance is insufficient because coma, and other aberrations remain under-corrected.

The system set forth in JP-A 4-181908 achieves high performance albeit being composed of a reduced number of

lens elements. However, this system actually costs much because it uses an inhomogeneous lens. Inhomogeneous lenses are still unsuitable for mass production of cameras, etc., and so are unfavorable.

The systems set forth in JP-A's 6-324262 and 6-331887 achieve high performance by using DOEs for lenses in telescopic systems. However, these systems fail to take full advantage of DOEs because the DOEs are used only for the purpose of making fine correction for chromatic aberrations.

Thus, all these prior art arrangements fail to make a reasonable compromise between low cost and high performance.

SUMMARY OF THE INVENTION

In view of such problems associated with the prior art, it is an object of the present invention to provide a high-performance yet inexpensive phototaking optical system making use of a diffractive optical element.

According to the first aspect of the invention, there is provided a phototaking optical system making use of a diffractive optical element, which comprises an aperture stop, at least two lenses, and at least one diffractive surface, and satisfies the following condition (1):

$$0<d_{DOE}/f<0.24 \quad (1)$$

Here f is a focal length of the overall phototaking optical system, and d_{DOE} is a distance on an optical axis of the phototaking optical system from the aperture stop to the diffractive surface.

According to the second aspect of the invention, there is provided a phototaking optical system making use of a diffractive optical element, which comprises an aperture stop, two lenses, and one diffractive surface.

According to the third aspect of the invention, there is provided a phototaking optical system making use of a diffractive optical element, which comprises an aperture stop, two lenses, positive and positive, in order from an object side of the phototaking optical system, and at least one diffractive surface, all being formed of a homogeneous medium.

According to the fourth aspect of the invention, there is provided a phototaking optical system making use of a diffractive optical element, which comprises an aperture stop, two lenses, positive and positive, in order from an object side of the phototaking optical system, and at least one diffractive surface, and satisfies the following condition (3):

$$-1<SF_1<0.15 \quad (3)$$

Here $SF_1=(r_A-r_B)/(r_A+r_B)$ where r_A is a radius of curvature of a surface of the first lens that faces the object side, and r_B is a radius of curvature of a surface of the first lens that faces an image side of the phototaking optical system.

According to the fifth aspect of the invention, there is provided a phototaking optical system making use of a diffractive optical element, which comprises an aperture stop, two lenses, positive and negative, in order from an object side of the phototaking optical system, and at least one diffractive surface.

According to the sixth aspect of the invention, there is provided a phototaking optical system making use of a diffractive optical element, which comprises an aperture stop, two lenses, negative and positive, in order from an object side of the phototaking optical system, and at least one diffractive surface.

The first to sixth aspects of the phototaking optical system according to the present invention are now explained with the features and advantages thereof.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** illustrates the diffractive action of a diffraction grating.

FIG. **2** illustrates a sectional shape of the kinoform.

FIG. **3** illustrates a sectional shape of the binary optical element.

FIG. **4** is a schematic representation showing the relation between wavelength and diffraction efficiency at a design order of 1 and a design wavelength of 500 nm.

FIG. **5** is a schematic representation illustrative of a diffraction efficiency change at design orders of 1 to 5.

FIG. **6** is a sectional schematic of Example 1 inclusive of an optical axis thereof.

FIG. **7** is a sectional schematic of Example 2 inclusive of an optical axis thereof.

FIG. **8** is a sectional schematic of Example 3 inclusive of an optical axis thereof.

FIG. **9** is a sectional schematic of Example 4 inclusive of an optical axis thereof.

FIG. **10** is a sectional schematic of Example 5 inclusive of an optical axis thereof.

FIG. **11** is a sectional schematic of Example 6 inclusive of an optical axis thereof.

FIG. **12** is a sectional schematic of Example 7 inclusive of an optical axis thereof.

FIG. **13** is a sectional schematic of Example 8 inclusive of an optical axis thereof.

FIG. **14** is a sectional schematic of Example 9 inclusive of an optical axis thereof.

FIG. **15** is a sectional schematic of Example 10 inclusive of an optical axis thereof.

FIG. **16** is a sectional schematic of Example 11 inclusive of an optical axis thereof.

FIG. **17** is a sectional schematic of Example 12 inclusive of an optical axis thereof.

FIG. **18** is a sectional schematic of Example 13 inclusive of an optical axis thereof.

FIG. **19** is a sectional schematic of Example 14 inclusive of an optical axis thereof.

FIG. **20** is a sectional schematic of Example 15 inclusive of an optical axis thereof.

FIG. **21** is a sectional schematic of Example 16 inclusive of an optical axis thereof.

FIG. **22** is an aberration diagram for Example 1, wherein (a), (b), (c), and (d) show spherical aberration, astigmatism, distortion, and chromatic aberration of magnification, respectively.

FIG. **23** is a similar aberration diagram for Example 5.

FIG. **24** is a similar aberration diagram for Example 7.

FIG. **25** is a similar aberration diagram for Example 9.

FIG. **26** is a similar aberration diagram for Example 11.

FIG. **27** is a similar aberration diagram for Example 12.

FIG. **28** is a similar aberration diagram for Example 14.

FIG. **29** is a similar aberration diagram for Example 15.

FIG. **30** is a sectional schematic illustrative of specific shapes of the diffractive surface used in the invention.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

First of all, the conditions required for the accomplishment of the object of the invention are explained in con-

junction with all the first to sixth aspects of the invention. So far, it has been proposed to use a one-lens system as a low-cost lens system. As the number of lenses comes down to one, however, the degree of freedom of design becomes very low because the power is determined by the lens specification alone and so there is no choice but to make a selection from bending shapes for the purpose of making correction of aberrations. With the one-lens system, therefore, it is structurally impossible to make correction for chromatic aberration of magnification and Petzval's sum. Even when such a one-lens system is used in combination with an aspheric surface, aberrations such as distortion and coma remain under-corrected. Thus, the one-lens system is inexpensive but has difficulty in achieving high performance.

If the system is made up of at least two lenses, it is then possible to make the degree of freedom of design so high that a sensible selection can be made from lens power profiles, aperture stop positions, and so on. It is thus possible to make good correction for the aforesaid aberrations that cannot be corrected by the one-lens system. To achieve a low-cost yet high-performance lens system, therefore, it is required to construct the system of at least two lenses.

It has been found, however, that the system, even when made up of two lenses, is still insufficient insofar as the correction of chromatic aberrations is concerned. The diffractive surface of a diffractive optical element, or DOE, on the other hand, has a reciprocal dispersion or Abbe number of −3.45. Therefore, if this diffractive surface is used for a refractive surface of a lens, it is then possible to make correction for chromatic aberrations without recourse to an additional lens. According to the invention, it is thus possible to achieve low cost and high performance by proper use of the DOE, as described below.

The first aspect of the invention as well as the features and advantages thereof are explained. With reference here to the effect of the DOE on the correction of aberrations, the DOE has very high dispersion; chromatic aberrations produced at the DOE increase with an increase in its power, resulting in performance loss. To make correction for chromatic aberrations in a well-balanced state, it is required to relatively decrease the power of the DOE.

Even when the DOE is used in this manner, however, there is often a deterioration of chromatic aberration of magnification. The effect of the DOE on the correction of chromatic aberration of magnification varies with not only power but also ray height. When the DOE having very large dispersion is placed at a position of considerable ray height, therefore, the chromatic aberration of magnification is over-corrected. This is a leading cause of the deterioration of chromatic aberration of magnification. In the practice of the invention, therefore, the diffractive surface is located in the vicinity of the aperture stop to lower ray height, thereby placing the chromatic aberration of magnification in a well-balanced state.

It is thus preferred that the position of the diffractive surface satisfies the following condition (1):

$$0<d_{DOE}/f<0.24 \quad (1)$$

Here f is a focal length of the overall phototaking optical system and d_{DOE} is a distance on an optical axis of the system from the aperture stop to the diffractive surface.

When the upper limit of 0.24 in condition (1) is exceeded, chromatic aberration of magnification produced at the diffractive surface becomes too large to be balanced against longitudinal chromatic aberration. At the lower limit of 0 the DOE interferes physically with the aperture stop.

To meet high-performance and low-cost requirements at the same time, it is desired for the position of the DOE to satisfy the following condition (2):

$$0.02<d_{DOE}/f<0.21 \quad (2)$$

The second aspect of the phototaking optical system according to the invention is then explained together with the features and advantages thereof.

First, a problem concerning unnecessary orders of light produced at a DOE is explained. The DOE is characterized by having a diffraction efficiency of 100% with respect to a specific wavelength alone, as can be seen from equation (c) regarding the prior art. Upon incidence on the DOE of a light ray whose wavelength is different from that wavelength, therefore, the design or m-th order diffraction efficiency drops. This in turn causes other orders of (e.g., m+1-th, and m−1-th) diffraction efficiencies to increase, resulting in the occurrence of unnecessary light. In this connection, diffraction efficiency changes at 350 nm to 700 nm wavelengths are illustrated in FIG. **4** on condition that the design order is 1 and the design wavelength is 500 nm. FIG. **4** shows that when the DOE is used in conjunction with white light, unnecessary light such as zero-order light and second-order light is produced and image quality is often adversely affected by such unnecessary light. Thus, even when aberration performance is improved by use of many DOEs, there is an image quality drop due to large influences of the unnecessary orders of light.

The placement of one diffractive surface is sufficient for the correction of chromatic aberrations. In other words, when a plurality of diffractive surfaces are used, the chromatic aberrations are over-corrected; chromatic aberrations produced at one diffractive surface must be corrected by another diffractive surface. In addition, an eccentricity of such diffractive surfaces, which may be caused by assembling, etc., leads possibly to performance loss.

To achieve the object of the present invention, therefore, it is desired that at least one diffractive surface be used in conjunction witn a lens arrangement consisting of two lenses.

The third aspect of the phototaking optical system according to the present invention is explained together with the features and advantages thereof.

The optimum arrangement of two lenses of positive power and positive power in the third, and fourth aspects of the photo-taking optical system according to the present invention is described just below.

In a conventional system comprising two lenses each having positive power, the curvature of each lens is not very strong because the positive power is divided into halves with respect to the focal length of the overall system. For this reason, the amount of higher-order aberrations produced is so small that monochromatic aberrations such as spherical aberration and coma are in a generally good state. For this lens system comprising positive lenses alone, however, there is no choice but to reduce the amount of aberrations produced at the individual lenses so as to reduce longitudinal chromatic aberration, but it is in principle impossible to reduce them to zero. Thus, this system is less than satisfactory in terms of performance.

By using at least one diffractive surface in conjunction with a lens arrangement consisting of two lenses and having a positive-positive power profile according to the present invention, it is possible to make effective correction for chromatic aberrations and, hence, improve performance.

Incidentally, it is expected that, in view of performance improvements, inhomogeneous medium lenses are prefer-

able to homogeneous medium lenses because not only chromatic aberrations but also monochromatic aberrations such as coma can be corrected. However, inhomogeneous lenses are much higher in cost than homogeneous lenses, and so are not suitable for use on cameras, etc. because cost reductions are hardly achievable even though the number of inhomogeneous lenses used is reduced. In addition, the quality control, and manufacture of inhomogeneous lenses are more difficult than those of homogeneous lenses, and so the inhomogeneous lenses are not suitable for application to mass-produced cameras, etc. Thus, the inhomogeneous medium lenses may be favorable for performance improvements, but are generally more unfavorable than the homogeneous medium because grave problems arise in connection with cost, and productivity.

To accomplish the object of the present invention, therefore, it is desired that the diffractive surface be used in conjunction with two lenses each having positive power.

The fourth aspect of the phototaking optical system according to the present invention is described together with the features and advantages thereof.

When the lens system is constructed of only two lenses, it is often difficult to correct large aberrations produced at one lens with another lens. It is thus required that the amount of aberrations produced at the individual lenses be reduced as much as possible. Especially with a lens system having a positive-positive power profile, it is difficult to correct the second lens for spherical aberration and coma because a light beam passing through the second lens is more slender than that passing through the first lens. It is thus required that the amount of aberrations produced at the first lens be reduced as much as possible. This is achieved by allowing the first lens to have a shape convex toward the object side of the system, so that the aforesaid aberrations can be well corrected with considerable distortion and astigmatism reductions.

Accordingly, it is preferable for the first lens to satisfy the following condition (3):

$$-1<SF_1<0.15 \quad (3)$$

Here $SF_1=(r_A-r_B)/(r_A+r_B)$ where r_A is a radius of curvature of the first lens that faces the object side of the system, and r_B is a radius of curvature of the first lens that faces the image side of the system.

Condition (3) defines the shape factor of the first lens. When the upper limit of 0.15 is exceeded, the effect of the first lens on the correction of aberrations becomes slender due to its positive power decrease. When the lower limit of −1 is not reached, aberrations such as coma become worse with performance loss because the convexity of the first lens toward the object side of the system vanishes.

To achieve ever-higher performance, it is preferable for the first lens to satisfy the following condition (4):

$$-0.5<SF_1<0.08 \quad (4)$$

For the second to fourth phototaking optical system embodiments, it is noted that their Petzval's sum cannot be reduced to a sufficient level because they are composed only of positive lenses, and so their peripheral performance becomes worse due to field of curvature. However, this is avoided by allowing the image plane to have a cylindrical shape whose major or minor side has a given curvature, thereby making the influence of field of curvature less.

The fifth aspect of the phototaking optical system according to the present invention is explained together with the features and advantages thereof.

The system constructed of two positive lenses each having positive power has a demerit of being incapable of reducing the Petzval's sum to a sufficient level because it is composed only of positive lenses. For this reason, the field of curvature increases, offering a certain problem in connection with the peripheral performance. In addition, some limitation is in principle placed on an overall length reduction because the principal point is positioned in the vicinity of the center of the system.

If the system is constructed of two lenses, positive and negative, in order from the object side thereof, it is then possible to make correction for the Petzval's sum, and reduce the overall length of the system because the principal point is shifted toward the object side of the system. With an arrangement consisting of two lenses and having a positive-negative power profile, it is impossible to achieve a power profile best suited for the correction of chromatic aberrations and so make sufficient correction therefor. This is because if the power of the arrangement is too strong, spherical aberration and coma then become worse.

By using at least one diffractive surface in conjunction with the arrangement having a positive-negative power profile according to the present invention, it is possible to make effective correction for chromatic aberrations and so improve performance.

Such a system is better in performance than a conventional lens system, and enables a camera to be made more compact because its overall length can be reduced.

To achieve the object of the present invention, therefore, it is preferable that at least one diffractive surface is used in conjunction with the arrangement consisting of a lens of positive power and a lens of negative power in order from the object side of the system.

The sixth aspect of the phototaking optical system according to the present invention is explained together with the features and advantages thereof.

An arrangement consisting of two lenses and having a negative-positive power profile is described with reference to the sixth aspect of the phototaking optical system according to the present invention. With the arrangement having a positive-positive power profile, the field of curvature increases under the influence of the Petzval's sum, offering a certain problem in connection with the peripheral performance, as previously stated. In addition, since the principal point is positioned in the vicinity of the center of the arrangement, it is often impossible to ensure a sufficient back focus when the focal length of the system is short.

If the arrangement is constructed of two lenses, negative and positive, in order from the object side of the system, it is then possible to make correction for the Petzval's sum. In addition, the principal point is shifted toward the image side of the system in such a manner as to make sure of the back focus. With a conventional arrangement consisting of two lenses of negative power and positive power, however, it is impossible to achieve a power profile best suited for the correction of chromatic aberrations and hence make sufficient correction therefor. This is because when the power of the arrangement is too strong, spherical aberration and coma become worse.

By using at least one diffractive surface in conjunction with an arrangement consisting of two lenses and having a negative-positive power profile according to the present invention, it is possible to make effective correction for chromatic aberrations and so improve performance.

Such a system is better in performance than a conventional lens system, and can physically make sure of a back focus when applied to an optical system having a reduced

focal length, for instance, a wide-angle lens system or an optical system having a small image size, e.g., a lens for monitor cameras.

To achieve the object of the present invention, therefore, it is preferable that at least one diffractive surface is used in conjunction with an arrangement consisting of two lenses of negative power and positive power in order from the object side of the system.

For the fifth, and sixth phototaking optical system embodiments where one of the two lenses is a negative lens, it is required that the power of the positive lens is increased so as to make sure of the power of the overall system. It is noted, however, that the correction of chromatic aberrations and Petzval's sum, the overall length reduction of the system, etc. cause the power of the system to become strong, resulting in performance loss due to increases in the amount of aberrations produced at the individual lens surfaces. It is thus desired that, in addition to at least one diffractive surface, at least one aspheric surface be used in conjunction with the lens arrangement so that the aberrations can be well corrected.

For the fifth, and sixth phototaking optical system embodiments, it is desired that the negative lens satisfy the following condition (5):

$$-1.2<f/f_{NEG}<-0.05 \quad (5)$$

Here f is a focal length of the overall phototaking optical system and f_{NEG} is a focal length of the negative lens.

Condition (5) gives a definition of the power of the negative lens. When the upper limit of −0.05 is exceeded, the power of the negative lens becomes too weak to have an effect on the correction of chromatic aberrations and Petzval's sum, and below the lower limit of −1.2, the power of the negative lens becomes too strong to make correction for coma and astigmatism even when used in combination with the aspheric surface.

To achieve ever-higher performance, it is desirable for the negative lens to satisfy the following condition (6):

$$-0.9<f/f_{NEG}<-0.15 \quad (6)$$

With reference here to the second, third, fourth, fifth, and sixth phototaking optical system embodiments, where to locate the aperture stop is explained. In a conventional arrangement consisting of two lenses, some severe limitation is placed on where to locate an aperture stop for the purpose of making sure of performance, because it is impossible to make sufficient correction for chromatic aberration of magnification. By use of a DOE, however, it is possible to make the degree of freedom regarding where to locate the aperture stop higher than would be possible in the art because it is possible to make good correction for chromatic aberration of magnification.

Especially if the aperture stop is positioned on the object or image side of the system, a lens member can be positioned irrespective of a space allowed for lenses, and so can be mounted within a camera with a high degree of design.

The placement of the aperture stop between two lenses is favorable for the correction of coma because upper and lower portions of marginal rays can be cut off by the barrel of lenses, etc.

In the first, and second phototaking optical system embodiments, two lenses each of positive power may be used. By doing so, spherical aberration and coma are kept in good condition and monochromatic aberrations are maintained in generally good condition as well, as previously explained with reference to the third, and fourth phototaking optical system embodiment.

In the first, and second phototaking optical system embodiment, two lenses of negative power, and positive power may be used. By doing so, it is possible to eliminate the problem regarding the Petzval's sum, as previously explained in connection with the sixth phototaking optical system embodiment. This also enables even a lens system having a short focal length to readily make sure of the back focus.

In the first, third, fourth, fifth, and sixth phototaking optical system embodiments, only one diffractive surface may be used. By doing so, the problem regarding the unnecessary order of light may be solved to some extent and so any image quality drop may be avoided, as previously explained with reference to the second phototaking optical system embodiment.

In the first, second, fourth, fifth, and sixth phototaking optical system embodiments, all the lenses may be formed of a homogeneous medium. By doing so, the problems regarding cost and productivity may be settled to some extent, as previously explained with reference to the third phototaking optical system embodiment.

With reference to the problem regarding the unnecessary order of light, the preferable design order is 1 in the first to sixth phototaking optical system embodiments. FIG. **5** shows diffraction efficiency changes when the design order is 1 to 5 in equation (c) explained with reference to the prior art. From FIG. **5** it is found that as the design order increases, the diffraction efficiency drops sharply with wavelength changes in a wide wavelength range in which phototaking optical systems are used. To reduce the occurrence of flare due to the unnecessary order of light, therefore, it is preferable that the design order is 1 at which the minimum diffraction efficiency is obtained.

In reference to the same problem, it is preferable in the first to sixth phototaking optical system embodiments to use a design wavelength λ_{DOE} at which the maximum diffraction efficiency is achieved, as defined below.

$$470 \text{ nm}<\lambda_{DOE}<550 \text{ nm} \quad (9)$$

Condition (9) gives a definition of design wavelength λ_{DOE} in such a manner that flare due to DOE does not noticeably show up, while taking into account the transmittance of lenses, the spectral properties of film, CCD, etc., and the spectral properties of a light source. Above the upper limit of 550 nm or below the lower limit of 470 nm flare becomes relatively noticeable.

In addition, the first to sixth phototaking optical system embodiments may be modified as follows.

In some cases, the diffractive surface of a DOE is formed in a plane shape. If this is done, it is then easy to fabricate the diffractive surface. However, such a plane form of diffractive surface is unfavorable because coma is likely to occur with an increase in the angle of incidence of light thereon. For this reason and in view of the correction of aberrations, it is preferable to impart a certain curvature to the surface of the DOE providing the diffractive surface.

For a conventional lens system, achromatization is achieved by using a negative lens relative to a positive lens. In the case of a DOE having reciprocal dispersion, however, achromatization is achieved by using a DOE of positive power relative to a positive lens. In the lens system according to the present invention, too, it is preferable that the diffractive surface has positive power.

At this time, it is preferable that the power of the diffractive surface satisfies the following condition (7):

$$0.02<f/f_{DOE}<0.5 \quad (7)$$

Here f is a focal length of the overall phototaking optical system and f_{DOE} is a power of the diffractive surface.

When the upper limit of 0.5 in condition (7) is exceeded, the power of the diffractive surface becomes too strong to cause over-correction of chromatic aberrations, resulting in performance loss, and when the lower limit of 0.02 is not reached, the power of the diffractive surface becomes too small to cause under-correction of chromatic aberrations, resulting in no performance improvement.

To achieve ever-higher performance, it is desired that the power of the diffractive surface satisfies the following condition (8):

$$0.05<f/f_{DOE}<0.25 \quad (8)$$

The diffractive surface is preferably in a kinoform configuration because unnecessary light is reduced with good image quality by increasing the efficiency of utilization of light of the phototaking optical system. It is also preferable to use a so-called binary optical element that is a stepwise approximation of the kinoform configuration.

Plastic DOEs are best suited for use on cameras, etc., because they can be mass-produced by monolithic molding. Low-hygroscopicity plastic DOEs are less susceptible to shape changes due to humidity, and so deterioration of performance due to environmental changes. When DOEs are constructed of glass, etc., it is not easy to provide fine diffraction gratings on the surfaces of lenses. For ease of manufacture, it is then preferable to provide a diffraction grating on the surface of a thin resin layer formed on the surface of glass. In view of productivity, it is then preferable to use a resin curable by ultraviolet rays, heat, etc.

When a phototaking element is a CCD, etc., it is required to make an optical system telecentric because the quantity of light must be obtained by making the angle of incidence of light substantially vertical to the CCD. However, such an arrangement is not preferable because of an increased overall length. It is therefore preferable to set the exit pupil of the optical system at a finite position.

Still other objects and advantages of the invention will in part be obvious and will in part be apparent from the specification.

The invention accordingly comprises the features of construction, combinations of elements, and arrangement of parts which will be exemplified in the construction hereinafter set forth, and the scope of the invention will be indicated in the claims.

Examples 1 to 16 of the phototaking optical system of the invention using a diffractive optical element are now explained below.

The diffractive surface used in the lens system of the present invention has been designed using the ultra-high index technique, and is more specifically expressed in the form of a refractive lens having a refractive index of 1001 as measured at a thickness of 0 and a d-line wavelength. In numerical data given later, too, the diffractive surface is given by an ordinary aspherical formula as described below. That is, the aspherical shape is given by

$$Z=CY^2/[1+\sqrt{\{1-(1+K)C^2Y^2\}}]+A_4Y^4+A_6Y^6+A_8Y^8+A_{10}Y^{10} \quad (e)$$

where Z is an axis representing an optical axis direction, Y is an axis representing a direction perpendicular to the optical axis, C is a curvature of a surface apex (=1/r where r is a radius of curvature), K is a conical coefficient, and A_4, A_6, A_8, and A_{10} are fourth, sixth, eighth, and tenth aspherical coefficients, respectively.

A surface that is in contact with the diffractive surface at a thickness of 0 is a surface of DOE substrate material. In actual production, a phase change is first found from a difference between the aspherical shape of the diffractive surface and the surface shape of the substrate material, and the index of refraction. Then, this phase change is converted into the pitch of a diffraction grating, which is in turn formed on the surface of the substrate material. For this reason, the aspheric surface defined by the ultra-high index refractive lens does not actually exist, although referred to as a diffractive surface. It is noted, however, that the surface Number ("NO.") referred to as the diffractive surface in the numerical data is denoted as a substrate surface in the sectional schematic corresponding to each example.

Some specific shapes of the diffractive surface, for instance, are shown in section in FIG. **30**. A diffractive surface depicted in FIG. **30**(*a*) comprises an alternation of transparent portions **21**, and opaque portions **22** whose thickness is substantially zero, and is called an amplitude modulation type. A diffractive surface depicted in FIG. **30**(*b*) comprises an alternation of portions having different indices of refraction, i.e., a high-refractive-index portions **23** and low-refractive-index portions **24**, and produces diffraction action through a phase difference due to a refractive index difference. A diffractive surface depicted in FIG. **30**(*c*) comprises an alternation of convex and concave portions, each in a rectangular form, and produces diffractive action through a phase difference due to a thickness difference. This may be called a two-level binary element. A diffractive surface depicted in FIG. **30**(*d*), called a kinoform, is in a saw-toothed form, and produces diffractive action through a phase difference due to a continuous thickness difference (see FIG. **2**). Diffractive surfaces depicted in FIG. **30**(*e*) and **30**(*f*) are binary elements with the kinoform approximated at four, and eight levels, respectively (see FIG. **3**). In the present invention, it is desired to use the kinoform of FIG. **30**(*d*), and the binary element of FIG. **30**(*e*) or **30**(*f*), with the kinoform approximated at four or more levels, because the quantity of light can effectively be used at an increased diffraction efficiency.

Sectional schematics of Examples 1 through 16 including their optical axes are shown in FIGS. **6** through **21**. Set out below are Examples 1 through 16.

EXAMPLES 1 TO 4

In Examples 1, 2, 3 and 4 an aperture stop is located between two positive lenses, as can be seen from FIGS. **6**, **7**, **8**, and **9**, respectively. In Example 1 a first positive lens in a meniscus form that is convex toward an object side of the system, an aperture stop, and a second positive lens in a double convex form are located in order from the object side, and a diffractive surface (DOE) is formed on the object side of the first lens. In Examples 2, 3, and 4, a first positive lens in a meniscus form that is convex toward an object side of the system, an aperture stop, and a second positive lens in a meniscus form that is convex toward an image side of the system, are located in order from the object side. A diffractive surface is formed on the image side of the first lens in Example 2, on the object side of the second lens in Example 3, and on the image side of the second lens in Example 4. In Examples 2, 3, and 4 the diffractive surface is formed on an acrylic resin substrate. Throughout Examples 1 to 4, all the diffractive surfaces are in an aspheric form.

EXAMPLES 5 & 6

In Examples 5, and 6 an aperture stop is located between an object side of the system and an arrangement consisting of two positive lenses, as can be seen from FIGS. **10**, and **11**,

respectively. More specifically, the aperture stop, a first positive lens in a meniscus form that is convex toward the object side, and a second positive lens in a meniscus form that is convex toward an image side of the system are located in order from the object side, and two aspheric surfaces are used, one on the object side of the first positive lens and another on the image side of the second positive lens. A diffractive surface is formed on the image side of the first positive lens in Example 5, and on the object side of the second positive lens in Example 6. In Example 6, both the positive lenses are formed of acrylic resin and a diffractive surface is formed on the substrate of the second positive lens. In Examples 5, and 6 the diffractive surface is in an aspheric form.

EXAMPLES 7 & 8

In Examples 7, and 8 an aperture stop is located between an image side of the system and an arrangement consisting of two positive lenses, as can be seen from FIGS. **12**, and **13**, respectively. More specifically, a first positive lens in a meniscus form that is convex toward an object side of the system, a second positive lens in a meniscus form that is convex toward the image side, and the aperture stop are located in order from the object side. In Example 7 aspheric surfaces are formed, one on the object side of the first positive lens and another on the image side of the second positive lens, and in Example 8 an aspheric surface is formed on the object side of the first positive lens. A diffractive surface is formed on the image side of the first positive lens in Example 7, and on the object side of the second positive lens in Example 8. In Example 7 both the positive lenses are formed of polyolefinic resin of low hygroscopicity and the diffractive surface is formed on a substrate of the first positive lens. In Example 8 the diffractive surface is formed on the surface of a thin resin layer on a glass substrate. In both Examples 7 and 8 the diffractive surfaces are in an aspheric form.

EXAMPLES 9 & 10

In Examples 9, and 10 an aperture stop is located between an object side of the system and an arrangement consisting of two lenses, positive and negative, as can be seen from FIGS. **14**, and **15**, respectively. More specifically, a first positive lens in a meniscus form toward the object side, a second negative lens in a meniscus form convex toward an image side of the system, and the aperture stop are located in order from the object side, and aspheric surfaces are formed, one on the object side of the first positive lens and another on the image side of the second negative lens. A diffractive surface is formed on the image side of the first positive lens in Example 9, and on the object side of the second negative lens in Example 10. In Example 9 both the lenses are formed of polyolefinic resin of low hygroscopicity and the diffractive surface is formed on a substrate of the first positive lens. In Example 10 the diffractive surface is formed on the surface of a thin resin layer on a glass substrate. In both Examples 9 and 10 the diffractive surfaces are in an aspheric form.

EXAMPLE 11

In Example 11 an aperture stop is located between two lenses, positive and negative, in order from an object side of the system, as can been from FIG. **16**. More specifically, a first positive lens in a meniscus form that is convex toward the object side, the aperture stop, and a second negative lens that is in a meniscus form that is convex toward an image side of the system are located in order from the object side. Aspheric surfaces are formed, one on the object side of the first positive lens and two on both sides of the second negative lens, and a diffractive surface is formed on the image side of the first positive lens. The first positive lens is formed of acrylic resin while the second negative lens is formed of polycarbonate resin, and the diffractive surface is formed on a substrate of the first positive lens. This diffractive surface is in an aspheric form.

EXAMPLES 12 & 13

In Examples 12, and 13 an aperture stop is located between an object side of the system and an arrangement consisting of two lenses, negative and positive, in order from the object side, as can be seen from FIGS. **17**, and **18**, respectively. More specifically, the aperture stop, a first negative lens in a meniscus form convex toward the object side, and a second positive lens in a meniscus form convex toward an image side of the system are located in order from the object side. Two aspheric surfaces are used in Example 12, one on the object side of the first negative lens and another on the image side of the second positive lens, and three aspheric surfaces are used in Example 13, two on both surfaces of the first negative lens and one on the image side of the second positive lens. A diffractive surface is formed on the image side of the first negative lens in Example 12, and on the object side of the second positive lens in Example 13. In Example 12 the diffractive surface is formed on a low-hygroscopicity polyolefinic resin substrate of the first negative lens. In Example 13 the diffractive surface is formed on the surface of a thin resin layer provided on a glass substrate. The diffractive surface is in an aspheric form in Example 12, and in a spherical form in Example 13.

EXAMPLE 14

In Example 14 an aperture stop is located between two lenses, negative and positive, in order from an object side of the system, as can be seen from FIG. **19**. More specifically, a first negative lens in a meniscus form that is convex toward the object side, the aperture stop, and a second positive lens in a double-convex form are located in order from the object side. Aspheric surfaces are formed, one on the object side of the first negative lens and another on the image side of the second positive lens, and a diffractive surface is formed on the object side of the second positive lens. The first negative lens is formed of polycarbonate resin, and the second positive lens is formed of polyolefinic resin having low hygroscopicity. The diffractive surface is formed on the substrate of the second positive lens. The diffractive surface is in a spherical form.

EXAMPLES 15 & 16

In Examples 15, and 16 an aperture stop is located between an image side of the system and an arrangement consisting of two lenses, negative and positive, in order from an object side of the system, as can be seen from FIGS. **20**, and **21**, respectively. More specifically, a first negative lens in a meniscus form that is convex toward the object side, a second positive lens that is in a meniscus lens convex toward the image side, and the aperture stop are located in order from the object side. Aspheric surfaces are formed in Example 15, one on the object side of the first negative lens and another on the image side of the second positive lens, and three aspheric surfaces are formed in Example 16, two on both surfaces of the first negative lens and on the image side of the second negative lens. A diffractive surface is

formed on the image side of the first negative lens in Example 15, and on the object side of the second positive lens in Example 16. In Example 15 the first negative lens is formed of polycarbonate resin on which the diffractive surface is provided. The diffractive surface is in an aspheric form in Example 15, and in a spherical form in Example 16.

Enumerated below are numerical data about Examples 1 to 16, wherein f=focal length, F_{NO}=F-number, F_B=back focus, ω=half field angle, r_1, r_2, etc.=radii of curvature of lens surfaces, d_1, d_2, etc.=spacing between lens surfaces, n_{d1}, n_{d2}, etc.=d-line refractive indices of lenses, and ν_{d1}, ν_{d2}, etc.=d-line Abbe number. The aspheric shape is represented by the aforesaid equation (e). Note that the abbreviation "DIFER. SF" indicates a diffractive surface.

As can be seen from the foregoing explanation, a high-performance optical system which, albeit being composed of a reduced number of lenses, is well corrected for chromatic aberrations can be achieved by proper use of diffractive surfaces, whereby a high-performance phototaking optical system used on cameras, etc. can be provided at low cost.

What we claim is:

1. A phototaking optical system making use of a diffractive optical element, which comprises an aperture stop, at

least two lenses having at least one diffractive surface, and satisfies the following condition (1):

$$0<d_{DOE}/f<0.24 \quad (1)$$

where f is a focal length of the overall phototaking optical system, and d_{DOE} is a distance on an optical axis of the phototaking optical system from the aperture stop to the diffractive surface.

2. A phototaking optical system according to claim **1**, wherein said at least two lenses are the only lenses in said phototaking optical system.

3. A phototaking optical system making use of a diffractive optical element, which comprises an aperture stop, one positive lens and another positive lens in order from an object side of the phototaking optical system, at least one of said lenses having at least one diffractive surface, and both said lenses being formed of a homogeneous medium.

4. A phototaking optical system making use of a diffractive optical element, which comprises an aperture stop, one positive lens and another positive lens in order from an object side of the phototaking optical system and at least one diffractive surface, and satisfies the following condition (3):

$$-1<SF_1<0.15 \quad (3)$$

where $SF_1=(r_A-r_B)/(r_A+r_B)$ wherein r_A is a radius of curvature of a surface of the first lens that faces the object side, and r_B is a radius of curvature of a surface of the first lens that faces an image side of the phototaking optical system.

5. A phototaking optical system making use of a diffractive optical element, which comprises an aperture stop, one negative lens and one positive lens in order from an object side of the phototaking optical system, at least one of said lenses having at least one diffractive surface.

6. A phototaking optical system according to claim **5**, which satisfies the following condition (5):

$$-1.2<f/f_{NEG}<-0.05 \quad (5)$$

where f is a focal length of the overall phototaking optical system and f_{NEG} is a focal length of the negative lens.

7. A phototaking optical system according to claim **5**, wherein at least one of said lenses has an aspheric surface in addition to the at least one diffractive surface.

8. A phototaking optical system according to claim **2** or **3**, wherein the aperture stop is located on a side of an arrangement consisting of the two lenses that faces the object side of the phototaking optical system.

9. A phototaking optical system according to claim **2** or **3**, wherein the aperture stop is located between the two lenses.

10. A phototaking optical system according to claim **2** or **3**, wherein the aperture stop is located on a side of an arrangement consisting of the two lenses that faces the image side of the phototaking optical system.

11. A phototaking optical system according to claim **1** or **4**, which includes only one diffractive surface.

12. A phototaking optical system according to claim **1** or **3**, wherein the diffractive surface is formed on a curved lens surface.

13. A phototaking optical system according to claim **1** or **3**, wherein both the lenses are formed of a homogeneous medium.

14. A phototaking optical system according to claim **1** or **3**, wherein the diffractive surface has a positive power.

15. A phototaking optical system according to claim **14**, wherein the diffractive surface satisfies the following condition (7):

$$0.02<f/f_{DOE}<0.5 \quad (7)$$

where f is a focal length of the overall phototaking optical system and f_{DOE} is a power of the diffractive surface.

16. A phototaking optical system according to claim **1** or **3**, which satisfies the following condition (9):

$$470 \text{ nm}<\lambda_{DOE}<550 \text{ nm} \quad (9)$$

where λ_{DOE} is a design wavelength at which a maximum diffraction efficiency is obtained.

17. A phototaking optical system making use of a diffractive optical element, which comprises an aperture stop, one positive lens and one negative lens in order from an object side of the phototaking optical system, at least one of said lenses having at least one diffractive surface, wherein said phototaking optical system satisfies the following condition (5):

$$-1.2<f/f_{NEG}<-0.05 \quad (5)$$

where f is a focal length of the overall phototaking optical system and f_{NEG} is a focal length of the negative lens.

18. A phototaking optical system making use of a diffractive optical element, which comprises an aperture stop, one positive lens and one negative lens in order from an object side of the phototaking optical system, at least one of said lenses having a diffractive surface, and at least one of said lenses having an aspheric surface.

19. A phototaking optical system making use of a diffractive optical element, which comprises an aperture stop and two lenses, at least one of said lenses having a diffractive surface, wherein the aperture stop is located between the two lenses.

20. A phototaking optical system making use of a diffractive optical element, which comprises an aperture stop and two lenses, at least one of said lenses having a diffractive surface, wherein the aperture stop is located on a side of an arrangement consisting of the two lenses that faces the image side of the phototaking optical system.

21. A phototaking optical system making use of a diffractive optical element, which comprises an aperture stop and two lenses, at least one of said lenses having a diffractive surface, wherein the diffractive surface is formed on a curved lens surface.

22. A phototaking optical system making use of a diffractive optical element, which comprises an aperture stop and two lenses, at least one of said lenses having a diffractive surface, wherein the diffractive surface has positive power.

23. A phototaking optical system making use of a diffractive optical element, which comprises an aperture stop and two lenses, at least one of said lenses having a diffractive surface, which satisfies the following condition (9):

$$470 \text{ nm}<\lambda_{DOE}<550 \text{ nm} \quad (9)$$

where λ_{DOE} is a design wavelength at which a maximum diffraction efficiency is obtained.

24. A phototaking optical system making use of a diffractive optical element according to claim **19** or **20**, wherein said two lenses are the only lenses in said phototaking optical system.

25. A phototaking optical system according to claim **22**, wherin the diffractive surface satisfies the following condition (7):

$$0.02<f/f_{DOE}<0.5 \quad (7)$$

where f is a focal length of the overall phototaking optical system and f_{DOE} is a power of the diffractive surface.

[57] **ABSTRACT**

Objective lenses (e.g., for microscopy), and adapters for such lenses, are disclosed providing adjustability of the amount of spherical aberration imparted to an image by an objective lens due to variations in cover glass thickness. The adapter can be axially inserted imagewise of the objective lens, or between a first objective lens and a second objective lens of an objective lens system. The adapter comprises an axially movable lens group comprising a cemented lens including a negative lens and a positive lens and a cemented surface having negative refractive power. Spherical aberration of the objective lens is adjusted by axially moving the movable lens group. Where r_1 is the curvature radius of the cemented surface, n_P is the refractive index of the positive lens, n_N is the refractive index of the negative lens, the lens satisfies the condition $|(n_N-n_P)/r_1|<0.3$.

FIG. 13

ADAPTERS FOR CORRECTING SPHERICAL ABERRATIONS OF OBJECTIVE LENS

FIELD OF THE INVENTION

This invention pertains to light microscopy. More specifically, the invention pertains to adapter lenses that are used in connection with a microscope objective lens system (or other objective lens system) to correct spherical aberrations arising from variations in the refractive index and thickness of a refractive body (e.g., cover glass, laboratory dish, parallel plate) located between a specimen and the objective lens system.

BACKGROUND OF THE INVENTION

In light microscopy, cover glasses or laboratory dishes and the like are frequently used to cover, enclose, or protect the specimen. Microscope objective lenses intended to be used with cover glasses and the like normally specify a specific refractive index and thickness of the cover glass. Consequently, whenever the thickness or refractive index of the cover glass or laboratory dish is not as specified for the objective lens, spherical aberrations can arise that degrade imaging performance of the objective lens and reduce contrast of the image.

Metallurgical microscopes and the like used to observe metal and semiconductor surfaces typically utilize objective lenses that are not designed to be used with a cover glass or other refractive body between the specimen and the objective lens. Thus, such objective lenses are designed without consideration of the thickness of a refractive body through which the lens would otherwise view the object. In actual practice, however, there are times when a glass plate or the like must be used to protect the surface of a semiconductor wafer or integrated circuit during microscopic examination. In such instances, the generation of spherical aberrations by the plate can make high-quality observations of the specimen impossible.

Immersion objective lenses adapted to be used with an immersion fluid such as water or oil are also adapted to be used with such fluids having a particular refractive index. If the refractive index of the immersion fluid changes, then unwanted spherical aberrations can arise that make high-quality observations impossible.

In certain conventional objective lenses intended for use with a refractive body situated between the objective lens and the specimen (e.g., cover glass or wall of a laboratory dish), an adjustable correcting lens (adjusted by turning a so-called "correcting ring") is conventionally employed to vary the internal spacing between lenses or lens groups within the objective lens. The amount by which the lens spacing is adjusted is a function of the amount of spherical aberration generated by the refractive body. The adjustment serves to offset changes in such spherical aberration as viewed by the observer. Microscope objective lenses of this sort are disclosed in Japanese laid-open patent document nos. Sho 60-205521 and Sho 60-247613.

Conventional adjustable objective lenses require that a considerable amount of air space be provided in front of (i.e., objectwise) and behind (i.e., imagewise) certain lens groups in the objective lens to provide a sufficient range of adjustment. Such space requirements significantly limit the degrees of freedom that can be exploited in the design of the objective lens, thus increasing the difficulty with which the performance of the lens can be optimized.

Another problem with conventional adjustable objective lenses is that the mechanical device used to move the movable lens(es) lenses had to be located in the objective lens. This undesirably increased the size and complexity of the objective lens.

With conventional objective lenses that are not designed to be used with an intervening cover glass or the like between the lens and the specimen, if a specimen were observed with a cover glass in place, spherical and other aberrations caused by the thickness of the cover glass reduce the contrast of the observed image, thus making high-quality observations impossible.

SUMMARY OF THE INVENTION

In view of the shortcomings of the prior art, as summarized above, the present invention provides, inter alia, adapters intended to be used with an objective lens system (e.g., microscope objective lens systemA) for adjusting the spherical aberration of the objective lens system.

A preferred embodiment of an adapter comprises, from the object side to the image side, a movable lens group comprising a negative lens cemented to a positive lens to define a cemented surface having negative refractive power. The movable lens group is axially movable on the optical axis. The adapter satisfies at least the following condition:

$$|(n_N-n_P)/r_1|<0.3$$

wherein n_P is the refractive index of the positive lens, n_N is the refractive index of the negative lens, and r_1 is the curvature radius of the cemented surface. The adapter is axially mountable to an objective lens system. If the objective lens system comprises only one objective lens, then the adapter is axially placed on the image side of the objective lens. If the objective lens system comprises first and second objective lenses (the second objective lens being, e.g., a so-called "tube lens" or "imaging lens"), then the adapter is axially placed between the first objective lens and the second objective lens. Movement of the movable lens group along the optical axis relative to the objective lens system allows correction of spherical aberration of an image formed by the objective lens system.

The adapter preferably also satisfies the conditions:

$$-0.6<(f_P+f_N)/(f_P-f_N)<0.6$$

$$-0.4<(\nu_P-\nu_N)/\nu_P<0.4$$

wherein f_P is the focal length of the positive lens, f_N is the focal length of the negative lens, ν_P is the Abbe number (relative to d-line light) of the positive lens, and ν_N is the Abbe number (relative to d-line light) of the negative lens.

The adapter can further comprise a first lens group situated imagewise of the movable lens group and a second lens group situated imagewise of the first lens group. The first lens group has a negative refractive power and a focal length f_1, and the second lens group has a positive refractive power and a focal length f_2. Such an adapter further satisfies the condition:

$$-0.6<(f_2+f_1)/(f_2-f_1)<0.6$$

The adapter can also comprise a positive lens situated objectwise of the movable lens group.

According to another aspect of the invention, objective lens systems are provided. A first representative embodiment of such a system comprises, objectwise to imagewise on an optical axis, an objective lens and an adapter removably attached to the image side of the objective lens. The adapter is coaxial with the objective lens when attached to the

objective lens, and comprises a movable lens group comprising a negative lens cemented to a positive lens. The resulting cemented surface has a negative refractive power and a curvature radius r_1. The movable lens group satisfies at least the condition:

$$|(n_N-n_P)/r_1|<0.3$$

in which the variables are as defined above. The movable lens group is movable on the optical axis relative to the first objective lens to adjust an amount of spherical aberration produced by the objective lens.

In the foregoing lens system, the adapter can further satisfy the conditions:

$$-0.6<(f_P+f_N)/(f_P-f_N)<0.6$$

$$-0.4<(\nu_P-\nu_N)/\nu_P<0.4$$

in which the variables are as defined above. The adapter can further comprise a first lens group situated imagewise of the movable lens group and a second lens group situated imagewise of the first lens group. The first lens group has a negative refractive power and a focal length f_1, and the second lens group has a positive refractive power and a focal length f_2. Such an adapter can further satisfies the condition:

$$-0.6<(f_2+f_1)/(f_2-f_1)<0.6$$

Another representative embodiment of an objective lens system further comprises a first objective lens and a second objective lens situated axially imagewise of the first objective lens. The adapter is situated between the first objective lens and the second objective lens.

According to another aspect of the invention, objective lens systems are provided that exhibit variable spherical aberration correction. One representative embodiment of such a lens system comprises, objectwise to imagewise on an optical axis, an objective lens and a spherical-aberration-correcting lens group (adapter) situated on the image side of the objective lens. Another representative embodiment comprises a first objective lens and a second objective lens, with the spherical-aberration-correcting lens group situated between the first objective lens and the second objective lens. In either instance, the spherical-aberration-correcting lens group comprises an axially movable cemented lens including a negative lens cemented to a positive lens for adjusting the spherical aberration of the objective lens(es). The spherical-aberration-correcting lens group preferably is removable from the objective lens(es).

The cemented lens preferably has a cemented surface having a negative refractive power. The lens system preferably satisfies the condition:

$$|(n_N-n_P)/r_1|<0.3$$

in which the variables are as defined above.

The lens system can further satisfy the conditions:

$$-0.6<(f_P+f_N)/(f_P-f_N)<0.6$$

$$-0.4<(\nu_P-\nu_N)/\nu_P<0.4$$

in which the variables are as defined above.

The spherical-aberration-correcting lens group can further comprise a first lens group situated imagewise of the movable lens group, and a second lens group situated imagewise of the first lens group. The first lens group has a negative refractive power and a focal length f_1, and the second lens group has a positive refractive power and a focal length f_2. The system preferably further satisfies the condition:

$$-0.6<(f_2+f_1)/(f_2-f_1)<0.6$$

The foregoing and additional features and advantages of the present invention will be more readily apparent from the following detailed description which proceeds with reference to the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** depicts general aspects of the placement and movement of an adapter lens according to the invention, in a converging light flux; this figure accompanies a discussion herein of the effect of the adapter lens on spherical aberrations.

FIG. **2** is an optical diagram of an adapter lens according to Example Embodiment 1 of the invention.

FIG. **3** is an optical diagram of the adapter lens of Example Embodiment 1 in axial alignment with a microscope objective lens.

FIG. **4** includes plots of spherical aberration, astigmatism, and coma exhibited by the microscope objective lens of FIG. **3** as used with a cover glass thickness of 0.17 mm but without an adapter lens according to the invention.

FIG. **5** includes plots of spherical aberration, astigmatism, and coma exhibited by the microscope objective lens of FIG. **3** as used with a cover glass thickness of 0.23 mm but without an adapter lens according to the invention.

FIG. **6** includes plots of spherical aberration, astigmatism, and coma exhibited by the microscope objective lens of FIG. **3** as used with the adapter lens of Example Embodiment 1 and with a cover glass thickness of 0.17 mm.

FIG. **7** includes plots of spherical aberration, astigmatism, and coma exhibited by the microscope objective lens of FIG. **3** as used with the adapter lens of Example Embodiment 1 and with a cover glass thickness of 0.23 mm.

FIG. **8** is an optical diagram of an adapter lens according to Example Embodiment 2 of the invention.

FIG. **9** includes plots of spherical aberration, astigmatism, and coma exhibited by microscope objective lens of FIG. **3** as used with the adapter lens of Example Embodiment 2 and with a cover glass thickness of 0.17 mm.

FIG. **10** includes plots of spherical aberration, astigmatism, and coma exhibited by microscope objective lens of FIG. **3** as used with the adapter lens of Example Embodiment 2 and with a cover glass thickness of 0.23 mm.

FIG. **11**(*a*) depicts axial movement of the movable lens group relative to rays of an "infinite correction" objective lens.

FIG. **11**(*b*) depicts axial movement of the movable lens group in a system as depicted in FIG. **11**(*a*) but including the lens group L_0.

FIG. **12**(*a*) is an optical diagram of an adapter according to the invention comprising the cemented movable lens group **M1** and the positive lens L_0, producing a convergent downstream light flux.

FIG. **12**(*b*) is an optical diagram of an adapter according to the invention comprising the cemented movable lens group **M1**, the positive lens L_0, and the lenses L_1, and L_2, producing a parallel downstream light flux.

FIG. **13** is an optical diagram of an objective lens system according to the invention, comprising an objective lens and an adapter located on the image side of the objective lens.

DETAILED DESCRIPTION

The present invention is directed to spherical-aberration-correcting adapter lens assemblies ("adapters") used in

conjunction with a microscope objective lens system or analogous lens system. An adapter according to the invention can serve to effectively cancel (or at least significantly reduce) spherical aberrations that otherwise would exist in the image formed by the objective lens system due to variations in the thickness or other refractive property of a "cover glass" placed between a specimen and the objective lens system.

As used herein, a "cover glass" is understood to encompass any of various conventional cover glasses, coverslips, laboratory dishes, plates, immersion fluids, and the like that can be placed between the objective lens system and the specimen, typically to protect or contain the specimen. Cover glasses according to this definition can be made of any suitable transparent material, such as glass or plastic, and thus exhibit a refractive property with respect to light passing through the cover glass.

The adapters according to the invention are preferably detachable from the objective lens. Thus, an adapter can be attached to the objective lens (e.g., inserted between an objective lens and an image plane of the objective lens, or inserted between a "first" objective lens and a "second" objective lens), inserted between an objective lens system and the objective-lens turret, or between the turret and the image formed by the objective lens system. By axially moving the movable lens group in the adapter, spherical aberrations generated by variations in the thickness or other refractive characteristic of the cover glass can be cancelled or otherwise controlled to the desired degree.

An adapter according to the invention generally comprises an axially movable lens group comprising a cemented lens **M1** (FIG. **1**) including (objectwise to imagewise) a negative lens N and a positive lens P. The axially movable lens group can also comprise, as required, additional single and/or cemented lenses. The cemented lens can further comprise additional lens(es) as required; e.g., the cemented lens can be a cemented triplet (positive-positive-negative, or negative-positive-negative). The cemented surface S of the cemented lens **M1** has a negative refractive power. Spherical aberration is corrected by axially moving the movable lens group. The adapter preferably satisfies the following condition:

$$|(n_N-n_P)/r_1|<0.3 \quad (1)$$

wherein r_1 is the curvature radius of the cemented surface, n_P is the refractive index of the positive lens P, and n_N is the refractive index of the negative lens N of the cemented lens **M1**.

Condition (1) stipulates the appropriate degree of spherical-aberration correction imparted by the cemented surface S of the cemented lens **M1** in the movable lens group. Exceeding the upper limit of condition (1) reduces the effect on correcting spherical aberration. I.e., the change in spherical aberration imparted by the movable lens group is prohibitively small per unit movement of the movable lens group along the optical axis AX, thereby providing insufficient correction of spherical aberration. Falling below the lower limit causes a higher order spherical aberration, which makes it difficult to effectively correct aberrations.

An adapter according to the invention also preferably satisfies conditions (2) and (3):

$$-0.6<(f_P+f_N)/(f_P-f_N)<0.6 \quad (2)$$

$$-0.4<(\nu_P-\nu_N)/\nu_P<0.4 \quad (3)$$

wherein f_P and f_N are the focal lengths of the positive lens P and the negative lens N, respectively, of the cemented lens **M1**, and ν_P and ν_N are the Abbe numbers (relative to d-line light; λ=587.6 nm) of the positive and negative lenses P, N, respectively.

Condition (2) establishes an appropriate range of focal lengths of lenses in the movable lens group. Exceeding the upper limit or falling below the lower limit of condition (2) causes the refractive index of the entire movable lens group to be so high that axially moving the movable lens group in an effort to correct spherical aberration causes excessive movement of the image. Such a situation makes it prohibitively difficult to ascertain whether image contrast has degraded due to defocusing or to spherical aberration. This, in turn, makes it prohibitively difficult to find a setting at which spherical aberration is optimally corrected, and to focus the image.

Exceeding the upper limit of condition (3) causes an excessive change in the correction of chromatic aberrations by the movable lens group whenever the movable lens group is axially moved, thus changing the "balance" achieved by correction of chromatic aberration. This also causes a reduction in contrast. Falling below the lower limit of condition (3) renders the movable lens group incapable of providing sufficient correction of chromatic aberrations as the movable lens group is axially moved. This results in degraded contrast with a change in the "balance" of chromatic aberration correction, making high-quality observations impossible.

The adapter of the present invention is preferably co-axially mounted with respect to the objective lens system. In the case of a so-called "infinite correction" objective lens system, the objective lens system with which the adapter is used typically comprises a "first" objective lens and a "second" objective lens (the second objective lens being, e.g., a so-called "tube lens" or "imaging lens"). With such a system, the adapter is preferably inserted coaxially ("intercalated") between the first objective lens and the second objective lens. (FIG. **3**, for example, shows the adapter intercalated between first and second objective lenses of an infinite-correction objective lens system.) A so-called "finite" correction" system typically lacks a second objective lens because imaging is performed by one objective lens. With a finite correction system the adapter is inserted between the actual objective lens and the image plane of the objective lens. (FIG. **13** shows the adapter inserted on the image side of an objective lens of a finite-correction objective lens system.)

Especially whenever the adapter is inserted into a parallel optical flux (such as between a first objective lens G1 and a second objective lens G2 of an objective lens system having infinite correction), the following condition (4) is preferably satisfied, especially whenever the adapter comprises (in addition to the movable group) a negative lens L_1 and a positive lens L_2:

$$-0.6<(f_2+f_1)/(f_2-f_1)<0.6 \quad (4)$$

wherein f_1 is the focal length of the negative lens L_2, and f_2 is the focal length of the positive lens L_2. Such an adapter is shown in FIG. **2**. It will be understood that the adapter shown in FIG. **2** can be inserted into either a parallel light flux or a non-parallel light flux.

A function of the movable lens group (comprising the cemented lens **M1**) is illustrated in FIG. **1**, which shows, by way of example, the cemented lens **M1** in two different positions along the optical axis AX. In FIG. **1**, a light flux from a point on an object (e.g., on the specimen) propagates along an optical axis AX and is converged by lenses in the objective lens situated toward the specimen. Moving the cemented lens **M1** along the optical axis AX changes

spherical aberration. I.e., in FIG. **1**, when the movable lens group is placed in a convergent light flux, the entrance height H of the light flux on the cemented surface S of the cemented lens **M1** changes. The greater the height H of the light flux incident on the cemented surface, the greater the spherical aberration imparted by the cemented surface. Thus, changing the height H correspondingly changes the spherical aberration.

If the light flux between the first objective lens and the second objective lens of the objective lens system is parallel, the objective lens system is characteristically an "infinite correction" objective lens system. If an axially movable lens group as described above were to be inserted between the first objective lens and the second objective lens of such a system, the height H (and thus spherical aberration) would not change with axial movement of the movable lens group, no matter how far along the optical axis the movable lens group were moved (FIG. **11**(*a*)). To make the adapter functional in such a situation, a lens group L_0 (see, e.g., FIG. **2**), preferably having a positive refractive power, can be inserted between the movable lens group and the first objective lens G1 of the objective lens system; the lens L_0 causes the light flux to be not parallel (preferably convergent) to the optical axis, and enables the movable lens group to provide variable control of the amount of spherical-aberration correction (FIG. **11**(*b*)). I.e., with such a configuration, moving the movable lens group along the optical axis would cause a corresponding change in the height H and thus a corresponding change in spherical aberration. The adapter in such a configuration comprises the movable lens group and the lens group L_0.

With an objective lens system that includes a first objective lens and a second objective lens, the movable lens group, and the lens L_0, the light flux leaving the movable lens group may not be parallel to the optical axis (FIG. **12**(*a*)). Thus, the image plane of the objective lens system changes with movement of the movable lens group along the optical axis. This can complicate use of the objective lens system for microscopy. To correct such a situation, a negative lens group L_1 can be used in combination with a positive lens group L_2 on the image side of the movable lens group (FIG. **12**(*b*)) to restore the image plane to the same position on the optical axis at which the image plane was located before the adapter was inserted. In such a configuration, the adapter comprises the lens group L_0, the movable lens group **M1**, the negative lens L_1, and the positive lens L_2.

Exceeding the upper limit or falling below the lower limit of condition (4) disrupts the desired balance of power between the positive lens L_2 and the negative lens L_1, which increases the absolute value of the Petzval's sum of the adapter. This, in turn, degrades the flatness of the image plane of the objective lens system.

An adapter according to the invention is axially inserted at least on the image side of an objective lens. Thus, in a "finite correction" objective lens system as representatively depicted in FIG. **13**, the resulting corrected objective lens system comprises the objective lens G1 and the adapter. The adapter shown in FIG. **13** comprises an axially movable lens group comprising a cemented lens M_1 including a positive lens P and a negative lens N.

In an "infinite correction" objective lens system as representatively depicted in FIG. **3** and corrected by including an adapter, the resulting corrected objective lens system comprises the adapter intercalated between the first objective lens G1 and the second objective lens G2.

Adapters (and objective lens systems) according to the invention now make it possible to correct spherical aberrations that would otherwise arise in an existing objective lens system used with, e.g., cover glasses having any thickness within a range of thicknesses rather than only a single specified thickness. This is accomplished by inserting an adapter according to the invention on the image side of an objective lens or between a first objective lens and a second objective lens of an objective lens system. This eliminates the need to use a "correcting ring" objective lens with its inherent limitations. Also, with a single adapter according to the invention, a much greater flexibility of microscopic observations can be realized without having to have on hand a large assortment of expensive objective lenses for correcting spherical aberrations arising from any of various cover glass thicknesses.

Several example embodiments of the invention are described below, which represent the current best mode of the invention. It will be understood that the invention is not intended to be limited to these example embodiments.

Example Embodiment 1

An adapter according to this example embodiment is shown in FIG. **2**. FIG. **3** shows the adapter of FIG. **2** intercalated between a first objective lens G1 and a second objective lens G2 of a microscope objective lens system exhibiting "infinite correction." In FIG. **3**, the first objective lens G1 has a focal length f_{G1}=10 mm, and the second objective lens has a focal length f_{G2}=200 mm. The magnification of the entire objective lens system shown in FIG. **3** is 20×, and the numerical aperture is 0.75.

Specifications for the objective lens system shown in FIG. **3** are listed in Tables 1 and 2. Data are listed in order from the object side. Table 1 lists optical data concerning the first and second objective lenses G1, G2 without the adapter being inserted; and Table 2 lists optical data with the adapter inserted. In each of Tables 1 and 2, the first column lists lenses, the second column lists surface numbers, the third column lists curvature radii (r), the fourth column lists axial distances (D) between adjacent surfaces, the fifth column lists refractive indices n(d) relative to d-line light (λ=587.6 nm), and the sixth column lists Abbe numbers ν(d) relative to d-line light of the respective optical components.

Tables 1 and 2 also list a lens mirror and tube prism that are not shown in FIG. **1**.

Plots of spherical aberration, astigmatism, and coma for the first and second objective lenses as used with a cover glass thickness of t=0.17 mm are shown in FIG. **4**. (For the spherical aberration plot in FIG. **4** as well as in FIGS. **5**–**7** and **9**–**10**, the line denoted "C" pertains to C-line light (λ=656.28 nm), the line denoted "d" pertains to d-line light (λ=587.56 nm), the line denoted "F" pertains to F-line light (λ=486.13 nm), and the line denoted "g" pertains to g-line light (λ=435.84 nm)). All determinations are based on the axial space (d_2) between the first objective lens G1 and the second objective lens G2 being 100 mm.

In FIG. **5** are plots of spherical aberration, astigmatism, and coma for the first and second objective lenses as used with a cover-glass thickness of t=0.23 mm. Comparing FIGS. **4** and **5**, it can be seen that FIG. **5** exhibits more pronounced aberrations than FIG. **4**.

Table 2 lists specifications of the first and second objective lenses used together with an adapter according to the present invention.

TABLE 2-continued

Lens	Surface No.	r (mm)	D (mm)	n (d)	ν (d)
		d_1 = 5 mm	t = 0.17~0.23 mm		
		d_2 = 78.55 mm	d_0 = 1.398~1.392 mm		

FIGS. **6** and **7** are plots of spherical aberration, astigmatism, and coma exhibited by the objective lens system of FIG. **3** (with adapter according to this example embodiment inserted between the first objective lens G1 and the second objective lens G2) as used with a cover glass thickness (t) of 0.17 mm and 0.23 mm, respectively. As can be seen by comparing FIGS. **5** and **7**, when the cover glass thickness (t) is changed from 0.17 mm to 0.23 mm, spherical aberration and other aberrations increase. However, by inserting an adapter according to this example embodiment between the first objective lens G1 and the second objective lens G2, spherical aberrations are corrected to a remarkable degree.

Example Embodiment 2

FIG. **8** shows the lens configuration of an adapter according to this example embodiment. The microscope objective lens system with which the adapter is used is, by way of example, the same as used with the adapter of Example Embodiment 1. Lens specifications are listed in Table 3 below.

FIGS. **9** and **10** are plots of spherical aberration, astigmatism, and coma exhibited by a microscope objective

lens system as shown in FIG. **3** used with an adapter according to this example embodiment and with a cover-glass thickness of t=0.17 mm and 0.23 mm, respectively. As can be seen by comparing FIG. **5** with FIG. **10**, when the cover glass thickness (t) is changed from 0.17 mm to 0.23 mm (and without an adapter present), spherical aberrations and other aberrations increase. However, by inserting the adapter of this example embodiment and axially moving the movable lens group to an appropriate position, spherical aberrations are corrected to a remarkable degree.

In Example Embodiments 1 and 2, the light flux on the object side and the image side of the subject adapter is parallel to the optical axis. Thus, the same beneficial function of reducing spherical aberrations can be realized by reversing the lens configuration of the adapter.

Values of variables and of conditions (1)–(4) as exhibited by Example Embodiments 1 and 2 are listed in Table 4 below.

Variable	Example Embodiment 1	Example Embodiment 2
n_P	1.766840	1.766840
n_N	1.548139	1.531721
r_1	19.5842	19.43468
Condition (1)	0.0112	0.121
f_P	38.418	38.809
f_N	−27.119	−27.257
Condition (2)	0.1724	0.17486
ν_P	45.869	48.966
ν_N	46.804	46.804
Condition (3)	−0.02038	0.02137
f_2	89.487	86.02
f_1	−39.038	−39.076
Condition (4)	0.392523	0.3752

Therefore, with an adapter according to this invention, spherical aberrations and other aberrations imparted to a objective lens system by variations in the thickness of a "cover glass" can be corrected to a high degree. By attaching such an adapter to an existing objective lens system, spherical aberrations can be controlled to the desired degree. It will be understood that, in addition to microscope objective lens systems, an adapter according to the invention can also be used with other optical systems such as a camera optical system.

Whereas the invention has been described in connection with several example embodiments, it will be understood that the invention is not limited to those embodiments. On the contrary, the invention is intended to encompass all alternatives, modifications, and equivalents as may be included within the spirit and scope of the invention as defined by the appended claims.

What is claimed is:

1. An adapter for correcting spherical aberration of an objective lens, the adapter comprising, from an object side to an image side on an optical axis:

(a) a movable lens group comprising a negative lens cemented to a positive lens to define a cemented surface having negative refractive power and a curvature radius r_1, the movable lens group being axially movable on the optical axis;

(b) the adapter satisfying the condition:

$$|(n_N-n_P)/r_1|<0.3$$

wherein n_P is the refractive index of the positive lens and n_N is the refractive index of the negative lens; and

(c) the adapter being axially mountable to an image side of an objective lens to allow correction, by axially moving the movable lens group relative to the objective lens system, of spherical aberration of an image formed by the objective lens.

2. The adapter of claim **1**, further satisfying the conditions:

$$-0.6<(f_P+f_N)/(f_P-f_N)<0.6$$

$$-0.4<(\nu_P-\nu_N)/\nu_P<0.4$$

wherein f_P is the focal length of the positive lens, f_N is the focal length of the negative lens, ν_P is the Abbe number (relative to d-line light) of the positive lens, and ν_N is the Abbe number (relative to d-line light) of the negative lens.

3. The adapter of claim **2**, further comprising:

a first lens group situated imagewise of the movable lens group, the first lens group having negative refractive power and a focal length f_1; and

a second lens group situated imagewise of the first lens group, the second lens group having positive refractive power and a focal length f_2, the adapter further satisfying the condition:

$$-0.6<(f_2+f_1)/(f_2-f_1)<0.6.$$

4. The adapter of claim **3**, further comprising a positive lens situated objectwise of the movable lens group.

5. The adapter of claim **1**, further comprising:

a first lens group situated imagewise of the movable lens group, the first lens group having negative refractive power and a focal length f_1; and

a second lens group situated imagewise of the first lens group, the second lens group having positive refractive power and a focal length f_2, the adapter further satisfying the condition:

$$-0.6<(f_2+f_1)/(f_2-f_1)<0.6.$$

6. The adapter of claim **5**, further comprising a positive lens situated objectwise of the movable lens group.

7. An objective lens system, comprising, objectwise to imagewise on an optical axis:

(a) an objective lens; and

(b) an adapter removably attached to the image side of the objective lens and coaxial with the objective lens when attached to the objective lens, the adapter comprising a movable lens group comprising a negative lens cemented to a positive lens to define a cemented surface having negative refractive power and a curvature radius r_1, the movable lens group satisfying the condition:

$$|(n_N-n_P)/r_1|<0.3$$

wherein n_P is th e refractive index of th e positive lens and n_N is the refractive index of the negative lens, the movable lens group being movable on the optical axis relative to the objective lens to adjust an amount of spherical aberration produced by the objective lens.

8. The lens system of claim **7**, wherein the adapter further satisfies the conditions:

$$-0.6<(f_P+f_N)/(f_P-f_N)<0.6$$

$$-0.4<(\nu_P-\nu_N)/\nu_P<0.4$$

wherein f_P is the focal length of the positive lens, f_N is the focal length of the negative lens, ν_P is the Abbe number (relative to d-line light) of the positive lens, and ν_N is the Abbe number (relative to d-line light) of the negative lens.

9. The lens system of claim 8, wherein the adapter further comprises:

a first lens group situated imagewise of the movable lens group, the first lens group having negative refractive power and a focal length f_1; and

a second lens group situated imagewise of the first lens group, the second lens group having positive refractive power and a focal length f_2, the adapter further satisfying the condition:

$$-0.6<(f_2+f_1)/(f_2-f_1)<0.6.$$

10. The lens system of claim 7, wherein the adapter further comprises:

a first lens group situated imagewise of the movable lens group, the first lens group having negative refractive power and a focal length f_1; and

a second lens group situated imagewise of the first lens group, the second lens group having positive refractive power and a focal length f_2, the adapter further satisfying the condition:

$$-0.6<(f_2+f_1)/(f_2-f_1)<0.6.$$

11. The lens system of claim 10, wherein the spherical-aberration-correcting lens group further comprises:

a first lens group situated imagewise of the movable lens group, the first lens group having negative refractive power and a focal length f_1; and

a second lens group situated imagewise of the first lens group, the second lens group having positive refractive power and a focal length f_2, the spherical-aberration-correcting lens group further satisfying the condition:

$$-0.6<(f_2+f_1)/(f_2f_1)<0.6.$$

12. An objective lens system exhibiting variable spherical aberration correction, the lens comprising objectwise to imagewise on an optical axis:

(a) a first objective lens;

(b) a second objective lens; and

(c) a spherical-aberration-correcting lens group situated between the first objective lens and the second objective lens, the spherical-aberration-correcting lens group comprising an axially movable cemented lens including a negative lens cemented to a positive lens for adjusting the spherical aberration of the first objective lens and the second objective lens, the spherical-aberration-correcting lens group being removable from between the first objective lens and the second objective lens.

13. The lens system of claim 12, wherein the cemented lens has a cemented surface having a negative refractive power, the lens system satisfying the condition:

$$|(n_N-n_P)/r_1|<0.3$$

wherein r_1 is the curvature radius of the cemented surface, n_P is the refractive index of the positive lens and n_N is the refractive index of the negative lens of the cemented lens.

14. The lens system of claim 13, further satisfying the conditions:

$$-0.6<(f_P+f_N)/(f_P-f_N)<0.6$$

$$-0.4<(\nu_P-\nu_N)/\nu_P<0.4$$

wherein f_P is the focal length of the positive lens, f_N is the focal length of the negative lens, ν_P is the Abbe number (relative to d-line light) of the positive lens and ν_N is the Abbe number (relative to d-line light) of the negative lens.

[57] **ABSTRACT**

Structural components are added to an interferometric objective to offset the effects of temperature variations. The components are mounted between the sleeve housing the optics of the objective and the collar housing the optics of the interferometer. Each component is coupled sequentially, such that the thermal response of the assembly is substantially the linear combination of the response of each component and is designed to cause a shift in the opposite direction to the shift produced by a temperature change in the unmodified device. The thermal characteristics and dimensions of the components are chosen empirically to provide a minimum shift between the reference mirror and focal point in the interferometric objective as a function of temperature.

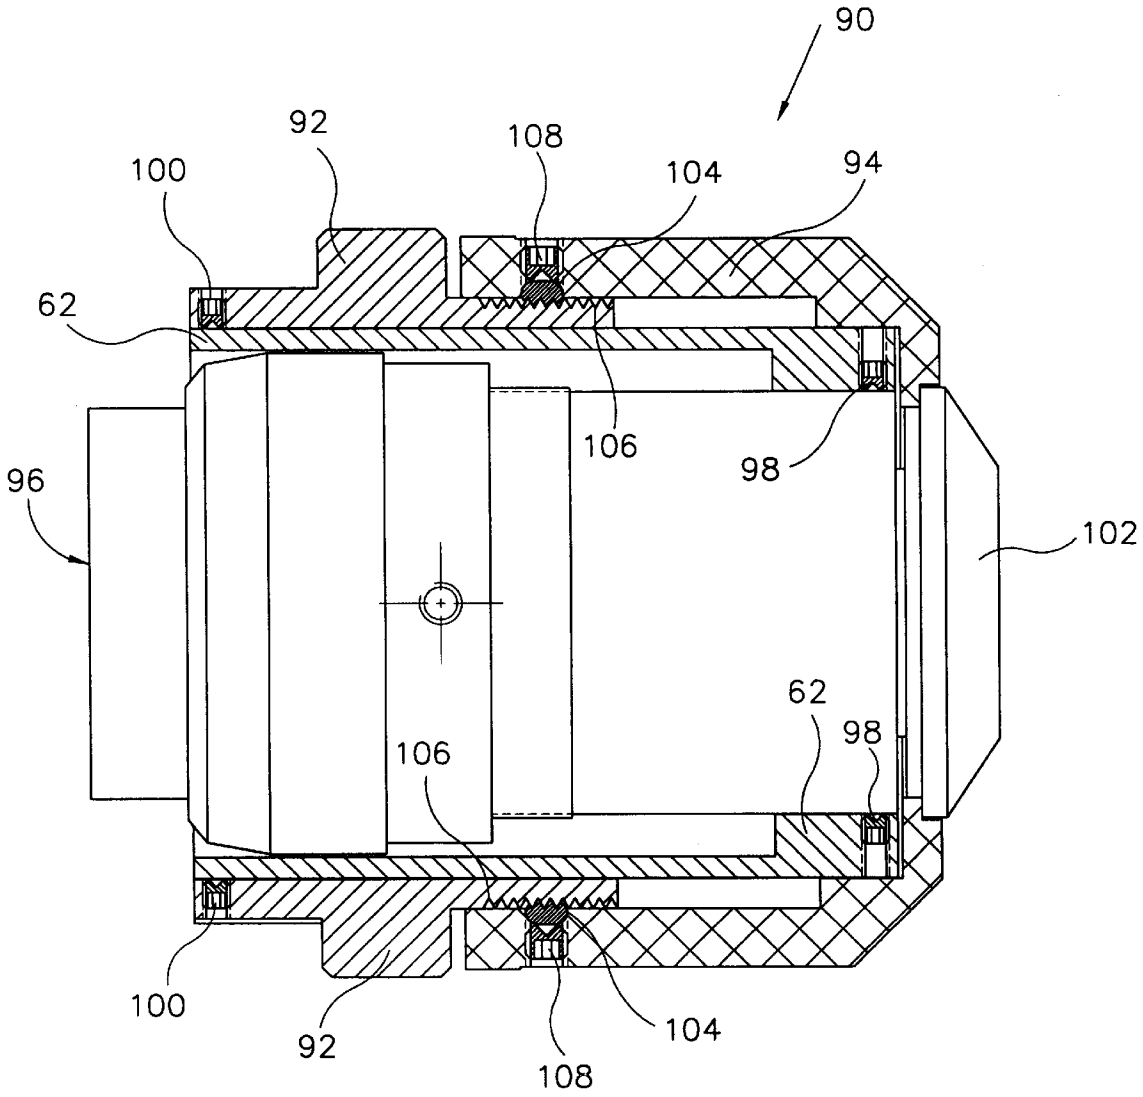

FIG. 12

METHOD AND APPARATUS FOR CORRECTING SHIFTS BETWEEN A REFERENCE FOCAL POINT AND A REFERENCE SURFACE AS A RESULT OF THERMAL EFFECTS IN AN INTERFEROMETRIC OPTICAL OBJECTIVE

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention is related in general to the field of interferometry and, in particular, to a method and apparatus for minimizing shifts between the focal point and the reference mirror caused by thermal effects in the optical microscope objective of an interferometer.

2. Description of the Related Art

Many interferometric devices utilize microscope objectives for focusing beams of light on a sample surface and a reference surface to produce interference fringes representative of the optical path difference (OPD) between the two. As illustrated in simple schematic form in FIG. **1**, typical interferometric apparatus **10** consists of a light source **12** directing a beam L of light through an illuminator **14** toward a beam splitter **16**, which reflects the light in the direction of a test surface S. The light reflected by the beam splitter **16** passes through a microscope objective **22** focused on the test surface S and incorporating an interferometer (not seen in the figure). The interferometer, such as a Mirau device, for example, comprises a beam splitter and a reference mirror, such that the light beam directed to the sample surface S is split and also directed to the reference mirror. As is well understood by those skilled in the art, the light beams reflected from the reference mirror and the test surface S (the reference and test beams, respectively) are combined to produce interference fringes as a result of the optical path difference between the reference mirror and the test surface S. The light is typically passed back through the interferometric microscope objective **22** and through the beam splitter **16** toward an imaging array **24** positioned in a camera **26** in coaxial alignment with the objective **22**. The imaging array **24** typically consists of individual charge-coupled-device (CCD) cells or other sensing apparatus adapted to record a two-dimensional array of signals corresponding to interference effects produced by the interferometer as a result of light reflected at individual x-y coordinates or pixels in the surface S and received at corresponding individual cells in the array. Appropriate electronic hardware (not shown) is also provided to process the signals generated by each cell and transmit them to a computer for further processing. Thus, an interference-fringe map is generated by detecting the intensity of the light signal received in each cell of the array **24**. Additional information about the test surface S can be gained by varying the OPD between the reference and test surfaces with a scanning device (not shown) translating either the reference surface or the test surface.

The present invention is directed at an unsolved problem caused by thermal effects in the typical interferometric objective **22** of the interferometer. As illustrated schematically in FIG. **2**, a conventional interferometric objective **22** consists of microscope-objective optics **30** adapted to focus the light beam L at a test focal point P on the test surface S of the object being measured. For the purpose of this disclosure, the light beam L is assumed to come from an object location an infinite distance behind the microscope objective, thereby locating the test focal point P defined here at the focal point of the objective. As one skilled in the art would readily understand, though, the disclosure applies equally to the case where the source of beam L is located a finite distance behind the objective and the test focal point P does not coincide with the focal point of the objective. Thus, while the "infinite conjugates" imaging condition, as understood in the art, is used here to simplify the description of the invention, the description can be generalized with no loss of accuracy to the "finite conjugates" imaging condition.

The optics in the objective **30** are rigidly housed in a coaxial support sleeve **32** substantially along the entire length of the objective. A focusing sleeve **34** is mounted on the support sleeve **32** so that it can move along the optical axis X of the assembly for focusing the light beam L at the test focal point P. To produce the fine adjustments required for interferometric applications, the focusing sleeve **34** is typically coupled to the support sleeve **32** by means of a threaded engagement (seen in FIG. **12**) along the interior of the sleeve **34**, such as on the inside surface of the end collar **36**.

As also shown in the enlarged partial view contained in FIG. **2**, the focussing sleeve **34** includes a beam splitter **38** and a reference flat **40** with a reference mirror **42** attached to the reference surface **44**. By rotating the focusing sleeve **34** with respect to the support sleeve **32**, their relative axial position is shifted as needed to focus the light beam L on the reference surface **44**. Obviously, the threaded engagement between the two structures is provided with the pitch necessary to produce the focusing adjustments required by the application. By design, once the beam L is focused on the object to be measured, the light reflected from the reference mirror **42** and from the test surface S is combined at the surface **46** of the beam splitter **38** and reflected back through the objective **30** for the necessary interferometric measurements. Therefore, it is critical for good interferometric measurements that the distance between the surface **46** on the beam splitter and the reference mirror **42** remain the same as the distance between the surface **46** and the test focal point P (that is, the reference focal point P' must remain on the mirror **42**). For the purposes of this disclosure, the distance between the splitter's surface **46** and the reference mirror **42** is defined as the "reference length" and the distance between the surface **46** and the test focal point P is defined as the "test length." Thus, the reference length is selected by design such that the position of the reference mirror **42** is conjugate to the location of the test focal point P after the focusing of the objective on the test sample.

In practice, thermal effects cause component shifts that result in material changes in the focal length of the objective. When that happens, the test length changes and a mismatch occurs between the focal position of the test surface and the position of the reference mirror. As shown in FIG. **3**, the nominal design configuration when the interferometric objective **22** is focused on the test surface S is illustrated by condition B, which is optimal, while mismatched configurations caused by thermal effects are shown as conditions A and C. Specifically, condition A is caused by a temperature change that results in an increase of the focal length of the objective, while condition C is produced by a temperature change that results in a decrease of the focal length. Under condition A, assuming, for purposes of illustration, that the distance between the splitter's surface **46** and the reference surface **44** (the reference length) remains unaffected by the change in ambient temperature, when the test beam is focused on the test surface S, the reference focal point P' is shifted beyond the reference mirror **42** and the image reflected by the mirror is out of focus. Similarly, under

condition C the reference focal point P'is shifted ahead of the mirror **42** with the same result. Obviously, the interplay between the coefficients of thermal expansion of the various components in the objective **22** determines exactly what happens as a result of any departure from the design temperature for the device. Moreover, the reference length does not in fact remain constant through temperature variations, but also contributes to the mismatch illustrated above. As discussed above with respect to the test focal point P, the "infinite conjugates" imaging condition is used for simplicity of disclosure, but the description can be generalized with no loss of accuracy to the "finite conjugates" imaging condition with respect to the reference focal point P' as well.

Thus, the temperature dependence of the characteristics of conventional interferometric objectives affects the performance of the instruments under varied temperature conditions. Therefore, it would be very desirable to provide a solution to this problem.

BRIEF SUMMARY OF THE INVENTION

One primary object of this invention is an interferometric objective that has performance characteristics substantially independent of ambient temperature variations.

Specifically, an important goal of the invention is an objective wherein the distance between the reflective surface of the beam splitter in the interferometer and the reference mirror remains substantially the same as the distance between that surface and the focal point of the objective during ambient-temperature variations.

Another object of the invention is a method and apparatus that can be implemented with conventional interferometric objectives.

Still another goal is a method and apparatus that are suitable for incorporation within existing instruments.

A final object is a procedure that can be implemented easily and economically according to the above stated criteria.

Therefore, according to these and other objects, the present invention consists of the addition of structural components in an interferometric objective to offset the effects of temperature variations. The components are mounted between the sleeve housing the optics of the objective and the collar housing the optics of the interferometer. Each component is coupled sequentially, such that the thermal response of the assembly is substantially the linear combination of the response of each component and is designed to cause a shift in the opposite direction to the shift produced by a temperature change in the unmodified device. The thermal characteristics and dimensions of the components are chosen empirically to provide a minimum separation between the reference mirror and focal point in the interferometric objective as a function of temperature.

Various other purposes and advantages of the invention will become clear from its description in the specification that follows and from the novel features particularly pointed out in the appended claims. Therefore, to the accomplishment of the objectives described above, this invention consists of the features hereinafter illustrated in the drawings, fully described in the detailed description of the preferred embodiment and particularly pointed out in the claims. However, such drawings and description disclose but one of the various ways in which the invention may be practiced.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a simplified schematic representation of prior-art apparatus used in phase shifting and vertical scanning interferometry.

FIG. **2** is a schematic representation of a conventional microscope objective incorporating interferometric optics in Mirau configuration.

FIG. **3** illustrates the mismatch between the test and the reference focal lengths of a conventional interferometer caused by ambient temperature variations.

FIG. **4** illustrates the reference length and the test length in the microscope objective of FIG. **2** under nominal temperature conditions.

FIG. **5** is a schematic representation of a conventional interferometric microscope objective modified according to the invention.

FIGS. **6–9** illustrate the typical, substantially linear relationship between the shift in the position of the reference focal point with respect to the reference mirror with temperature changes in four commercial interferometric objectives.

FIG. **10** is a plot of average measured height of a fixed structure versus focal point shift to illustrate the parabolic nature of the correlation.

FIG. **11** shows four plots of average height measurements of fixed structures as a function of temperature variations for the same objectives of FIGS. **6–9** with one objective modified according to the invention.

FIG. **12** is a schematic representation of a conventional interferometric microscope objective modified according to an alternative embodiment of the invention.

DESCRIPTION OF THE PREFERRED EMBODIMENTS OF THE INVENTION

The present invention is based on the discovery that the shift in position of the reference focal point with respect to the reference mirror in an interferometric objective as a function of temperature variations is roughly linear within the temperature range of interest. Accordingly, since the thermal expansion of most materials within a relatively narrow temperature range is also substantially linear, the invention consists of adding structural components to the objective with the appropriate thermal characteristics required to offset the objective's thermal response and empirically produce an assembly with an effective coefficient of thermal expansion substantially equal to zero within the temperature range of interest.

Referring to the drawings, wherein like parts are designated throughout with like numerals and symbols, FIG. **4** illustrates the optimal condition for operation of a conventional interferometric objective **22**. The distances traveled by the reference beam RB and the test beam TB are defined in terms of structural segments in the objective **22**. Note that a longitudinal position **48** is chosen to represent an average circumferential line of rigid connection within the attachment collar **36** coupling the support and focusing sleeves **32,34**. In fact, the two sleeves are coupled through a surface (the threaded interior surface of the attachment collar **36** mating with the threaded exterior surface of the support sleeve **32**), but the approximation is necessary to provide a longitudinal position corresponding to an effective point of attachment between the two sleeves. Thus, after entering the objective **22**, the reference beam RB (at that point coextensive with the beam L) travels a distance D**1** from the entry point **50** to the point of attachment **48**, then a distance D**2** to the splitter's surface **46**, and finally a distance D**3** to the reference focal point P'. Similarly, the test beam TB travels a distance D**4** from the entry point **50** to the focal point P. The goal of the invention is to manipulate the thermal

characteristics of the objective's components so that the paths to the reference mirror and to the test focal point (and therefore also to the reference focal point) retain substantially equal lengths in spite of temperature fluctuations. Expressed mathematically, it is desired that

$$D1(T)+D2(T)+D3(T)=D4(T), \quad (1)$$

where T is the temperature of the objective.

For various specific objectives, we discovered that the difference between the two paths as a function of temperature is substantially linear; that is,

$$\Delta D(T)=D1(T)+D2(T)+D3(T)-D4(T)=a+bT, \quad (2)$$

where a and b are the intercept and slope of a straight line equation. Note that $a=-bT_n$, T_n being the nominal temperature of the instrument at which $\Delta D(T_n)=0$ by design. Therefore, the goal is to modify the effective coefficient of expansion of the objective so that

$$\Delta D(T)=a+bT\approx 0 \quad (3)$$

for all T in the range of interest. This condition is achieved, of course, when $b\approx 0$.

This understanding of the structure and physical characteristics of the various components in an interferometric objective make it possible to judicially select appropriate materials and components to offset thermal effects. Referring to FIG. **5**, the structure of an interferometric objective **60** modified according to the invention is illustrated. The collar portion **35** (FIGS. **2** and **4**) housing the splitter **38** and reference flat **40** in the original focusing sleeve **34** is separated from the cylindrical portion of the sleeve and coupled to the support sleeve **32** by two new, substantially cylindrical components **62** and **63**. These components are coupled sequentially to increase the length of the material responsive to thermal effects and provide an opportunity to control the assembly's behavior by selecting materials with the appropriate thermal characteristics. Thus, a first component **62** is attached to and directed backward from the forward portion of the support sleeve **32**; then, a second component **63** is attached to and directed forward from the backward portion of component **62**, and is finally coupled to the original collar portion **35**. Thus, a thermal effect will result substantially in the linear combination of the effect on each individual segment of the assembly.

In this new configuration, the distances traveled by the reference beam RB and the test beam TB are defined in terms of the new structural segments in the objective **60**. As in the case of FIG. **4**, longitudinal positions **48** and **64** are chosen to represent average points of rigid connection within respective attachment collars **36** and **66**. The position **64** is intended to represent the position of an effective circumferential line of attachment between the support sleeve **32** and the first component **62**; and the position **48** represents the position of an effective circumferential line of attachment between the first component **62** and the second component **63**. The second component **63** is then connected to the collar portion **35** so as to form an integral member (such as by a solid connection along the annular surface **37**). As in the case illustrated in FIG. **4**, in fact the various members constituting the structure of the objective **60** are coupled through surface attachment (one of which is threaded for focusing purposes), but the line-contact approximations are necessary to provide longitudinal positions corresponding to effective points of attachment between the various components.

Based on the configuration of FIG. **5**, after entering the objective **60**, the reference beam RB (coextensive with the beam L at the point of entry) travels a distance D**0** forward from the entry point **50** to the splitter's surface **46**, and then a distance D**4** backward to the reference focal point P'. Similarly, the test beam TB travels a distance D**5** from the entry point **50** to the focal point P. Analyzing the thermal effects on the structure of the objective **60**, the distance D**0** varies as a result of the composite lengthening or shortening of the support sleeve **32**, the first component **62**, the second component **63**, and the collar portion **35**. So long as the contact surfaces in the attachment collars **36** and **66** are relatively small in comparison to the lengths of the various members (so that the effective-point-of-attachment approximation discussed above is valid), the distance D**0** can be expressed in terms of the distance D**1** from the entry point **50** to the point of attachment **66** between the support sleeve **32** and the first component **62**, the distance D**2** to the point of attachment **48** of the first component **62** to the second component **63**, and the distance D**3** to the splitter's surface **46**, as follows

$$D0(T)=D1(T)-D2(T)+D3(T). \quad (4)$$

Since the goal of the invention remains to manipulate the thermal characteristics of the objective's components so that the reference and test lengths remain substantially equal in spite of temperature fluctuations, the following new identity becomes the desirable goal of the invention

$$D1(T)-D2(T)+D3(T)+D4(T)=D5(T), \quad (5)$$

where T is the temperature of the objective.

That is, the length and material of the components **62** and **63** can be selected so that the shift caused by a temperature differential ΔT between the reference and test lengths is substantially zero within the temperature range of operation. Since the total path length variation ΔD with temperature is the result of the cumulative effect of the length change in each structural segment, the change along the reference beam caused by a temperature differential ΔT is given by

$$\Delta D=\Delta D1-\Delta D2+\Delta D3+\Delta D4 \quad (6)$$

Assuming that the support sleeve **32** and the collar portion **35** are made of the same material **1** with a coefficient of thermal expansion k_1 and that the components **62** and **63** are made of materials **2** and **3** with coefficient of thermal expansion k_2 and k_3, respectively, Equation 6 can be expressed in terms of the length and thermal-expansion coefficient of each segment, as follows

$$\Delta D=k_1D1(\Delta T)-k_2D2(\Delta T)+k_3D3(\Delta T)+k_1D4\ (\Delta T). \quad (7)$$

Furthermore, based on the experimental observation that over the temperature of interest the length of the test beam D**5** varies approximately linearly with temperature, the following can be written:

$$\Delta D5=KD5(\Delta T) \quad (8)$$

where K is an approximate linear expansion coefficient including both mechanical and optical temperature effects on the length of the test beam.

Setting Equation 7 equal to ΔD**5** yields the relation necessary to produce zero relative shift between the reference and test lengths as a function of temperature, thereby producing the approximate a thermal behavior that is desired

for the interferometric objective of the invention. This relation can be written as:

$$KD5=k_1(D1+D4)-k_2D2+k_3D3. \quad (9)$$

Based on Equation 9, it is possible to judiciously select materials for components **62** and **63** that will approximate the desired zero-shift behavior. Once k_2 and k_3 are selected, lengths for D2 and D3 can also be selected to fit the equation, and then optimized by empirical testing to account for the analytical approximations of the procedure. We found that this theoretical approach, further refined with empirical data, produces great improvements in the performance of conventional interferometric objectives.

For example, a Nikon objective model CF Plan 50x/0.55 DI, Part No. 405001, originally constructed with a support sleeve **32** (about 3.6 cm long) and a focusing sleeve **34** made of brass, was modified according to the invention by providing intermediate components **62** and **63** substantially as shown in FIG. **5**. Invar **36** (an iron alloy with 36% nickel and small quantities of manganese, silicon, and carbon) was selected for component **62**. Invar **36** is used in optical instruments because of its very low coefficient of thermal expansion (~1.26 ppm/° C.) over the limited temperature range of interest for most commercial applications (typically between 4 and 38° C.). An aluminum alloy (alloy 6061, made with 0.6 silicon, 0.25 copper, 1.0 magnesium, and 0.2 chromium, having a coefficient of thermal expansion of ~23.6 ppm/° C.) was selected for component **63**. The combination showed excellent thermal behavior for the purposes of the invention, where D2 and D3 were approximately 3.6 cm and 3.8 cm long, respectively.

FIGS. **6–9** illustrate the typical, substantially linear relationship between the shift in the position of the reference focal point P' with respect to the reference mirror **42** with temperature changes in four commercial interferometric objectives. Note that each figure represents data from three sets of measurements fitted with a straight line for a given objective. Each line 70,72,74,76 represents the particular thermal characteristics of its corresponding objective.

Based on the discovery illustrated in FIGS. **6–9**, the corrective approach disclosed above was followed with the object of designing intermediate components **62** and **63** that would reduce the slope of the lines **72–76** to zero. In order to provide flexibility of design for the components **62** and **63** of the invention, we found that the materials selected should preferably combine a relatively low with a relatively high coefficient of thermal expansion. By incorporating the Invar **36** and aluminum components described above in the tested Nikon objectives in a structural configuration of the type shown in FIG. **5**, we were able to change the objective's thermal characteristics and produce a substantially a thermal response. In fact, the thermal response of the modified objectives was so small that it was not possible to directly measure the shift in the position of the reference focal point P' with respect to the reference mirror **42** as a function of temperature changes because it was found to be within the measurement error.

In order to overcome this difficulty, we exploited a correlation, which is well known in the art, between measured heights and focal point shifts resulting from temperature variations. It is known that height measurements of a specific structure on a test surface decrease for temperatures both below and above the nominal temperature of the instrument (that is, the temperature at which the reference mirror **42** is in focus by design or calibration), producing parabolic plots of height versus focal-point-shift of the type shown in FIG. **10** (wherein the data are curve fitted to illustrate their parabolic nature). A corresponding parabolic plot is also produced by height-versus-temperature measurements. Therefore, the effectiveness of the invention was confirmed by plotting the measured average height of a fixed structure in a sample surface as the position of the focal point with respect to the reference mirror (or viceversa) was changed by induced temperature variations. In practice, a flattening of the height-versus-temperature curve produced by the structural modifications of the invention is a measure of a corresponding flattening of the shift-versus-temperature curve of FIGS. **6–9**, which is the goal of the invention.

Accordingly, the invention was tested by plotting average height measurements of a fixed structure as a function of temperature within the range of interest. The structure used consisted of laser texture bumps in a computer drive disk. FIG. **11** shows such plots for the same objectives of FIGS. **6–9** with one objective (#4) modified according to the invention. The parabolic data **80**, **82** and **84** correspond to unmodified objectives with nominal temperatures of about 20, 22 and 25° C., while the substantially linear data **86** correspond to the objective modified according to the invention. Note that data **82** and **86** were fitted by least squares techniques to illustrate the parabolic and substantially linear nature of these data. It is clear from the figure that the addition of components **62** and **63** produced a substantially a thermal objective for which no nominal temperature is identifiable.

It is understood that the concept of the invention is applicable to minimize thermal effects in optical devices with different structural configurations from the objective of FIG. **4**. Components may be added with different lengths and shapes as determined necessary to neutralize focal-point thermal shifts within the temperature range of interest. FIG. **12** is an assembly drawing of another embodiment **90** of the invention where the second component **63** is divided into a fixed portion **92** and a rotatably-movable focusing portion **94**. A commercial interferometric objective **96**, such as the Nikon objective described above, is mounted to the components constituting the invention. One end of a cylindrical first component **62** made of Invar alloy is fixedly connected to the support sleeve of the objective (not seen in the drawing) by means of radial set screws **98**. The fixed portion **92**, made of aluminum alloy, is fixedly connected to the other end of the first component **62** by means of similar set screws **100** (note that no other fixed contact exists between the two structures, so that they are free to move with respect to one another as a result of thermal effects). Finally, the focusing portion **94** is fixedly connected to the collar **102** containing the interferometric optics in the objective **96** and is screwably connected to the fixed portion **92**. The screwable connection is provided by means of radially-distributed threaded inserts **104** meshed with conforming threads **106** (shown enlarged for convenience) in the outer surface of the fixed portion **92**, so that the focusing portion **94** can be rotated and shifted axially to focus the test beam on a sample surface (not shown). Set screws **108** are also used to cause and adjust the engagement of the inserts **104** with the threads **106**.

The invention has been described for convenience illustrating an interferometric objective in horizontal position. In practice, these objectives are usually mounted in vertical position and translated to perform vertical scanning downward from an initial reference position. Similarly, the invention has been described in terms of the effective addition of two new components having a length approximately equal to that of the objective, but different lengths and more or less components could obviously be used if necessary to achieve

the goals of the invention. For example, the first and second components **62**,**63** in FIG. **5** could be extended beyond the length of the objective to provide additional overall thermal expansion. Equivalently, multiple layers of Invar and aluminum components could be connected sequentially and stacked to produce the same effect. Finally, materials with different thermal-expansion characteristics could be used to match the requirements of the particular application.

It is also understood that the concept of the invention is applicable in equivalent fashion not only to interferometric microscope objectives but to any optical device exhibiting a substantially linear focal point misalignment in response to thermal effects and where a second surface must be held in focus throughout some temperature range of interest. In devices exhibiting a nonlinear, but known, thermal response, the invention could still be practiced by assuming a linear behavior over a limited range around the nominal temperature of the instrument. For example, the device's thermal response could be approximated by a linear model over the range of interest and the model could then be used as described to minimize thermal shifts.

Therefore, various changes in the details, steps and components that have been described may be made by those skilled in the art within the principles and scope of the invention herein illustrated and defined in the appended claims. While the present invention has been shown and described herein in what is believed to be the most practical and preferred embodiments, it is recognized that departures can be made therefrom within the scope of the invention, which is not to be limited to the details disclosed herein but is to be accorded the full scope of the claims so as to embrace any and all equivalent processes and products.

We claim:

1. In an optical device including a reference surface fixed in a first support structure and lens means housed in a second support structure for focusing a beam of light onto said surface along an optical axis, said first and second support structures being mechanically connected by rigid coupling means having a length responsive to thermal effects, and the optical device having an optimal operating condition at a predetermined nominal temperature wherein a focal point position of said lens means coincides with a location of said reference surface along said optical axis, a method for maintaining substantial coincidence of said focal point position with said location of the reference surface with temperature variations, the method comprising the following steps:

establishing a first functional relationship between a range of temperature variations and shifts produced thereby in said focal point position with respect to an entry point in the optical device;

establishing a second functional relationship between said range of temperature variations and shifts produced thereby in said location of the reference surface with respect to the entry point in the optical device;

altering said length responsive to thermal effects by introducing at least one additional component in the rigid coupling means connecting the first and second support structures; and

selecting a length and a coefficient of thermal expansion of said at least one additional component adapted to maintain a substantial identity between said first and second functional relationships such that said shifts in the focal point position and in the location of the reference surface with respect to the entry point in the optical device are approximately equal, thereby causing said optimal operating condition to be substantially maintained within the range of temperature variations.

2. The method of claim **1**, wherein said optical device consists of an interferometric microscope objective, said first structure consists of a collar fixedly housing said surface, and said second structure consists of a sleeve fixedly housing said lens means.

3. The method of claim **2**, wherein said first and second functional relationships are substantially linear.

4. The method of claim **2**, wherein said at least one additional component comprises a first component coupled to said sleeve and a second component coupled to said collar.

5. The method of claim **4**, wherein said first and second components are coupled to one another so as to produce an increase in said length responsive to thermal effects.

6. The method of claim **3**, wherein said at least one additional component comprises a first component coupled to said sleeve and a second component coupled to said collar.

7. The method of claim **6**, wherein said first and second components are coupled to one another so as to produce an increase in said length responsive to thermal effects.

8. The method of claim **5**, wherein said first component comprises a portion made with an iron-nickel alloy and said second component comprises a portion made with an aluminum alloy.

9. The method of claim **7**, wherein said first component comprises a portion made with an iron-nickel alloy and said second component comprises a portion made with an aluminum alloy.

10. In an optical device including a reference surface fixed in a first support structure and lens means housed in a second support structure for focusing a beam of light onto said surface along an optical axis, said first and second support structures being mechanically connected by rigid coupling means having a length responsive to thermal effects, and the optical device having an optimal operating condition at a predetermined nominal temperature wherein a focal point position of said lens means coincides with a location of said reference surface along said optical axis, apparatus for maintaining substantial coincidence of said focal point position with said location of the reference surface with temperature variations, the apparatus comprising:

at least one additional component incorporated in the rigid coupling means connecting the first and second support structures;

wherein said at least one additional component is selected according to the following procedure:

establishing a first functional relationship between a range of temperature variations and shifts produced thereby in said focal point position with respect to an entry point in the optical device;

establishing a second functional relationship between said range of temperature variations and shifts produced thereby in said location of the reference surface with respect to the entry point in the optical device; and

establishing a length and a coefficient of thermal expansion for said at least one additional component adapted to maintain a substantial identity between said first and second functional relationships such that said shifts in the focal point position and in the location of the reference surface with respect to the entry point in the optical device are approximately equal, thereby causing said optimal operating condition to be substantially maintained within the range of temperature variations.

11. The apparatus of claim **10**, wherein said optical device consists of an interferometric microscope objective, said

first structure consists of a collar fixedly housing said surface, and said second structure consists of a sleeve fixedly housing said lens means.

12. The apparatus of claim **11**, wherein said first and second relationships are substantially linear.

13. The apparatus of claim **11**, wherein said at least one additional component comprises a first component coupled to said sleeve and a second component coupled to said collar.

14. The apparatus of claim **13**, wherein said first and second components are coupled to one another so as to produce an increase in said length responsive to thermal effects.

15. The apparatus of claim **12**, wherein said at least one additional component comprises a first component coupled to said sleeve and a second component coupled to said collar.

16. The apparatus of claim **15**, wherein said first and second components are coupled to one another so as to produce an increase in said length responsive to thermal effects.

17. The apparatus of claim **14**, wherein said first component comprises a portion made with an iron-nickel alloy and said second component comprises a portion made with an aluminum alloy.

18. The apparatus of claim **16**, wherein said first component comprises a portion made with an iron-nickel alloy and said second component comprises a portion made with an aluminum alloy.

19. The apparatus of claim **10**, wherein said first functional relationship is based on length and coefficient-of-thermal-expansion parameters for the optical device and said second functional relationship is based on length and coefficient-of-thermal-expansion parameters for said coupling means.

20. The apparatus of claim **13**, wherein a length and a coefficient of thermal expansion for each of said first and second components are selected using the following identity between said first and second functional relationships:

$$KD5=k_1(D1+D4)-k_2D2+k_3D3,$$

wherein D**1** is an effective optical length along the optical axis for said sleeve from said entry point; D**2** and D**3** are effective optical lengths along the optical axis for the first component coupled to the sleeve and the second component coupled to the collar, respectively; D**4** is an effective optical length along the optical axis for the collar; D**5** is an optical distance of the focal point from the entry point; k_1 is a coefficient of thermal expansion for the sleeve and the collar; k_2 and k_3 are coefficients of thermal expansion for the first component coupled to the sleeve and the second component coupled to the collar, respectively; and K is an approximate linear expansion coefficient including both mechanical and optical temperature effects for the optical device.

21. The method of claim **1**, wherein said first functional relationship is based on length and coefficient-of-thermal-expansion parameters for the optical device and said second functional relationship is based on length and coefficient-of-thermal-expansion parameters for said coupling means.

22. The method of claim **4**, wherein a length and a coefficient of thermal expansion for each of said first and second components are selected using the following identity between said first and second functional relationships:

$$KD5=k_1(D1+D4)-k_2D2+k_3D3$$

wherein D**1** is an effective optical length along the optical axis for said sleeve from said entry point; D**2** and D**3** are effective optical lengths along the optical axis for the first component coupled to the sleeve and the second component coupled to the collar, respectively; D**4** is an effective optical length along the optical axis for the collar; D**5** is an optical distance of the focal point from the entry point; k_1 is a coefficient of thermal expansion for the sleeve and the collar; k_2 and k_3 are coefficients of thermal expansion for the first component coupled to the sleeve and the second component coupled to the collar, respectively; and K is an approximate linear expansion coefficient including both mechanical and optical temperature effects for the optical device.

[57] **ABSTRACT**

A system for an examination of an eye of a patient, the system including: (a) a head set attached to the head of the patient; (b) a screen attached to the head set, such that the eye of the patient is covered by the screen; (c) a plurality of light sources attached to the screen, such that light is projected from at least one of the light sources directly to a preselected area of the retina of the eye of the patient to form reflected light; (d) a light receiving device attached to the head set to receive the reflected light and to transmit a signal according to the received reflected light; (e) an eye tracking device to determine the position of the eye relative to the light receiving device; and (f) a microprocessor for receiving the signal and for analyzing the signal to determine a size of a pupil of the eye and an amount of light reflected from the retina of the eye, such that a pupillary light response is measured to perform the examination. Also provided is a method for using the system of the present invention to perform an examination of the visual field of an eye of the patient. Preferably, the light receiving device is also able to continuously track, or follow, the position of the eye relative to the light receiving device. The method of examination preferably includes the steps of tracking the position of the eye, stimulating a preselected area of the retina with light at a retinal threshold intensity and then measuring both pupillary size and the amount of reflected light in order to determine the field of vision of the patient.

AUTOMATED THRESHOLD-RELATED OBJECTIVE PERIMETRY

FIELD AND BACKGROUND OF THE INVENTION

The present invention is concerned with methods and equipment for diagnostic tests of the eyes, and more particularly, with an automatic system for examination of the field of vision of a patient. The system is mounted on a head set and is equipped to continuously track eye movement so as to focally project a spot of retinal threshold-related light stimuli on preselected retinal areas, regardless of the direction of the gaze of the patient or of the orientation of the head of the patient. The system can concomitantly measure the pupil size and intensity of light reflected through the pupil as a result of the light projected.

The examination of the field of vision of a patient is an extremely important diagnostic tool used to identify and analyze diseases and defects of the retina and as visual pathways, such as glaucoma, optic neuropathy, multiple sclerosis and compression of the visual pathways. In the past, such an examination was performed with manually operated field of vision test instruments known as perimeters. Manually operated perimeters require the services of a physician or a skilled technician in order to examine the patient. In the most widely used system, known as the Goldmann system, the patient must sit still, head clamped in place, and constantly watch a fixation target at the center of a hemispherical screen to eliminate any uncertainties caused by head and eyes movements. A small point of light of varied intensity, size and color is projected onto the screen and its position is varied by the operator. The limits of the visual field are determined on the basis of the manual or verbal indications of the patient as to when the point of light comes into or goes out of view as the light is moved radially between the periphery and the center of his view. The examiner must continuously watch the patient to ascertain that the eye of the patient is fixated on the center of the screens since the examination results are artefactual if the eyes of the patient are not immobile. These factors render the examination of the extent of the field of vision using the commonly available Goldmann system is basically subjective, dependent to a large extent on the skill of the examiner, the fatigue level of the patient and the ability of the examiner to communicate with the patient. Thus, the Goldmann system is not operable for small children and patients who must remain in a supine position.

More recently, automatic perimeters have been marketed and used. However, even these instruments rely upon the Goldmann system and incorporate the control of a microprocessor in order to more efficiently measure the effect of light stimuli from external sources. Other prior art instruments have added a head set or helmet to eliminate any effect of head movements on the final results, as disclosed in United Kingdom Application No. 2096791 and two reports from the IOVS [J. Whiteside-Michel et al., "Virtual Reality Visual Field Test.", IOVS/97, 38:4, S569; and L. Brigatti et al., "Virtual Perimetry: A Novel Perinmetric Technique", IOVS/97, 38:4, S572]. Alternatively, various systems have been disclosed which use more objective means for perimetry such as pupillary size determination during Humfrey perimetry, as disclosed in U.S. Pat. No. 5,490,098. U.S. Pat. No. 5,114,222 discloses a method which includes a light stimulus moved in a continuous circular path according to decreased pupillary response. U.S. Pat. No. 5,459,536 discloses an instrument which includes a device to track eye movement, so that such movements can be incorporated into the final analysis of the results. However, all of these instruments and methods perform indirect measurements in which the light stimulus is projected in front of the eyes of the patient, rather than directly stimulating the retinal nerve fibers with fight.

There is thus an unmet medical need for a method and a system which objectively examines the visual field of a patient in which the retinal nerve fibers are directly stimulated by a retinal threshold-related light stimulus, such that the change in pupillary size in response to this light is automatically measured, and such that this measurement is cross-checked by determination of the change in the amount of light reflected from the retina, such that the patient does not need to remain substantially immobile during the examination and such that the method and system can be used to examine patients which must remain supine or who cannot otherwise comply with the requirements of prior art manual perimetry methods.

SUMMARY OF THE INVENTION

According to the present invention, there is provided a system for an examination of an eye of a patient, the system including: (a) a head set attached to the head of the patient; (b) a screen attached to the head set, such that the eye of the patient is covered by the screen; (c) a plurality of light sources attached to the screen, such that light is projected from at least one of the light sources directly to a retina of the eye of the patient to form reflected light; (d) a light receiving device attached to the head set to receive the reflected light and to transmit a signal according to the received reflected light; and (e) a microprocessor for receiving the signal and for analyzing the signal to determine a size of a pupil of the eye and an amount of light reflected from the retina of the eye, such that a pupillary light response is measured to perform the examination.

Preferably, the light receiving device also collects a visual image of the pupil, the visual image indicating an apparent shape of the pupil, such that a location of the pupil and a position of the eye relative to the light receiving device is determinable from the apparent shape. More preferably, the light sources are in a form of a dense grid, such that a particular light source is able to illuminate a specific area of the retina. Most preferably, the microprocessor transmits a return signal to the light sources, such that the particular light source is selected according to the location of the pupil in order to illuminate the specific area of the retina. Also most preferably, an characteristic of light projected by the at least one light source is determined according to the return signal, the characteristic being selected from the group consisting of an intensity and a wavelength of the light.

According to other preferred embodiments of the present invention, the light source is of a type selected from the group consisting of halogen lamp, mercury arc lamp and LED. Preferably, the halogen lamp and the mercury arc lamp feature a plurality of optic fibers for focusing the emitted light on the retina of the eye.

According to another embodiment of the present invention, there is provided a method for determining a visual field of an eye of a patient, the method comprising the steps of: (a) providing an instrument for determining the visual field, the instrument featuring: (i) a head set attached to the head of the patient; (ii) a screen attached to the head set, such that the eye of the patient is covered; (iii) a plurality of light sources attached to the screen; (iv) an eye tracking device; (v) a light receiving device attached to the head set;

and (vi) a microprocessor; (b) continuously following a position of the eye relative to the light receiving device; (c) projecting light from at least one of the light sources directly onto a preselected area of a retina of the eye; (d) measuring an amount of reflected light from the retina and capturing a visual image of a pupil of the eye with the light receiving device; (e) calculating a pupillary light response from the amount of reflected light and from the visual image of the pupil with the microprocessor; and (f) determining the visual field of the eye from the pupillary light response.

Hereinafter, the term "patient" refers to any subject, particularly a human or higher mammal, capable of being examined with the system of the present invention.

BRIEF DESCRIPTION OF THE DRAWINGS

The invention is herein described, by way of example only, with reference to the accompanying drawings, wherein:

FIG. **1** is an illustration of the system of the present invention.

FIG. **2** is a sensor block diagram of the present invention.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

The present invention is of an automatic perimetry system, including an instrument for automated perimetry measurements and a method for operating the instrument. The system includes a headset to be placed on the head of a patient. The headset supports a screen for background illumination; an eye tracking device; a plurality of light sources for focal retinal stimulation; and two light receiving devices, one for each eye. The light sources are preferably capable of emitting light of an adjustable intensity, such that the intensity of the light matches the threshold of the retina to light stimuli. Preferably, each light receiving device is able to follow the position of the eye, to measure the amount of light reflected from the retina, and to visually capture an image of the pupil itself. Thus, the eye tracking device is preferably incorporated within the light receiving device.

The output of the light receiving devices, in terms of both the amount of light reflected from the retina and the image of the pupil, is sent to a microprocessor. From this output, the microprocessor continuously calculates both the resulting pupillary area and the correct amount of reflected light to determine the pupillary light response. Preferably, the microprocessor incorporates information about the position of the eye relative both to the particular active light source and to the light receiving device, such that even if the eye moves, the pupillary light response can be accurately determined. The position of the pupil relative to the light receiving device and the light sources can be determined from the visual image of the pupil. When the pupil is viewed straight on, the pupil appears to be round. If the eye moves so that the pupil is now viewed at an angle, the shape of the pupil appears to change to an oval. Thus, the microprocessor, or more accurately the software instructions performed by the microprocessor, is able to determine the position of the pupil from the visual image.

The microprocessor also directs the light emission from the different light sources to preselected loci on the retina of the eye of the subject, according to the above analysis of the output of the light receiving devices. For example, in order to stimulate one particular area of the retina, the microprocessor must select one particular light source which is focused on that area. In order to determine which light source should be selected, the microprocessor preferably first determines the position of the eye, and hence of the retina, relative to the plurality of light sources. Next, the particular light source which can stimulate the desired retinal area at that moment is selected. The output of the light receiving device is then analyzed as described previously.

Since both the light emission source and the light receiving devices are attached to the headset; the pupil size, amount of reflected light and eye movement can be continuously monitored. Such continuous monitoring permits consensual pupillary monitoring whereby movement of the head and eyes of the patient during perimetry testing does not affect the test results, thus objectively measuring the visual field by automatic determination of the pupillary light response.

The principles and operation of a system according to the present invention may be better understood with reference to the drawing and the accompanying description.

Referring now to the drawing, FIG. **1** illustrates the automatic perimetry system of the present invention. A system **11** includes a head set **12**, in a view partially cut away to show the interior. Head set **12** is attached to the head **13** of a patient, preferably by straps **14**. Head set **12** preferably has an oval shape with a hemispherical construction covering the eyes and the upper part of the face of the patient. Such a construction enables a hemispherical screen **16** to be placed within head set **12**. A plurality of light sources **19** are attached to hemispherical screen **16**. Preferably, hemispherical screen **16** is very close to the eyes of the patient, even as close as about 2 cm. Also preferably, light sources **19** substantially cover the surface of hemispherical screen **16** in the form of a dense grid, for example. Such a grid enables a particular light source **19** to be selected for emitting light in a highly focused manner. Also, such a grid eliminates the need for any mechanical movement of light sources **19** in order to focus on a particular portion of the retina, since simply illuminating one particular tight source **19** would stimulate only one specific area of the retina, automatically giving focus to the emitted light.

Light sources **19** are preferably in the form of a LED, in which the light is generated by a power supply device **20** also attached to head set **12**, more preferably mounted on the outer periphery of head set **12**. Alternatively and preferably, light could be generated by a halogen lamp or a mercury arc lamp connected to power supply device **20** and then directed to the retina by a bundle of fiber optics, the end of each fiber forming a point on the dense grid. In any case, light is focused on a specific area of the retina regardless of any movements of the head or eyes of the patient for a number of reasons. First, light sources **19** are directly attached to head set **12** so that light sources **19** move with the movements of the patient. Second, in the preferred embodiment of a dense grid of light sources **19**, a specific area of the retina is illuminated by the emission of light from one particular light source **19**. These features enable the emitted light to be correctly reflected from the retina of the patient.

Once light is reflected from the retina of the eye of the patient, the reflected light is detected by a light receiving device **21** mounted in the inner periphery of head set **12**. Light receiving device **21** is preferably supplied with energy by power supply device **20**. Light receiving device **21** preferably is a CCD camera, although alternatively light receiving device **21** could be at least one photomultiplier tube. A CCD camera is more preferable because such a camera is capable of continuous video monitoring of the

pupil, including both the capture of a visual image of the pupil and the measurement of the amount of light reflected from the retina. Such information can be used to determine the position of the eye relative to the horizontal and vertical axes, as well as to cross-check the eye position by using the Hirshberg corneal reflex. Thus, light receiving device **21** preferably collects a visual image of the pupil and the amount of light reflected from the retina, and then transmits this information in the form of signals.

These signals obtained by light receiving device **21** are then transmitted through a communication link such as a cable **41** to a microprocessor **26**. Microprocessor **26** operates software (not shown), which permits the analysis of the received data to determine the measured pupillary light response. In particular, the software preferably first analyzes the visual image of the pupil in order to determine the location of the pupil relative to both the particular light source **19** which was illuminated and to light receiving device **21**. As noted previously, such an analysis could include the determination of the apparent shape of the pupil from the visual image which gives information about the position of the pupil relative to light receiving device **21**, and hence to light source **19**. Next, the software determines the size of the pupil both directly from the visual image and also from the amount of light reflected from the retina, which is determined by the size of the pupil. Finally, all of this information is analyzed to determine if the response to stimulation of a particular area of the retina was normal or abnormal.

The software also uses the analysis to enable microprocessor **26** to send return signals to light sources **21**, causing the right intensity of light to be generated by the desired light source **21**, such that light is projected to an area of the retina selected by the software in order to more accurately assess the field of vision. Each area of the retina can thus be examined separately, regardless of the movement of the eye or the position of the pupil, without any voluntary activity on the part of the patient.

Preferably, microprocessor **26** is able to connect and download the data into a computer or alternatively directly to a printer. According to other preferred embodiments, microprocessor **26** also controls the wavelength of light emitted by light sources **19**. Such control could permit additional types of ocular examinations to be performed with system **11**.

While the invention has been described with respect to a limited number of embodiments, it will be appreciated that many variations, modifications and other applications of the invention may be made.

What is claimed is:

1. A system for an examination of an eye of a patient, the system comprising:

(a) a head set attached to the head of the patient;

(b) a screen attached to said head set, such that the eye of the patient is covered by said screen;

(c) a plurality of light sources attached to said screen, such that light is projected from at least one of said light sources directly to a retina of the eye of the patient to form reflected light;

(d) a light receiving device attached to said head set to receive said reflected light and to transmit a signal according to said received reflected light; and

(e) a microprocessor for receiving said signal and for analyzing said signal to determine a size of a pupil of the eye and an amount of light reflected from said retina of the eye, such that a pupillary light response is measured to perform the examination.

2. The system of claim **1**, wherein said light receiving device also collects a visual image of said pupil, said visual image indicating an apparent shape of said pupil, such that a location of said pupil and a position of the eye relative to said light receiving device is determinable from said apparent shape.

3. The system of claim **2**, wherein said light sources are in a form of a dense grid, such that a particular light source is able to illuminate a specific area of said retina.

4. The system of claim **3**, wherein said microprocessor transmits a return signal to said light sources, such that said particular light source is selected according to said location of said pupil in order to illuminate said specific area of said retina.

5. The system of claim **4**, wherein an characteristic of light projected by said at least one light source is determined according to said return signal, said characteristic being selected from the group consisting of an intensity and a wavelength of said light.

6. The system of claim **1**, wherein said light source is of a type selected from the group consisting of halogen lamp, mercury arc lamp and LED.

7. The system of claim **6**, wherein said mercury arc lamp features a plurality of optic fibers for focusing said emitted light on said retina of the eye.

8. The system of claim **6**, wherein said halogen lamp features a plurality of optic fibers for focusing said emitted light on said retina of the eye.

9. A method for determining a visual field of an eye of a patient, the method comprising the steps of:

(a) providing an instrument for determining the visual field, the instrument featuring:

(i) a head set attached to the head of the patient;

(ii) a screen attached to said head set, such that the eye of the patient is covered;

(iii) a plurality of light sources attached to said screen;

(iv) an eye tracking device attached to said head set;

(v) a light receiving device attached to said head set; and

(vi) a microprocessor;

(b) continuously following a position of the eye with said eye tracking device;

(c) projecting light from at least one of said light sources directly onto a preselected area of a retina of the eye, said light being at a retinal threshold intensity;

(d) measuring an amount of reflected light from said retina and capturing a visual image of a pupil of the eye with said light receiving device;

(e) calculating a pupillary light response from said amount of reflected light according to said position of the eye and from said visual image of said pupil with said microprocessor; and

(f) determining the visual field of the eye from said pupillary light response.

[57] **ABSTRACT**

The present invention relates to image-formation on any selected kind of objective body. The characterizing features reside in such that, based upon fed image data, required images are formed on an image-transferable sheet acting for image carry-over service and in reliance on sublimation image transfer technique, and then, by the use of said sheet with said images thus formed thereon, the formed images thereon are transferringly applied on the objective body. By adopting the above measures, the objective body can be formed sharply and clearly with any desired images, irrespective of kind and configuration thereof, with such superior results of highly improved unity and solidability between the formed images and the objective body to be decorated with.

IMAGE FORMATION ON OBJECTIVE BODIES

This is a Division of application Ser. No. 08/395,850 filed Feb. 28, 1995 which in turn is a continuation of 08/034,186, filed Mar. 18, 1993, now U.S. Pat. No. 5,451, 560 which in turn is a continuation of 07/467,415, filed Jan. 19, 1990, now abandoned, which in turn is a division of application Ser. No. 07/138,384 filed Dec. 8, 1987, now U.S. Pat. No. 4,923,848.

TECHNICAL FIELD

This invention relates to methods and apparatus for the formation of images as prints on objective bodies through transfer of images preformed by the sublimation transfer technique, and more specifically it relates to such systems as adapted for the formation of images on any selected objective body, such as cards, clothes, papers, and transparent sheets, although these are not limitative to the present invention.

BACKGROUND ART

Reliance is made generally upon the normal printing technique for formation of images on objective bodies. For the execution of the printing technique, provision and use of printing plates (forms or blocks) are requisite. No matter how simple the image-printing is, the plate-making is a very time-consuming the laborious procedure. This is much more so in the printing of various and complexed image combinations, such as those of graphic or portrait images combined with characters, letters or barcodes, as an example, representing extremely complicated and troublesome work.

Further, in the normal printing operation, various operating conditions including ink selection and the like, must be carefully considered, depending upon the kind and nature of the printing object, thus the best selection thereof is highly delicate and not as simple as expected.

The present invention is proposed upon careful consideration of the foregoing facts, and an object of the invention is to provide a unique process for the formation of sharp and clear images regardless of the kind and nature of the object to be printed upon, and usable and effective materials and apparatuses for carrying out this unique process.

The method of thermal image transfer (sublimation image transfer) on clothes or fabrics with the use of thermal transfer dyestuffs has been practiced for a long time. In this conventional process, a dyestuff picture layer carrying thermal transfer dyestuff is formed on a substrate sheet which is then subjected to heat in an overlapped state on a cloth or fabric, the dyestuff thereby being transferred thermally onto the latter for forming the desired images thereon. By utilizing this technique, and with recent development of the image forming technology concerning fine thermal printers and the like, various fine image forming processes have been proposed to provide fine images which are comparable to photographic images and are transferred onto plastic films from thermal transfer sheets carrying thermal transfer dyestuffs.

According to these recently proposed processes, various images of cameras, or TVs, graphic images of personal computers and the like can be reproduced easily in the form of hard copies on the surface of a transferred material such as a paper or the like sheet carrying thereon a fixedly attached layer of polyester resin, as an example. These images thus reproduced represent an amply high level comparable to those obtained by photography or fine printing arts.

The thermal transfer process so far set forth has an advantage in that it can form any image in a convenient manner yet entails a problem in that it is limited to image-transferred products preferably of polyester and the like materials which must be dyed with thermal transfer dyes. On the other hand, the image-transferred products must be limited to specifically selected shapes, preferably film, sheet or the like configuration, and thus, such materials as wood, metal, glass or ceramics cannot be formed with images in this way. Further, even if the material is plastics such as polyester or the like, and when the image-forming surface is curved or undulated, or physical body other than sheet, even if it represents a plane surface, it is almost impossible to reproduce images precisely thereon, which naturally constitutes a grave problem in the art.

With recent development and enlargement of utilizing fields of various card-style products, such as cash-cards, telephone-cards, prepayment cards; and ID-cards, there are increasing demands for providing these cards with images, symbols and codes, so as to give various other functional and/or decorative effects. Most of these cards are of planar form, but they are frequently not pliable and/or have uneven rough portions due to provision of characters and symbols, resulting in great difficulty in the scheduled image formation relying upon the thermal image transfer process.

There is therefore an urgent demand among those skilled in the art for the provision of a unique technique capable of forming sharp and clear images of desired patterns on the surface of an objective body of any preferred kind of material and having any shape and configuration and surface condition of any kind, and indeed, for combining and unifying image- and decoration effects.

DISCLOSURE OF THE INVENTION

The present invention is basically based on such a principle that a first image transfer pattern is formed on an image transfer material, preferably an image image-transferable sheet, and in the form of dyestuff through the sublimation image transfer process executed by first image transfer means, depending upon given image data, preferably including those of letters, characters, symbols, line images, graduated graphic representations, and then the first transfer pattern is transferred to second transfer means for retransferring the images onto an objective body so as to provide a final product.

Based upon the image data fed from various image data input means and at the first image-transfer means, a thermal head is actuated to execute printing operation through a dyestuff film (thermal image-transfer sheet) on an image-transfer material (or more specifically on an image-transferable material which means an image-transferable sheet. This image-printing is carried out according to the sublimation or sublimative image transfer technique. Thus, in this case, the dyestuff on the dyestuff film is transferred or shifted under the influence of heat energy from the thermal head onto the image-transferable material through sublimation, thus providing the first image-transferred means. Since this first image-transferred means has been thus formed with the images by the sublimated dyestuff, they are, then, transferred onto the second image-transferable means which will be brought into tight contact with the object to be decorated and subjected to heat and pressure for execution of further image-transfer operation to provide the final desired product.

In the present invention, the image-transfer material (image-transferable sheet) is, as above referred to, formed

with images by the sublimative image transfer technique for providing first image-transfer means which has highly sharp and clear images as the operation and results of the characterizing feature of the sublimation image-transfer technique. Therefore, because of the transfer of such sharp and clear images onto the object, it becomes possible to form the images thereon, and indeed, practically irrespective of the kind and nature of the object. In this way, thus, fine image-formation is assured onto practically any objective substance.

And further, by execution of control of the thermal energy applied during the sublimative image-transfer step, the resulting color effect is superior and the image quality is good.

The images sublimatingly applied and formed in the foregoing way are subjected to a further transfer, and onto a substrate product, for providing a final decorative product as desired. In this final product, it should be noted that the underlying layer underneath the images during the sublimative image-transfer stage appears now at the top, acting thus as a kind of protecting layer upon up-and-down positional conversion during execution of the second and final image-transfer stage, resulting in realization of various and numerous effects. As an example, attainment of substantial reduction of contamination, improvement of light resistance, weather resistance and chemical resistance; substantial reduction of color fading; provision of glazing effect; easier and simpler introduction of granular and/or undulated image appearance.

The inventive process is carried into effect basically in such a manner that an image-reception layer provided on one surface of an image-transferable sheet is subjected to an image-forming step with the use of dyestuff capable of depositing therein depending upon the fed image data, so as to form the required images, and then, the image-reception layer of the image-transferable sheet, having been image-fixed and thus now image-carrying, is stuck onto the surface of the object to be decorated upon.

As for the image-transferable sheet adapted for use in the image-transfer during execution of the inventive process, it consists basically of a sheet-like substrate and a reception layer attached, however, in a separable manner, onto one surface thereof. As a modification of the inventive process from the basic mode set forth above, the sheet-like substrate is caused to remain, even after completion of the image-transfer step, as may be occasionally required. In this modified case, it is unnecessary to make the image-reception layer of the image-transfer sheet separable.

Under occasion, the inventive process may be brought into effect in such a way that the image-reception layer of the image-transfer sheet is transferred upon execution of the image-forming step, and indeed, once onto an intermediate image-transfer substrate which is then retransferred, together with the once transferred image-reception layer, onto the surface of an object to be decorated on; and thus, in a retransferring manner.

BRIEF DESCRIPTION OF THE DRAWINGS

In the accompanying drawings:

FIG. **1A** is a block diagram, showing a preferred embodiment of the apparatus according to the present invention;

FIG. **1B** is a schematic view illustrating at (a), (b) and (c), several image-transfer steps for the execution of a process according to the invention;

FIG. **1C** is a schematic view of an image-transfer step, using a platen roll;

FIG. **1D** is a plan view of part of a multi-color dyestuff film adapted for use in an image-forming step;

FIG. **1E** is a schematic view for the illustration of several image-transfer steps;

FIG. **2** is a flow chart of successive operation steps with use of a data-processor, shown in FIG. **1**, functioning as an operating center;

FIG. **3A** is a schematic block diagram, showing a data-processor for the printer;

FIG. **3B** is a block diagram of a sublimative image-transferring printer adopted in the present invention, as a preferred embodiment thereof;

FIG. **4** is a schematic block diagram, showing a color correction unit shown in FIG. **3A**, and several related parts cooperating therewith;

FIG. **5** is a schematic block diagram of a comparator and several related parts cooperating therewith;

FIG. **6** is a circuit block diagram of an image-transfer head shown in FIG. **1B**;

FIG. **7** is a graph showing operational characteristics of a color tone or -gradation corrector unit shown in FIG. **3A**;

FIG. **8** is a table for the illustration, as an example, of picture- or image-elements, as expressed in binary signals;

FIG. **9** is a table showing a conversion operation, as an exampler of a parallel/series converter shown in FIG. **3A**;

FIG. **10** is a flow chart, illustrating the operation of the sublimative image transfer printer;

FIG. **11** is a plan view of a final decorative product prepared according to the inventive technique;

FIG. **12** is a sectional view of the product card shown in FIG. **11**, and taken along a section line A—A shown therein;

FIGS. **13** through **31** are a series of sectional views, respectively illustrating several structural examples of image-transferable sheets, suitable for use in the invention; and

FIGS. **32** (*a*), (*b*), and (*c*) are sectional views, indicating final transfer steps.

BEST MODES FOR CARRYING OUT THE INVENTION

Referring now to FIG. **1A** and FIG. **1B**, (a), (b) and (c), a basic schema of the inventive image data processing and image formation will be illustrated. First, in FIG. **1A**, numeral **101** represents an image input means which is adapted for forming image data based upon optical and the like inputs delivered from a TV-camera, line sensor or the like. Other than those above enlisted only by way of example, video; CD; TV; scanner; personal computer, captain system, capable of providing R.G.B.- and picture image and the like signals may also be utilized in a similar way. The image signal data delivered from the image input means are fed through a data processor **104** to a memory **105** for being stored therein. These stored data can be taken out from the memory and fed through data processor **104** to display means **102** for being displayed thereat.

To the data processer **104**, a mouth/tablet digitizer and/or the like position data processer **103** is electrically connected for introducing position data concerning displayed images appearing at the display **102**. In addition, key board and the like character data input means **106** and font generator **109** are provided for introducing character data. Still further, a barcode generator **110** is provided for introducing barcode when necessary. By the use of these means and units, various additional processing modes can be executed.

The thus processed data are subjected to conversion at a data converter **107** into proper data adapted for operating a sublimation transfer printer and fed forward through a driver **108** to the thermal head.

In this case, by controlling the current duration period to the thermal element of the thermal head, the transfer quantity from the dyestuff film (thermal transfer sheet) is controlled depending upon the thermal energy of the element for realization of the desired gradation degree of concentration on the transfer sheet. There are two different modes of such control of current duration period as follows:

(a) A method for controlling the pulse length corresponding to the picture element in the impressed data to the thermal element of the thermal head or, more specifically, a series data introduced as input to the shift register shown in FIG. **6** and to be described more specifically hereinafter.

(b) A method for controlling the number of pulses of the pulse series corresponding to the picture elements of the data impressed upon the thermal element in the thermal head (in this case, the pulse length being constant).

The degree of gradation of the transfer image can be controlled in the above mentioned way by the regulation of the current-conducting period depending upon the desired gradation degree. On the other hand, the image concentration can be controlled by adjusting the pulse length or the number of pulses contained in the pulse series in correspondence to the picture elements contained in the data as introduced in the shift register and depending upon the driving mode of the thermal head. Further in this case, if the number of gradation of introduced image data is larger than that which can be expressed by the printer unit, a proper conversion operation can be performed by the known strobe control method. As an example, in such case, the conversion of gradation number **256** to **64** may be executed by a ROM, and the thus reduced gradation number can be used as output.

Next, referring to FIG. **1**B at (a) and (b), reference numeral **121** represents a thermal head which receives signals from the driver **108** shown in FIG. **1**A. This thermal head **121** is arranged in opposition to platen roll **122**, forming the printing position therebetween. The dyestuff film (thermal transfer sheet) is fed from a delivery roll **123** to a winding roll **124** through this printing position, these structural and functional features being commonly employed in both the arrangements shown in FIG. **1**B at (a) and (b).

In the case of FIG. **1**B, (a), the mechanism is so arranged that card or sheet style transfer sheets are printed with dyestuff images.

On the other hand, in the case of FIG. **1**B, (b), the mechanism is so arranged that cards are continuously produced with the use of a film style transfer sheet and a dyestuff film in combination.

Now turning back to FIG. **1**B, (a), a number of transfer sheets (cards, sheets or the like) have been stacked and stored within a storage casing **125** and are being thrust upward from below by a spring so that the uppermost sheet is kept in pressure contact with a take-out roll **126**. With the rotation of the roll **126**, the sheets are successively delivered from the casing **125** by conveyer belts **127**, **128** onto a platen roll **122**. Each one of the sheets is fixed on the peripheral surface of the platen roll, now positionally indexed, by means of a gripper or the like mechanical attaching and separating means, static attracting means, or electromagnetic attaching means. Then, the roll **122** is so rotated that the transfer sheet is positioned at the ready-for-printing-position.

Next, the thermal head **121** is brought into pressure contact with the transfer sheet through the intermediary of the dyestuff film, and then the thermal head **121** is energized with electric current while the dyestuff film and platen roll **122** are moved in synchronism for the execution of image transfer (first image transfer).

Upon execution of the image transfer, the platen roll **122** is rotated, the gripper is released and the take-out roll **129** is rotated and brought into pressure contact for taking out the image transfer sheet onto a tray **130**.

The thus taken-out sheet is brought into overlapped state with a new image transfer sheet, not shown, and then, both the sheets are fusingly united together by pressure application of a heated roll, not shown, for execution of a second transfer step job. The whole operation has thus been completed. Before the fusion process, the sheets may be subjected to punching, trimming and/or the like processing, if necessary.

By execution of the foregoing operational steps, a monocolor printing operation has been completed. However, in the case of multicolor printing, use is made of tricolored or quadruple colored dyestuff film and the corresponding printing operations must be repeated. In this case, upon completion of a single monocolor printing procedure, the platen roll is rotated without contact of the take-out roll **129**, until it arrives again at the printing-initiation position, and so on.

In the following, a tricolor printing job will be illustrated with reference to FIG. **1**B, (b), and with use of three different series color zones, of cyan, magenta and yellow.

First, a platen roll **122** is positionally indexed, and an image transfer sheet taken out from the roll **131** and a dyestuff film taken out from the roll **123** are brought into pressure contact in an overlapped state. Then a thermal head **121** is pressed against the platen roll **122** through the intermediary of the overlapped sheets. At this stage, the platen roll **122** is rotated counterclockwise while synchronism is kept between the platen roll **122** and the dyestuff film, and the thermal head **121** is kept electrically energized. In this way, the first color printing is executed.

Further, the dyestuff film is fed to the second color zone position, and then, the. platen roll **122**, the dyestuff film and the image transfer sheet are fed forward clockwise around the center roll **122**. Thus a second color printing step is executed.

Further, the print-serviced two color sections of the film is fed back counter clockwise around the center of the platen roll **122** for the execution of a third color printing step. Then, each card sheet is taken out from the stack **200** under the action of take-out rolls or the like, not shown, towards and between a pair of thermal transfer rolls **132**, **133**, brought into overlapping state with the image transfer sheet positionally indexed and already subjected to image transfer steps as was described above, and finally subjected to a picture printing operation by pressurizing application of the thermal image transfer rolls **132**, **133** from both sides of each taken-out card, and so on.

The color-printing step with the use of the thermal head is carried into effect in the following manner, as an example.

(First color printing)

Platen roll, image transfer sheet and dyestuff film perform the printing while they are moved in the counterclockwise direction.

(Second color printing)

Platen roll and image transfer sheet are moved in the clockwise direction while the dyestuff film is moved at the same speed and in the counterclockwise direction for performing the color printing under consideration.

(Third color printing)

Platen roll, image transfer sheet and dyestuff film are moved in the counterclockwise direction for execution of the color printing under consideration.

In the modified arrangement shown in FIG. **1**B, (c), thermal image transfer rolls **132**, **133** have been replaced by a flat press type image transfer head having up-and-down movable flat printer elements **132'**, **133'**.

It should be noted that in the course of the foregoing first and second image transfer steps, image reversal phenomenon is necessarily brought about upon execution of each image transfer step. In other words and more specifically, when two successive image transfer steps in the foregoing sense are executed, reverse images which have once appeared will return to the original normal images. Therefore, when the printed-out products are to be provided upon execution of the first image transfer step, it is necessary to provide reversed image data in the signal processing system. For this purpose, it is only necessary to reverse the addressing order at the data introduction or readout stage into or from the memory.

In the modified arrangement shown in FIG. **1**C, the foregoing platen roll means has been replaced by a metal block **141** lined with a rubber plate **142** in an overlapped manner. The image transfer sheet and dyestuff film are fed out from respective rolls **131** and **123**. With the use of this modified arrangement, the dyestuff surface layer of the dyestuff film can be brought into tight contact with the image-receiving surface layer of the image transfer sheet, and thermal energy will be transferred evenly form the thermal head **121** to the dyestuff film.

In this case, the image transfer sheet is delivered from the roll **131**, and the desired zone or region of the sheet is set underneath the rubber plate **142** (step **1**).

At the same time, the dyestuff film shown in FIG. **1**D on an enlarged scale is delivered from the roll **123** and a selected one of the different color regions is set underneath the rubber plate **142** (step **2**).

Next, the thermal head **121** is brought into the rear surface of the dyestuff film which is the opposite surface to the dyestuff-coated front layer, and the head **121** is driven while it is being translated in the direction shown by an arrow A, images thereby being formed at the specifically allocated zone(s) or region(s) of the image transfer sheet (step **3**).

Further, the thermal head **121** and rolls **416** and **418** are shifted downwards as shown by arrows B, so as to form an idle gap between the image transfer sheet and the dyestuff film for allowing the latter to shift towards the next following color region (step **4**).

Further, the thermal head **121** and rolls **416** and **418** are returned to their original positions, whereupon the third and further succeeding steps are repeatedly executed until a certain predesired number of color printings are completed.

As shown in FIG. **1**D, the dyestuff film is colored to have several different color regions denoted by Y (yellow), M (magenta), C (cyan) and Bk (black). However, the arrangement order is not limited to that shown: Y; M; C and Bk. In addition, as occasionally required, the Bk-region may be dispensed with. Further, as the color elements to be adopted in the Y, M, C-system may not be limited to the three primary colors provided by the subtractive color mixture. On occasion, a characterizing color which means such a color as preadjusted to provide an objective specifically selected one may be used to form the images concerned. As a further modification, the arrangement shown in FIG. **1**C may be so modified that the traveling direction of the image transfer sheet is selected to be perpendicular to that of the dyestuff film.

FIG. **2** is an operation flow chart for showing schematically operational modes taking the data processor **104** adopted in the embodiment shown in FIG. **1** as the centrum of description. The operational contents of several working parts downstream of the data converter **107** will be set forth separately hereinbelow. Now referring to FIG. **2**, in combination with FIG. **1** and at the step of **S101**, image pickup operation is carried out by means of the image pickup means **101**. For execution of this step, it may be better to pick up the face of a person per se which is to be represented on the card, or alternatively, a photograph, portrait or imagery product thereof will do. Depending upon the nature of the object, a TV camera, line sensor or the like instrument may naturally be selectively utilized.

The data taken by the image pickup means **101** are stored through the data processor **104** at a memory **105** (**S102**). By the use of these stored data, image or images is/are displayed at the display **102** (**S103**). Since this display image is not yet subjected to any processing, it is generally unsuitable for representing on the card. However, under certain circumstances, it may be represented thereon as it is.

Then, the operator observed the displayed image or images on the display unit **102** and adjudges whether additional processing is necessary or not (**S104**). If it is not necessary, he will manipulate the key board **106** to make a certain operation, resulting in the termination of processing at the data processing unit **104**, data being fed out therefrom to the succeeding data converter **107**.

On the contrary, when additional processing is necessary, the operator observes carefully the displayed image or images on the unit **102** and adjudges whether the picture image data, or character data or barcode data should be processed. If the picture image data should be processed, such an operation is made for selecting the proper mass of trimming or layout within the menu range of position-data input means **103**. By the execution of this operation, functions and operations at steps **S105** and **S106** can be executed at one stroke. If trimming is taken as an example, the next step is executed in such a way that position data are fed from the position input means **103** to the data-processer **104** with the use of a carsor. When a tablet digitizer is used as the position data input means, the carsor image displayed in an overlapped manner on the displayed picture image appearing at the display unit **102** by carsor manipulation is positionally specified beforehand in registration with the specified position on the card, for determining the trimming range. Then the operation is carried out in such a way that the picture image data outside the specified trimming range are canceled. By completing these operations, data processing operations relating to step **107** are executed, and, then, the mass for completion of the menu range is selected out. By these measures, steps progress through **S109** to **S102**, and data storing is executed, and further, display representation is brought about through step **S103**. If there is no need for additional processing, an operation termination manipulation is carried out as before at key board **106**, and further operations will be made through data converter **107**.

As for the layout, the operation is carried out with the position data input means **103**, similarly as in the foregoing trimming operation. More specifically, layout is selected out in the menu range of position data input means **103**, and the overall configuration of the card and the display position of picture image are shown at display unit **102**. Then, image inclination correcting operation and the like are carried out so as to realize correspondence thereof with the displayed positional information, the processing operations relating to step **S108** thereby being brought about. After completion of these operations, the mass for the ending in the menu range is selected.

In this way, when selection is made from the menu range by reliance on the position data input means **103**, trimming or layout operation can be brought about. At this stage, when manual operation is carried out at the key board **106**, introduction of character data is executed (**S110**). As the character data in this sense, in the case of ID card, as an example, the name and/or birthday, month and year of the owner may be used. The data introduced from the key board **106** in accordance with the output character style from the font generator **109** are shown at the display unit **102** in the specified positions on the displaying surface and respectively arranged in accordance with display items. The operator acknowledges these items and detailed displays of the represented images. When he acknowledges them as being true, he will operate the key board **106** for showing the operation ending (**S111**).

Upon ending the operations as described above, the data are stored in memory **105** (**S102**) and represented at the display **102**. The operator will acknowledge again this fact, and upon the execution of this, the operations are terminated.

As for the barcode introduction, the data are subjected to inputing at steps **S112** and **S113**, as in a manner similar to the character data introduction as set forth above. The barcodes and the like data may be introduced separately through printing or other mechanical method.

In FIG. **3**A, a data processing circuitry usable in the sublimation image transfer printing method is shown only schematically. As shown, the circuitry **107** comprises a picture element density converter **3**; a color corrector **4**; a gradation corrector **10**; a memory **11**; a switch **12**; a buffer **13** and parallel/series converter **14**. The picture element density converter **3** is connected to a picture image input unit **100**.

The unit **100** serves for generation of three primary color data of R.G.B.- or Y.M.C.-mode from original picture images and is connected through the picture element density converter **3** to the color corrector **4**. The converter **3** converts the picture element density of the image data fed from the unit **100** to the desired one, by subtracting or supplementing, as the case may be, image data for each color element. It should be mentioned that for attaining high quality hard copies, conversion of the picture element density to at least 10 lines/mm or so is preferable.

Color corrector **4** consists preferably of a color decoder, level adjuster or color converter, and serves to correct three primary color data converted to those of a predetermined density of picture elements in consideration of characteristics of the image transfer ink in the image transfer sheet and in addition to provide black color data.

The data processing circuitry **107** is connected through a driver **108** to the sublimation image transfer printer.

In FIG. **4**, an example of the color corrector **4** is shown schematically in structure. As shown, it comprises adders **6**Y; **6**M and **6**C, a black color data calculator **7**, and primary and secondary color correction circuits **8** and **9**. Primary color correction circuit **8** serves for making correction of turbidity of the image transfer ink, while secondary color correction circuit **9** provides a capability of arbitrary and selective correction control relative to specifically selected color hue.

The gradation corrector **10** is so arranged as to make correction of the gradation of the data for each color Y, M, C or K (representing black color) fed from the foregoing color corrector **4** when necessary. For this purpose, the corrector **10** includes a gradation circuit (not shown) and the like, whereby a certain mode of highlight stressing or shadow stressing is introduced and realized.

The memory **11** functions to preserve temporarily the data of each color delivered from the gradation corrector **10**, a selection switch **12** being provided at the output side of the memory for selective writing-in of the data of each color to the buffer **13**. The buffer **13** is capable of writing-in the data of one line of the image transfer head **16** and kept in connection with the parallel/series converter **14** adapted for converting parallel data into series data. Additionally, in the simplified machine, black color data series is dispensed with in some instances.

In FIG. **5**, a schematic construction of the parallel/series converter **14** is shown. As shown, parallel data delivered from the buffer **13** are fed to an input side of a comparator **22**, while outputs from a counter **23** are fed to another input side of the comparator **22** which delivers the converted series data to the driver **15** for driving a thermal head **121**.

If necessary, however, the comparator **22** may be replaced by a converter table, not shown, utilizing a parallel/series converting ROM.

In FIG. **6**, a detailed circuit schema of the thermal head **121** is shown. As shown, series data delivered from the comparator **22** are fed into a shift register SR and thence, after being subjected to latching at a latch circuit LT, fed to thermal elements HE through NAND gates NA which are fed at respective one side inlets with strobe signals.

Next, referring to FIG. **3**A, the operation of the data processing circuitry **107** will be described more specifically.

First, when three primary color image data are fed from the picture image inlet circuit **100** to the picture element density converter **3**, the latter converts these three primary color data to those which represent a predetermined picture element density and then are fed to the color correction unit **4**. In this case, it is assumed that the unit **4** is fed with three primary color data expressed in respective concentration signals, which are of yellow: **Y0**; of magenta: **M0** and of cyan: **C0**, respectively, in the present example.

These data: **Y0**; **M0** and **C0** are, as shown in FIG. **4**, fed through respective adders **6**Y; **6**M and **6**C to the black color data calculator **7**, to provide a K-output as expressed mathematically by the following formula:

$$K=\min(Y, M, C)$$

wherein, "min" represents a function which provides a possible minimum value.

These data: **Y0**, **M0** and **C0** are fed from the converter **3** to the primary color correction circuit **8** to provide primarily corrected data **Y1**, **M1** and **C1** which are thence fed to the secondary color correction circuit **9** to provide, through calculation, secondarily corrected data: **Y2**, **M2** and **C2**, respectively. These are then fed to respective adders **6**Y, **6**M and **6**C, which add them to respective data **Y0**, **M0** and **C0**, to provide respectively added output data Y, M, and C to be fed to the gradation correcter circuit **10**, respectively, after being utilized for calculation of the K-output signal value.

The primary color correction circuit **8** serves to calculate primarily corrected data: **Y1**, **M1** and **C1** which are necessarily utilized for correct-out of transfer ink turbit. In this case, the original data: **Y0**, **M0** and **C0** are subjected to matrix calculation to provide the primarily corrected data **Y1**, **M1** and **C1**, as follows:

$$Y1=k_{11}\cdot C0-k_{12}\cdot M0+k_{13}\cdot Y0$$

$$M1=k_{21}\cdot C0+k_{22}\cdot M0-k_{23}\cdot Y0$$

$$C1=k_{31}\cdot C0+k_{32}\cdot M0-k_{33}\cdot Y0$$

where, k_{ij} represents weight coefficients:

i=1–3; and

j=1–3.

The secondary color correction circuit **9** serves to calculate secondary color correction data **Y2**, **M2** and **C2** from primary color correction data **Y1**, **M1** and **C1** by modifying the latter to make certain thereto by performing matrix calculations so as to provide a capability for making an arbitral and selective color control at a certain specifically selected-out color hue, in the following manner:

$$Y2 = Y1 + l_{11} \cdot \Delta B + l_{12} \cdot \Delta C + l_{13} \cdot \Delta G + l_{14} \cdot \Delta Y + l_{15} \cdot \Delta R + l_{16} \cdot \Delta M$$

$$M2 = M1 + l_{21} \cdot \Delta B + l_{22} \cdot \Delta C + l_{23} \cdot \Delta G + l_{24} \cdot \Delta Y + l_{25} \cdot \Delta R + l_{26} \cdot \Delta M,$$

and

$$C2 = C1 + l_{31} \cdot \Delta B + l_{32} \cdot \Delta C + l_{33} \cdot \Delta G + l_{34} \cdot \Delta Y + l_{35} \cdot \Delta R + l_{36} \cdot \Delta M$$

wherein, l_{ij} represents weight coefficients:

i=1–3;

j=1–6;

ΔB, ΔC, ΔG, ΔY, ΔR, ΔM:

characterizing color data.

Thus, when these secondary correction data **Y2**, **M2** and **C2** are added to the corresponding original data **Y0**, **M0** and **C0** by means of respective adders **6Y**, **6M** and **6C** and under proper selection of weight coefficients k_{ij} for primary color correction circuit **8**, any color discrepancy of the ideal color of the ink appearing on the printed picture images under the action of the sublimation transfer printer can be arbitrarily ammended. In this case, when the weight coefficients l_{ij} for the secondary correction circuit **9** are selected out properly, the color tone of the printing picture images can be modified to an arbitrary degree.

Further, as for the black color data K, correction data **K2** can be calculated by the following formula. With use of these correction data **K2**, which are added to the original black color data K, the desired correction can be executed in a similar manner.

$$K2 = K + m1 \cdot \Delta B + m2 \cdot \Delta C + m3 \cdot \Delta G + m4 \cdot \Delta Y + m5 \cdot \Delta R + m6 \cdot \Delta M$$

wherein, Mi represents weight coefficients:

i=1–6.

In this way, output data: Y, M, C and K delivered from the color correction circuit **4** are introduced into the gradation corrector **10** as inputs thereof, and each constituent of these data can be subjected to correction as desired.

FIG. **7** shows several characteristic curves illustrating corrections by means of the gradation corrector **10**. More specifically, **f0** represents a standard characteristic curve; **f1** a highlight-stressing operation curve; **f2** a shadow-stressing operation curve; **f3** a highlight-and-shadow stressing operation curve; and **f4** a medium tone stressing operation curve.

As indicated in FIG. **7**, by presetting, as necessary, the tone-reproducing characteristics, which determine the relationship between that concentration of color data and that of the prints printed by means of a sublimation image transferring printer, a color tone similar to that possessed by the original image can be reproduced. More specifically, when no correction is adopted, the curve **f0** is used, while in the case of correction, any selected one of these curves **f1** to **f4** may be utilized depending upon the part of gradation to be stressed. Further, it should be noted that the tone reproducing characteristic curves are not exclusively limited to those which have been specifically shown and described above. As an example, the control of gradation correction by color tone reproducing characteristic mentioned above is executed by a gradation circuit, not shown, and the setting of the color tone reproducing characteristic is brought about by manipulation of any selected one of the control knobs, not shown, which are provided separately for "highlight"; "medium tone" and "shadow".

Y.M.C.K.-data subjected to correction by the gradation corrector **10** are once stored in the memory unit **11**. The thus stored data may be read out from the memory for each color by manipulation of the selection switch **12** and, after provisional storing, per one line of transfer head **16**, at the buffer **13**, introduced into the parallel/series converter **14** for conversion thereby into corresponding series data.

Another example of the data processing circuit for the sublimation transfer printer is shown only schematically in FIG. **3**B. As shown, the processing circuit in **107'** comprises a level regulator **503**; a color converter **504**; an A/D converter **505** and a parallel/series converter **14**.

As the image data introduced into the processing circuit **107'**, those which have been subjected to conversion into R.G.B.-signals in the color decoder **502** from composite video signals delivered from a T.V. camera, VTR or the like are used. On the other hand, R.G.B.-signals delivered from a personal computer, captain system or the like means are introduced as input into the level adjuster **503**.

As the color correction method with the use of the foregoing arrangements, it is possible, more specifically, to adjust the hue saturation and/or brightness in the color decoder **502**, or to adjust the signal level of each color light of R.G.B.-system in the level regulator **503**.

As an example, the color conversion from R.G.B.- to Y.M.C.-system can be executed in the color converter **504**. The simplest possible method in this color conversion is to procure the opposite color to each of the normal colors.

The thus produced color signals of Y.M.C.-system is subjected to A/D conversion and then fed successively through the parallel/series converter **14** and the driver **108** to the thermal head, not shown, to carry out printing in the sublimation transfer principle.

Additionally, in normal cases, with the use of the foregoing system composition, input image data must be of static mode. However, by provision of memory means in front of the color decoder or at an intermediate position between the A/D converter and parallel/series converter, animating images can be processed.

The series data converted in the foregoing manner in the data converter **107** or **107'** are fed to the shift register SR shown in FIG. **6** by n-image elements and then, upon being subjected to latching in the latch circuit LT are further delivered to NAND gate NA as its inputs. When a strobe signal ST is fed as input to the NAND gate NA, the foregoing n-image element data is fed to the thermal element HE.

FIG. **8** is a schematic diagram, showing signals for respective image elements. The gradation has been so selected that the first image element is at the highest gradation level, while the n-th image element corresponds to the lowest gradation level, and that the second to (n-1)th image elements vary linearly in gradation levels so as to provide representatively a better understandable example of the invention.

Next, the operation of the parallel/series converter **14** will be described.

First, as shown in FIG. **5**, image elements data A, consisting of parallel data, more specifically, comprising parallel eight bit data A**0**–A**7**, are fed to one-side inputs of comparator **22**, while another side inputs thereof are fed with outputs B, comprising eight bit increment outputs B**0**–B**7**, of counter **23**. The counter **23** counts clock signals in increments, the outputs B**0**–B**7** being successively varied.

The comparator **22** performs comparison between the two inputs A and B, so as to deliver successively outputs of binary "1" until the increment output B is brought into coincidence with image elements data A, or more specifically, under the condition of A>B and A=B, while, thereafter, binary "0"-outputs are delivered therefrom. More specifically, comparator **22** will continue to deliver binary "1" until an increment value which corresponds to the weight of concentration of image element data A is given thereto. As an example, if the image element data A has a concentration of gradation **128** of a total 256, output "1" will be repeated to deliver 128 times first and then, output "0" will follow after again 128 times, so as to provide in total a specific series data peculiarly in this case.

These series data are taken out from the comparator **22** in the form of A>B- and A≧B-outputs and of A=B-outputs through an attributed OR-gate **24**, and in the present example, the gradation consists of 256 steps or increments. However, in practice, the gradation may represent a smaller number of steps. As an example, if the incrementing bit is B**1** instead of hitherto employed B**0**, the gradation will have 128 steps; and if B**2** is employed, it will have only 64 steps. In this way, the gradation setting may be varied in a simple manner.

When in the foregoing way, the output B from the counter **23** is stepwise incremented, such series data consisting of a first series of "1" will be delivered until the relationship between the image elements data A and the output B from counter **23** becomes A B, and of a second series of "0" issued thereafter, as shown in FIG. **8**.

In FIG. **9**, a conversion mode at the parallel/series converter **14**, which, however, is different from that shown in FIG. **8**, as an example, is shown again in the form of a matrix. As shown, when the image data are of 8-bit parallel kind, as an example, the gradation data are ranged from 0 to 255, providing, therefore, binary series data from "00 . . . 00" to "11 . . . 11".

In this way, the data, per line in the transfer head **16**, kept preserved in the buffer **13** are fed to the parallel/series converter **14** for providing as outputs therefrom into corresponding series data which are then delivered through the driver **15** to the transfer head **16** and thus recorded on a print paper P supported on the transfer drum **17**.

FIG. **10** represents a flow chart illustrating the operation of the sublimate printer as employed in the present invention.

At the first step S**1**, print papers are set in position and the printing ribbon is also set in position ready for performing the required procedure.

At the second step S**2**, printing operation is initiated, and line printings are executed, line by line, accompanying necessary intermittent line shifts, with relation to any selected one of four colors; C (cyan); M (magenta); Y (yellow) and K (black) being carried out. Refer to S**3** and S**4**. When line printings with the selected-out single color have been completed (S**5**), the image transfer sheet is replaced by another color sheet (S**6**) and so on. In this way, line printings are completed in all four colors. In this case, it is naturally most preferable to use a long extended single transfer sheet on which four color ink regions are repeatedly printed in a certain predetermined pattern. The image reception paper is initiated to make print from a certain prescribed position for each of these colors (S**8**). When all of the printing steps have been completed with the four colors, the paper is discharged from position (S**9**) and the printing operation is terminated to be repeated.

In FIG. **11**, a card style sample of the final products according to this invention is shown in front view at **200**. FIG. **12** is a sectional view thereof. Numeral **201** represents the substrate material of the card; **202** a display layer; **203** a surface protecting layer; and **204** a display image as an example. Depending upon the kind of usage and when necessary, the protecting layer **203** may be dispensed with. It should be noted that the display image **204** on the display layer **202** is represented by a sublimative dyestuff, as a characterizing feature of the present invention.

As the main and substantial material of the image transfer sheet, various plain papers, converted papers, plastic resin sheets or the like may be used per se or in combination. When a plastic resin sheet which can be colored directly with a sublimative dye or dyes is used, these image transfer substrates (articles or objects) as at **201** can be united each with the display layer **202**. Each of these substrate materials, when it is of the card style, may have generally such dimensions: thickness of 0.68 to 0.80 mm and size: 11 to 8×8 to 5 cm.

As the material of the display layer **202**, various known materials which may be colored with sublimative dyestuffs, such as polyethylene, polypropylene, polyester, ABS, AS, polyvinylchloride, polyvinyl/vinyl acetate copolymer, polystyrene, polyacrylate, polyester, polyamide, polyurethane and the like plastic material, may be advantageously utilized. As will be more specifically described hereinafter, this material layer can be united with the substrate material layer **201**. In the case of such unified structure with substrate layer **201**, the thickness and size dimensions may be substantially as the same as before. However, when normal and/or converted papers or metals, which are practically impossible to color with sublimative dyestuffs, are used as the substrate layer **201**, various methods can be utilized for desired coloring. As an example, a solution including at least any selected one of plastic resin materials capable of coloring with sublimative dyestuffs may be coated on the substrate surface, or alternatively used in the form of a film which is laminated thereon. This kind of film preferably has a thickness of about 3 to 50 μm or so. One of main characterizing features represented in and by the final products **200** is that the appearing display image or images as at **204** is/are formed at least partially or wholly with a sublimative dyestuff or dyestuffs. Additionally, the process for formation of such images can be executed in the conventional art.

As an example, the processing method may be executed conventionally as follows.

As an example, a sublimative image transferable sheet, such as a paper sheet, plastic resin film or sheet capable of acting as the carrier is coated on its surface with any suitable binder resin carrier carrying sublimative a dyestuff or dyestuffs under heat, is overlapped on the display layer **202** and then subjected to heat from behind the heat-transferable sheet, preferably in the pattern mode, so as to transfer the dyestuff or dyestuffs into the display layer **202**. It is proper to select the molecular weight of 250 or larger of the dyestuff, for improving the fastness thereof. However, a molecular weight higher than 370 is more favorable. In the

case of provision of the surface protecting layer, there is practically no limitation to the selectability of the dyestuff molecular weight.

The sublimative image transfer may be executed directly on the surface of substrate **201** provided with the display layer **202**. Or alternatively, a carrying, image transferable sheet is prepared separately and, after formation of the image **204** thereon, may be stuck onto or laminated on the substrate **201**.

Image-carrying and Image-transferable Sheet

In the following, structure, material, usage and application purpose of the image-transferable sheet to be employed in the present invention will be described in detail:

FIG. **13** illustrates only basically and in schematic sectional view the image-transferable sheet adopted in the present invention, while FIGS. **14** through **19** and **22** through **24** illustrate preferable embodiments thereof.

The basic structure of the image transferable sheet **310** is characterized in that, as shown in FIG. **13**, a sheet-like substrate **301** is provided at its one surface with an image-reception layer **302** capable of peel-off from the substrate. By adopting such a structural configuration of the image-transferable sheet, the image-reception layer **302** can be formed with the required image or images with the use of an image transferable sheet having thermally shiftable dyestuff, and then, the image-formed, image-reception layer **302** is peeled off from substrate **301** and attached firmly preferably as by sticking, on the surface of any selected object or article with use of any suitable means. In this way, various conventional drawbacks inherent in the comparative. Conventional technique can be basically overcome.

More specifically, as the material of the aforementioned image-reception layer **302**, limitation must be imposed to those which can be colored with thermally shiftable or transferable dyestuff. However, upon formation of necessary images and upon peel-off from the sheet-like substrate **301**, the image-reception layer **302** may be attached fixedly onto the surface of glass-made, metal-made or wooden-made products or plastic-resin made ones which are very difficult to color with thermally shiftable and transferable dyestuffs, indeed, by reliance on conventional sticking techniques as properly adopted in consideration of the specific nature and kind of the material of decorative products to be ornamented. Further, the image-formed and peeled-off, image-reception layer **302** from the sheet substrate **301**, is highly thin and thus sufficiently pliable so that it may be applied even onto any uneven and complicated surface of a product to be decorated or ornamented, having undulations, convexities, concavities, recesses and projections. Therefore, a maximum possible better fitness of the image-reception layer to be ornamented is attained and guaranteed by the present invention. Thus, practically no limitation in the attaching use thereof may be encountered. Further, in sharp contrast to conventional sealing seals and the like, the very thin image-reception layer bearing necessary images can be applied easily to the product per se in a very uniform manner, thus providing no raised and thickened feeling, and giving rise to no foreign feeling upon attachment.

FIG. **14** shows a further example of the image transferable sheet **310**, In this case, there is provided a parting agent layer **303** on the surface of image-reception layer **302**. Between the latter and the sheet substrate **301**, there is provided a parting agent layer **303'**. If necessary, however, any one of the two layers **303**; **303'** may be dispensed with.

The first parting agent layer **303** is provided for prevention of thermal fusion between the image-reception layer **302** and an image transferable sheet, not shown, as may occur during image transfer and formation on the first layer **302** through transfer of thermally transferable dyestuff from the said transferable sheet to the first layer. If there is no risk of such thermal fusion of the above nature, or when the image-transferable sheet has been already provided with such a parting agent layer, the present provision thereof may be unnecessary. As for another parting agent layer **303'**, it is for the purpose of making the latter peel-off operation, to be executed after image-forming step, easier. When the sheet-like substrate **301** is made of polyester or the like material which has, as it is, sufficient separability from image-reception layer **302**, provision of parting agent layer may naturally be dispensed with.

FIG. **15** illustrates a still further example of image transferable sheet **310**. In this case, between the image-reception **302** and the sheet-like substrate **301**, an intermediate layer **304** and/or parting agent layer **303'** is/are provided. The laminating order is optional and thus not binding. The intermediate layer **304** will serve to assist the image formation to be rather firm and beautiful, the image formation being carried out by transferring the thermally shifting and transferring dyestuff from the image transferable sheet to the image-reception layer **302**. For this purpose, the intermediate layer **304** may take, for example, the form of a cushioning layer or heat insulating layer. When a cushioning layer is provided as the intermediate layer **304**, the cohesion between the image transferable sheet and the image reception layer **302** is greatly improved and the thermal shift and transfer of the dyestuff during image formation with the use of a thermal head is evenly executed, the image formation thereby being carried out amply in correspondence with the supplied image signals. Further, when a heat insulating layer consisting of a highly heat-insulative material is used as the intermediate layer **304**, ineffective release of the heat applied during shift and transfer of the dyestuff from the image transferable sheet to the image-reception layer **302** can be reduced to a minimum possible, the effective thermal efficiency thereby being correspondingly improved and ample image formation being accelerated. If necessary, however, these cushioning layer and heat-insulating layer can be prepared independently and arranged concurrently in any arranging order.

Additionally, when the intermediate layer **304** is arranged at a higher level than the parting agent layer **303'**, the intermediate layer **304** will be conjointedly peeled off in the case of peel-off of the image-reception layer **302**. On the contrary, when the intermediate layer **304** is arranged at a lower level than the parting agent layer **303'**, the intermediate layer will remain on the sheet-like substrate **301** after execution of the separation of image-reception layer **302**. In this case, therefore, the intermediate layer **304** may be made preferably and at least substantially transparent, when the peeled-off image-reception layer **302** is stuck on a decorative product, while directing the surface of parting agent layer **303** towards the latter.

In the modifications shown in FIGS. **16**, **17**, and **18**, modified from the foregoing embodiment shown in FIG. **15**, a further protecting layer **305** is provided between the image-reception layer **302** and the sheet-like substrate **301**. This protecting layer **305** serves to prevent deterioration of the formed images in the image-reception layer **302** when the latter is stuck on the decorating product while directing the surface (more specifically the image-formed surface) towards the product. For example, this protecting layer **305** is prepared from a superior material which exhibits at least one of desirous properties such as antiwearing, light-fast,

weather proofing and anti-chemical qualities. With the use of the protecting layer **305** having these superior qualities, the images can represent improved fastness in the above various aspects, even after execution of the foregoing sticking procedure.

In the modification shown in FIG. **16**, the protecting layer **305** is arranged between the intermediate layer **304** and the parting agent layer **303'**.

In the further modification shown in FIG. **17**, the protecting layer **305** is arranged between the image-reception layer **302** and the parting agent layer **303'**.

In still another modification shown in FIG. **18**, the intermediate layer **304** takes the role of the protecting layer **305**.

In each of these modifications, the protecting layer **305** is arranged in neighboring relationship with the partition agent layer **303'**, whereby the image-formed and remotely arranged, image-reception layer **302**, kept in its up-and-down reversed state, is capable of adhering securely to the decorative product, so as to be positioned as an uppermost layer, as may be required. In a still further modification shown in FIG. **19**, derived from that shown in FIG. **14**, a sticking layer **306** is further provided between the image-reception layer **302** and the partition agent layer **303**. It should be noted, however, that such a sticking layer as at **306** may be provided in any one of other foregoing examples and modifications, if necessary, in neighboring relationship with the parting agent layer **303'**.

The provision of such a sticking layer as at **306** is highly valuable when the image-formed and peeled-off, image-reception layer is adhering without position reversal onto the decorative product. With this arrangement mode, the protecting layer **305** shown in FIGS. **16**, **17**, and **18** may be dispensed with. If, however, the protecting layer **305** is composed of a material in the form of a sheet-like substrate, the part to be peeled off is thereby strengthed, the peel-off procedure thus being greatly facilitated.

By previous provision of the sticking layer **306**, the image-formed and peeled-off, image-reception sheet **302** can be caused to adhere as it is onto the decorative product without use of a separate sticking agent. As the sticking layer **306**, an ordinary sticking agent which is active at room temperature can be used. Or alternatively, a heat-sensible or light-sensitive sticking agent may be used, if necessary.

In the foregoing, the main structure of the image transferable sheet employed in the present invention has been described in detail. However, other structural modes than those set forth hereinbefore which occur easily to those skilled in the art may be employable in the invention, and thus they may be included within the scope of the invention without departing from the appended claims.

It should be further noted that, in the present invention, the sheet-like substrate may be provided on its one surface with an image-transferable layer capable of peeling off through the intermediary of only one weakly sticking layer.

FIG. **22** shows only schematically in a sectional view a preferred embodiment of such an image-transferable sheet, denoted with same reference numeral **310**.

As shown in FIG. **22**, the image-transferable sheet **310** represents a basic structural characteristic such that any suitable sheet-like substrate **301** is provided on one of the surfaces with an image-reception layer **302** through an only weakly sticking intermediate layer **402**, the layer **302** thus being easily peeled-off when desired. By providing the image-transferable sheet with such a structural characteristic as set forth above, desired positive or negative images are formed by transferring thermally shiftable and transferable dyestuff from the image heat transferable sheet to the image-reception layer **302**, and the thus image-formed layer is peeled off from the sheet-like substrate **301** and then attached onto any suitably selected product with the use of proper means or attached per se thereon without the peeling-off operation, the substrate then being peeled off, whereby an image-formed final product can be obtained.

In the foregoing example, it should be noted that the image reception sheet **302** per se has only a thin thickness and thus represents only poor feedability during the sheet-feeding period within the printer at the time of image formation, insufficient cushioning effect and only insufficient thermal efficiency during the printing operation, and further, it is very difficult to treat in advance of as well as after execution of the image formation. Therefore, the coexistence of the image-reception layer **302** and the sheet-like substrate **301** is absolutely necessary. In addition, it is a requisite requirement that the image reception layer **302** be easily peeled off from the sheet-like substrate **301** upon execution of the image-forming operation, and thus, the layer **302** and the sheet **301** should not be stuck too strongly together. In order to satisfy this requirement, provision is made of weakly stuck layer **402** therebetween. Thus, it should be noted that the term "weakly stuck" employed in this specification and appended claims may be defined as "to be separable by finger's end and the like means from each other without entailing destruction or breakage of the parts originally stuck together". It is worthwhile to say, in considering the relative relationship between the image-reception layer **302** and the sheet-like substrate **301**, there is no necessity to provide the weakly-stuck layer **402** if the aforementioned peeling-off is very easy to bring about.

FIG. **23** illustrates still another modification of the image-transferable sheet **310** denoted by the same reference numeral **310** only for simplicity and convenience, wherein a further parting agent layer **303** is provided on the surface of image-reception layer **302**.

This layer **302** is provided for occasional thermal sticking between the thermal image transferable sheet, not shown, and the image reception layer **302** in the progress of thermal shift and transfer of the dyestuff from the sheet to the layer **302**. This provision of the parting agent layer **303** may be dispensed with if there is no risk of occurrence of such disadvantageous sticking attachment or the sheet under consideration has already been fitted with such a parting agent layer.

A modification shown in FIG. **24** from that shown in FIG. **23** has such a modified structure that a protecting layer **305** is provided between the image-reception layer **302** and the weakly stuck layer **305**. This layer **305** serves to prevent otherwise occurring deterioration of the images at the image-reception layer **302** which has been formed with preferably reversed images and subjected to peeling-off, together with protecting layer **305**, preferably a plastic sheet layer, from the sheet-like substrate **301** and finally stuck onto the decorative product, while directing the image-formed surface of the image-reception layer towards the product. The protecting layer **305** is made of a material having various excellent physical properties, such as anti-wearing-, light-fastness and antichemical characteristics. Provision of such a protecting layer improves various fastness performances of the formed images after sticking attachment of the image-reception layer **302**.

When necessary, a separate parting agent layer, not shown, may be provided between the protecting layer **305**

and the weakly stuck layer **402** for providing easy peel-off capability between these two layers **305** and **402**, as being applicable to the example shown in FIG. **24**. If the surface of the protecting layer **305** should have sufficient peel-off capability, it is natural to provide such an intermediate parting agent layer as above.

Further, in the case of the image-transferable sheet **310**, it is naturally easy to separate from each other through a peel-off operation, upon the formation of necessary images thereon and before practical use thereof as the image-transfer sheet, and a cut-out slit as at **407** in the sheet-like substrate **301** may be provided for attaining such an easy separation as stated above at a portion of the sheet **310** in proximity to one end thereof. Upon the provision of such a cut-out slit as at **407**, the thus formed flap-like portion can be easily folded out by the operator's finger-tip, thereby affording convenience in a peel-off operation.

The usable materials and composing methods of the foregoing image transferable sheets will now be described.

As a material usable for the sheet-like substrate may be any one or any combination of the following categories:

(1) synthetic paper (polyolefin-series; polystyrene series and the like);

(2) fine quality paper; art paper; coated paper; cast-coated paper, wall paper; back-up paper; backing paper; resin-, emulsion- or synthetic rubber-imprignated paper; resin-admixed paper; paper board; cellulose fiber paper;

(3) polyolefin-, polyvinyl chloride-, polyethylene terephthalate; polystyrene; polymethacrylate; polycarbonate and the like plastic film or sheet. Use of the synthetic paper belonging to the foregoing category (1) is highly suitable for the purpose of the present invention since the surface thereof generally represents a microvoid layer which provides a low heat conductivity and thus a high heat-insulating peformance. A laminated material representing any combination of the foregoing categories (1), (2) and (3) can be used in the present invention. A representative and recommendable example of such a laminate is that of cellulose fiber paper and synthetic paper or that of cellulose fiber paper and plastic resin film or sheet. Among others, use of the first mentioned kind of laminate will provide an advantage in that the thermal instability such as thermal elongation or shrinkage possessed by the synthetic paper component is compensated for by the cellulose fiber paper, whereby a high thermal sensibility is demonstrated during the printing step due to low thermal conductivity of the synthetic paper component. Further, in the case of the present paper combination, however, a further modified combination of a three-layer laminate: synthetic paper-cellulose fiber paper-synthetic paper may be more advantageously employed for making the frequently appearing lesser by providing a well-balanced structure between both the surfaces of the final laminate.

As the synthetic paper mentioned above, any suitable one usable as a synthetic paper substrate used as a component of the image-transferable sheet layer may be used. As a recommendable example thereof, having a fine porous fine paper structure layer, the synthetic paper called "YUPO", manufactured and sold by Oji Yuka Goseishi Kabushiki Kaishar Tokyo, may be mentioned. This paper layer having a fine pore structure may be prepared in such a way that a suitable plastic resin material containing a filler of finely divided state is subjected to a mechanical elongation step. When the image-transferable sheet composed of the synthetic paper sheet containing finely divided air as above mentioned is formed with images through a thermal image transfer setp, the concentration of. the thus formed images is surprisingly high and no fluctuation of image configuration and concentration is encountered, thanks to the heat insulation effect provided by the very existence of fine air pores, in addition to the improved thermal energy efficiency. Especially, due to the advantageous cushioning effect provided by the air-filled fine pores, the image-receiving layer is supposed to be rather advantageously affected during the image formation step. As an alternative measure, the paper-like layer containing the above-mentioned fine air pores may be, if desired, provided directly with the core material consisting of the cellulose fiber paper or the like.

It is further possible to use plastic film in addition to the cellulose fiber paper in the laminate described above. Still further, a laminate of said cellulose fiber paper and plastic film composed together can be used.

As the method for co-sticking of synthetic paper and cellulose fiber paper, use of a known adhesive agent is naturally adopted, as an example. Or alternatively, the extrusion-laminating, heat-adhesion, or the like process may be relied upon, as the case may be. On the other hand, as the sticking-process between the synthetic paper and the plastic film, the lamination process to be carried out simultaneously with the formation of the film may be adopted. Calendering or the like method may be utilized for the same purpose. Selection of any suitable one of the several foregoing sticking processes depends upon the kind of material or the like condition of the partner member to be stuck together with the synthetic paper. As for the adhesive agent mentioned above, emulsion adhesive such as ethylene-vinyl acetate copolymer, polyvinyl acetate or the like, aqueous solution type adhesive polyester containing carboxyl radicals; or the like may be mentioned. On the other hand, as the laminating use adhesive, organic solvent solution type one such as polyurethane-, acrylic- or the like, may be mentioned.

The material for the image-reception layer must be suitable for reception of heat-transfer dyestuff, such as sublimative disperse dye from the image transfer sheet and holding and maintaining the thus formed images thereon. From the view point of image-holding and blocking prevention, use of such synthetic resin as having glass transition temperature higher than 40° C. may be advantageous. For example, the synthetic resins set forth in the following items (a) through (e) may be used separately or in combination.

(a) Ester bond-bearing resins: Polyester resin; polyacrylic ester resin; polycarbonate resin; polyvinyl acetate resin; styrene acrylate resin; vinyltoluene acrylate resin and the like.

(b) Urethane bond-bearing resins: Polyurethane resin and the like.

(c) Amide-bond carrying resins: Polyamide resins (nylons).

(d) Urea-bond carrying resins: Urea resins and the like.

(e) Other high polar-bond carrying substances: Polycaprolacton resin; polystyrene resin; polyvinylchloride resin; polyacrylonitrile resin and the like.

The image-reception layer may be prepared from a resin mixture of saturated polyester and vinylchloridevinyl acetate copolymer. As the saturated polyester, such commercialized products: "Vylon 200"; "Vylon 290"; "Vylon 600"; "Vylon 103" and the like, manufactured and sold by Toyoboseki K.K., Osaka, Japan; "KA-1038C" (manufactured and

sold by Arakawa Kagaku K.K., Osaka, Japan; "TP 220"; "TP 235", manufactured and sold by Nippon Gosei K.K., Osaka, Japan; may be advantageously used. The vinyl chloride-vinyl acetate copolymer may have preferably 85–97 wt. % of vinyl chloride component, the polymerization degree being between about 200 and 800. The vinyl chloride-vinyl acetate copolymer may further contain a vinyl alcohol component, maleic acid component within the purpose of the invention in addition to the main components. According to our experiments, it has been found that these modified copolymers should have rather superior compatibility with polyester resin. The image-reception layer may be, if necessary, composed of polystyrene resin, for example, in this case, styrene monomer, preferably styrene, α-methyl styrene, and vinyl toluene may be used separately or in the form of copolymer or saying in general sense polystyrene resin. Further, such styrene copolymer resin may be used as specifically recommendable material in the above sense, comprising said styrene monomer(s) with other monomer, preferably for example, acrylic acid ester, methacrylic acid ester, acrylonitrile, methacrylonitrile and the acrylic or methacrylic monomer, or further styrene copolymer resin comprising maleic acid anhydride.

It should be noted, however, that among others, polyester series resin is especially superior for the purpose of the present invention.

In any of the foregoing embodiments, however, white pigment is preferably admixed with the material of the image-reception layer for improving the whiteness thereof and further accentuating the sharpness and fineness of the images when transferred thereto and to provide a manually writing-on performance. As the white pigment for this purpose, the following materials may be used separately or in any combination: titanium oxide; zinc oxide; china clay calcium carbonate; finely divided silica and the like.

For further improving the whiteness fluorescent whiteness-increasing agent or -bleaching agent may be added to. Further, for improving the light fastness of transferred images, ultraviolet absorption agent and/or photostabilizing agent may be added to, preferably in a quantity of 0.05 to 10 and 0.5 to 3 weight parts per 100 weight parts of the material resin composing the image-reception layer.

The image-transferable sheet used in the present invention is preferably constituted for improving the separability from the image-transfer sheet in such a way that the surface of the image-reception layer is formed with a partition agent layer, or instead, such agent is admixed to the image-reception layer. As for the partition agent to be used for this purpose, polyethylene wax; Amido Wax, Teflon Powder or the like solid wax; surface active agents such as fluorine-contained agent or phosphoric acid ester series surfactant; silicone oil or the like may be selectively used. Among others, silicone oil may be advantageously utilized.

The silicone oil may be used in oily state, but a hardenable type thereof may be rather advantageous. As the hardenable silicone oil, reaction-hardening one, photo-hardening one, catalytically hardening or the like one may be used selectively according to necessity. However, use of the reaction-hardenable one is most highly recommendable. Silicone oil of this type may be obtained, as example, by reacting amino-modified silicone oil with epoxy-modified silicone oil to obtain a reaction-hardened product. As for the amino-modified silicone oil, "KF-394", "KF-857", "KF-858"; and "X-22-3680"; "X-22-3801C" (manufactured and sold by Shinetsu Kagaku Kogyo K.K., (Tokyo, Japan)) and equivalents thereof may be used. As for the epoxy-modified silicone oil, "KF-100T"; "KF-101"; "KF-60-164"; and "KF-103" (manufactured by Shinetsu, above mentioned) and equivalents thereof may be used. Further, as the catalytically hardenable and photohardenable silicone oils in the above sense, "KS-705F"; "KS-770" of the catalytic hardenable or hardened silicone oils, manufactured by Shinetsu; and "KS-720" and "KS-774" of the photo-hardenable or hardened silicone oils (manufactured equally by Shinetsu) and equivalents thereof may be used. The adding quantity of each of these hardenable or hardened silicone oils may advantageously range from 0.5 to 30 wt. % depending on the material of the resin composing the image-reception layer.

At least a part of the image-reception layer is coated with a solution or dispersion of any of the foregoing partition agents in a suitable solvent and dried and further treated, a suitable parting layer being provided thereon. A particularly suitable partition agent for the formation of this kind of partition layer is the aforementioned reaction type hardenable one obtainable by reacton of an amine-modified silicone oil with an epoxy-modified one. The thickness of the partition layer is 0.01–5 μ, preferably 0.05–2 μ.

It should be noted that when silicone oil is admixed during formation of the image-reception layer, the silicone oil will bleed out after coating and the parting agent layer can be formed by the hardening even after such bleeding. In order to improve the parting ability between the image transferable layer and sheet-like substrate, it is possible to provide a parting layer consisting of a heat-hardenable resin, preferably of the melamine series, and having better affinity for the image transferable layer compositions. For the same purpose as above, however, without special provision of the parting layer, a protecting layer consisting of polymethyl methacrylate resin or cellulose acetate propionate can be provided.

For the formation of the image transferable layer, a solution or dispersion of a material composition suitable for the purpose is applied on the sheet-like substrate through conventional coating or printing. As an alternative way, a separate film or sheet for the image transferable layer **302** is formed preparatorily on a provisional carrier sheet or film and then, as a succeeding step, subjected to an image-transfer onto the substrate.

The intermediate layer is made of either a cushioning or a porous material. In some cases, the intermediate layer may additionally function as the adhesive layer.

The cushioning layer is mainly composed of such a resin which has a value of 100%-modulus as defined at JIS-K-6031 (Japanese Industrial Standard) of less than 100 kg/cm^2. If this value should exceed the above prescribed value, the rigidity will become much higher than that recommended for the intermediate layer. When the layer is formed with such disadvantageous material resin, sufficient adhesion between the heat image-transfer sheet and the image-reception layer cannot be maintained during the printing step. The lower limit of the prescribed 100%-modulus is of the order of 0.5 kg/cm^2 in actual practice.

Preferable kinds of resin to be used for the above purpose, may be enlisted as follows:

polyurethane resin; polyester resin; polybutadine resin; polyacrylic acid ester resin; epoxy resin; polyamide resin; rosin-modified phenol resin; terpene phenol resin; ethylene/vinylacetate copolymer resin; and the like.

These resins can be used independently or in combination of two or more kinds. Since these resins are rather viscous and tend to give rise to manufacturing troubles inorganic additives may be admixed, such as, for example, silica; alumina; clay; calcium carbonate; amide series substance such as amide stearate; and/or the like.

The cushioning layer is preferably formed with the use of one or more of the above specified resins, occasionally with the addition of suitable additive(s); solvent or diluent, prepared into a coating agent or printing ink which is then applied on, according to a known coating or printing process and then subjected to drying to provide a coating. The thickness of the coating should be between 0.5–50 μm, preferably 2–20 μm or so. With a thickness less than 0.5 μm, the coating will not be able to compensate for the surface irregularities on the substrate, thus being ineffective for the desired purpose. On the other hand, when the thickness exceeds the above specified maximum value or more specifically 50 μm, the overall thickness of the image-transferable layer becomes much too large, so that handling troubles may be encountered during wind-up and overlapping procedures, without attaining further effect as desired. In addition, in this case, a loss of production economy will be inevitably introduced.

The thus obtainable improvement of intimate adhesion between the heat-image transfer sheet and the thermally image-transferable sheet by the provision of the above intermediate layer may be conceivably attributed to the lower rigidity of the intermediate layer per se, whereby it is liably to be deformed under the influence of the printing pressure, and further to the generally relatively low glass transition temperature and softening temperature of the aforementioned kinds of resin resulting in further lowering of rigidity and tendency to deform than at room temperatures upon reception of heat energy during the image printing step.

The porous layer may be formed generally in the following four ways: 1) through 4).

1) Emulsion of polyurethane or the like resin, methylmethacrylate-butadiene series synthetic rubber latex is foamed by mechanical agitation, coated, and dried on the sheet substrate into a layer.
2) The synthetic resin emulsion or synthetic rubber latex is admixed with a foaming agent and the liquid mixture is coated and dried on the substrate into a layer.
3) Vinyl chloride-plastisol, polyurethane or the like synthetic resin or styrene-butadiene series or the like synthetic rubber is added with a foaming agent and the liquid mixture is coated on the substrate and subjected to heating to provide a foamed layer formed thereon.
4) A thermoplastic resin or synthetic rubber is dissolved in an organic solvent to provide a solution, and a non-solvent (including that containing aqueous main component), and the latter solution are mixed together to provide a liquid mixture, said nonsolvent being less volatile than the organic solvent and having a considerable mutual solubility with the solvent, and showing, however, non-solubility with the thermoplastic resin or synthetic rubber. The thus prepared liquid mixture is then coated on the sheet-like substrate and dried, to provide a porous membrane upon microcoagulation of the constituents. The resulting microporous layer can be utilized for the above purpose.

It should be noted that the layers produced by any of the foregoing three processes 1) to 3) have rather large foams contained therein, and thus when the foaming solution for the image-transferable layer is applied thereon and dried, the latter may exhibit excessively coarse surface conditions. Therefore, in order to obtain an optimumly image-transferable smooth surface capable of providing transferred images of high uniformity, provision of the micro-porous layer prepared by the process as set forth in the foregoing item 4) is highly recommendable.

As the thermoplastic resin suitable for the formation of the above porous layer, saturated polyester; polyurethane; vinylchloride-vinylacetate copolymer; cellulose acetopropionate and the like can be used. Further, as the synthetic rubber usable for the same purpose, those of styrene-butadiene series, isoprene series, urethane and the like series may be used. Still further, as the organic solvent and non-solvent liquid used for the formation of the microporous layer, various known substances may be used. Generally speaking, however, methyl ethyl ketone; alcohol and the like are representatively used. On the other hand, as the non-solvent, water is mostly used.

The thickness of the porous layer usable in the present invention is preferably greater than 3 μm, especially preferably in the range of 5 to 20 μm. With the use of a porous layer having a thickness of less than 3 μm, the desired cushioning and heat-insulating effects cannot be attained.

As was referred to hereinbefore in the description stage for the formation of the image-transferable layer, the intermediate layer may act simultaneously as the sticking layer in some cases.

This kind of intermediate layer(s) may be provided on one or both of the surfaces of the thermally image-transferable sheet.

In practice, however, an electrostatic charge may accumulate in the material of the thermally image-transferable sheet during its processing step or during running through the printer. As a countermeasure, a proper antistatic agent may be applied on one surface of the image-transferable layer or on the bottom surface of the thermally image-transferable sheet or it can be included in the material of the image-transferable layer. As the antistatic agent in this sense, a surfactant such as a cation-exchange agent (for example, a quaternary ammonium salt, polyamide derivatives and the like) may be advantageously used. Further, an anion exchange type surfactant, such as alkyl sulfonate may be used. Otherwise, amphoteric ion type surfactants or even, non-ionic surfactants may be used for the same purpose.

On the other hand, the antistatic agents may be coated on the surface of image-reception layer by gravure-coating, bar-coating or the like process or alternatively, these agents may be kneaded with the material resin and then subjected to transfer towards the surface during the coating formation and drying step for preparing and providing the image-transferable layer. As the antistatic agents to be admixed with the image-transferable layer material resin, cation-type acrylic polymers may be employed.

The protecting layer is peeled off together with the image-transferred layer, from the sheet-like substrate, and then stuck, in inverted reversed state, onto any desired decorative object, the protecting layer thereby being positioned at the uppermost position, for improving the anti-wearing-light-proofing and anti-chemical performances of the image-bearing layer. As the material adapted for the formation of the protecting layer, for example, alkyd resin; phenol-modified alkyd resin; aminoalkyd resin; phenol resin; urea resin, melamine resin; silicone resin, thermosetting acryl resin, thermosetting polyurethane resin and the like thermosetting resin or normal temperature setting resin; further, ultraviolet hardenable resin; electron ray hardenable and the like activating energy flux hardenable resins or thermoplastic resins such as polyester-; polyurethane-; polyvinyl acetate resin; vinyl chloridevinyl acetate copolymer resin; polyolefin resin, acryl resin and the like, can be used.

Preparation and use of a protecting layer comprising one or more of the above-mentioned resins are made in such a way that the material resin is dissolved in a properly selected

solvent according to the necessity, so as to provide a coating liquid or ink, as the case may be, which is provided between the parting layer and the image transferable layer. The thickness thereof is generally 0.5 to 20 μm. It is also possible to form the protecting layer with the use of a resin film which consists of polyester-; acryl-; acrylpolyol-; polyvinyl chloride-; olefin resin or the like resin. It is further possible advantageously to admix an ultraviolet ray absorbing agent and/or photostabilizer to the material of the protecting layer.

The protecting layers prepared and formed in the foregoing way are thus not made integral with the sheet-like substrate or parting layer and, therefore, the peel-off operation of the sheet-like substrate upon execution of the image transfer is very simple and easy.

It is further recommendable, if necessary, to provide a slip-promoting layer on the bottom surface of the sheet-like substrate, which surface is naturally the one opposite to the image-transferable layer side, so as to properly adjust the friction between the image-transferable sheet and feed roll paper or carrier belt acting during passage through the printer and to improve the running performance of the thermally image-transferable sheet in the printer.

The slip-promoting layer can be formed by adding an organic powder such as polyethylene wax fluorine resin powder or an inorganic powder such as talc, according to necessity, to a resin such as polymethyl methacrylate resin; vinyl chloride-vinylacetate copolymer; vinyl chloride copolymer; cellulose acetate butylate; cellulose acetate propionate; styrene-acryl series or the like resin and kneading the resulting mixture to prepare a composition, applying this composition as a coating on the sheet substrate either directly or after application of a suitable primer treatment, and drying the coating thus applied. A suitable quantity of the slip-promoting layer is 0.5 to 5 g/m^2 after drying.

In the embodiments shown in FIGS. **22**, **23**, and **24**, as the adhesive agent to be used in the slightly weak or weak adhesive layer, it should be noted that those conventionally used adhesives for adhesive tapes and seals can all be used. Preferred examples are polyisoprene rubber; polyisobutyl rubber; styrene butadiene rubber; butadiene acrylonitrile rubber and the like rubber-series resins; (meth)acrylic acid ester-series resins; polyvinyl ether-series resins; polyvinyl acetate-series resins; vinylchloride-acetate copolymer series resins; polystyrene-series resins; polyester-series resins; polyamide-series resins; polychlorinated olefin-series resins; and polyvinyl butyrol-series resins. To the suitably selected adherent may be added a proper quantity of a stickness improver, such as rosin; dammar; polymerized rosin; partially hydrogenated rosin; ester rosin; polyterpene-series resins, terpene-modified substances; petroleum-originated resins; cycropentadiene-series resins; phenol resins; styrene resins; xylene resins; and coumarone-indene resin. Further, when necessary, to the mixture may be added a softening agent, filler; antiaging substance or the like conventional agent(s). As the material for the formation of slightly or weak-adherent layer said above, emulsion type adhesive, preferably of acryl acid ester series can be used. As for the parting function after a long time of preservation, emulsion type adhesives are highly recommendable. These adhesive agents are easily procurable from market.

When necessary, these adhesives are added with proper organic solvent(s) for the adjustment of the viscosity, and then applied by roll coating, die-coating, knife coating, gravure coating or the like conventional technique on the surface of the sheet-like substrate, image-reception layer or protecting layer, so as to provide an adhesive agent layer. The thus formed adhesive layer is preferably of a thickness of 1–50 μm, although this is not limitative.

Formation of Images

In the following, the decorating process according to this invention will be set forth in detail. Utilization of the image-transferable sheet according to this invention constitutes an important main feature thereof.

In FIGS. **20** and **21**, basic practising processes will be described first.

The embodiment shown in FIG. **20** is a result of the use of the transferable sheet shown in FIG. **13**. First, a known transfer sheet **320** is applied onto the image-transferable sheet **310** in an overlapped manner such that the dye-carrying layer **321** is kept in opposition to the image-reception layer **302** of image-transfer sheet **320**, and heat energy is applied, as schematically shown by a plurality of arrows, in accordance with image signals fed at a thermal head, not shown, from the side of image-transferable sheet **310**, or preferably, from the side of the image-transfer sheet **320**, thereby forming the desired images as at **307** in the image-reception layer **302**. Next, the image-reception layer **302** formed therein with the desired images **307** is peeled off from sheet-like substrate **301** and stuck onto the decorative product **306**. Or alternatively, both the sheets **302**; **301** are stuck onto the product **306** without preparatory peeling-off. In the latter case, the peel-off step may be executed after execution of the stickingly attaching step. In the above former case, and in such a case where an adhesive agent layer **306** has preparatorily provided between image-reception layer **302** and sheet-like substrate **301** as was set forth hereinbefore, the sticking attachment is carried into effect in such a way that the adhesive layer **306** is kept in opposing contact with the product **330**, and then the sticking operation is brought about by application of heat and pressure or light and pressure, depending upon the nature and structure of the layer **306**. In this way, the decoration according to the present invention is completed as a preferred one mode thereof.

On the other hand, if there is no preparatory provision of the adhesive layer, either the surface of product **330** or of the peeled-off image reception layer **302**, may be coated with the adhesive agent, and the latter layer **302** per se or otherwise in the up-and-down reversed state may be stickingly attached onto the product **330** (refer to FIG. **21**).

Since the image-reception layer **302** is composed generally of such thermoplastic resin material as is liable to be colored with thermally transferable dyestuff, it can be thermally and fusingly attached to plastic resin-made formings, clothes or metals even with provision of an adhesive layer, if necessary.

In this case, the image-bearing layer **302**, the image thereof having been formed in the aforementioned way, is stuck on, through the intermediary of the adhesive agent layer **306** as shown in FIG. **25**, while retaining the sheet-like substrate **301** on the surface of the image-reception layer **302**.

A modification of the last-mentioned mode is shown in FIG. **26**. In this case, sheet-like substrate **301** is formed on the surface of the product **330** and the image-reception layer **302** is formed as the outermost layer. Further, in this case, sheet-like substrate **301** and product **330** may be stuck together, and, through the intermediary of a suitable adhesive layer, sticking layer or heat-sealable sheet or the like.

As for the transparent film usable as the said sheet-like substrate, it must be transparent to such a degree as not to conceal the images formed in the image-reception layer, and, in addition, it must have superior surface properties such as,

for instance, antiwearing characteristics. As an example, polyolefine; polyvinyl chloride; polyethylene terephthalate; polystyrene; polymethacrylate; polycarbonate and the like plastic resin-made films may be used upon variously surface conditioning. If these transparent films should be too thick, the images will be raised, and the unitary feelings may be lost when these are stuck on respective products to be decorated. Therefore, the film thickness is preferably of the order of 0.5 to 50 μm.

In the case of a further embodiment of the present invention, the image reception layer of image transferable sheet which has been, however, formed with necessary images is subjected to image transfer treatment onto an intermediate image transferable substrate, the latter is then subjected to an image-retransfer with the images, and the thus retransferred images are again transferred onto the surface of the product to be decorated. In the following, this image transfer mode will be set forth in detail.

Embodiments shown in FIGS. **27**, **28** and **29** represent such a process for execution of image transfer operation as by the intermediary of intermediate image transfer sheet **510**. First, as shown in FIG. **27**, a thermally image-transfer sheet **320** having a thermal transferable dyestuff layer **321** is overlapped to image-transfer sheet **510** which is, at this stage, not formed with images **307** and thus consists of a thermal image-transferable sheet, in such a way that the dyestuff layer **321** or more specifically the parting layer **322** is in opposition to the image-reception layer **302** of the foregoing sheet **510**. In such a case, however, that heat energy is supplied in accordance with image-forming signals delivered from the thermal head, not shown, and, indeed, preferably from the side of the sheet **320** as hinted by a plurality of double-line arrows for thermal formation of desired images (positive images) as at **307** in the image-reception layer **302**, it is highly recommendable to provide an adhesive layer **402** between the layer **302** and sheet-like substrate **301**.

Then, with the use of the image transfer sheet **510** formed with positive images **307**, the images of layer **302** are transferred, as shown in FIG. **28**, to a separate intermediate substrate **501**, which is, however, fitted with a protecting film layer **305**, thus, the transfer being carried out, in fact, onto the latter, and indeed, with the correspondingly inverted images, attached with same reference numeral only for convenience, from the foregoing layer **302**. In this case, it is preferable to subject the adhesive layer **402** of the image-transfer sheet **510** to the image-transfer operation, together with the image-reception layer **302**. Further, as for the intermediate image-transfer substrate **501**, it is recommendable to provide the protecting film layer **305** through the intermediary of a weak-adhesive layer **402'** as shown. The thus provided intermediate image-transfer sheet **610** represents generally the image-transferable sheet.

FIG. **29** illustrates the step for transfer of the image-reception layer **302** now carrying positive images **307** onto the object **330** to be decorated and under utilization of the previously described intermediate image-transfer sheet **610**.

More specifically, the intermediate image-transfer sheet **610** is overlapped onto the said object **330** in such a way that the adhesive layer **402** of the former in opposition to the surface of the object **330** and pressurized together. Then, the intermediate transfer substrate **501** together with the weak-adhesive layer **402'** is peeled off from the remainder of the thus-pressurized assembly, the now image-carrying layer **302** formed with positive images **307** covered with protecting the film layer **305** thereby remaining in the transferred state on the product **330**. In the case of no provision of the protecting film layer **305** on the intermediate image-transferable sheet **610**, the layer **302** remains in an exposed state. Therefore, an overcoat layer, if necessary, can be provided on the now image-carrying layer **302**.

The previously set forth process carried out by the use of said intermediate image-transferable sheet can be executed by means of the apparatus which is shown schematically in FIG. **1**E.

In this apparatus, more specifically, there is provided a carrier system comprising a series of rolls **411**, **412**, **413** and **414** for conveying the intermediate transfer substrate (sheet), arranged in addition to the apparatus shown in FIG. **1**B. More specifically, the substrate is drawn out from feed roll **414**, conveyed through successive rolls **413**; **412** and retransferred onto one of the products **200**. Other operations are same as set forth hereinbefore with reference to FIG. **1**B. Further, in the case of FIG. **1**E, the final product may take the form of a roll-like substrate which is subjected to an image transfer operation through the intermediate substrate, by transferring its image-carrying, image-transferable layer, for later being punched out properly. Alternatively, under occasion, it may be subjected to half-cut operations downstream of roll **122**.

As was set forth herein above, the preferable method for the formation of desired images on the image-transferable sheet is carried out by use of a heat image-transfer sheet comprising a sheet-like substrate having a layer including a thermally transferable dye (evaporative dye). The heat image-transfer sheet which can be utilized in this method is known per se. And almost every kind of these known sheets can be useful in the practice of the present invention. It should be noted that by employing the foregoing image-transfer method, mono-color or full-color images can be easily formed as occasion may desire.

It should be further noted that details of such heat image-transferable sheet can be easily understood with reference to our U.S. patent application Ser. No. 833039. As for the heat image-transferable sheet usable in the present invention, the coating layer of the sheet (coating film) may include a parting agent. By adopting this measure, the image-reception layer of the image-transferable sheet or the surface thereof, to be subjected to sublimative image-transfer, must not have a separate parting agent layer, the adhesive ability between the image-reception and the surface of object to be decorated can be still further improved upon execution of the sublimative image-transfer and image-formation at the image-reception layer and adherent attachment thereof to the object. As the parting agent to be included in the coating layer of the thermally image-transferable sheet (coating film), silicone oil; silicone resin; phosphoric ester or the like surfactant; and/or chelate- and the like agents, may be selectively utilized. These agents, upon mixed, will ooze out from inside to the outer surface of the coating layer, resulting in providing a better parting quality. However, it is preferable to properly select the kind and nature of the parting agent to be used for this purpose, being such that the agent cannot transfer to the image-reception layer of the image transferable sheet during the sublimating image-transfer stage. The adding quantity of the parting agent may preferably be 3–25 wt. parts based upon the total amount of resin and coating composing the coating layer taken as 100 wt. %.

In practice, any kind of conventionally known heat transfer sheets is overlapped on the thermally image-transfer sheet employed in the present invention, and then necessary heat energy of 5–100 mJ/mm^2 is applied by use of a

conventionally known heat transfer unit, for instance, "Video-printer: VY-100" manufactured and sold by Hitachi Seisakusho, Tokyo, or its equivalent machine, for the formation of necessary images on the image-reception layer of the image-transfer sheet as set forth hereinbefore.

Peel-off operation for removal of the image-reception layer formed with necessary images in the above manner may be carried into effect in a very easy manner, so as to provide it in a thin film carrying the images thereon. In case where the thus-peeled off film carrying the images is provided beforehand with an adhesive layer, composed of a suitable adhesive agent as was referred to, at the opposite surface to the image-carrying one, the peeled-off film can be, as it is, stuck on the object to be decorated. It is natural that this adhesive attachment procedure can be performed only partially and locally on selected part of the whole surface of the object, or totally thereon, as the case may be. On the contrary, if the peel-off film is provided beforehand with no adhesive layer, the film can be subjected occasionally to a heat fusion onto the surface of the object, if the physical properties or material kind thereof is suitable for such kind of thermal fusion. Or alternatively, a properly selected adhesive agent can be preparatorily applied onto the surface of the film or object, and then, the stick-on job can be executed.

If the image-reception layer is provided preparatorily with a parting layer thereon, as was referred to, the latter layer can be removed off partially or wholly, by grinding or rubbing operation after execution of the sublimating image-transfer job, for avoiding otherwise occurrence of ill effect by the very presence of parting layer in the adhesive attachment of the image-carrying layer film onto the decorative object.

In case of that where the image-transferable sheet is provided with a protecting layer and the latter is composed of a plastic resin film, this film may preferably be cut into pieces or subjected to punch-cuttings.

FIG. **32** illustrates successive die-cutting steps in sectional views, serving for the above purpose. In this case, as shown in FIG. **32** at (a), only image-reception layer **305** of the image-transferable sheet **310**, which has been image-formed through the way of the foregoing image-transfer step, are die-cut by operation of a cutter **801**. Next, as shown in FIG. **32** at (b), a pair of hot stamps **132**'; **133**' are used to execute a pressurizing job under heat from opposite sides, thereby the decorative product **330** being processed into a final product provided tightly with an image-reception layer and a protecting layer, as shown in FIG. **32** at (c).

Further, when occasion desires, the image-carrying film is reversed up-and-down in position after execution of the peel-off job, and, the film is stuck onto the product to be decorated in such a state that the image-carrying surface of the film is kept in direct opposition to the product's decorating surface. In this case, however, it would be rather preferable that in advance of preparatory peel-off of the image-reception layer, the image-carrying transferable sheet is stuck onto the surface of the product to be decorated, and indeed, preferably with use of an adhesive agent, in such a way that the image-carrying layer is kept in direct opposition to the product surface and finally, the sheet-like substrate is peeled off, so as to leave the image-carrying surface on the product's surface.

As in the foregoing, when the images are once reversed and then stuck onto the object to be decorated, the forming images are preferable to reverse in mode (mirror-like relationship) the original to those of reversed mode.

It is further possible that the transfer or sticking-on of the image-carrying layer is carried out through the intermediary of a separate fusing sheet.

In FIG. **30**, use of such fusing sheet **701** for reimage-transfer operation of image-carrying layer **2** already formed with necessary images **307**, however, of reversed mode, and onto the surface of a product.

More specifically, the image-transferable sheet **310** is overlapped onto the product **330** to be decorated in such a way that the image-reception layer **302** carrying the necessary images **307** is kept in opposition to the surface of the product, and indeed, through the intermediary of a fusing seat **701** and then these three components are pressurized together. Further, sheet-like substrate **301**, together with parting layer **303**', is peeled off, thereby the image-reception layer **302**, now having positive images **307** formed thereon, and protecting the latter, being transferred onto the product **330**. It will be seen in this case, that there is no need for this transfer job, to provide in advance on adhesive layer on the surface of image-reception layer **302** and/or on the surface of the product **330**, and further that a direct heat fusion onto the surface of the product **330** which may be composed of plastic resin, textile fabric, metal or the like common material, however, through the intermediary of a heat-fusible or heat-sealable sheet.

In case where the protecting layer **305** is of plastic resin, similar composing technique as mentioned above may be employed by substituting a weak-sticking layer **402**' for parting layer **303**'.

As the heat-fusible or heat-sealable sheet as at **701** employable in the present invention, it may be composed of one or other material capable of adhering under heat, pressure or both, especially suitable one of those which become soft to be adhesive upon heating. These heat adhering materials in the form of sheets will be, upon softening, charge the pores, meshes or stitches of the product material composed preferably of textiles, woven or non-woven; knits, rough-surface papers or meshed materials, thereby the surface of the product becoming highly smooth for well receiving the image-reception layer **302** for desired image-retransfer with trouble, which effect is superior in the art.

On the contrary, when such heat-fusible or heat adhesive sheet materials which may be called "heat bond sheets" as at **701** are not utilized, it is highly difficult to realize the image-retransfer operation onto certain kind of objects such as rough-surfaced or rough-meshed fabric or the like. Even if the retransfer job could be executed, the obtained images may be blurred and the adhesive may be insufficient, on account of the very thin thickness of the image-reception layer **302**, thus giving rise to technical and commercial troubles.

As for the heat fusible sheet **701** to be used in the foregoing manner, ethylene/vinyl acetate copolymer, nylon copolymer; epoxy/phenol copolymer; epoxy/vinyl copolymer; acrylic resin; polyester resin; or polyolefin resin and the like thermoplastic resins (heat sensible adhesive agents) which are formed into sheets or films may be used. These materials must be softened at 100–250° C. or so to represent viscous adhesive characteristics. These materials are, when used, capable of being stuck to both the image-transferred product **330** and the image-carrying layer **302**.

These heat bond sheets **701** have generally thickness of 1–200 μm. When the surface of the product **330** to be decorated is relatively smooth, the sheet selected out may be of relatively thin thickness, while, on the contrary, when the surface of the decorative product **330** is relatively rough, as in the case of textile fabrics, unwoven fabrics, meshed fabrics or the like, use of thicker heat bond sheets is rather recommendable.

As set forth above, the use of heat bond sheets is highly recommendable in the decorative image-transfer onto rough surface products, such as those of rough fabrics, woven or non-woven, knitted clothes, meshed one or the like, thereby a better quality image-transfer being executed, in spite of the meshed or highly undulating surface conditions of the objects to be decorated.

Further in the present invention, during the adhering attachment of the image-reception layer already formed with necessary images onto the object or product, an additional processing step is preferably introduced for prevention of occasional interference in the foregoing adhering attachment step, by rubbing-off or grinding-off part or whole of the parting layer, provided on the surface of the now image-carrying layer, upon completion of the sublimating image-transfer step.

Still further, in such a case that the image-transferable sheet is fitted with a protecting layer which is composed of a plastic resin film, the latter must in advance be subjected to punching or the like cutting step for cutting the film into desirously sized pieces.

FIG. **32** represents such a die-cut (half-cut) process in sectional schema. In this case, at first, as shown at (a) of FIG. **32**, the image-reception layer **302** of an image-transferable sheet **310**, now formed with necessary images through a sublimative image-transfer step, and the protecting layer **305**, are subjected to a die-cutting process by means of a cutter **801** to shape a desired shape. And then, as shown at (b) in FIG. **32**, the cut-out piece is subjected to a pressurizing step under heat by means of a pair of hot stamps **132**'; **133**' to provide a final decorative object., as shown at (c) in FIG. **32**, which is composed of a product **330** to be decorated, however, now attached integrally and jointly with image-carrying layer **302** and protecting layer **305**.

Applied Products

The products applicable with the inventive process for decorating purposes are not limited to occasionally employed kind, shape and nature of the materials. Preferred examples of the usable product may be: cartons; vessels or packages; bags; cassette cases; cassette halves; floppy cases; paper packages and envelopes; stock certificates; personal and bank cheques; bills; bonds; certificates; notifications; car tickets; travel tickets; betting tickets; tax stamps; postage stamps; entrance tickets, money-exchangeable papers and documents; cash-cards, credit cards, orange cards, telephone cards; member's cards; greeting cards; postcards, name cards; driver's certificates; IC-cards; optical cards and the like various cards; accounting cards and documents-envelopes; tags; ORP-sheets; slide films; bookmark slips; calendars; posters; pamphlets; menus; passports; POP-goods and articles; coasters; displays; nameplates; keyboards; cosmetics; personal ornaments (watches; cigarette lighters); stationaries; construction materials; radio-receiving sets; T.V.-sets; speakers; table calculators; automotive gauge boards; emblems; keys; clothes; wearing commodities; footwears; appliances; OA-instruments; sample books; tickets in general; albums; computer graphic and/or medicare graphic image printouts; and the like, where the material kinds, sizes and configurations are regardless for purposes of the invention.

The aforementioned goods and instruments may have printed or the like other images in advance of execution of the process of the invention. Or conversely, the goods and instruments can be formed with necessary images in accordance with the present process, and then, additional images may be formed in conventional printing or the like process.

As an example, when the invention is applied to a card style intermediate product, it is possible to combine image-forming means of the present invention with conventional recording means. As the latter, magnetic recording by use of a magnetic material layer; optical recording by use of an optical recording layer; preferably composed of a membrane having low melting point metal; application of hologram; embossing formation of characters and numerals; application of personal face photograph; engraved formation of personal face or the like; human signatures; recorded information with use of IC-memory; mechanical printing; formation of bar codes; formation of characters and patterns by use of printer, typewriter or pen plotter may be used independently or in any combination.

In the following, the present invention will be more fully described by way of preferred embodiments. In these embodiments, parts or % will be given by weight, not otherwise specifically referred to.

As the image transfer film (dye film) used for sublimating transfer onto the image-transferable sheets, a polyester film, 6 μm thick, subjected to a heat-resisting treatment on one surface thereof only, and bearing color ink composition areas of yellow, magenta and cyan, respectively, was used. The coating rate of the color ink composition was 1.0 g/m^2 when measuring at the dry state,

These color ink compositions were as follows.

Yellow ink composition	
polyvinyl butyral resin ("Eslek-BX-1", manufactured and sold by Sekisui Kagaku K. K., Tokyo)	4.80 parts
dispersion dye ("PTY-52, Disperse Yellow-141", manufactured and sold by Mitsubishi Kasei Kogyo Co., Ltd., Tokyo)	5.50 parts;
methyl ethyl ketone	55.00 parts;
toluene	34.70 parts;
(parting agent	1.03 parts)
Magenta ink composition	
polyvinyl butyral resin (same as above in the case of yellow color ink)	3.92 parts;
dispersion dye ("MS Red G, disperse red 60", manufactured and sold by Mitsui Toatsu K. K.)	2.60 parts;
dispersion dye ("Macrolex Red Violet R, Disperse Violet 26", manufactured and sold by Beyer A. G., West Germany)	1.40 parts;
methyl ethyl ketone	43.34 parts;
toluene	43.34 parts;
(parting agent	0.40 part)
Cyan color ink composition	
polyvinyl butyral resin (same as in said yellow color ink composition)	3.92 parts;
dispersion dye ("Kayaset Blue-714, solvent blue-63", manufactured and sold by Nippon Kayaku K. K., Tokyo)	5.50 parts;
methyl ethyl ketone	68.18 parts;
(parting agent	0.94 parts)

Each of the foregoing color ink compositions was prepared wish and without addition of parting agent.

As the parting agent occasionally used in each of the foregoing color ink compositions, any of the following specific agents may be employed:

(a) silicone alkyd parting agent, "KR-5206", manufactured and sold by Shinetsu Kagaku Kogyo K.K., Tokyo;

(b) graft polymer of silicone and acryl, "GS-30", manufactured and sold by Toa Gosei Kagaku K.K.;

(c) silicone graft polymer, "US-3000", manufactured and sold by the above company;

(d) phosphoric acid ester, natrium salt, "RE-410", manufactured and sold by Toho Kagaku Kogyo K.K.;

(e) natural phosphoric acid ester, "Lecytin", manufactured and sold by Ajinomoto Co., Ltd., Tokyo;

(f) silicone oil, "KF 412", manufactured and sold by Shinetsu Kagaku Kogyo K.K., Tokyo;

(g) aluminum chelate agent, "ALM", manufactured and sold by Ajinomoto; and

(h) titanium chelate agent, "TTS", manufactured and sold by Nippon Soda K.K., Tokyo.

EXAMPLE A-1

As the substrate, a laminate of a synthetic paper, "Yupo FPG 150 μm thick" manufactured and sold by Oji Yuka Co., Ltd., Tokyo, and a polyester film, 6 μm thick, was prepared and coated on the polyester film side surface by a wire bar with a mixture of pull-separating varnish, "Hakurinisu 45" manufactured and sold by Showa Ink Co., Ltd., Tokyo, with an ultra-violet absorbing agent, or more specifically, 2.5-bis (5'-tert-butylbenzoxazolyl (2))-thiofin, 0.5% based on the resin content of the varnish, and dried up to provide a protecting layer of 1 g/m^2, when weighed upon drying.

Then, on the surface of the foregoing protecting layer, an ink composition adapted for the formation of an image-reception layer was coatingly applied and dried up. The applied quantity amounted to 7 g/m^2 when measured upon drying.

Ink composition for the formation of image-reception layer	
polyester resin (manufactured and sold by Toyobo K.K.)	100 parts;
amino-modified silicon ("KF-393", manufactured and sold by Shinetsu Kagaku Kogyo K.K., Tokyo)	5 parts;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu Kagaku Kogyo)	5 parts;
solvent (methyl ethyl ketone/toluene/ cyclohexanon 4/2/2)	900 parts.

The ink composition was coated, dried up and cured one day under normal temperature. Then, the layer was kept at 100° C. for 30 minutes under heat, for letting the silicone to bleed up to the surface, to provide an image-transferable layer formed on its surface with a hardened silicone layer.

On the thus-provided image-reception layer, a sublimating image-transfer film was overlapped which is composed of cyan color sublimative dye (molecular weight being higher than 250) carried by a proper binder resin and thermal energy is fed thereon from a thermal head adapted for receiving electric signals representing cyan color components obtained by a color analysis of a portrait photograph, as an example, for providing portrait images corresponding thereto. Then, two successive sublimative image-transfer jobs were executed with use of respective sublimating image-transfer films carrying sublimative magenta and yellow color dyes, each molecular weight being higher than 250, and substantially in the manner set forth above. In this way, after all, an overall combined display image composed of a full color portrait, in combination with several characters and graphics, was provided.

The image-reception layer of the sheet, now carrying these display images, was overlapped on the card substrate composed of a polyester resin sheet, 100 μm thick, which had been primed to white-opaque state, and pressurized together at 160° C. by means of heated pressure rolls. Then, the polyester film was peeled off at the interface with the protecting layer, thereby providing a final product card transferrd with image-reception layer now carrying the desired image display.

It was found that the overall surface of the product card was generally smooth and showing no raised feeling of the thus-formed and displaying images. Even upon an accelerated testing of the product card for three months held in an atmosphere of 40° C., the images showed no blurrings as well as no interlayer separation. Further, according to an accelerated light-proof test carried out as prescribed in JIS-Standard with use of a carbon arc lamp, the results showed to be classified to JIS-4 or -5 corresponding to an acceptable superior performance. Additionally, a surface scratch test and the like showed also superior durability.

EXAMPLE A-2

The foregoing image-transferable sheet, now image-carrying, as processed in Example A-1, is then subjected to a peel-off operation for separating the image-carrying layer from the sheet. Then, an adhesive agent of polyester series was coated on the exposed surface of the peeled-off film, and stuck under pressure on a curved surface part of a telephone set. The images could follow up to the stuck curvature into a unitary solid mass, and indeed, without inviting any stuck-on feeling, contrary to the case when a sticky loose-leaf stamp should have been stuck on. In this way, miracle viewing feelings as obtainable with direct-printing operation only, were created and maintained.

EXAMPLE A-3

A white polyester film, baked on one surface thereof with melamine coating, "E 20", 100 μm thick, manufactured and sold by Toray Co., Ltd. Tokyo, is formed on the opposite surface with a slipping layer, same as in the following Example C-2, through application of polyurethane primer. And an identification mark was provided thereon through the way of regular printing technique. On the melamine resin-baked surface of the white polyester resin film, a layer of peeling varnish (of polymethyl methacrylate-series), manufactured and sold by Showa Inku. Co., Ltd., Tokyo) was applied in dry quantity of 2 g/m^2 and.dried up to provide a definite layer.

On the thus-formed protecting layer, the following image-reception layer-forming composition was coated and dried up, so as to form an image-heat transferable sheet. The coated composition was in quantity of 6 g/m^2 by dry weight.

Image-reception layer-forming composition	
polyester resin ("Vylon 600", Tg: 47° C., manufactured and sold by	80 parts;

-continued

Image-reception layer-forming composition	
Toyobo, Osaka)	
polyester resin	20 parts;
("Vylon 290", Tg: 77° C., manufactured and sold by Toyobo)	
amino-modified silicone	7 parts;
("KF-393", manufactured and sold by Shinetsu Kagaku Kogyo)	
epoxy-modified silicone	7 parts;
("X-22-343", manufactured and sold by Shinetsu Kagaku Kogyo)	
solvent	800 parts.
(methyl ethyl ketone/toluene = 1/1)	

On the image-reception layer of the foregoing heat image-transferable sheet, reversed images composed of full color portrait images together with characters and graphics by use of a thermal head, as in the same way with Example A-1, were formed.

Next, the image-reception layer, however, now carrying the reversed images formed in the foregoing manner was brought into contacting and overlapping state with the image displayable surface on a card style substrate made of white color polyester resin, 125 μm thick, preparatorily primer treated as before, and pressurized together under the action of thermal rolls, and the white polyester film, 100 μm, was peeled off between the protecting layer and the melamine-baked layer, thus providing a final card-style product transferred with the image-reception layer now carrying the necessary images.

The surface of the final card style product represented a smooth and slippery, without fear of interlayer separation and with superior light resistant power.

EXAMPLE A-4

A white foam polyester resin film, "Merinex", 125 μm thick, manufactured and sold by ICI, was provided with an identification mark on one surface thereof, with regular printing technique.

Then, on the opposite surface of the white foam polyester resin film to the foregoing surface formed with the identification mark, a coating of a polyurethane-series primer was applied and dried up. Further, the following protecting layer-forming composition was applied in dry quantity of 3 g/m^2 and dried up to form a protecting layer.

Protecting layer-forming composition	
acrylic polyole	41 parts;
("Acrit 6416MA", manufactured and sold by Taisei Kako K. K.)	
toluene	36 parts;
methyl ethyl ketone	27 parts;
diisocyanate	6 parts.
("Colonate", manufactured and sold by Nippon Polyurethane K. K.)	

On the above protecting layer, the following composition was applied in dry quantity of 3 g/m^2 and dried up, to provide an intermediate layer.

Intermediate layer-forming composition	
polyester resin	15 parts;
("Vylon 290", manufactured and sold by Toyo Boseki (Toyobo) K. K., Osaka)	
toluene/methyl ethyl ketone = 1/1	85 parts.

On the thus-formed intermediate layer, an image-reception layer which is substantially same with that in the foregoing Example A-3 was provided, so as to form an image-transferable sheet. Then, as same in the foregoing Example A-3, correspondingly inverted images were formed on the image-reception layer and further then, subjected to transfer onto the card substrate by use of thermal rollers. In this way, a final product card, having an image transferable, yet now image-formed layer, was provided.

This card showed favorable results of light-resisting test. Further, it showed a better scratch test result than the foregoing card obtained in Example A-3.

EXAMPLE A-5

Substrate

A white polyester film, "20", 100 μm thick, manufactured and sold by Toray Co., Ltd., Tokyo, was used.

Intermediate layer-forming composition	
Polyester resin	15 parts;
("Vylon 600", manufactured and sold by Toyo Boseki K. K., Osaka)	
toluene/methyl ethyl ketone = 1/1	85 parts.
(dry weight: 5 g/m^2)	
Protecting layer-forming composition	
"Hakuri-Nisu"	2 g/m^2
(acrylic resin varnish, manufactured and sold by Showa Ink K. K.)	
(dry weight)	
Image-reception layer-forming composition	
polyester resin	10 parts;
("Vylon 600", manufactured and sold by Toyo Boseki K. K., Osaka)	
polyester resin	5 parts;
("Vylon 200", supplied by Toyo Boseki K. K.)	
toluene/methyl ethyl ketone = 1/1	85 parts;
amino-modified silicone	1 part;
("KF-393", manufactured and sold by Shinetsu Kagaku Kogyo)	
epoxy-modified silicone	1 part.
("X-22-343", supplied by Shinetsu Kagaku Kogyo)	
(coated quantity (dry) 5 g/m^2)	

With use of the foregoing composition and processed in similar way as in Example A-3, to provide a final card product, having an image-reception layer transferred with necessary images.

EXAMPLE A-6

Substrate

White polyester resin film, "E-20", 100 μm thick, manufactured and sold by Toray was coated with polyurethane-series primer and dried up.

Parting layer-forming composition	
melamine resin ("Meran 45", manufactured and sold by Hitachi Kasei)	100 parts;
hardener (para-toluenesulfonic acid)	20 parts;
(coating quantity (dry), 2 g/m^2)	
Protecting layer-forming composition	
vinylchloride-vinylacetate ("Vinylite VYHH", manufactured and sold by Union Carbide Corp.)	15 parts;
methyl ethyl ketone = 2/1	85 parts;
(coating quantity (dry): 2 g/m^2)	
Intermediate layer-forming composition	
polyurethane resin ("Takelac T-3350", manufactured and sold by Takeda Pharmaceutical Company, Osaka, of 23%-concentration)	50 parts;
isopropyl alcohol	15 parts;
toluene	25 parts;
methyl ethyl ketone	10 parts.
(coating quantity (dry) 5 g/m^2)	
Image-reception layer composition	
polystyrene resin ("Picolastic D125" (Tg = 53° C.), manufactured and sold by Hercules	15 parts;
toluene/methyl ethyl ketone = 1/1	85 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu Kagaku)	1 part;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu Kagaku)	1 part.
(coating quantity (dry): 6 g/m^2)	

The foregoing composition was prepared and used as in the same manner with Example A-3, to provide a card with the image-reception layer subjected to image-transfer as desired.

EXAMPLE B-1

As the substrate, a polyester resin film, 6 μm thick, was used and a polyester resin-series primer was coated on one surface thereof and dried up. Further, the following ink composition was applied and dried up. The coating quantity of the composition was set to about 7 g/m^2.

Image-reception layer-forming composition	
polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki K.K.)	100 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu Kagaku)	5 parts;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu Kagaku)	5 parts;
solvent (methyl ethyl ketone/toluene/ cyclohexanone = 4/2/2)	900 parts.

The ink composition was coated, dried up and left standing for a full day, and then subjected to heat treatment at 100° C. for 30 minutes, so as to bleed the silicone towards the film surface for providing thereon an acceptable image-reception layer composing the active surface.

Then, a sublimative image-transferable film, composed of a resin binder evenly mixed with a proper amount of sublimative cyanic dye, the molecular weight being higher than 250, was overlapped on the above image-reception layer and applied with heat energy -by means of a thermal head supplied with electric signals corresponding to cyanic color components of a portrait full color photograph as determined by regular color analysis, thus providing cyanic color component images.

Next, as for magenta and yellow color components, similar respective processings were executed and finally, full color display portrait images could be formed.

Then, the exposed surface of image-reception layer of the thus-display image-formed film was overlapped on a card substrate composed of a white opaque, hard vinyl chloride resin sheet, 100 μm thick and pretreated with a conventional primer, and then this assembly was subjected to heat and pressure by means of a pair of heated rolls. In this way, a card product stuck with an image-transferable and now carrying layer was provided.

The surface of this card was generally smooth and slippy, the thus-formed images thereon providing no raised feelings. In an accelerated test of these formed images in hot atmosphere of 40° C. for a continuous period of three months, there were no appreciable image blurring and interlayer separation. Upon execution of a light exposure test in accordance with prescribed conditions in JIS with use of an arc lamp, the results were classified to JIS-4 to 5 Classes which means as acceptable and better image quality. Scratch test results were also superior.

EXAMPLE A-3

A sticking layer, 1 μm thick, was formed with a polyamide resin sticking agent on the image-carrying surface of the image-transferable sheet, image-formed in the manner as described in foregoing Example B-1, and the thus provided sheet was stuck on the curved surface of a glass tumbler. These images express practically no stuck-on feelings, rather providing such a touch and viewing feeling as if they had been formed by the regular and direct printing technique.

EXAMPLE C-1

With use of the image-transferable sheet prepared in the foregoing Example A-1, images were formed substantially in accordance with procedures mentioned therein, however, with exception of the formation of reversed images, and then, the image-carrying layer was, without execution of the foregoing peel-off operation, stuck on a portion of curved outer surface of a glass tumbler, whereupon the sheet-like substrate was peeled off, together with the weak-sticking layer. The thus-applied images represent almost no sticking-on grip and viewing feeling, as if they should have been applied through regular and direct-printing technique.

EXAMPLE C-2

On the surface of a transparent polyester film, 12 μm thick, employed as a protecting film, the following image-reception layer forming composition was applied to form a coated layer (in quantity of 6 g/m^2 when measuring upon drying), dried up and left as it was for full one day. Then, it was held at 100° C. for 30 minutes, to form an image-reception layer. On the surface thereof, a parting surface layer was found to exist, which was composed of a combined hardened product of amino-modified silicone resin and epoxy-modified silicone resin.

Image-reception layer-forming composition	
polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki)	100 parts;
amino-modified silicone resin ("KF-393", manufactured and sold by Shinetsu)	7 parts;
epoxy-modified silicone resin ("X-22-343", manufactured and sold by Shinetsu)	5 parts;
solvent (methyl ethyl ketone/toluene = 1/1)	800 parts.

As the substrate, on the other hand, white polyester resin film, "E-20", 75 μm, manufactured and sold by Toray, was used and coated on one surface thereof with a polyurethane-series primer and dried up. Then, the following composition (in the dried quantity of 1 g/m^2) and dried up, so as to provide a smooth and stick layer.

Smooth layer-forming composition	
polymethyl methacrylate resin ("Dianal BR-85", manufactured and sold by Mitsubishi Rayon Co., Ltd., Tokyo)	12 parts;
polyethylene wax ("MF8F", manufactured and sold by Dulacon Co.)	0.5 part;
toluene/methyl ethyl ketone = 1/1	85 parts.

On the opposite surface of the white-polyester resin sheet to the smoothed surface there, a primer coating of polyurethane-series is applied and dried up, and further coated thereon with the following composition, in quantity of 3 g/m^2, so as to provide a weak-sticky layer.

Weak-sticky layer-forming composition	
weak-sticky adhering agent ("Esdyme AE-206", manufactured and sold by Sekisui Kagaku Kogyo K. K., Tokyo)	50 parts;
water	50 parts.

The weak-sticky adhering layer is brought into contact with the protecting film consisting of a polyester film, 12 μm thick, at the opposite surface to the image-reception layer, and then subjected to heat and pressure, to provide an image-transferable sheet. Upon bringing the image-reception layer of the image-transferable sheet and the dyestuff layer of the heat-image transfer sheet into contact with each other, heat energy was applied from a thermal head, as in the similar manner mentioned in the foregoing Example A-1, and thus heat image-transfer job was executed, so as to provide reversed mode images for expressing a full color portrait as well as characters and graphics.

Next, the image-reception layer formed with the reversed images thereon was overlapped onto the image-displayable surface of a card style substrate, 100 μm thick, made of a white color polyester resin material preparatorily applied with a primer layer by coating a composition, consisting of "Vylon 200", 100 μm thick, manufactured and sold by Toyo Boseki K.K., and then subjected together to heat and pressure by means of at least a heated roll at 160° C. Then, the white polyester film, 75 μm thick, and the weak-sticky adhesive layer were peeled off in unison, for providing a final decorative product card having the image-reception layer transferred with images and carrying dislay images.

This card had a highly smooth surface and was not liable to invite any interlayer separation and showed superior light fastness.

In place of white color polyester-made card substrate preparatorily formed with a primer layer, such a modification was prepared and experimented that the white polyester sheet was formed on its rear surface with a magnetic layer, while, on its front surface there is formed with a write-on layer which consists of proper filler and resin as conventionally, so as to provide a telephone card. This processed telephone card had the write-on layer provided with display images formed by image-transfer.

EXAMPLE C-3

On the surface of a transparent polyester film, 9 μm thick, used as the protecting layer, an intermediate layer was provided by coating. The coated amount was 5 g/m^2 as measured upon being dried up.

Intermediate layer-forming composition	
polyurethane resin ("Takelack T-3350", solid content 23%, manufactured and sold by Takeda Pharmaceutical Co., Ltd., Osaka)	50 parts;
isopropyl alcohol	15 parts;
toluene	25 parts;
methyl ethyl ketone	10 parts.

Onto the intermediate layer, the following composition was applied for the formation of an image-reception layer. The coated quantity was 5 g/m^2 as measured upon being dried up.

Image-reception layer-forming composition	
polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki)	10 parts;
polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki)	5 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	1 part;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	1 part;
solvent (methyl ethyl ketone/toluene = 1/1)	85 parts.

On the other hand, a white color polyester film, which was similar to that employed in the foregoing Example C-2 was formed with a slidingly smooth layer, as well as a weak-sticking adhesive layer, the latter being brought into intimate contact with a transparent polyester film, 9 μm thick, at the opposite surface to the image-reception layer and then, subjected to heat and pressure, for providing a heat image-transferable sheet. As further processed in the similar manner in the foregoing Example C-2, full-color photographic images (reversed images) were thus formed on the image-reception surface. In this way, a final product card, having its image-reception layer transferringly formed with display images.

EXAMPLE C-4

Substrate

White color polyester sheet, "E-20", 100 μm thick, manufactured and sold by Toray was formed thereon with a

polyurethane-series primer coating. Then, a weak-sticking layer was applied thereon with use of the following composition.

Weak-sticking layer-forming composition	
weak-sticking agent ("Esdyne AE-206", manufactured and sold by Sekisui Kagaku Kogyo K. K., Tokyo)	50 parts;
water	50 parts.
Protecting layer-forming composition	
polyester resin ("Vylon-200", manufactured and sold by Toyo Boseki)	15 parts;
diisocyanate ("Colonate L", manufactured and sold by Nippon Polyurethane Co., Ltd.)	1 part;
toluene/methyl ethyl ketone = 1/1	84 parts.
Image-reception layer-forming composition	
polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki K. K.)	10 parts;
vinyl chloride-vinyl acetate copolymer resin ("Vinylite VAGH" (Tg = 79° C.), manufactured and sold by Union Carbide Corp)	5 parts;
toluene/methyl ethyl ketone = 1/1	85 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	1 part;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	1 part.

With use of the above composition and processed substantially same as in the foregoing Example C-2, a final card product was obtained.

EXAMPLE D-1

An image-transferable sheet was prepared as in the foregoing Example A-1 and thermally image-transferred with reversed mode images of a full color portrait photograph, to provide an intermediate image-transfer medium. The latter is overlapped by its image-reception layer onto the surface of a sheet of rough-textured cotton cloth, however, through the intermediary of an acrylic acid ester-vinyl acetate copolymer sheet, 100 μm thick. Then, the assembly was subjected to heat and pressure. Then, the substrate sheet and weak-sticky adhesive layer, together, were peeled off. The thus transfered images have sufficient surface smoothness, showing superior surface conditions.

Without use of the bond-attaching sheet in the above process and when similar image-transfer job as above was performed, the resulted images followed the surface undulations appearing disadvantageously on the material product of the rough fabrics and thus were highly uneven, and further, on account of insufficient adhering performance acting between the image-receiving layer and the woven fabrics serving as product material, easy and frequent separations took place therebetween.

EXAMPLE D-2

In the similar way as was disclosed in the foregoing Example D-1, an intermediate image-transfer medium carrying reversed images was prepared and overlapped on a polymethacrylate board preparatorily subjected to surface-roughening operation through a conventional sand-blasting step, and through the intermediary of a bond-adhering sheet pressurized together under heat, as was employed in Example D-1. Then, the sheet-like substrate was peeled off, together with the weak adhesive layer. The thus-provided images were highly smooth and even in spite of the highly rough and undulating conditions at the surface to be image-transferred. In addition, the image-carrying surface showed superior results in various resisting tests.

Without use of the foregoing bond-sticking layer, the similarly transferred images showed considerable undulations and distortions. Further, on account of insufficient adhering performance, easy and frequent peel-offs of applied images were feared.

EXAMPLE D-3

On the surface of a polyester resin film, 25 μm thick, the following composition adapted for the formation of bond-sticking layer was coated and dried up, in dried quantity of 5 g/m^2, to provide a film formed thereon a bond sticking sheet.

Bond-sticking sheet-forming composition	
polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki)	15 parts;
methyl ethyl ketone/toluene = 1/1	84 parts.

The bond-sticking sheet surface, together the polyester resin film proper, was brought into contact with the image-representing surface of a white color polyester made-card substrate, 25 μm thick, and then, subjected to heat and pressure by means of at least a heat roll kept at 200° C., arranged to supply heat energy from the side of the polyester resin surface, thereby heat bonding the bond-sticking sheet onto the card surface, whereupon the polyester resin film being forcedly peeled off.

Further then, as in the similar way as adopted in foregoing Examples C-2; A-3; A-4 and C-3, use is made of the image-reception layers representing reversed images thereon, the respective image-reception layers were whereupon brought into contact with the card's bond-sticking surface of the card and subjected to heat and pressure by use of at least a heat roll kept at 200° C. Then, the white color polyester resin substrate was peeled off, together with the weak-sticky adhering layer. In this way, a final product card displaying the portrait photograph was obtained.

EXAMPLE D-4

Substrate

A white color polyester resin sheet, "E-20", 100 μm thick, manufactured and sold by Toray Co. Ltd., was coated with a polyurethane-series primer. On the surface of the thus precoated sheet, the following composition was coated to form a weak-sticking adhesive layer.

Weak-sticking adhesive component	
weak-sticking adhesive agent, ("Esdyne AE-206", manufactured and sold by Sekisui Kagaku)	50 parts.
Image-reception layer-forming composition	
polyester resin	7.5 parts;

-continued

("Vylon 200", manufactured and sold by Toyo Boseki) polyester resin	7.5 parts;
("Vylon 290", manufactured and sold by Toyo Boseki) toluene/methyl ketone = 1/1	85 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	1 part;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	1 part.

The foregoing compositions were prepared. On the other hand, a polyester resin film, 25 μm thick, was coated on one surface thereof with a 15%-solution of polyester resin, "Vylon 200", manufactured and sold by Toyo Boseki, in toluene/methyl ethyl ketone=1/1 and dried up. The coating quantity was adjusted to 5 g/m^2 when measuring in dried state. In this way, a bond-sticking sheet was provided.

Then, the coated surface of the thus prepared bond-sticking sheet was brought into contact with the image display surface of a card style substrate of white color hard vinyl chloride or the like resin material preparatorily subjected to a primer coating treatment in overlapping state and then, the whole assembly was subjected to heat and pressure with use of at least a heated roll to 130° C., thus the bond-sticking layer being stuck on the card surface. Under this condition, the polyester resin film, 25 μm thick, was peeled off.

Then, the image-reception layer, now carrying thereon reversed images, was brought into contact with the bond-sticking sheet and the resulted whole was subjected to heat and pressure by use of at least a heated roll and the white color polyester resin substrate, together with the weak-sticking adhesive layer, was peeled off. In this way, the card, now displaying the portrait images, was provided.

EXAMPLE D-5

Substrate

Same as in the foregoing Example D-4.

Weak-sticking adhesive layer

Same as in the foregoing Example D-4.

Protecting layer-forming composition

polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki)	15 parts;
diisocyanate ("Colonate L", manufactured and sold by Nippon Polyurethane)	1 part;
toluene/methyl ethyl ketone = 1/1	84 parts.

Image-reception layer-forming composition

polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki)	10 parts;
toluene/methyl ethyl ketone = 1/1	85 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	1 part;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	1 part.

EXAMPLE D-6

Substrate

Same as in the foregoing Example D-4.

Weak-sticking adhesive layer

Same as in the foregoing Example D-4.

Image-reception layer-forming composition

polyester resin ("Vylon 600", manufactured and sold by Toyo Boseki)	10 parts;
vinyl chloride-vinyl acetate copolymer resin ("Vinylite VAGH", manufactured and sold by Union Carbide Corp.)	5 parts;
toluene/methyl ethyl ketone = 1/1	85 parts.

The foregoing materials and compositions were prepared and processed in the similar way as in the foregoing Example D-4, to provide a final product card, displaying the desired portrait images as were desired.

EXAMPLE E-1

On a polyethylene terephthalate film, 9 μm thick, a solution of saturated polyester resin, "Vylon 600", manufactured and sold by Toyo Boseki, in toluene/methyl ethyl ketone=1/1, was coated by reliance of the known reverse roll-coating process, and dried up. The coated quantity was 7 g/m^2 when measuring in dry condition. In this way, a weak-sticking adhesive layer could be formed.

On the weak-sticking adhesive layer, the following composition, 3 g/m^2 (dry), was coated by means of an oblique-lined gravure roll for solid and full printing use and in the reverse roll-coating process, and then dried up, to provide an image-reception layer.

Image-reception layer-forming composition

polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki)	70 parts;
polyester resin, ("Vylon 290", manufactured and sold by Toyo Boseki)	30 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	5 parts;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	5 parts;
methyl ethyl ketone (wt. ratio 1/1)	700 parts.

On the opposite surface to the image-reception layer of the thus-prepared image-transferable sheet, a synthetic paper substrate, "Yupo FPG 110", 110 μm thick, manufactured and sold by oji Yuka K.K., coated with "Vylon 600" as the adhesive agent in quantity of 10 g/m^2 (dry) was stuck intimately together.

On the other hand, a polyethylene terephthalate film substrate, 6 μm thick, preparatorily provided on one surface thereof with a heat-resisting layer was used and the following composition was applied on the opposite surface of the substrate with use of a wire bar and dried up, in the quantity of 1 g/m^2 (dry), so as to provide a dyestuff layer. In this way, a heat image-transferable sheet was prepared and provided.

Dyestuff layer-forming composition	
dispersion dye ("Kayaseo Blue-136", manufactured and sold by Nippon Kayaku K. K.)	4 parts;
ethylhydroxyethyl cellulose	6 parts;
methylethylketone/toluene (wt. ratio: 1/1)	90 parts.

The dyestuff layer of the foregoing heat image-transfer sheet was brought into contact with the image-reception layer of the image-transferable sheet in overlapping manner, then, heat energy was applied from a thermal head from the side of heat-resisting layer of the heat image-transfer sheet, thereby dyestuff being transferred to the image-reception layer of image-transferable sheet, and indeed, for the formation of positive images.

Then, the image-transferable sheet, now carrying the required positive images was stuck together under heat and pressure at 140° C. for 5 seconds on the intermediate image-transfer substrate prepared in the following manner, in mutually opposed manner. Then, the synthetic paper "Yupo" was peeled off at the intersurface between the polyester resin film and the "Vylon 600" layer. In thus way, the inventive image-transfer sheet (intermediate image-transfer medium) carrying the corresponding reverse images was provided.

Method for the Preparation of Intermediate Image-transfer Substrate

A sheet of fine quality or stick paper, unit weight: 82 g/m^2 was applied with a coating, about 20 μm thick, of polyethylene resin through conventional extrusion coating process. Thereon, further, a catalyst-added toluene solution of a parting agent silicone, "KS-707", manufactured and sold by Shinetsu was applied and dried up in quantity of about 2 g/m^2 (dry), for the purpose of curing. Thereon, still further, the following coating liquid composition was applied by means of a conventional coating bar and dried up, to provide an intermediate image transfer substrate. The thus coated and dried resin quantity was measured to 7 g/m^2.

Coating liquid composition	
polyester resin ("Vylon 200", manufactured and sold by Toyo Boseki)	100 parts;
methyl ethyl ketone/toluene (mixing ratio by weight : 1/1)	700 parts.

A sheet of coated paper, pretreated for pore filling, was coated, in the similar manner as above, with the foregoing liquid composition, to provide an image-transferable medium. On and with the presently coated surface, the image carrying surface of the foregoing intermediate image-transfer medium is brought into opposing contact and stuck together under heat and pressure at 140° C. for 7 seconds. Finally, the laminate of fine-quality paper and polyethylene was peeled off, to provide a final decorative product now displaying the positive images as required.

It will thus be seen that by adopting the above processing steps, the positive images formed under the action of the thermal head are transferred, through the intermediary of intermediate image transfer medium, onto the final object to be decorated, and indeed, in the form of positive mode. It will be further seen that, since the dyestuff is well distributed within the image-reception layer, the transferred positive images are highly sharp and fresh, in addition to much profundities.

Since a resin layer was overlappingly applied on the thus-formed images, weather fastness, frictional durability and light-fastness of the finally formed images could be highly and amazingly improved. When suitable ultraviolet absorbing agent, antioxydant, quenching agent and/or radical scavenger is added to, further improvement of the light-fastness can be attained.

EXAMPLE E-2

The substrate of image-transferable medium adopted in the foregoing Example E-1 was replaced by a hard polyvinyl chloride card, 100 μm thick, and other processing modes were same as in Example E-1. In this way, a high quality, positive-image transferred, decorative final product was successfully provided. When the image include human portrait photograph, the final product was highly useful for ID-card.

EXAMPLE E-3

The substrate of image-transferable medium adopted in the foregoing Example E-1 was replaced by a transparent polyester film, and other processing modes were same as employed therein. In this way, a transparent film formed with the wanted positive images of better quality as before was obtained. This film was highly useful in OHP-services.

EXAMPLE E-4

A sheet of high quality paper, unit weight: 104 g/m^2, was coated with a layer of polypropylene resin, thickness: about 20 μm, through the way of conventional extrusion coating technique, then the coating was further coated with a silicone solution for use in parting service and hardenable under electron rays and dried up. The quantity of the coating silicone was about 1 g/m^2 upon drying. In this way, an electron-hardened, provisional substrate was provided. On this substrate, the following, image-reception layer-forming composition was applied as a layer by use of a coating bar, and then dried up, for providing an image-reception layer. The coated resin quantity in the above last step amounted about 5 g/m^2.

Image-reception layer-forming composition	
polystyrene ("Picolastic D 150" (Tg = 69° C.), manufactured and sold by Rika-Hercules Co., Ltd.	100 parts;
amino-modified silicone ("KF-393", manufactured and sold by Shinetsu)	7 parts;
epoxy-modified silicone ("X-22-343", manufactured and sold by Shinetsu)	7 parts.

Further processing was carried out as was set forth in the foregoing Example E-2, for providing a final product card, carrying thereon the wanted positive images of same superior quality, as was in Example E-2.

EXAMPLE E-5

On the image transferable medium used in the foregoing Example E-4, however, in the present Example, a thermoplastic resin, adhesive, polyolefine-series film, "Adwin

500", manufactured and sold by Showa Denko K.K., Tokyo, was applied as a layer. Other materials were used and processed as set forth therein. In this way, a decorative final product formed with necessary positive was obtained with superior results.

Industrial Availabilities

As will be well understood from the foregoing detailed description of the invention, it is possible according to the present inventive system, to form highly easily and evenly the desired images sharply and attractingly on any product and object to be decorated or graphically ornamented, substantially irrespective of material kind and configuration thereof, and indeed, with a surprising unitary touch and feeling with the substrate. Therefore, the invention can be utilized broadly and conveniently in such various industrial fields, where unitary formation of various images, characters, symbols, numerals and graphics, on and to the articles, objects and substrate products to a sufficiently miracle and attracting degree.

We claim:

1. An apparatus for forming required images on an objective body, comprising in combination:

means for processing image data fed thereto;

means for forming images, on the basis of image data, on an image-reception layer of a first intermediate transfer substrate for image-transfer by reliance on a sublimation image transfer system;

means for transferring the image-reception layer of the first intermediate transfer substrate which has been subjected to image forming operation once onto a second intermediate transfer substrate; and

means for retransfer of the image-reception layer stuck on the second intermediate transfer substrate onto said objective body.

2. The apparatus of claim **1**, wherein said image data processing means is provided with image reversing means.

OBJECTIVE OPTICAL SYSTEM FOR ENDOSCOPES

BACKGROUND OF THE INVENTION

a) Field of the invention

The present invention relates to an objective optical system for endoscopes, and more specifically to an objective optical system for endoscopes which is configured to allow a plurality of adapter optical systems to be attached and detached thereto and therefrom for changing a direction toward a visual field, a field angle and an observation distance.

b) Description of the prior art

Conventionally, medical endoscopes which permit inserting elongated insert sections into living bodies for observing organs in the living bodies and passing forceps through forceps channels for sampling tissues of living bodies for detailedly diagnosing, diseased parts in detail are widely used. Industrial endoscopes which permit observation and inspections of interiors of boilers, turbines, chemical plants and so on are widely known in industrial fields.

Attached to an industrial endoscope, in particular, is a direct view type adapter for observing a diseased part which is located in the longitudinal direction before the insert section or a side-view type adapter for observing an inside wall which is located sideways in a direction perpendicular to the inserting direction. In practice, one simultaneously selects an adapter which has a field angle that is optimum for a location to be observed and another adapter which has an optimum observation distance (or a depth of field) and so on.

It is effective from an economical viewpoint to configure such an expensive endoscope as a tip adapter type endoscope which can be equipped with adapters having a direction of a visual field, a field angle and an observation distance matched with a location to be observed.

Also widely used in the industrial fields are electronic endoscopes which provide images of qualities remarkably improved owing to progress made in solid-state image pickup devices (CCD's).

A conventionally known example of such electronic endoscopes is an electronic endoscope disclosed by Japanese Patent Kokai Publication No. Hei 2-74,912 which has a composition shown in FIG. **1**. This conventional electronic endoscope has no mechanism of the tip adapter type described above and is not versatile in the industrial fields. When an attempt is made to configure this electronic endoscope as the tip adapter type by dividing a lens system thereof into a subsystem which is located before an aperture stop S and replaceable with an adapter, and another subsystem located after the aperture stop S, for example, it is necessary to dispose a light guide to be used in an illumination system at a location of a lens unit L. A reason to select this disposition is that it is optimum to dispose a light guide G so that it turns below a side-viewing prism P as shown in FIG. **2** for attaching a side-viewing adapter.

When the light guide is disposed at the location of the lens unit L in the electronic endoscope disclosed by Japanese Patent Kokai Publication No. Hei 2-74,912, an objective optical system of this electronic endoscope has a large outside diameter at its tip. For disposing the light guide without enlarging its outside diameter, it is necessary to reduce an outside diameter of the lens unit L or a number of optical fibers which are to be used for composing a light guide. As a result, rays are eclipsed by the lens unit L or illuminating rays are reduced, thereby making brightness insufficient.

On the other hand, there is known an objective optical system for tip adapter type electronic endoscopes which has a composition shown in FIG. **3**. This objective optical system for tip adapter type endoscopes is configured to concentrate all light guides at the location of the lens unit L for correcting the defect of the electronic endoscope disclosed by Japanese Patent Kokai publication No. Hei 2-74,912.

In the recent years where images of having higher qualities and full-screen sizes are strongly demanded, it is expected that electronic endoscopes which can provide images suited for display on high definition televisions (HDTV's) will be adopted in the near future.

For obtaining images of such high qualities, however, it is necessary to configure picture elements so as to have a smaller size, or lower illuminance per picture element on an image surface, thereby making it difficult to maintain the conventional image brightness. Further, it is known that depths of field are reduced by reducing sizes of picture elements.

For correcting the defects described above, it is necessary to reserve a required depth of field by enlarging an F number of an objective lens system and compensate for brightness by increasing a number of optical fibers that are used for making the light guide.

In the field of the endoscopes which should desirably have smaller diameters, however, it is undesirable to increase the number of optical fibers that are used for making the light guide since such increase results in enlarging the diameters of the endoscopes. In the case of the objective optical system for the tip adapter type of electronic endoscopes illustrated in FIG. **3**, the objective optical system has an outside diameter which is enlarged by increasing the number of optical fibers. When the objective optical system for tip adapter type endoscopes is configured to provide a full-size screen, it may not accept an increase in the heights of rays caused by enlarging an image side and allow a visual field to be eclipsed. In FIG. **3**, the reference symbol AD represents an adapter lens system and the reference symbol M designates a master lens system.

SUMMARY OF THE INVENTION

A primary object of the present invention is to provide an objective optical system for endoscopes which permits using lens elements having relatively small outside diameters and reducing outside diameters of tips of endoscopes without reducing numbers of optical fibers to be used for composing light guides, and more specifically an objective optical system for tip adapter type endoscopes.

The objective optical system according to the present invention is characterized in that it is disposed, in an object side tip of an endoscope, in parallel with an illumination optical system which is inserted in a longitudinal direction and tied up in a bundle, and that it comprises lens elements which are disposed in the object side tip of the endoscope and have an outside diameter smaller than that of lens elements located in the vicinity of an image pickup device disposed on the object side in the endoscope.

The objective optical system for endoscopes according to the present invention which has the object side tip having a small outside diameter permits reducing outside diameters of tips of endoscopes without reducing numbers of optical fibers which are to be used for composing light guides.

Further, the objective optical system for endoscopes according to the present invention is characterized in that it is configured as an adapter type objective optical system for

endoscopes having a tip to and from which an adaptor comprising an aperture stop for the objective optical system can freely be attached and detached.

The objective optical system for endoscopes according to the present invention consists, as exemplified in FIG. **4**, of a lens unit A which is disposed as a tip on the object side and a lens unit B which is disposed on a side of an image pickup device; the lens unit A having an outside diameter smaller than that of the lens unit B.

A tip adapter lens system AD having a small outside diameter is freely attachable and detachable, as shown in FIG. **5**, to and from the object side of an objective optical system (master lens system) M which is composed of the lens unit A and the lens unit B shown in FIG. **4**.

An image of an object to be observed is allowed by the adapter lens system AD to pass through an aperture stop **S1** and fall nearly perpendicularly onto an image receiving surface of an image pickup device disposed in the objective optical system (master lens system) M. In other words, a nearly telecentric optical system is composed of the adapter lens system AD and the master lens system M.

Furthermore, the optical objective system for endoscopes according to the present invention is characterized in that it is configured so as to satisfy the following conditions (1) and (2):

(1) $1.4 \leqq f_A/F_B \leqq 7.2$

(2) $2.3 \leqq f_A/f_M \leqq 10$

wherein the reference symbol f_A represents a focal length of the lens unit A, the reference symbol f_B designates a focal length of the lens unit B and the reference symbol f_M denotes a focal length of the objective optical system (master lens system) M.

Moreover, the objective optical system for endoscopes according to the present invention is characterized in that the lens unit A having a small diameter comprises a cemented lens component which consists of a negative lens element and a positive lens element, and is configured so as to satisfy the following conditions (3) and (4):

(3) $n_1 > n_2$

(4) $\upsilon_{d1} < \upsilon_{d2}$

wherein the reference symbols n_1 and n_2 represent refractive indices of the negative lens element and the positive lens element respectively of the cemented lens component, and the reference symbols υ_{d1} and υ_{d2} designate Abbe's numbers of the negative lens element and the positive lens element respectively of the cemented lens component.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** shows a sectional view illustrating a composition of a conventional objective optical system for endoscopes;

FIG. **2** shows a sectional view illustrating a composition of another conventional objective optical system for endoscopes;

FIG. **3** shows a sectional view illustrating a composition of still another objective optical system for endoscopes;

FIG. **4** shows a sectional view illustrating a composition of a first embodiment of the objective optical system for endoscopes according to the present invention;

FIG. **5** shows a sectional view illustrating the first embodiment of the objective optical system according to the present invention in a condition where an adapter lens system is attached to the objective optical system;

FIG. **6** shows a sectional view illustrating a composition of a master unit which comprises the objective optical system for endoscopes according to the present invention;

FIG. **7** shows a sectional view illustrating a condition where an adapter unit which comprises the adapter lens system according to the present invention is attached to the master lens unit shown in FIG. **6**;

FIGS. **8**A, **8**B and **8**C show views illustrating a condition of a light guide disposed in the master unit shown shown in FIG. **6**;

FIGS. **9**A and **9**B show sectional views illustrating a composition of a light guide to be used in an endoscope which uses the objective optical system according to the present invention;

FIGS. **10** through **12** show sectional views illustrating compositions of second through fourth embodiments of the objective optical system for endoscopes according to the present invention;

FIGS. **13**A and **13**B show sectional views illustrating a composition of a tip of an endoscope which comprises the fourth embodiment of the present invention and a light guide;

FIGS. **14** through **19** show sectional views illustrating compositions of fifth through tenth embodiments respectively of the objective optical system for endoscopes according to the present invention; and

FIG. **20** shows a perspective view descriptive of a tip adapter type endoscope system according to the present invention.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

The objective optical system for endoscopes according to the present invention consists, as exemplified in FIG. **4**, of a lens unit A which is disposed as an object side tip and a lens unit B which is disposed on a side of an image pickup device; the lens unit A having an outside diameter smaller than that of the lens unit B.

A tip adapter lens system AD is freely attachable and detachable, as shown in FIG. **5**, to and from the object side of an objective optical system (master lens system) M which is composed of the lens unit A and the lens unit B shown in FIG. **4**. Such a lens system is also referred to as an adapter type objective system.

The objective optical system (master lens system) M and the adapter lens system compose a nearly telecentric system wherein an image of an object to be observed is allowed by the adapter lens system AD to pass through an aperture stop **S1** and fall nearly perpendicularly onto an image receiving surface **12** of an image pickup device **13**.

Further, the optical system according to the present invention is characterized in that it is configured so as to satisfy the following conditions (1) and (2):

(1) $1.4 \leqq f_A/f_B \leqq 7.2$

(2) $2.3 \leqq f_A/f_M \leqq 10$

wherein the reference symbol f_A represents a focal length of the lens unit A, the reference symbol f_B designates a focal length of the lens unit B and the reference symbol f_M denotes a focal length of the objective optical system (master lens system) M.

The condition (1) defines a ratio between the focal length of the lens unit A and that of the lens unit B. Images formed by a simultaneous type electronic endoscope which uses a color mosaic filter may be affected by color shading or luminance shading. Since such a defect is dependent on angles of incidence of rays on image pickup surfaces, it is desirable that an objective optical system -for electronic endoscopes is a telecentric system.

If the upper limit of 7.2 of the condition (1) is exceeded, the lens unit B must have a short focal length for configuring the objective optical system so as to satisfy the telecentric condition and an offaxial principal ray will have a large inclination angle. Accordingly, the lens unit A will have a function of a lens which refracts rays having very low heights and must use a lens element having a very short radius of curvature or a high refractive power. As a result, the lens unit A will have a small outside diameter and can hardly be manufactured in practice. Further, a strong refractive power of the lens unit A is undesirable for correction of aberrations since such a strong power degrades balance of coma. For correcting coma, it is necessary to weaken the refractive power of the lens unit A by reserving a wide airspace therein. However, such an airspace is undesirable since the airspace makes it difficult to configure the objective optical system so as to satisfy the telecentric condition and prolongs a total length thereof.

If the lower limit of 1.4 of the condition (1) is exceeded, the lens unit B will have a long focal length and the offaxial principal ray will be high on the lens unit A, whereby it must have a large outside diameter contrary to the object of the present invention. Further, when an adapter lens system is to be attached to the tip of the objective optical system for composing an adapter type electronic endoscope as described above, a sectional area of a light guide LG which is to be disposed in an objective optical system frame of the endoscope is inevitably restricted by the lens unit since it is desirable to dispose the light guide in the vicinity of the lens unit A. Accordingly, a large outside diameter of the lens unit A is undesirable since it results in insufficiency of brightness by narrowing an area allowed for a light guide or enlarges an outside diameter of the tip of the endoscope.

The condition (2) defines a ratio between the focal length of the lens unit A and that of the objective optical system (master lens system). If the upper limit of 10 of the condition (2) is exceeded, the master lens system M will have a focal length too short for obtaining the objective optical system according to the present invention. In case of a telecentric optical system, an aperture stop is disposed at a location of a front focal point of a lens unit disposed after the aperture stop, or the master lens system M. Accordingly, the master lens system has a short total length but the adapter lens system undesirably has a large outside diameter when the upper limit of the condition (2) is exceeded. When an attempt is made to lower rays by strengthening a refractive power, for example, of a cemented lens component consisting of lens elements **L2** and **L3** disposed in the adapter lens system shown in FIG. **5**, it is necessary to impart a very strong refractive power to this cemented lens component since rays are high on this lens component which is disposed close to the aperture stop. As a result, it will be difficult to manufacture this cemented lens component in practice and spherical aberration will undesirably be aggravated. When the cemented lens component is disposed apart from the aperture stop and has a weakened refractive power, in contrast, the adapter lens system will undesirably have a large outside diameter and a long total length.

If the lower limit of 2.3 of the condition (2) is exceeded, the master lens system M will have a long focal length for configuring the objective optical system so as to satisfy the telecentric condition. As a result, the master lens system will have a large total length. Accordingly, an endoscope which has a tip bending mechanism will have a remarkably prolonged non-flexible distal end which is a fatal defect for an endoscope. Further, the offaxial principal ray will have too small an inclination angle and the lens unit A will undesirably tend to have a large outside diameter.

It is desirable that the lens unit A which comprises at least one cemented lens component and has a positive refractive power as described above is configured so as to have a composition described below. Speaking concretely, it is desirable to compose the lens unit A, in order from a side of the aperture stop, of a negative lens element **L4** and a positive lens element **L5** which has at least one surface convex toward an image surface.

In FIG. **5**, asymmetry of strong coma produced by the negative lens element **L1** disposed in the adapter lens system is corrected favorably by the surface of the lens element which is convex toward the image surface (r_{12} in FIG. **5**). Further, spherical aberration and curvature of field which are produced by the positive lens element disposed in the adapter lens system AD and the master lens system M are corrected to practically allowable levels by a negative function of the cemented surface (r_{11} in FIG. **5**) formed between the lens elements **L4** and **L5** of the cemented lens component disposed in the lens unit A.

Further, it is desirable, for the cemented lens component **L4**, **L5** or the lens unit A comprising at least one cemented lens component and having a positive refractive power, to compose the cemented lens component, in order from the side of the aperture stop **S1**, of the negative lens element **L4** and the positive lens element **L5** having at least one surface convex toward the image surface so as to satisfy the following conditions (3) and (4):

(3) $n_1 > n_2$

(4) $\upsilon_{d1} > \upsilon_{d2}$

wherein the reference symbols n_1 and n_2 represent refractive indices of the negative lens element and the positive lens element respectively of the cemented lens component, and the reference symbols υ_{d1} and υ_{d2} designate Abbe's numbers of the negative lens element and the positive lens element respectively of the cemented lens component.

The conditions (3) and (4) are required for correcting chromatic aberration produced by a front lens unit disposed before the aperture stop, longitudinal chromatic aberration in particular practically favorably, with the cemented lens component described above. Though this chromatic aberration can be corrected to a certain degree with the cemented lens component disposed in the front lens unit, it is difficult to correct the chromatic aberration sufficiently favorably since the cemented lens component is disposed in the vicinity of the aperture stop. For this reason, correction of the chromatic aberration is aided by the cemented lens component used in a rear lens unit disposed in the image side of the aperture stop.

When the conditions (3) and (4) are satisfied by the cemented lens component, it is possible to configure the master lens system M so as to have a small outside diameter, and correct practically favorably aberrations which are produced by the objective optical system as a whole consisting of the adapter lens system AD and the master lens system M.

Now, description will be made of the tip adapter type endoscope according to the present invention. Shown in FIGS. **6** and **7** are sectional views illustrating a composition of the tip adapter type endoscope according to the present invention: FIG. **6** showing only the master unit M, whereas FIG. **7** showing a combination of the master unit M' and a tip adapter unit AD' comprising an adapter lens system AD.

The master unit M' shown in FIG. **6** consists of the above-mentioned master lens system M which is disposed in a master unit frame **13** and a light guide **14** which passes therethrough. The master unit M' is further equipped with a focus adjusting frame **15** which is adjustably fitted, for example by screwing, in a master lens system receiving

frame **16**. Further, integrally fitted in the focus adjusting frame **15** is a focus adjusting lens unit (the lens unit A in FIG. **1**) which is movable back and forth in a direction along an optical axis together with the focus adjusting frame **15** which is moved relatively to the master lens receiving frame **16** by a moving means, for example, of a screw type. By this focus adjusting mechanism, the master unit M' is adjusted to optimum focused conditions. For this adjustment, it is generally desirable to focus the master lens system on infinite distance so as to minimize a variation in focused condition between the master lens system M and the adapter lens system AD. For this reason, it is effective to select a finite distance for adjusting a focused condition of the master unit M' by using a jig lens or the like (not shown). When variations of focused conditions are too large among adapter lens systems AD which are to be used in combination with the master lens system M, the focused conditions can be adjusted as described below. A means for moving adapter lens systems in the direction along the optical axis is disposed in an adapter unit AD' and the variations of the focused conditions are adjusted by this moving means. For example, the focused conditions can be adjusted by reserving an adjustable airspace between the negative lens element L**1** and the cemented lens component consisting of the lens elements L**2** and L**3** shown in FIG. **5** and moving the lens elements in the axial direction of the endoscope. Since the airspace reserved between the lens element L**1** and the cemented lens component consisting of the lens elements L**2** and L**3** has a very large correction coefficient for the positions of focus, these positions can be moved by slightly moving this airspace in the axial direction.

An adapter unit for observing an object located at a short distance or a long distance can be prepared by adjusting the airspace for intentional change of a position of focus. A more adequate observation range can be obtained by selecting different apertures of the aperture stop for the short distance and the long distance. Therefore, the aperture stop according to this embodiment has a variable diameter.

A desired direction toward a visual field, a desired field angle and a desired observation distance can be obtained by integrating the master unit M' having an adjusted position of focus with the adapter unit AD' as shown in FIG. **7**. Disposed in the adapter unit AD' are the adapter lens system and an adapter side illumination system **23**, **24**. The adapter unit AD' having such a composition is freely attachable and detachable to and from the master unit M' with an adapter fitting frame **22** or the like. The adapter fitting frame **22** is attached to the master unit M' by a means such as a knurling tool and the adapter unit AD' is equipped with a means for preventing it from coming off.

It is desirable that an illumination system for leading illumination light from a light source to the tip adapter type endoscope is configured as shown in FIGS. **8**A, **8**B, **8**C, **9**A and **9**B. Speaking concretely, the illumination system for the tip of the endoscope according to the present invention is characterized in that a light guide is divided, in a tip frame of an endoscope, into at least two branches each passing in the axial direction of the endoscope and having at least one bending in the tip frame of the endoscope, and that the two branches are formed again into a single light guide. Speaking concretely with reference to FIG. **8**A and FIG. **9**A, a light guide for leading illumination light from a light source (not shown) is branched into two light guides **26***a* and **26***b* in the tip of the endoscope as shown in FIG. **8**A and FIG. **9**A. As shown in FIG. **8**C (sectional view taken along the C—C line in FIG. **8**A), the branched light guides **26***a* and **26***b* pass through spaces which are not occupied by an image pickup device having a relatively large diameter (spaces between the image pickup device and the outer frame of the endoscope), are bent to have bendings **27** as shown in FIG. **8**A and FIG. **9**B, and are integrated with each other so as to form a light guide **28** as shown in FIG. **8**B (sectional view taken along the B—B line in FIG. **8**A).

By configuring a light guide as described above, it is possible to pass a large number of light guides through the tip of the endoscope and use an image pickup device which has a large image size corresponding to the full screen size. Further, by attaching cover glass plates **30** to end surfaces of the branched light guides **26***a* and **26***b* as shown in FIG. **9**B, it is possible to assure a watertight condition for the lens system, absorb variations of the light guides **16***a* and **16***b* in the longitudinal direction and facilitate assembly of the light guides.

Now, the preferred embodiment of the objective optical system for endoscopes according to the present invention will be described below with reference to the accompanying drawings.

The objective optical system for endoscopes according to the present invention uses lens elements having a small diameter as lens elements to be disposed in a tip out of lens elements adopted for composing the optical system, thereby making it possible to pass a large number of optical fibers through light guides composing an illumination optical system, or obtaining a bright illumination optical system. Further, the objective optical system according to the present invention is characterized in that it is configured as the adapter type permitting attaching and detaching adapter units comprising adapter lens system having different field angles, directions toward visual fields, and so on.

Therefore, each of the embodiments described below is an adapter type objective optical system for endoscopes in which an adapter is attached to the optical system according to the present invention (master lens system).

FIGS. **4** through **9** show a first embodiment of the present invention: FIG. **4** showing a composition of a master unit M' (FIG. **6**) comprising an objective optical system (master-lens system) M, whereas FIG. **5** showing an adapter unit AD' (FIG. **7**) comprising an adapter lens system AD, and freely attachable and detachable to and from the master unit M'.

The first embodiment is an example wherein a direct viewing adapter lens system AD having a field angle of 120° is attached to the master lens system M.

In the first embodiment illustrated in FIG. **4**, the objective optical system (master lens system) M consists of a lens unit A which is composed of a cover glass plate C**2**, and a cemented lens component consisting of a negative lens element L**4** and a positive lens element L**5**, and a lens unit B which is composed of a field lens FL. Further, disposed in the objective optical system (master lens system) M are a low pass filter F**1**, an infrared cut filter F**2**, a CCD cover glass plate C**3** and a CCD image pickup surface **12**. The cover glass plate C**2** is used for maintaining the objective optical system in a watertight condition, whereas the cover glass plate C**3** is adopted for preventing the CCD image pickup surface from being deteriorated. It may be considered, as represented by the reference symbol B in FIGS. **4** and **5**, that the lens unit B comprises the field lens FL, the low pass filter F**1**, the infrared cut filter F**2** and the cover glass plate C**3**. These optical elements have a diameter which is substantially equal to that of the image pickup surface, whereas the lens unit A has a diameter smaller than that of the lens unit B.

The adapter lens system AD which is freely attachable and detachable to and from the objective optical system

(master lens system) M in FIG. **5** is composed of a negative lens element **L1**, a cemented lens component which consists of a positive lens element **L2** and a negative lens element **L3**, and a cover glass plate **C1**. This adapter lens system AD uses, in addition to the negative lens element **L1**, the cemented lens component consisting of the lens elements **L2** and **L3** for correcting chromatic aberration, curvature of field and astigmatism to levels at which these aberrations pose no problem in practical use of the objective optical system. Further, the cover glass plate **C1** is disposed for maintaining the adapter lens system in a watertight condition, thereby preventing a visual field from being dimmed by water vapor, etc. The adapter lens system has a small diameter like the lens unit A.

In the first embodiment, the adapter lens system AD is attached to the objective optical system (master lens system) M for obtaining a wide field angle of 120° so that the objective optical system is efficiently usable for a far visual field or an object located at a relatively long distance. For this embodiment, an illumination system is to be composed as already described above with reference to FIGS. **8A**, **8B**, **8C**, **9A** and **9B**.

The first embodiment has numerical data listed below:

first embodiment

$f = 0.582$, image height = 0.5055,

object distance = −8.0860

$r_1 = \infty$

$d_1 = 0.0886 \quad n_1 = 1.88300 \quad \nu_1 = 40.78$

$r_2 = 0.3372$

$d_2 = 0.1440$

$r_3 = 0.7794$

$d_3 = 0.3988 \quad n_2 = 1.76182 \quad \nu_2 = 26.55$

$r_4 = -0.3285$

$d_{17} = 0.0410$

$r_{18} = \infty$ (image)

$f_M = 1$, $f_A = 2.856$, $f_B = 1.594$, $f_A / f_B = 1.792$

$f_A / f_M = 2.856$

A second embodiment of the objective optical system according to the present invention has a composition illustrated in FIG. **10**, wherein an adapter lens system is attached to a master lens system as in FIG. **5**. An objective optical system (master lens system) M used in the second embodiment is the same as that adopted in the first embodiment. The second embodiment adopts an adapter lens system AD which is composed of a negative lens element **L1**, a cemented lens component which consists of lens elements **L2** and **L3**, and an aperture stop. The adapter lens system used in the second embodiment is different from that adopted for the first embodiment in that the former is composed of a negative lens element **L2** and a positive lens element **L3** which are disposed in order from the object side. The reference symbol **C1** used in FIG. **10** represents a cover glass plate. The adapter lens system has a field angle of 80° and is configured for direct viewing.

The second embodiment has the following numerical data;

second embodiment

$f = 0.794$, image height = 0.5055,

object distance = −21.0456

$r_1 = \infty$

$d_1 = 0.0886 \quad n_1 = 1.51633 \quad \nu_1 = 64.15$

$r_2 = 0.3932$

$d_2 = 0.1329$

$r_3 = 3.4298$

$d_3 = 0.0665 \quad n_2 = 1.51633 \quad \nu_2 = 64.15$

$r_4 = 0.4338$

$d_4 = 0.4209 \quad n_3 = 1.88300 \quad \nu_3 = 40.78$

$r_5 = -7.9322$

$d_5 = 0.0066$

$r_6 = \infty$ (stop)

$d_6 = 0.0886 \quad n_4 = 1.88300 \quad \nu_4 = 40.78$

$r_7 = \infty$

-continued

$d_7 = 0.0576$

$r_8 = \infty$

$d_8 = 0.0886$ $n_5 = 1.51633$ $\nu_5 = 64.15$

$r_9 = \infty$

$d_9 = 0.0443$

$r_{10} = -2.1850$

$d_{10} = 0.0665$ $n_6 = 1.78472$ $\nu_6 = 25.71$

$r_{11} = 0.5047$

$d_{11} = 0.3434$ $n_7 = 1.69680$ $\nu_7 = 55.53$

$r_{12} = -0.8824$

$d_{12} = 0.2437$

$r_{13} = 1.1630$

$d_{13} = 0.9260$ $n_8 = 1.72916$ $\nu_8 = 54.68$

$r_{14} = \infty$

$d_{14} = 0.1772$ $n_9 = 1.54814$ $\nu_9 = 45.78$

$r_{15} = \infty$

$d_{15} = 0.3545$ $n_{10} = 1.51400$ $\nu_{10} = 75.00$

$r_{16} = \infty$

$d_{16} = 0.1661$ $n_{11} = 1.49700$ $\nu_{11} = 81.61$

$r_{17} = \infty$

$d_{17} = 0.0410$

$r_{18} = \infty$ (image)

$f_M = 1$, $f_A = 2.886$, $f_B = 1.594$, $f_A / f_B = 1.792$, $f_A / f_M = 2.856$

A third embodiment of the objective optical system according to the present invention has a composition shown in FIG. **11**, wherein an adapter lens system AD is attached to an objective lens system M. This master lens system selected for the third embodiment is also the same as that used in the first or second embodiment.

Further, the adapter lens system AD is composed, in order from the object side, of a negative lens element **L1**, a positive lens element **L2** and an aperture stop, and is configured as a direct-viewing adapter lens system having a field angle of 80°. This adapter lens system corrects aberrations to practically allowable levels and uses a single lens element in place of the cemented lens component used in the second embodiment. Further, an image side surface of the positive lens element **L2** is configured as a planar surface for enhancing adherability to the aperture stop and eliminating the necessity of a cover glass plate which would otherwise be used for maintaining the adapter lens system in a watertight condition. The third embodiment requires a smaller number of parts and uses no cemented lens component, thereby eliminating a cementing step and remarkably lowering a manufacturing cost of the objective optical system.

This adapter lens system may be configured so as to intentionally tilt an image surface on the positive side so that the objective optical system is used exclusively for observing pipes. Further, the adapter lens system may be adjusted so that the third embodiment is to be used exclusively for observing objects located at short distances or long distances as described above. In other words, it is possible to change a location of focus and an observation range by adjusting an airspace reserved in the adapter lens system (airspace d_2 between the lens elements **L1** and **L2**) and varying a diameter of the aperture stop at the same time.

Listed below is numeical data of the third embodiment:

third embodiment

$f = 0.817$, image height = 0.5055,

object distance = −21.045

$r_1 = \infty$

$r_{15} = \infty$ (image)

$f_M = 1$, $f_A = 2.856$, $f_B = 1.594$, $f_A / f_B = 1.792$, $f_A / f_M = 2.856$

An objective optical system preferred as a fourth embodiment of the present invention has a composition shown in FIG. **12**, wherein an adapter lens system configured for side-viewing is attached to an objective optical system (master lens system) M. The adapter lens system is composed, in order from the object side, of a negative lens element **L1**, a visual field changing prism P, a positive lens element **L2** and an aperture stop **S1**. The objective optical system (master lens system) M is the same as that used in the first, second or third embodiment.

The fourth embodiment is an optical system in which a side-viewing adapter lens system having a field angle of 120° is attached to the objective optical system (master lens

system) M. The fourth embodiment which comprises the visual field changing prism P and permits side viewing is suited in particular for observing inside surfaces of pipes, outside surfaces of heat exchange pipes of nuclear reactors and so on.

FIGS. **13**A and **13**B show an example wherein the tip illumination system described above is applied to the optical system preferred as the fourth embodiment. A light guide **42** used in an adapter lens system shown in FIG. **13**A may be formed by molding. Further, it is desirable that the light guide **42** has an end surface **42'**, on a side of a light source, which has a shape substantially matched with that of a light guide disposed in a master lens system M as shown in FIG. **13**B (sectional view taken along the B—B line in FIG. **13**A) for minimizing loss of illumination light coming from a master unit when the adapter lens unit is attached. This shape of the light guide is applicable also to an optical system to which a direct-viewing adapter lens system is attached. Further, it is desirable that the light guide has a nearly circular end surface on the object side. Since a circular end surface is capable of minimizing loss of the illumination light and ununiformity of illumination, the end surface should desirably have a nearly circular shape.

Selected for the fourth embodiment is the following numerical data:

fourth embodiment

$f = 0.563$, image height = 0.5055,

object distance = −5.0953

$r_1 = \infty$

$d_1 = 0.0997$ $n_1 = 1.51633$ $\nu_1 = 64.15$

$f_M = 1$, $f_A = 2.856$, $f_B = 1.594$, $f_A / f_B = 1.792$, $f_A / f_M = 2.856$

A fifth embodiment of the present invention has a composition illustrated in FIG. **14** wherein an adapter lens system is composed of a negative lens element **L1**, a field stop **S2**, a positive lens element **L2**, an aperture stop **S1** and a cover glass plate **C1**. The fifth embodiment is an example wherein a direct-viewing adapter lens system having a field angle of 120° is attached to a master lens system M. In this embodiment, a focal length of an objective optical system is shortened by restricting only a portion of an entire image area. The fifth embodiment therefore makes it possible to obtain a range of observation depth which is broader than that obtainable with any one of the first through fourth embodiments. The first or fourth embodiment provides a field angle of 120° in a diagonal direction of an image area but has a field angle as narrow as approximately 70° in a direction along a shorter side.

The fifth embodiment which restricts the image area in a direction nearly matched with the shorter side of a monitor screen provides a merit that it permits observing a tubular object such as a pipe in all directions nearly at the same time within a circular visual field having a field angle of 120°.

Listed below is numerical data selected for configuring the fifth embodiment:

fifth embodiment

$f = 0.323$, image height = 0.2880,

$f_M = 1$, $f_A = 2.856$, $f_B = 1.594$, $f_A / f_B = 1.792$, $f_A / f_M = 2.856$

A sixth embodiment of the present invention has a composition illustrated in FIG. **15**. In this embodiment, an adapter lens system is composed, in order from the object side, of a negative lens element **L1**, a field stop **S2**, a visual field changing prism P, a positive lens element **L2**, an aperture stop **S1** and a cover glass plate **C1**.

The sixth embodiment is configured as a side-Viewing objective optical system by adding the visual field changing prism P to the adapter lens system which is used in the fifth embodiment. Since the adapter lens system selected for the sixth embodiment has an observation range broader than that of the side-viewing adapter lens system used in the fourth embodiment, it provides a merit that the sixth embodiment can be placed closer to an object for observation.

The sixth embodiment has numerical data listed below:

sixth embodiment

$f = 0.321$, image $= 0.2880$,

object distance $= -1.7058$

$r_1 = \infty$

$d_1 = 0.0886$ $n_1 = 1.88300$ $\nu_1 = 40.78$

$r_2 = 0.3152$

$r_{18} = \infty$

$d_{18} = 0.1661$ $n_{11} = 1.49700$ $\nu_{11} = 81.61$

$r_{19} = \infty$

$d_{19} = 0.0410$

$r_{20} = \infty$ (image)

$f_M = 1$, $f_A = 2.856$, $f_B = 1.594$, $f_A / f_B = 1.792$, $f_A / f_M = 2.856$

The objective optical system (master lens system) M is common to all the first through sixth embodiments described above.

A seventh embodiment of the present invention has a composition illustrated in FIG. **16**, wherein an objective optical system (master lens system) M is composed, in order from the object side, of a lens unit A which is composed of a cemented lens component consisting of a negative lens element **L4** and a positive lens element **L5** and a lens unit B which is composed of a field lens FL. Further, the seventh embodiment additionally comprises a cover glass plate **C1**,

a low pass filter F1, an infrared cut filter F2, a CCD cover glass plate C3 and a CCD image pickup surface.

An adapter lens system adopted for the seventh embodiment is composed, in order from the object side, of a negative lens element L1, a positive lens element L2 and an aperture stop S1.

In the seventh embodiment, the objective optical system (master lens system) M is configured so as to have an outside diameter as small as possible while satisfying the conditions (1) and (2) so that an increased number of light guides can pass therethrough. It is undesirable to configure the lens unit A so as to have a smaller outside diameter since such an outside diameter will allow eclipse of a visual field, production of flare, etc. and aggravation of aberrations to unallowable levels. Attached to the objective optical system (master lens system) M is an adapter lens system having a field angle of 80°.

The seventh embodiment has the following numerical data:

seventh embodiment

$f = 0.727$, image height = 0.4567,

object distance = −19.0114

$r_1 = \infty$

$d_1 = 0.0800$ $n_1 = 1.51633$ $\nu_1 = 64.15$

$r_2 = 0.4400$

$d_2 = 0.2239$

$r_3 = 0.5969$

$d_3 = 0.1990$ $n_2 = 1.78472$ $\nu_2 = 25.71$

$r_4 = \infty$ (stop)

$d_4 = 0.0155$

$r_{12} = \infty$

$d_{12} = 0.3202$ $n_8 = 1.51400$ $\nu_8 = 75.00$

$r_{13} = \infty$

$d_{13} = 0.1501$ $n_9 = 1.49700$ $\nu_9 = 81.61$

-continued

$r_{14} = \infty$

$d_{14} = 0.0370$

$r_{15} = \infty$ (image)

f_M=1, f_A=9.484, f_B=1.010, f_A/f_B=9.885

f_A/f_M=9.984, outside diameter of lens unit A=2.4 mm, outside diameter of lens unit B=5.4 mm, (outside diameter of lens unit A)/(outside diameter of lens unit B)=0.44

An eighth embodiment of the present invention has a composition illustrated in FIG. 17. In the eighth embodiment, an adapter lens system AD is composed of a negative lens element L1, a positive lens element L2 and an aperture stop S1, whereas an objective optical system (master lens system) M is composed of a lens unit A which is composed of a cover glass plate C2, a cemented lens component consisting of a negative lens element L4 and a positive lens element L5, and a lens unit B which is composed of a field lens FL, a low pass filter F1, an infrared cut filter F2, a CCD cover glass plate C3 and a CCD image pickup surface.

In the eighth embodiment also, the lens unit A disposed in the master lens system M is configured so as to have an outside diameter as small as possible while satisfying the conditions (1) and (2). In the eighth embodiment, it is undesirable to configure the lens unit A so as to have a smaller outside diameter since such an outside diameter will enhance rays on the lens unit B. As a result, it is necessary to enlarge an outside diameter of the lens unit B, thereby producing inconvenience of a necessity to enlarge an outside diameter of a tip of the endoscope or reduce a number of optical fibers to be disposed in light guides. The eighth embodiment is an example wherein an adapter lens system AD which has a field angle of 80° is attached to the master lens system M.

Selected for the eighth embodiment is numerical data which is listed below:

eighth embodiment

$f = 0.825$, image height = 0.5228,

object distance = −21.7640

$r_1 = \infty$

$d_1 = 0.0916$ $n_1 = 1.51633$ $\nu_1 = 64.15$

$r_2 = 0.4946$

$d_2 = 0.2108$

$r_3 = 0.9964$

$d_3 = 0.2199$ $n_2 = 1.78472$ $\nu_2 = 25.71$

$r_4 = \infty$ (stop)

$d_4 = 0.1983$

$r_5 = \infty$

$d_5 = 0.0916$ $n_3 = 1.51633$ $\nu_3 = 64.15$

$r_6 = \infty$

$d_6 = 0.0458$

$r_7 = -3.2009$

$d_7 = 0.0687$ $n_4 = 1.78472$ $\nu_4 = 25.71$

-continued

$r_8 = 0.5537$

$d_8 = 0.3551$ $n_5 = 1.69680$ $\nu_5 = 55.53$

$r_9 = -0.9075$

$d_9 = 0.2978$

$r_{10} = 1.2448$

$d_{10} = 0.9576$ $n_6 = 1.72916$ $\nu_6 = 54.68$

$r_{11} = \infty$

$d_{11} = 0.1833$ $n_7 = 1.54814$ $\nu_7 = 45.78$

$r_{12} = \infty$

$d_{12} = 0.3666$ $n_8 = 1.51400$ $\nu_8 = 75.00$

$r_{13} = \infty$

$d_{13} = 0.1718$ $n_9 = 1.49700$ $\nu_9 = 81.61$

$r_{14} = \infty$

$d_{14} = 0.0424$

$r_{15} = \infty$ (image)

f_M=1, f_A=2.3, f_B=1.707, f_A/f_B=1.347,

f_A/f_M=2.3, outside diameter of lens unit A=3 mm, outside diameter of lens unit B=4.4 mm, (outside diameter of lens unit A)/(outside diameter of lens unit B)=0.68

In each of the seventh and eighth embodiments, it may be considered that the lens unit B used in the master lens system comprises the field lens FL, the low pass filter F**1**, the infrared cut filter F**2** and the cover glass plate C**3**.

In the numerical data of the first through eighth embodiments described above, the reference symbols r_1, r_2, . . . represent radii of curvature on respective lens surfaces, the reference symbols d_1, d_2 . . . designate thicknesses of respective lens elements and airspaces reserved therebetween, the reference symbols n_1, n_2 . . . denote refractive indices of the respective lens elements, and the reference symbols υ_1, υ_2 . . . represent Abbe's numbers of the respective lens elements. Further, the reference symbol f designates a focal length of the optical system as a whole comprising the adapter lens system and the reference symbol f_M denotes a focal length of the master lens system only. The numerical data is normalized to f_M=1.

Out of the embodiments described above, the seventh embodiment is configured to have a ratio (outside diameter of lens unit A)/(outside diameter of lens unit B) of 0.44 which is the smallest of all the ratios or a largest difference between the outside diameters of all the differences selected for the embodiments and the eighth embodiment is configured to have a ratio of 0.68 between the outside diameters which is the largest of all the ratios or a smallest difference between the outside diameters of all the differences selected for the embodiments. Ratios between the outside diameters selected for the other embodiments are between the values adopted for the seventh and eighth embodiments.

When an adapter lens system type objective optical system such as that according to the present invention uses an adapter lens system having a wider field angle, a lens element which is to be disposed on the object side in the optical system tends to have a large outside diameter. For this reason, it is desirable to select for an endoscope tip such a composition as that adopted for a ninth embodiment of the present invention illustrated in FIG. **18**. Schematically shown in this drawing is an adapter lens system which is seen from a side of its tip and has a partially cut objective optical system. Since an image pickup device generally has a rectangular shape, it is unnecessary to shape lens elements circular. Accordingly, a ray which is incident highest on the image pickup device (in a diagonal direction in a visual field) is not eclipsed when an objective optical system **72** is partially cut as shown in FIG. **18**. Further the lens element may be rectangular.

When lens elements cannot be laid within a tip frame or when it is desired to configure an endoscope tip thinner, an illumination lens **73** may be composed of parts which are integrated after shaping as shown in FIG. **18**. An illumination lens having such a shape may be manufactured by shaping or molding a material such as a resin.

Since the image pickup device is rectangular as described above, circular lens elements are apt to allow flare to be produced by detrimental rays (rays outside a visual field). Accordingly, it is possible to select a composition such as that shown in FIG. **19** illustrating a tenth embodiment of the present invention. Shown in this drawing is a side-viewing adapter lens system as seen from a side of its end surface (from above) which is not circular unlike the ordinary flare stop. Detrimental rays to be incident on an image pickup surface can be eliminated by using a flare stop **75** which has a partially cut circular shape. A plurality of portions of a flare stop may be cut off and a flare stop having such a shape may be used in an objective optical system.

FIG. **20** is a perspective view schematically showing an endoscope system which uses the tip adapter lens system type objective optical system for endoscopes according to the present invention. In this drawing, an adapter that is optimum for an object to be observed is selected from among a group of adapters **77** and attached to an endoscope body **78**. In this condition, an image of the object is imaged on a light receiving surface of an image pickup device disposed in the endoscope through the attached adapter lens system and the objective optical system for endoscopes, transferred as image data through a universal cord **80** to a camera control unit **82** for required conversion of the image data, and output to a monitor for display. An illumination light beam emitted from a light source is led through light guides (not shown) so that an illuminator lens disposed in a tip of the endoscope will irradiate the object at proper distribution and intensities.

I claim:

1. An endoscope tip assembly, comprising:

a light guide bundle;

an objective optical system arranged parallel to said light guide bundle, wherein said objective optical system comprises an image side unit and an object side unit, said object side unit being disposed on an object side of said image side unit;

an image pick up element constructed and arranged to be in communication with said objective optical system; and

an adapter lens system which is detachably disposed on the object side of said object side unit,

wherein said image side unit and said image pickup element are secured with respect to each other in a common frame,

wherein each constituent lens of said image side unit has a larger diameter than each constituent lens of said object side unit,

wherein each optical element of said adapter lens system has a diameter which is smaller than a diameter of any lens in said image side unit, and

wherein said adapter lens system comprises an aperture stop.

2. An endoscope tip assembly, comprising:

a light guide bundle;

an objective optical system arranged parallel to said light guide bundle; and

an image pick up element constructed and arranged to be in communication with said objective optical system;

wherein said objective optical system comprises an image side unit and an object side unit, said object side unit being disposed on an object side of said image side unit,

wherein each constituent lens of said image side unit has a larger diameter than each constituent lens of said object side unit,

wherein said object side unit comprises at least one cemented lens component, and

said image side unit has a positive refractive power and satisfies the following conditions (1) and (2):

(1) $1.4 \leqq F_A/f_B \leqq 7.2$

(2) $2.3 \leqq f_A/f_B \leqq 10$

wherein the reference symbols f_A and f_B represent focal lengths of the object side lens unit and the image side lens unit respectively, and the reference symbol f_M designates a total focal length of the objective optical system as a whole.

3. An endoscope tip assembly, comprising:

a light guide bundle;

an objective optical system arranged parallel to said light guide bundle;

an image pick up element constructed and arranged to be in communication with said objective optical system; and

an adapter lens system which is detachably disposed on the object side of said object side unit,

wherein said objective optical system comprises an image side unit and an object side unit, said object side unit being disposed on an object side of said image side unit,

wherein said image side unit and said image pickup element are secured in a common frame,

wherein each constituent lens of said image side unit has a larger diameter than each constituent lens of said object side unit,

wherein each optical element of said adapter lens system has a diameter which is smaller than a diameter any lens in said image side unit,

wherein said adapter lens system comprises an aperture stop, and

wherein said object side unit comprises at least one cemented lens component, and

said image side unit has a positive refractive power and satisfies the following conditions (1) and (2):

(1) $1.4 \leqq f_A/f_B \leqq 7.2$

(2) $2.3 \leqq f_A/f_M \leqq 10$

wherein the reference symbols f_A and f_B represent focal lengths of the object side lens unit and the image side lens unit respectively, and the reference symbol f_M designates a total focal length of the objective optical system as a whole.

4. An endoscope tip assembly according to claim 2 or 3, wherein said at least one cemented lens component in said object side unit comprises, in order from a side of the aperture stop, a negative lens element and a positive lens element, said positive lens element having at least one surface which is concave toward said image side.

5. An endoscope tip assembly according to claim 4 satisfying the following conditions (3) and (4):

(3) $n_1 > n_2$

(4) $\upsilon_{d1} < \upsilon_{d2}$

wherein the reference symbols n_1 and n_2 represent refractive indices of the negative lens element and the positive lens elements respectively, of said cemented lens component, and the reference symbols υ_{d1} and υ_{d2} designate Abbe's numbers of the negative lens element and the positive lens element, respectively, of said cemented lens component.

6. An endoscope tip assembly, comprising:

a light guide bundle;

an objective optical system arranged parallel to said light guide bundle;

an image pick up element constructed and arranged to be in communication with said objective optical system; and

an adapter lens system which is detachably disposed on the object side of said object side unit,

wherein said objective optical system comprises an image side unit and an object side unit, said object side unit being disposed on an object side of said image side unit,

wherein each constituent lens of said image side unit has a larger diameter than each constituent lens of said object side unit,

wherein each optical element of said adapter lens system has a diameter which is smaller than a diameter any lens in said image side unit,

wherein said adapter lens system comprises an aperture stop,

wherein said object side unit comprises at least one cemented lens component, and said image side unit has a positive refractive power,

wherein said at least one cemented lens component in said object side unit comprises, in an order from a side of said aperture stop, a negative lens element and a positive lens element,

said positive lens element having at least one surface which is concave toward said image side,

said adapter lens system is selectable from a plurality of different types of adapter lens systems each of which are attachable and detachable from the object side of said object side unit,

wherein each optical element of said plurality of different types of adapter lens systems has a diameter which is smaller than that of any lens included in said image side unit;

wherein said adapter lens system comprises an aperture stop,

said adapter lens system can be selected for varying at least one of a field angle, a viewing direction and an observation distance, and said objective optical system satisfies the following conditions:

(1) $1.4 \leqq f_A/f_B \leqq 7.2$

(2) $2.3 \leqq f_A/f_M \leqq 10$

(3) $n_1 > n_2$

(4) $\upsilon_{d1} < \upsilon_{d2}$

wherein the reference symbols f_A and f_B represent focal length of the object side lens unit and the image side lens unit, respectively, the reference symbol f_M designates a total focal length of the objective optical system as a whole, the reference symbols n_1 and n_2 represent refractive indices of the negative lens element and the positive lens element, respectively, of said cemented lens component, and the

reference symbols υ_{d1} And υ_{d2} designate Abbe's numbers of the negative lens element and the positive lens element, respectively, of said cemented lens component.

7. An endoscope tip assembly according to claim **6**, wherein said adapter lens system further comprises a moving means for moving, in a direction along an optical axis, some lens elements included in said adapter lens system and some lens elements included in at least one of said object side unit and said image side unit.

8. An endoscope tip assembly according to claim **7**, wherein said aperture stop has a variable aperture, and

said adapter lens system is configured to change an observation distance by moving some lens elements disposed in said adapter lens system, at least one but not all lenses of said object side unit and said image side unit, and varying a diameter of said aperture stop.

9. An endoscope tip assembly, comprising:

a light guide bundle;

an objective optical system arranged parallel to said light guide bundle;

an image pick-up element constructed and arranged to be in communication with said objective optical system; and

an adapter lens system which is detachably disposed on the object side of said objective optical system,

wherein some lenses of said objective optical system and said image pick-up element are secured with respect to each other in a common frame,

wherein said some lenses secured in said common frame have larger diameters than a diameter of a lens which is arranged on an object side of a lens secured in said common frame,

wherein each optical element of said adapter lens system has a diameter which is smaller than a diameter of any lens in said some lenses, and

wherein said adapter lens system comprises an aperture stop.

[57] **ABSTRACT**

A lens moving mechanism for finely moving at least a lens portion of an objective lens in a direction of an optical axis of the objective lens. The lens moving mechanism includes a holding member holding the lens portion and a disc-like disc cam member provided with a cam surface, which lies in a peripheral portion of the disc-like disc cam member. The disc cam member is rotated to thereby move the holding member on a track conforming to the cam surface.

LENS MOVING MECHANISM FOR FINELY MOVING A PORTION OF AN OBJECTIVE LENS BY ROTATING A HOLDING MEMBER

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to a lens moving mechanism suitable for a photo-taking lens with an auto focus function in which an optical lens unit is finely moved in the direction of the optical axis thereof to thereby effect the detection of an in-focus state.

2. Related Background Art

As the auto focus device of a video camera, there is known a so-to-speak mountain climbing system in which the degree of minuteness of a photographing image field is detected from a high frequency component in an image signal and the position of a lens is controlled so that the degree of minuteness may become maximum. This system is described in detail in Japanese Laid-Open Patent Application No. 56-51164, and this system will hereinafter be described briefly with reference to FIG. **6** of the accompanying drawings. In FIG. **6**, the reference numeral **100** designates a lens, the reference numeral **101** denotes a signal processing portion, and the reference numeral **102** designates a motor.

The light of an object entering the lens **100** is converted into an electrical signal by the signal processing portion **101**. By the utilization of the fact that the high frequency component of this electrical signal is small if the in-focus state of the lens **100** is insufficient, and becomes greater as the lens is more in focus, the signal processing portion **101** causes the converted electrical signal of an image pickup device to pass through a high-pass filter, whereafter it detects and integrates the electrical signal over a period during which an image field is formed, i.e., a field period (in the case of a television system, 1/60 sec.), and detects the state of the focus.

Then, a focus lens is moved by the motor so that a high frequency signal may be obtained, and there is obtained the in-focus state.

Now, when detecting the direction of out-of-focus, it is usually practiced to finely move (wobble) some lens in the photo-taking lens **100** in forward and backward directions along the optical axis thereof.

Heretofore, in such a zoom lens device, as a lens moving mechanism for finely moving a lens unit, use has usually been made of a system as shown in FIG. **7** of the accompanying drawings. In FIG. **7**, the reference numeral **103** denotes a finely moved lens unit, the reference character **103***a* designates a holding member holding the lens **103**, and the reference numeral **104** denotes the fixed portion (fixed barrel) of a lens device body. The lens holding member **103***a* is fitted in an aperture (not shown) formed in the fixed portion and is supported for rectilinear movement in the direction of the optical axis. The reference character **105***a* designates the external thread of a feed screw directly connected to the motor, and disposed parallel to the optical axis and engaged with an internal thread **103***b* provided on the lens holding member **103***a*.

Under such a construction, the lens **103** is finely moved by the rotational operation of a motor **105** and the in-focus direction is detected by the signal processing portion.

Now, in this system, out-of-focus is caused by the fine movement of the lens unit and therefore, in a lens device for photographing, and particularly a TV or video lens device

handling moving images, it is necessary to suppress the out-of-focus within a range in which a variation in an image signal is detectable and moreover to such a degree that it is not conspicuous to the eyes. Also, after the detection by wobbling, a focus lens unit is moved and therefore, to realize auto focus quick in response, it is important to effect the wobbling at high speed.

Here, the amount of variation in the focus by the wobbling is determined by the amount of movement of the lens unit **103**, but the amount of movement of the lens unit **103** which satisfies the above-described condition is related to the depth of focus. That is, when the depth of focus is shallow, the variation in the focus will be conspicuous unless the amount of movement of the lens unit **103** is made small, and when the depth of focus is deep, the variation in the focus cannot be detected unless the amount of movement of the lens unit **103** is made great. On the other hand, the depth of focus greatly varies depending on the focal length of the zoom lens and the F value of the aperture, and the difference between the time when the depth of focus is deepest and the time when the depth of focus is shallowest is on the order of several tens of times. Accordingly, the amount of movement of the lens unit **103** by the wobbling must also be varied as much as several tens of times between the minimum and the maximum.

Heretofore, however, in the lens moving mechanism used for wobbling, use has been made of a feed screw in which the amount of feed relative to the rotation of the motor **105** is constant and therefore, it has been necessary to make the total number of revolutions of the feed screw for moving the lens unit small when the depth of focus is shallow, and very great when the depth of focus is deep. Therefore, to effect the wobbling when the depth of focus is deep, it has been necessary to rotate the motor a lot and thus, much time has been taken until the end of the wobbling and after all, this has led to the problem that the response of auto focus becomes slow. Conversely, if the lead of the feed screw is made great so that the lens unit can be moved quickly when the depth of focus is deep, the number of revolutions of the motor when the depth of focus is shallow becomes very small and therefore, it has become difficult to move the lens unit with good accuracy.

On the other hand, in the lens device for photographing, as a mechanism for moving a lens unit for optical tracking adjustment or the like in the direction of the optical axis thereof, use is made of one as shown in FIGS. **16**A and **16**B of the accompanying drawings. In these figures, the reference numeral **71** designates a movable lens unit, the reference numeral **72** denotes a lens holding member holding the lens **71**, and the reference numeral **73** designates the fixed portion (fixed barrel) of a lens barrel body which corresponds to an outer cylinder, and the lens holding member **72** is fitted in an aperture formed in the fixed portion **73** and is rectilinearly movable in the direction of the optical axis. The reference numeral **74** denotes a ring member having a cam slot, and fitted to the outer periphery of the fixed portion **73** and rotatable about the optical axis. The reference numeral **75** designates a pin member mounted on the lens holding member, and fitted in a straight groove formed in the fixed portion **73** and the cam slot of the ring member **74**.

In the construction as described above, when as shown in FIGS. **16**A and **16**B, the ring member **74** is manually rotated or electrically rotated by the use of a motor or the like, the pin member **75** moves along both of the cam slot of the ring member **74** and the straight groove of the fixed portion **73**, and the lens holding member **72** on which the pin member **75** is mounted rectilinearly moves in the direction of the

optical axis. The movable lens unit **71** is then rectilinearly moved in the direction of the optical axis, whereby the intended optical lens adjustment is achieved.

In the above-described example of the conventional art, however, the lens holding member **72** rectilinearly moves while frictionally sliding by the aperture in the fixed portion **73** and the fitted portion and therefore, for the lens holding member **72** to move smoothly with a small force, it is necessary that there be a suitable gap in the fitted portion between the lens holding member **72** and the fixed portion **73**. This has led to the possibility that as shown in FIG. **17A** of the accompanying drawings, the lens holding member **72** becomes eccentric or as shown in FIG. **17B** of the accompanying drawings, an inclination is caused to the lens holding member **72** by backlash and the optical performance is deteriorated.

SUMMARY OF THE INVENTION

It is an object of the present invention to provide a lens moving mechanism which can easily follow any variation in the depth of focus of a photo-taking lens.

It is also an object of the present invention to prevent the occurrence of the eccentricity or inclination of a lens when the lens is moved.

The present invention provides a lens moving mechanism for finely moving a lens portion of a phototaking lens in the direction of the optical axis thereof, characterized by a holding member holding the lens portion, and a disc-like disc cam member provided with a cam surface, the disc cam member being rotated to thereby move the holding member on a track conforming to the cam surface.

Specifically, the disc cam member repeats forward rotation and reverse rotation about a predetermined axis and is rotatively controlled, and the cam surface is of a shape in which the distance from the axis becomes gradually longer or shorter.

It is also an object of the present invention to prevent the occurrence of the inclination or eccentricity of a movable lens caused by the movement in the direction of the optical axis thereof in the conventional art, and in the present invention, a holding member holding the lens is held relative to an outer cylinder by a disc-like resilient member so that the holding member may be pressed in the direction of the optical axis by a pressing member, and particularly, the resilient member is constructed of a metallic thin plate, whereby eccentricity in a direction perpendicular to the optical axis is suppressed even if the lens is moved in the direction of the optical axis.

BRIEF DESCRIPTION OF THE DRAWINGS

FIGS. **1A** and **1B** show a lens moving mechanism according to the present invention.

FIGS. **2A** and **2B** show the shape of a disc-like cam according to the present invention.

FIGS. **3A** and **3B** show the shape of a disc-like cam according to the present invention.

FIG. **4** is a block diagram of an entire camera carrying thereon the lens moving mechanism according to the present invention.

FIGS. **5A** and **5B** show a second embodiment of the lens moving mechanism according to the present invention.

FIG. **6** is a control block diagram of a zoom lens according to the conventional art.

FIG. **7** shows a lens moving mechanism according to the conventional art.

FIGS. **8A** and **8B** show the moving mechanism according to the present invention.

FIGS. **9A** and **9B** are views of the mechanism shown in FIGS. **8A** and **8B** as it is seen from the front thereof.

FIGS. **10A** and **10B** show another lens moving mechanism according to the present invention.

FIG. **11** shows still another lens moving mechanism according to the present invention.

FIG. **12** shows yet still another lens moving mechanism according to the present invention.

FIG. **13** shows a sixth embodiment of the lens moving mechanism according to the present invention.

FIG. **14** shows the holding structure for a further form of the lens moving mechanism according to the present invention.

FIGS. **15A** and **15B** show the lens moving mechanism according to the present invention as it is carried on a camera.

FIGS. **16A** and **16B** show the mechanism for moving a lens array such as an optical tracking adjusting mechanism.

FIGS. **17A** and **17B** show a lens moving mechanism according to the conventional art.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

First, FIG. **4** shows the lens moving mechanism of the present invention. In FIG. **4**, the reference numeral **51** designates a focus lens unit for focusing, the reference numeral **52** denotes a zoom lens unit for effecting a focal length change, the reference numeral **53** designates an aperture portion for adjusting exposure, the reference numeral **54** denotes a lens unit finely movable in the direction of the optical axis thereof to aid focus detection, the reference numeral **56** designates a lens drive portion for driving the lens, the reference numeral **57** denotes a relay lens unit having the imaging action, and the reference numeral **58** designates a lens drive portion for driving the focus lens unit **51**. Each lens unit is comprised of a plurality of lenses. The reference numeral **59** denotes an image pickup device such as a CCD, the reference numeral **60** designates a control portion for controlling the lens drive portions **56** and **58** and performing the automatic focus function, and the reference numeral **61** denotes a circuit for causing the control of an entire camera to be executed. The reference numeral **62** designates a zoom lens drive portion and a lens position detecting portion. The reference numeral **63** denotes an aperture drive portion and an aperture position detecting portion.

In such a construction, the lens unit **54** for focus detection is designed such that even if it is finely moved in the direction of the optical axis, the image magnification thereof hardly varies and only the focus thereof is out. Accordingly, by the lens unit **54** being finely moved (wobbled) in the direction of the optical axis by the lens drive portion **56**, the focus position on the image pickup surface of the image pickup device **59** is finely varied and this variation can be detected as a variation in an image signal. This signal variation is sent to the circuit **61** on the camera side and is signal-processed thereby, and the amount and direction of the out-of-focus are calculated and are outputted to the control portion **60**. The control portion **60** outputs a drive signal conforming to the amount and direction of the out-of-focus, and the focus lens **51** is driven by the lens drive portion **58**, whereby auto focus can be effected.

FIGS. **1A** and **1B** show the specific lens moving control mechanism **56**, **54** shown in FIG. **4**. In FIGS. **1A** and **1B**, the

reference numeral **1** designates a finely movable lens portion (corresponding to the lens unit **54** in FIG. **4**), and the reference numeral **2** denotes a holding member holding the lens portion **1** and fitted to a fixed portion **3** (fixed barrel) and movable in the direction of the optical axis. The reference numeral **4** designates a disc cam formed with a cam surface on the outer periphery thereof, and connected to the output shaft of a stepping motor **5** mounted on the fixed portion **3** and having its cam surface disposed so as to contact with the end surface of the lens holding member **2**. The motor **5** is controlled so as to repeat forward rotation and reverse rotation.

Also, in FIGS. **1A** and **1B**, the disc cam **4** is directly connected to the output shaft of the motor **5**, but alternatively may be connected to the output shaft through a speed reduction mechanism. The reference numeral **6** denotes a spiral member having a springy property and incorporated between the lens holding member **2** and the fixed portion **3** and biasing the holding member **2** so as to normally contact with the cam surface of the disc cam **4**. The reference numeral **10** designates a photosensor which detects light reflected from a light reflecting portion **40** provided with the cam **4** to thereby detect the rotated position of the cam **4**.

FIGS. **2A** and **2B** are graphs showing the cam shape of the disc cam **4** and the relation between the angle of rotation and the displacement of the cam. In FIGS. **2A** and **2B**, when the center of rotation of the disc cam **4** is defined as the Z-axis and with the position of the cam surface contacted by the lens holding member **2** when wobbling is not being effected, that is, when the lens portion **1** is at a reference position, or the angle when the center of action of the cam surface forwardly and reversely rotated is the reference as $\theta=0$, the cylinder coordinates system $r\theta z$ is taken, the shape of the cam is such a shape that, as is apparent from the characteristic graph thereof, it slightly moves the lens portion **1** back and forth up to a certain range (from $-\theta_1$ to $+\theta_1$) with $\theta=0$ as the center, and greatly moves the lens portion **1** when that range is exceeded. Within the range of use of the cam, the amount of variation in the position (distance) r of the cam surface relative to the angle θ, specifically the shape of this disc-like cam is such a shape that at angles $-\theta a$ to θa within a relatively separate range in the range of use of the cam surface, within the range of $-\theta a$ to **0**,

$$\frac{\partial^2 r}{\partial \theta^2} < 0$$

is satisfied, and within the range of 0 to θa,

$$\frac{\partial^2 r}{\partial \theta^2} > 0$$

is satisfied, and the cam is worked so that the movement distance of the lens portion may become longer away from the center of pivotal movement.

In the construction as described above, when the motor **5** is repetitively rotated in the forward direction and reverse direction, the disc cam **4** connected to the output shaft thereof is likewise rotated. At this time, the lens holding member **2** is urged against the disc cam **4** by the spring **6** and therefore, when the disc cam **4** is rotated and the displacement of the cam surface thereof contacting with the lens holding member **2** varies, the lens holding member **2** moves back and forth in the direction of the optical axis following it, and the lens portion **1** moves back and forth in the direction of the optical axis. In this manner, wobbling is accomplished.

Now, in the present embodiment, by the use of the disc cam of the aforedescribed shape, rotation is controlled up to a maximum angle θ_2 less than one full rotation of the cam when the depth of focus is deep, and it is made possible to effect wobbling at high speed. On the other hand, when the depth of focus is shallow as shown in FIG. **2**, use is made of the cam surface in which the amount of displacement of the cam is small ($-\theta_1$ to θ_1) and therefore, even when the amount of movement of the less unit is small, the number of revolutions of the motor does not become so small and the lens unit can be wobbled with good accuracy.

As described above, by the lens moving mechanism of the present embodiment, wobbling can be done at high speed even when the depth of focus is deep and the amount of movement of the lens is great, and moreover, wobbling becomes possible even when the depth of focus is shallow and the amount of movement of the lens is small. Of course, the control of these angles of rotation is effected on the basis of zoom position information which determines the depth of focus, and the aperture value.

FIGS. **3A** and **3B** show the cam shape of a disc cam in a second embodiment of the present invention. However, it is to be understood that this embodiment is similar to the first embodiment in the portions other

than the disc cam. In FIGS. **3A** and **3B**, when a cylinder coordinates system $r\theta z$ similar to that of FIGS. **2A** and **2B** is taken, the disc cam in the present embodiment is characterized in that within the range of a minute angle $\Delta\theta$ in the vicinity of the position of $\theta=0$ corresponding to that when the wobbling lens unit is at the reference position, the distance r between the z-axis and the cam surface is constant and the shape of the cam is set such that within the range of $\Delta\theta$,

$$\frac{\partial^2 r}{\partial \theta^2} \simeq 0$$

is satisfied, and within the other ranges,

$$\frac{\partial^2 r}{\partial \theta^2} > 0$$

is satisfied.

The present embodiment solves the problem that if the stopped position of the disc cam deviates from the position of $\theta=0$ due to the stop accuracy or the like of the motor when the wobbling operation is not being performed, the wobbling lens unit will move from the reference position and will be out of focus. Again, in the present embodiment, during the wobbling, the motor is rotated so as to rotate the disc cam outside the range of $\Delta\theta$, whereby there is obtained the same effect as that of the first embodiment.

The initial position setting of the cam will now be described.

As previously described, when the motor **5** is driven, the non-linear cam **4** is rotated, and the lens **1** is moved in conformity with the rotation of the cam **4**. On the other hand, a reflecting portion **4***a* for reflecting light is provided on a portion of the cam **4** as shown in FIG. **1B**, and the photosensor **10** is fixed so that light emitted from the light emitting portion of the photosensor may be reflected by the reflecting portion **4***a* and the light may enter the light receiving portion of the photosensor. Design is also made such that when the initial position setting of the lens **1** during the closing of a power source switch is necessary, the motor **5** is driven to thereby rotate the cam **4** and the light of the photosensor **10**

is reflected by the reflecting portion **4***a* and when it arrives at the photosensor **10**, the control circuit senses the signal thereof and stops the motor **5**. Thus, the non-linear cam is used and a sensor for position setting is provided on a portion of the cam, thereby effecting the minute vibration of the wobbling lens and reliable initial position setting necessary for focus adjustment.

In the foregoing, there have been shown embodiments in which the lens holding member is directly moved and controlled by the cam.

FIGS. **5**A and **5**B show another embodiment.

In FIGS. **5**A and **5**B, the reference numeral **1** designates a movable lens unit, the reference numeral **2** denotes a lens holding member holding the movable lens, and the reference numeral **3** designates the fixed portion (fixed barrel) of a lens barrel body. The reference numeral **20** denotes a metallic thin resilient disc with copper as a chief component, and holding the lens holding member **2** in the inner diameter thereof and having its outer diameter fixed to the fixed portion **3**. However, the lens holding member **2** and the resilient disc **20** are not rotatable relative to the fixed portion **3**. The reference numeral **4** designates a cam similar to that previously described, and rotatable relative to the fixed portion **3**. The reference numeral **11** denotes a sling-like plate having pointed-end pin members **11***a* and **11***b* mounted on one surface thereof at two positions symmetrical with respect to the center of the optical axis, and having a conical hole **13** and a V-shaped groove **14** formed on the other surface thereof at positions deviated by 90° with respect to the positions of the pin members **11***a* and **11***b*. However, it is to be understood that the positions of the conical hole **13** and the V-shaped groove **14** deviate by 180° from each other. Also, the tip ends of the pin members **11***a* and **11***b* bear against the end surface of the lens holding member **2**. FIG. **5**A shows the essential portions when the lens is seen from above it, and FIG. **5**B shows the essential portions when the lens is seen from sideways thereof.

A conical hole **15** is formed in that wall surface of the fixed portion **3** which is opposed to the conical hole **13**, and a ball member **16** is interposed between the cylindrical holes **13** and **15**. Further, a through-aperture **17** is formed in that wall surface of the fixed portion **3** which is opposed to the V-shaped groove **14**. A ball member **18** is fitted in the through-aperture **17** so as to protrude to the opposite sides of the through-aperture **17**, and one surface of the ball member **18** fits in the V-shaped groove **14** and the other surface of the ball member **18** bears against the cam surface of the cam member **4**. The cam member **4** is supported for rotation relative to the fixed portion **3** and is electrically rotatable by a motor or the like.

The reference character **4***b* designates a disc having a slit and mounted for rotation in synchronism with the cam member **4**. The reference numeral **21** denotes a photointerrupter disposed so as to embrace the disc **4***b*, and such that the slit of the disc **4***b* passes the photointerrupter **21** when the cam member **4** and the disc **4***b* are rotated.

In such a construction, when the cam member **4** is electrically rotated, the ball member **18** is pushed by the cam surface and is moved toward the ring-like plate **11** through the through-aperture **17** to push the ring-like plate **11**. The plate **11** has its movement in a direction perpendicular to the optical axis regulated by the effects of the ball member **16** interposed between the groove **13** and the conical hole **15** opposed to each other and the ball member **18** fitted in the V-shaped groove **14** and the through-aperture **17** and therefore, it is inclined toward the lens holding member **2** side with the ball member **16** as a fulcrum. Thereupon, the pin member **12** pushes the lens holding member **2**, which is thus moved in the direction of the optical axis.

On the other hand, when the cam member **4** is reversely rotated to thereby decrease the displacement of the cam surface bearing against the ball member **18**, the lens holding member **2** is moved in a direction opposite to that described above by the resilient force of the resilient disc **20**.

Particularly, in this embodiment, the ring-like plate **20** pushing the lens holding member **2** is inclined with the ball member, **16** as a fulcrum and therefore, due to the principle of levers, the ratio between the amount of displacement pushing the holding member **2** at the position of the pin member **12** and the amount of displacement given from the disc cam member **4** to the ring-like plate **11** through the ball member **18** is equal to the ratio between the distance from the ball member **16**, which provides the fulcrum, to the pin member **12** and the distance from the ball member **16** to the ball member **18**. That is, the amount of displacement of the cam becomes greater by the above-described distance ratio times of the amount of movement of the lens. Thus, there is obtained the effect that when it is desired to move the lens unit by a minute amount, the influence of the working error of the cam becomes small as compared with a case wherein the amount of displacement of the cam and the amount of movement of the lens unit are equal to each other, and the working of the cam becomes easier and the accuracy of the lens position becomes better.

As described above, the design is made such that the disc cam worked so that the amount of variation in the displacement of the cam may increase relative to the direction of rotation is disposed at a right angle with respect to the optical axis of the lens system and the disc cam is rotated so as to move the wobbling lens unit in the direction of the optical axis, whereby even when the depth of focus is deep, wobbling can be accomplished at high speed without the number of revolutions of the motor being remarkably increased and moreover, even when the amount of movement of the lens is small, wobbling can be accomplished with high accuracy.

FIGS. **8**A, **8**B, **9**A and **9**B show an embodiment of the present invention. In these figures, the reference numeral **1** designates a movable lens unit, the reference numeral **2** denotes a lens holding member holding the movable lens unit, and the reference numeral **3** designates the fixed portion (fixed barrel) of a lens barrel body. The reference numeral **20** denotes a metallic thin resilient disc with copper as a chief component, held so as to cover the whole of the circumference of the lens holding member **2** and having its outer diameter portion fixed to the fixed portion **3**. The lens holding member **2** and the resilient disc **20** are not rotatable relative to the fixed portion **3**. The reference numeral **15** designates a cam member having surface cams **15***a* on the end surface thereof and rotatable relative to the fixed portion **3**. The reference numeral **16** denotes an operating ring member connected to the cam member **15** through a pin member **17** and rotatable relative to the fixed portion **3**. The reference numeral **18** designates cam follower members provided on the holding member, and two or more such cam follower members are mounted on the lens holding member **2**, at positions symmetrical with respect to the center of the optical axis, and bear against the two surface cams of the cam member **15**. Here, the cam member is formed of a number of surface cams of the same shape corresponding to the number of the cam follower members **18**. Also, the resilient disc **20** is substantially flat in a no-load condition, but is always deformed when it is incorporated into the mechanism of the present embodiment, and is mounted with

its resilient force normally creating an urging force between the cam followers **18** and the surface cams of the cam member **15**.

In such a construction, when the operating ring **16** is manually rotated or electrically rotated by a motor or the like, the cam member **15** connected thereto by the pin member **17** is also rotated. When the cam member **15** is rotated, the cam followers **18** are pushed out by the surface cams of the cam member **15**, as shown in FIG. **8**B, and the lens holding member **2** is moved in the direction of the optical axis and the lens unit **1** is likewise moved. The resilient disc, which is formed of a metallic thin film as previously described, may be deformed in the direction of the optical axis, but hardly becomes eccentric relative to a direction perpendicular to the optical axis.

On the other hand, when the operating ring **16** is reversely rotated from the above-described state, the cam member **15** is also reversely rotated and the amount of displacement of the surface cams at the position whereat the cam followers **18** bear decreases. At this time, the lens barrel (lens holding member) **2** is being pushed toward the cam member side by the resilient force of the resilient disc **20** and therefore, the cam followers **18** are moved in accordance with the surface cams, and the lens holding member **2** also fluctuates in a direction opposite to that described above.

By the operating ring **16** being rotated in this manner, the movable lens unit **1** can be moved back and forth in the direction of the optical axis.

FIGS. **9**A and **9**B are views of the present embodiment as it is seen from the direction of the optical axis in FIGS. **8**A and **8**B. The lens holding member **2** is held by the resilient disc as shown in FIGS. **9**A and **9**B, but the resilient disc is subjected to the force with which the lens holding member is pushed dispersed by the inner diameter thereof, and is deformed into a conical shape. At this time, only a force perpendicular to the surface of the resilient disc is applied and therefore, the center of the disc does not change and it does not happen that the optical axis of the lens unit becomes eccentric. Also, the lens holding member is being pushed by the symmetrically disposed cam followers and therefore is parallel-moved, and no inclination of the optical axis of the lens unit occurs. Further, the present embodiment is simple in structure and therefore, it is possible to make it compact and light in weight and it is also possible to manufacture it inexpensively.

As described above, according to the present embodiment, it becomes possible to realize a compact and light-weight lens moving mechanism, in which the optical axis of the lens unit does not become eccentric and inclined, at low costs.

In the present embodiment, the resilient disc is a doughnut-shaped one as shown in FIG. **9**A, but alternatively a resilient disc **20** having one or more through-apertures **20***a* as shown in FIG. **9**B may be used to obtain a similar effect. In this case, however, the shape and positions of the through-apertures **20***a* in the resilient disc **20** must be in a relation symmetrical with respect to the positions of the cam followers **18** pushing the lens holding member **2** at the center of the optical axis. This is because when the cam followers are at symmetrical position as on line X—X, if the lens holding member **2** is pushed, the resilient disc **20** will be deformed symmetrically as viewed from the cam followers **18** and the lens holding member **2** will move without being inclined, but if the cam followers **18** are at asymmetrical positions as on line Z—Z, the resilient disc **9** will be deformed asymmetrically and therefore, the lens holding member **2** will become inclined.

Also, in the present embodiment, the lens barrel and the resilient disc are constructed as discrete parts, but it can be readily analogized that even if the two are formed integrally with each other, a similar function and effect will be obtained.

FIGS. **10**A and **10**B show another embodiment of the present invention. This embodiment is one in which instead of the ring-like plate **11** in the embodiment shown in FIGS. **5**A and **5**B, a resilient plate **31** is used and the fulcrum is fixed to the fixed portion **3** by a screw **32**. However, for the convenience of illustration, the ball member **18** is replaced by a pointed-end pin member **33**, but they are the same in their roles. The other members designated by the same reference numerals as those in FIGS. **5**A and **5**B are similar in construction.

In FIGS. **10**A and **10**B, when the cam member **4** is rotated, the pin **33** moves along the displacement of the cam and the resilient plate **31** is pushed. When the resilient plate **31** is pushed, the resilient plate **31** is deformed about the fixed portion of the screw **32** and flexure is created, as shown in FIG. **10**B. At this time, the pin member **12** mounted on the resilient plate **31** is also pushed out toward the lens holding member **2** side and therefore, the lens unit **1** is moved back and forth in the same manner as in the embodiment of FIGS. **5**A and **5**B.

The effect of this embodiment is the same as that of the embodiment of FIGS. **5**A and **5**B, but in this embodiment, the resilient plate **31** is deformed and the amount of displacement thereof is a high-order function of the distance from the fixed portion by the screw **32** and therefore, the ratio of the displacement of the position of the pin member **12** to the displacement given at the position of the cam member **19** becomes smaller than in the embodiment of FIGS. **5**A and **5**B wherein the amount of displacement becomes a linear function of the distance from the fulcrum. That is, when an attempt is made to move the lens unit by the same amount, if the dimensional relation is the same, the amount of displacement of the cam becomes greater in this embodiment than in the embodiment of FIGS. **5**A and **5**B. Thus, when the lens unit is finely moved, the working of the cam becomes easy and the effect that the accuracy of the lens position becomes better becomes greater.

FIGS. **11** to **13** show examples in which in each of the previous embodiments, the cam member for moving the lens is replaced by a feed screw.

First, FIG. **11** shows an example in which the cam member **15** of FIGS. **8**A and **8**B is replaced by a ring member **41** formed with a thread on the outer periphery thereof and is brought into engagement with an internal thread formed on the inner diameter of the fixed portion **3** to thereby constitute a feed screw. In this construction, when the operating ring **16** is rotated, the ring member **41** is rotated through the pin member **17** and by the effect of the feed screw, the ring member **41** is moved in the direction of the optical axis to thereby push the lens barrel **2** and thus, the lens unit **1** is moved.

Next, FIG. **12** shows an example in which in the embodiment of FIGS. **5**A and **5**B, the cam member is replaced by a feed screw. In FIG. **12**, the reference numeral **42** designates a male screw which is the feed screw, and the reference numeral **43** denotes a female screw. The male screw **42** is connected to the output shaft of a motor **44**. The reference numeral **45** designates a pin member mounted on the female screw **43** and fitted in a slot formed in the fixed portion **3** and not rotatable from the interval thread **43** but axially rectilinearly movable. The reference numeral **46** denotes a pointed-end pin member mounted on the female screw **43**

and fitted in a V-shaped groove **14** in the ring-like plate **11** to push the ring-like plate **11**. In this construction, when the male screw **42** is rotated, the female screw **43** is rectilinearly moved and the ring-like plate **11** is pushed and thus, the lens unit **1** is moved.

FIG. **13** shows an example in which the cam member of FIGS. **10**A and **10**B is replaced by a feed screw, and in this example, a female screw **43** is constructed integrally with a resilient plate **31**. Thus, when a male screw **42** is rotated, displacement is directly given to the resilient plate **31**, and as in the third embodiment, the lens unit **1** can be moved.

As described above, even if the cam member for moving the lens is replaced by a feed screw, the lens unit can be likewise moved and the same effect can be obtained.

FIG. **14** shows an embodiment in which a plurality of resilient discs **4** for holding the lens barrel **2** are used. This embodiment solves the problem that when the lens barrel **2** is held by a resilient disc **4**, the position of the hold lens barrel **2** is liable to become unstable when the weight of the movable lens unit **1** or the lens barrel **2** is heavy or when the full length of the movable lens unit **1** in the direction of the optical axis is great. This also holds true of the aforedescribed other embodiments.

FIGS. **15**A and **15**B show an example in which the lens moving mechanism according to the present invention is carried on a photographing lens device and is utilized in an apparatus wherein a lens unit is finely moved in the direction of the optical axis thereof to thereby effect focus detection. FIG. **15**B shows an example in which a photographing lens device carrying thereon the lens moving mechanism according to the present invention is mounted on a camera.

As described above, the lens moving mechanism of the present invention is suitable for use in the focus detecting device of a lens device with the automatic focus adjusting function as described above, and thereby, it becomes possible to realize a lens device with a very highly accurate and high-speed automatic focus adjusting function.

What is claimed is:

1. A lens moving mechanism for finely moving at least a lens portion of an objective lens in a direction of an optical axis of the objective lens, said lens moving mechanism comprising:

a holding member holding the lens portion; and

a disc-like disc cam member provided with a cam surface, which lies in a peripheral portion of said disc-like disc cam member, said disc cam member being rotated to thereby move said holding member on a track conforming to said cam surface,

wherein when the angle of rotation is zero, the center of action of the forwardly and reversely rotated cam surface of said disc cam member is the reference, the angle of the cam surface within a certain range of use thereof is θa and the distance from the center of an axis of rotation to the cam surface is r, such that in the range of −θa to **0**,

$$\frac{\partial^2 r}{\partial \theta^2} < 0$$

is satisfied, and in the range of 0 to θa,

$$\frac{\partial^2 r}{\partial \theta^2} > 0$$

is satisfied.

2. The lens moving mechanism of claim **1**, wherein said disc cam member repeats forward rotation and reverse rotation about a predetermined axis of rotation and is rotatively controlled, and said cam surface has a shape in which the distance from the predetermined axis becomes gradually longer or shorter.

3. The lens moving mechanism of claim **1**, wherein said holding member is held relative to an outer cylinder by a disc-like resilient member.

4. The lens moving mechanism of claim **3**, wherein said resilient member is a metallic thin plate.

5. A lens driving apparatus for detecting a focus state, said apparatus comprising:

a lens barrel;

an objective lens comprising a plurality of lens units, said objective lens having an optical axis; and

a rotating member rotating about a predetermined axis of rotation to finely move a lens unit of said plurality of lens units of said objective lens in a direction of the optical axis, said lens unit being connected to said lens barrel by a disk-like resilient member, and said rotating member having a peripheral surface such that a distance from the predetermined axis of rotation to the peripheral surface is gradually changed,

wherein said lens unit is moved forwardly or backwardly in a direction of the optical axis of said objective lens according to rotation of the peripheral surface, and

wherein said rotating member is configured to repeat forward rotation and reverse rotation about the predetermined axis of rotation for detection of a focus condition.

6. An apparatus according to claim **5**, further comprising a motor connected to the predetermined axis of rotation of said rotating member.

7. An apparatus according to claim **6**, further comprising a control circuit for controlling focus detection, to repeat the forward rotation and reverse rotation.

8. An apparatus according to claim **5**, further comprising a ring-shaped member having a plurality of bearing portions bearing against said lens unit, said ring-shaped member being inclined by said rotating member with respect to a fulcrum, so that said lens unit is driven in an optical direction by said bearing portions.

[57] **ABSTRACT**

A low-magnification interference microscope objective is rendered parfocal with a high-magnification objective by folding the light beam to the side of the optical axis of the objective, thereby maintaining the original optical path length while shortening the mechanical length of the objective. The beam is reflected by a mirror, causing it to travel some distance out to the side, and then it is reflected back toward the beamsplitter by an additional pair of mirrors. After a final reflection within the beamsplitter, the resulting beam is coaxial with the original optical axis, while the physical length of the objective has been substantially reduced. This approach makes it possible to obtain a desired distance from the mounting shoulder of the objective to the focal point.

FOLDED LOW-POWER INTERFERENCE MICROSCOPE OBJECTIVE

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention is related in general to the field of interferometry and, in particular, to a novel interference microscope objective with a folded optical path to reduce the physical length of the objective.

2. Description of the Related Art

It is desirable to provide interferometric instruments with the flexibility of operating at different magnifications. Accordingly, interferometers used to measure surface roughness are often equipped with a rotatable turret capable of accommodating multiple interference microscope objectives with different optical power. In such a configuration, it is very important that the objectives be substantially parfocal, as defined below, to minimize the need for focussing after switching from one objective to another.

In surface profilometry applications, interference microscope objectives are typically used with magnifications in the 1.5× to 10× range. Based on current commercial availability, microscope objectives commonly used for these applications are used with a tube lens with a specific reference focal length (for example, typically 200 mm for Nikon, 180 mm for Olympus, and 160 mm for Zeiss objectives). Therefore, the focal length of these objectives varies inversely with their power according to the relation $f_{objective}=f_{Reference}/\text{power}$. For example, a 50× Nikon objective has a focal length of 4 mm; a 20× Nikon objective of 10 mm; and so on. Obviously, low power objectives have a relatively long focal length, which makes it difficult to design them with a physical length sufficiently short to fit alongside high power objectives that may be less than half their length. The problem is further exacerbated by the necessity of introducing a beamsplitter between the objective's lens and the test sample for interference purposes.

In practice, objectives in the 2.5× to 50× range are substantially similar in size and can be mounted coplanarly on a turret such that the distance between their mounting shoulder and their focal point is the same. For the purposes of this disclosure, multiple objectives characterized by this condition are defined as "parfocal" objectives. Referring to the Wyko 2.5× microscope objective **10** shown in FIG. **1**, for example, which includes a beamsplitter for interference purposes, the distance D between its mounting shoulder **12**, which in operation abuts the mounting plane **14** of the objective turret **16**, and its focal point F (shown coincident with a sample surface S) is approximately 48 mm. The corresponding distances for comparable Wyko 5×, 10×, 20× and 50× objectives are about 49, 45, 45 and 45 mm, respectively.

Therefore, these reference objectives are readily rendered parfocal by adding collars of different lengths to each one to provide a common nominal parfocal distance D' to the focal point F. This modification is illustrated in the Wyko 10× objective **20** shown in FIG. **2**, also including a beamsplitter for interference purposes, where an extension collar **22** is inserted between the shoulder **12** of the objective and the plane **14** of the turret **16** so as to increase the distance D by about 6.35 mm to a nominal parfocal distance D' of approximately 51.35 mm. Using this approach, all objectives with powers in the range between 2.5× and 50× are modified in a relatively simple manner for parfocal use in a single turret having a mounting plane **14** that produces a substantially focussed condition when the object under test is placed at about the distance D' from the plane **14**. Thus, once an object is in focus for one objective, it remains substantially so when the turret **16** is rotated and other objectives are placed in operation.

For the purpose of this disclosure, the focal point F is assumed to be coincident with the location of the sample surface S. This describes the "infinite conjugates" imaging condition, in which the objective forms an image of the sample an infinite distance above the objective. This image then acts as an object for the tube lens, which forms a (typically) magnified image of the sample at a fixed location in space. As one skilled in the art would readily understand, though, the disclosure applies equally to the case where the focal point is above the sample surface, and an image of the surface is formed a finite distance above the objective without the use of a tube lens. Thus, while the "infinite conjugates" imaging condition is used here to simplify the description of the invention, the description can be generalized with no loss of accuracy to the "finite conjugates" imaging condition. It can also be applied to the case where the focal point is below the sample surface S.

Unfortunately, 1.5× and 2× objectives have a relatively long focal length that in practice is not suitable for the same solution. For example, the distance D for Wyko 1.5× and 2.0× objectives is about 115 mm, about 64 mm too long for fitting within the nominal parfocal distance D' of 51.35 mm used for the more powerful, and shorter, objectives. Thus, it is clear that low-power objectives could not be mounted parfocally on a turret alongside more powerful objectives. If sufficient space were provided to mount both, focussing a "short" objective would cause an adjacent "long" objective on the turret to physically contact the test sample or the microscope stage. The same could happen while rotating the turret to place the long objective in operation. It is noted that for the purpose of this disclosure "low-power" objectives are considered to be those with magnifications of 1.5× and 2×, while "high-power" objectives are those with magnifications of 2.5× to 50×. Although these definitions do not correspond to normal microscopy usage, where high power typically would refer to magnifications somewhat greater than 2.5×, they are appropriate for the description of the invention, which regards the physical length of the objectives in relation to their power of magnification.

Several practical difficulties prevent the design of a turret/microscope assembly with sufficient height D' to accommodate all objectives of interest in a substantially parfocal condition (that is, theoretically, very tall collars **22** could be used with high-power objectives to obtain the same nominal parfocal distance D' for all objectives). One problem with this approach is that degraded illumination would result for the more powerful objectives due to a substantial misalignment along the optical axis of their entrance pupils with respect to the less powerful objectives. This misalignment of the entrance pupils would also cause the light beam to pass through different portions of the collection optics for the high-power versus the low-power objectives. In addition, the telecentricity of microscope objectives, which prevents changes in magnification during focussing, makes it difficult to substantially shorten the length of the low-power objective in a practical and economically feasible manner. Finally, the problem is further complicated by the fact that interference objectives require a beamsplitter in the optical path. Since Michelson interferometers, which employ a cube beamsplitter placed between the last lens and the test object, are most suitable for low-magnification objectives, the additional space occupied by the beamsplitter further decreases the length available for placement of the other optical

components of the objectives while maintaining a given parfocal length.

Accordingly, there is still a need for a low-power interference objective that is substantially commensurate in length with higher-power objectives for concurrent use mounted in parallel on a rotatable turret. This invention is directed at providing a novel approach to that end.

BRIEF SUMMARY OF THE INVENTION

One primary goal of this invention is a design of interference microscope objectives suitable for mounting on a rotatable turret in parfocal condition, such that minimal focussing is required when switching from one objective to another.

Another objective of the invention is the design of 1.5× and 2× interference microscope objectives that have substantially the same mechanical length as higher-power objectives (such as 2.5× to 50× magnification) having a tube lens with a common reference focal length.

Another important goal of the invention is a solution that provides substantially uniform illumination with all objectives mounted on the turret.

Still another objective is a solution that is practically feasible even accounting for the space occupied by the beamsplitter required for the interference portion of the objective.

Another object of the invention is an approach that is particularly suitable for implementation in a Michelson interferometric arrangement.

Finally, a goal of the invention is the development of a method and apparatus that are suitable for implementation with relatively minor modifications to existing interference microscope objectives and interferometric surface profilers.

Therefore, according to these and other objectives, the invention consists of folding the light beam to the side of the optical axis of the objective, thereby maintaining the original optical path length while shortening the mechanical length of the objective. The beam is reflected by a mirror, causing it to travel some distance out to the side, and then it is reflected back toward the beamsplitter by an additional pair of mirrors. After a final reflection within the beamsplitter, the resulting beam is coaxial with the original optical axis, while the physical length of the objective has been substantially reduced. This approach makes it possible to obtain the desired distance from the mounting shoulder of the objective to the focal point.

Various other purposes and advantages of the invention will become clear from its description in the specification that follows and from the novel features particularly pointed out in the appended claims. Therefore, to the accomplishment of the objectives described above, this invention consists of the features hereinafter illustrated in the drawings, fully described in the detailed description of the preferred embodiment and particularly pointed out in the claims. However, such drawings and description disclose but one of the various ways in which the invention may be practiced.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a simplified schematic representation of a conventional interference microscope objective mounted on a turret to illustrate the fixed distance between its mounting shoulder and the objective's focal point.

FIG. **2** is a schematic representation of a microscope objective mounted on a turret by means of an extension collar to obtain parfocal conditions at a predetermined distance between the turret's mounting plane and the objective's focal point.

FIG. **3** is a simplified schematic representation of a conventional, 1.5× magnification, interference microscope objective to illustrate its long physical structure with an optical path that is coaxial with the optical axis of the objective.

FIG. **4** is a simplified schematic representation of a 1.5×-magnification interference microscope objective according to the present invention, wherein its physical structure is substantially shortened and its optical path is folded outside the optical axis of the objective.

FIG. **5** is a simplified schematic representation of a conventional, 5× magnification, interference microscope objective having substantially the same physical length of the 1.5×-magnification objective of the invention, thereby providing a parfocal pair for mounting on an interference microscope turret.

DESCRIPTION OF THE PREFERRED EMBODIMENTS OF THE INVENTION

Although folding beams have been utilized for various purposes in the optical arts, for example in binoculars, the heart of this invention lies in the recognition that the technique of folding a beam can be used advantageously to make a low-power microscope objective parfocal with other objectives. This approach provides a simple solution to a yet unresolved problem and constitutes a useful advance in the art of microscopy in general and interferometric profilometry in particular.

As illustrated in schematic form in FIG. **3**, a typical low-power (1.5× and 2×) interference microscope objective **30** comprises a first optical member **32** downstream of a light source (not shown), followed by second and third optical members **34** and **36**, respectively, through which the light beam L is passed toward a test surface S. A beamsplitter **38** reflects a portion of the light sideways in the direction of a reference surface R. The reference beam LR is focused on the surface of the reference surface R, while the test beam LT is focused on the test or sample surface S. The beams reflected from the reference mirror R and the test surface S pass back up through the optics of the objective and upward to a solid-state detector array (not shown), where interference fringes are produced as a result of the optical path difference between the path from the beamsplitter **38** to reference mirror R and the path from the beamsplitter to the test surface S. The detector array may be replaced by an eyepiece for manual viewing.

An interference microscope objective **40** according to the invention is illustrated in FIG. **4**. Taking the objective **30** of FIG. **3** as an example, the idea is to produce a physically shorter interference microscope objective with the same optical characteristics of the original objective. A reflective surface **42** is positioned between the first optical member **32** and the second optical member **34** to fold the light beam L to the side of the optical axis A in a direction opposite and normal to the plane of the reference mirror R. The second optical member **34** in turn is positioned along the folded beam at the same optical distance from the first optical member **32** as in the original objective. The beam is then folded twice by two reflective surfaces **44** and **46**, each disposed sequentially at a 45° angle to the incident light to direct the beam toward the beamsplitter **38** through the third optical member **36**. The beamsplitter **38** is positioned with respect to the incident beam such that a portion of the light (the reference beam LR) is passed through to reach the

reference surface S and another portion (the test beam LT) is reflected and directed along the optical axis A toward the test surface S.

Obviously, so long as the optical distances between the various optical components are maintained, the optical characteristics of such a physically shortened objective remain unchanged. Thus, the physical length of a low-magnification objective can be shortened to match a desired distance between the objective's mounting shoulder **12** and its focal point P in order to enable a parfocal design of a plurality of objectives with great variation in magnification. A substantially parfocal 5×-magnification objective **50**, with the same tube-lens reference focal length as the shortened 1.5×-magnification objective **40**, is shown in FIG. **5** for comparison.

While the presence of the beamsplitter in low-power interferometric microscope objectives is one of the key motivators for this invention, the technique outlined here is applicable to non-interferometric objectives as well. This can be seen in the design of a 1×, 0.5×, or even lower power objectives with a fixed parfocal length. In general, the difficulty of such a design increases with the ratio of the focal length to the parfocal length. For a sufficiently low power objective, this invention provides a means for simultaneously obtaining the required focal and parfocal lengths.

There is an additional benefit obtained with substantially parfocal and parcentric objectives, independent of the use of a turret. Parcentricity is defined as the property of having a common optical axis among objectives. This results in a sample in the center of the field-of-view in one objective being in the center of the field-of-view in the other objectives, and is independent of the parfocality. This benefit is realized in the case where the tip/tilt adjustment (important in interference microscopy) is obtained by adjusting the orientation of the light source, illumination and collection optics, turret, scanning mechanism, and camera all together rather than the case where these elements are fixed and the sample stage is adjusted. In such case, adjustment of the tip/tilt setting will change only the observed slope of the sample. This is in contrast to the case of non-parfocal objectives, where the tip/tilt can be ideal for only a single parfocal length, and tip/tilt adjustment will be accompanied by an effective translation of the sample when viewed with objectives of different parfocal lengths. This will be the case whether the objectives are mounted together on a turret, or mounted singly onto the system.

As one skilled in the art would readily recognize, the invention has been described in terms of three optical members because such would be the nature of the optics found in a conventional low-magnification telecentric microscope objective, but the concept of the invention is applicable to any combination of optical members so long as the optical distances between them are maintained in the folded beam. Similarly, each optical member may comprise one or more lenses, as necessary to achieve the desired optical behavior. The invention has also been described in terms of three reflective surfaces because they represent one way to fold a light beam to the side and back toward the reference surface. On the other hand, other arrangements, possibly involving fewer or more reflective surfaces, could also be used. It is understood that a reflective surface could be a conventional front-surface mirror disposed at an angle with respect to the beam, a right-angle prism, a total internal reflection prism, or any other optical device used to reflect light. Further, the angle through which the beam is deviated by the reflective surfaces may or may not be 90 degrees, as illustrated in this disclosure. It is also possible for the beam to travel in more than one plane, rather than the single plane employed here; that is, there need not be a common meridional plane among the reflective surfaces. Finally, the invention is particularly directed to interference microscopy, but it is clear that it could be applied advantageously to conventional (non-interferometric) microscope objectives as well.

Various other changes in the details, steps and components that have been described may be made by those skilled in the art within the principles and scope of the invention herein illustrated and defined in the appended claims. Therefore, while the present invention has been shown and described herein in what is believed to be the most practical and preferred embodiments, it is recognized that departures can be made therefrom within the scope of the invention, which is not to be limited to the details disclosed herein but is to be accorded the full scope of the claims so as to embrace any an all equivalent processes and products.

I claim:

1. In an interferometric device comprising a movable objective turret adapted to receive a plurality of interference microscope objectives mounted in parfocal arrangement with respect to a sample stage, wherein a light beam is alternatively passed through any one of the objectives toward the sample stage to perform interferometric measurements on a sample surface, an interference microscope objective that comprises:

(a) an objective housing adapted for mounting on the turret with an optical axis in substantial alignment with the light beam;

(b) a plurality of optical members mounted within said housing at predetermined optical distances along an optical path toward the sample stage;

(c) a reference surface disposed at a predetermined angle with respect to said optical axis;

(d) first means for folding the light beam to a first direction away from said optical axis;

(e) second means for folding the light beam from said first direction to a second direction toward said reference surface; and

(f) means for splitting the light beam traveling in said second direction into a reference beam directed toward the reference surface and a test beam directed toward the sample stage.

2. The microscope objective of claim **1**, wherein said first and second means for folding the light beam are reflective means.

3. The microscope objective of claim **1**, wherein said reference surface is disposed substantially at a right angle with respect to said optical axis.

4. The microscope objective of claim **2**, wherein said first means consists of a right-angle prism.

5. The microscope objective of claim **2**, wherein said second means consists of a pair of right-angle prisms.

6. The microscope objective of claim **3**, wherein said first reflective means consists of a right-angle prism.

7. The microscope objective of claim **6**, wherein said second reflective means consists of a pair of right-angle prisms.

8. The microscope objective of claim **7**, wherein said test beam is aligned with said optical axis.

9. The microscope objective of claim **2**, wherein said plurality of optical members consists of first, second and third optical members; said first reflective means is positioned between the first and second optical members; and said second reflective means is positioned between the second and third optical members.

10. The microscope objective of claim 9, wherein said reference surface is disposed substantially at a right angle with respect to said optical axis.

11. The microscope objective of claim 10, wherein said first reflective means consists of a right-angle prism.

12. The microscope objective of claim 11, wherein said second reflective means consists of a pair of right-angle prisms.

13. An interference microscope objective having an optical axis substantially perpendicular to a plane containing a test surface, comprising:

a beamsplitter producing a reference beam directed to a reference surface and a test beam directed to the test surface;

a plurality of optical members disposed at predetermined optical distances along an optical path to the beamsplitter;

first means for folding a light beam traveling in said optical path to a first direction away from said optical axis; and

second means for folding the light beam to a second direction toward said beamsplitter.

14. The objective of claim 13, wherein said plurality of optical members consists of first, second and third optical members; said first means is positioned between the first and second optical members; and said second means is positioned between the second and third optical members.

15. The objective of claim 14, wherein said first means consists of a reflective surface folding the light beam at a 90-degree angle, and said second means consists of a pair of reflective surfaces each folding the light beam at a 90-degree angle.

16. The objective of claim 14, wherein said test beam is substantially coaxial with said optical axis.

17. An interferometric device comprising;

an objective turret movable between alternative positions;

a plurality of interference microscope objectives, each including an objective housing mounted on the objective turret;

means for alternatively passing a light beam through any one of the interference microscope objectives along an optical axis thereof toward a sample stage to perform interferometric measurements on a sample surface; and

a reference surface disposed at a predetermined angle with respect to said optical axis;

wherein at least one of said interference microscope objectives comprises

(a) a plurality of optical members mounted within the housing at predetermined optical distances along an optical path toward the sample stage;

(b) first means for folding the light beam to a first direction away from said optical axis;

(c) second means for folding the light beam from said first direction to a second direction toward said reference surface; and

(d) means for splitting the light beam traveling in said second direction into a reference beam directed toward the reference surface and a test beam directed toward the sample stage;

such that said plurality of interference microscope objectives is in parfocal arrangement with respect to the sample stage.

18. The interferometric device of claim 17, wherein said first and second means for folding the light beam are reflective means.

19. The interferometric device of claim 17, wherein said reference surface is disposed substantially at a right angle with respect to said optical axis.

20. A method for achieving parfocal conditions between a first interference microscope objective and a second interference microscope objective of substantially greater magnification power in an interferometric device, comprising the following steps:

(a) providing a movable objective turret adapted to receive said objectives in alignment with an optical axis substantially perpendicular to a test surface;

(b) providing a plurality of optical members in said first objective, said members being disposed at predetermined optical distances along an optical path to a beamsplitter adapted to produce a reference beam directed to a reference surface and a test beam directed to the test surface;

(c) folding a light beam traveling in said optical path to a first direction away from said optical axis;

(d) folding the light beam from said first direction to a second direction toward said optical axis; and

(e) folding the light beam from said second direction to a third direction substantially parallel to said optical axis;

wherein said folding steps are carried out along said optical path to the beamsplitter such that the first interference microscope objective achieves a substantially parfocal relation with respect to the second interference microscope.

21. The method of claim 20, wherein said plurality of optical members consists of first, second and third optical members; said step (c) is carried out by folding the light beam between the first and second optical members; said step (d) is carried out by folding the light beam between the second and third optical members; and said step (e) is carried out by folding the light beam in the beamsplitter.

22. The method of claim 21, wherein said step (c) is carried out with a reflective surface folding the light beam at a right angle, and said step (d) is carried out with a pair of reflective surfaces each folding the light beam at a right angle.

23. The method of claim 22, wherein said third direction is substantially coaxial with said optical axis.

[57] **ABSTRACT**

A low cost objective lens system that provides complete axial color correction with no substantial residual color dependent aberrations such as spherochromatism or chromatic coma. The objective lens system includes a first lens element having an aspherical lens surface and a second lens element having a diffractive optical surface and an aperture disposed between the first and second lens elements. The axial separation of the aspherical lens surface and the diffractive optical surface may be determined by the condition $0.5<L_A/efl<1.25$ where L_A is the axial distance from the lens element with the aspherical surface to the lens element with the diffractive optical surface and efl is the effective focal length of the objective lens system. The diffractive optical surface is optically dispersive and is preferably placed on the refractive lens element in the system having the highest optical power. The objective lens system does not exhibit residual color dependent aberrations such as spherochromatism and chromatic coma. The aspherical lens surface is preferably located on the object side of the aperture stop to provide the most advantageous coma correction and spherical aberration correction. The aspherical lens surface further corrects residual monochromatic aberrations such as astigmatism and distortion.

OBJECTIVE LENS SYSTEM UTILIZING DIFFRACTIVE OPTICAL ELEMENT

FIELD OF THE INVENTION

This invention relates generally to optical lens element configurations and, more particularly, to an objective lens system utilizing a lens element having an aspherical surface and/or a lens element having a diffractive surface. Even more particularly, this invention relates to an objective lens system utilizing an aspherical lens surface that is selectively located on the optical axis to correct coma in addition to the basic correction of spherical aberration. The diffractive lens surface may be located on the refractive element with the most optical power to correct the axial color aberration so that chromatic errors are not propagated through the remainder of the optical system.

BACKGROUND OF THE INVENTION

High performance passive and active optical lens systems need very high quality optical elements in order to obtain the required degree of performance. Optical lens systems are composed of multiple individual lens elements designed to achieve the necessary performance over a specified field of view and specified spectral band. The three main considerations in the design of an optical system are cost, weight, and performance.

To control the costs of optical systems, the optical systems are generally designed to contain only spherical surfaces. The use of aspherical surfaces in optical systems can reduce the number of elements needed to achieve the required performance. However, lens elements having aspherical surfaces are significantly more expensive to manufacture than lens elements having only spherical surfaces. Therefore, the decision to use aspherical surfaces in place of spherical surfaces in a particular optical lens system depends upon whether the weight of the optical system is a more critical factor than the cost of the system or whether the cost of the system is a more critical factor than the weight of the optical system.

Examples of optical systems that can require very high quality optical systems are passive and active infrared sensors and infrared camera systems. The number of optical materials that are transmissive at infrared wavelengths is limited. Most infrared lens elements are made from the four materials, germanium, silicon, zinc sulfide, and zinc selenide, all of which are dispersive. The dispersive characteristic of these materials results in an optical system that contains more elements than the optical system would if less dispersive materials were available. The additional elements are necessary to correct chromatic aberration, which is a consequence of dispersion and causes light to have different focal points depending upon wavelength.

The image produced by an optical system has other aberrations that take many forms, such as spherical aberration, spherochromatism, and coma. Spherical aberration results when spherical lens surfaces are used and causes light striking nearer the periphery of the lens to be focused closer to the lens while light striking near the center is focused farther away from the lens. Spherochromatism (or spherochromatic aberration) is a type of spherical aberration in which the focal points of light rays vary with the wavelength of the light. Coma is an aberration that distorts images formed by off-axis light rays that do not strike the lens at its center.

Conventional optical systems therefore require additional lens elements to correct for aberrations, thereby adding cost, weight, size, and complexity to the lens system in order to correct for the aberrations introduced into the lens system. The curvatures of the spherical surfaces of the elements are designed to reduce both the spherical and chromatic aberrations to an acceptable amount. However, without corrective lenses, conventional optical systems would be limited by chromatic aberration to low speeds or low focal ratios.

One alternative to adding lens elements to correct for aberrations is to use diffractive surfaces, such as one of many types of computer-generated Fresnel zone plates manufactured on at least one side of a lens element. A high efficiency binary approximation of a Kinoform-type Fresnel zone plate, called a binary grating surface, has been disclosed for use in infrared systems by Swanson and Veldkamp in "Diffractive optical elements for use in infrared systems," Optical Engineering, Vol.28 (6), pp. 605–608 (June 1989). The use of the diffractive surface can be used with a spherical or conventional lens. When used with a spherical surface, the spherical surface provides focusing and the diffractive surface corrects for as much of the spherical aberration as possible. However, the use of a diffractive surface to correct for spherical aberration results in a significant amount of spherochromatism. In addition, because low speeds or focal ratios are required to limit this chromatic aberration, the usable optical speed is significantly limited.

In an attempt to solve these shortcomings, in U.S. Pat. No. 5,044,706, Chen proposed an optical element having aspherical and binary grating optical surfaces. In embodiment of Chen, the optical element is a positive meniscus optical element made of germanium having a useful spectral bandpass in the infrared wavelength region. A telescope system incorporating two of the optical elements has an aspherical surface and a diffractive surface. In another of Chen's embodiments, an objective element having a convex aspherical surface and a concave binary grating surface is used in the telescope. The necessity of using two of the optical elements each having an aspherical surface and a diffractive surface results in an optical system that uses fewer lens elements than previous optical systems. However, as can be appreciated by one of ordinary skill in the art, the resulting optical systems are very expensive. The fabrication of a lens element having an aspherical surface and a diffractive surface is very difficult and expensive. In addition, the alignment of a system using one or more of the combined lens elements is critical to the performance of the optical system.

Accordingly, there is a need for a low cost objective lens system that has improved aberration correction and that provides axial color and spherochromatism correction so that chromatic aberration is not propagated through the optical system.

SUMMARY OF THE INVENTION

An objective lens system in accordance with the present invention solves the above and other problems associated with conventional objective lens systems by maintaining the same level of performance with less expensive lens elements. The objective lens system in accordance with the present invention provides complete axial color correction with no substantial residual color dependent aberrations such as spherochromatism or chromatic coma.

The above and other objects and advantages of the present invention are attained in one embodiment of the present invention through an objective lens system that includes a first lens element having an aspherical surface and a second lens element having a diffractive optical surface and an

aperture stop disposed between the first and second lens elements. The axial separation of the aspherical surface and the diffractive optical surface is determined by the condition $0.5<L_A/efl<1.25$ where L_A is the axial distance from the lens element with the aspherical surface to the lens element with the diffractive surface and efl is the effective focal length of the objective lens system. The second lens element is a refractive lens element having the most optical power in the objective lens system. The diffractive optical surface is optically dispersive and provides axial color correction and prevents chromatic errors from being propagated to the remainder of the optical system. The diffractive optical surface primarily provides axial color correction and the objective lens system does not exhibit residual color dependent aberrations such as spherochromatism and chromatic coma. The aspherical lens surface is located on the object side of the aperture stop and provides coma correction and spherical aberration correction. The aspherical lens surface further corrects residual monochromatic aberrations such as astigmatism and distortion.

These and other advantages of the present invention will become more apparent upon a reading of the detailed description of the preferred embodiment that follows, when considered in conjunction with the drawings of which the following is a brief description. It should be clear that the drawings are merely illustrative of the currently preferred embodiment of the present invention, and that the invention is in no way limited to the illustrated embodiment. As will be realized, the invention is capable of other embodiments and its several details are capable of modifications in various obvious aspects, all without departing from the scope of the invention. The present invention is best defined by the claims appended to this specification.

BRIEF DESCRIPTION OF THE DRAWINGS

The novel features believed characteristic of the invention are set forth in the appended claims. The invention itself, however, as well as a preferred mode of use, and further objects and advantages thereof, will best be understood by reference to the following detailed description of an illustrative embodiments when read in conjunction with the accompanying drawings, wherein:

FIG. **1** is a schematic diagram of an objective lens system according to the present invention;

FIG. **2**A is an enlarged cross-sectional view of a portion of a Fresnel phase plate having a kinoform diffractive surface and showing the microscopic details thereof;

FIG. **2**B is an enlarged cross-sectional view of a portion of a binary optical element having two surfaces which approximate the kinoform diffractive surface shown in FIG. **2**A and showing the microscopic details thereof;

FIG. **2**C is an enlarged cross-sectional view of a portion of a binary optical element having 4 surfaces which approximate the Kinoform diffractive surface shown in FIG. **2**A and showing the microscopic details thereof;

FIG. **2**D is an enlarged cross-sectional view of a portion of a binary optical element having 8 surfaces which approximate the kinoform diffractive surface shown in FIG. **2**D and showing the microscopic details thereof;

FIG. **3** is a front view of a diffractive Fresnel phase plate showing the concentric relationship of the diffractive rings;

FIG. **4** is a graphical representation showing the relationship of the values used to define and manufacture a diffractive optical element.

FIGS. **5**A–**5**E illustrate in graphical form ray aberrations in millimeters of the objective lens system shown in FIG. **1**; and

FIGS. **6**A–**6**C illustrate in graphical form longitudinal spherical aberration, astigmatic field curves and distortion of the objective lens system shown in FIG. **1**.

DETAILED DESCRIPTION

The following detailed description is of the presently preferred embodiment of the present invention. It is to be understood that while the detailed description is given utilizing the drawings briefly described above, the invention is not limited to the illustrated embodiment. In the detailed description, like reference numbers refer to like elements.

Referring now to the Figures, the preferred embodiment of the present invention will now be described. According to standard practice in the optical art, drawings of optical lens systems, such as those shown in the Figures, have the object space, defined as all the space from the first element of surface of a system towards the object and beyond, on the left in the drawing. Similarly, the image space, defined as all the space from the last element or surface of a system towards the image and beyond, is on the right in the drawings. All surfaces in the drawings of the optical lens systems are sequentially numbered from the object side to the image side. The plane of the aperture stop is considered a surface and is included in the numbering.

FIG. **1** is a schematic diagram of an objective lens system **100** according to the present invention. The objective lens system **100** includes a first lens element **102**, an aperture stop **104**, a second lens element **106**, and a third lens element **108**. The objective lens system **100** forms an image on an image plane **110** of an object (not shown) located at infinity. The objective lens system **100** has an optical axis **101**. The lines **103** are known as ray traces and symbolically represent light or other radiation passing through the optical system and function as a fundamental lens design tool, called analytical ray tracing. One skilled in the art would understand that the rays are sequentially traced through a series of surfaces (refractive and diffractive) and thereby yield a measurement of the performance of the optical lens system.

Surface **2** on the first lens element **102** is an aspherical surface. The aspherical surface is defined by the following equation:

$$z=(curv)Y^2/[1+(1-(1+K)(curv)^2Y^2)^{1/2}]+AY^4+BY^6+CY^8+DY^{10},$$

where "curv" is base radius of curvature, "K" is a conic constant, and the values "A–D" are aspherical constants.

The first lens element **102** and the second lens element **106** are located on the optical axis **101** so that the objective lens system **100** satisfies the condition:

$$0.5<L_A/efl<1.25,$$

wherein L_A is the axial distance from the surface **2** of lens element **102** to the surface **4** of lens element **106** and efl is the effective focal length of the objective lens system **100**. As is known in the optical art, the effective focal length of a combination lens system is the focal length of the combination system if the combination of lenses was replaced by a single thin lens. If L_A/efl is less than 0.5, the off axis aberrations are difficult to correct and the aspheric surface becomes less effective in correcting coma and astigmatism. If L_A/efl is greater than 1.25, spherochromatism becomes more pronounced, the diffractive surface is located too far away from the spherical aberration correction produced by the aspheric surface, and is unable to provide the independent chromatic aberration correction achieved when the condition is satisfied.

The aspherical lens surface **2** is located on the object side of aperture **104** so that the specific aberration correction provided by the aspherical lens surface is the most advantageous aberration correction that can be provided by the aspherical lens. The aspherical lens surface corrects residual monochromatic aberrations such as spherical, coma, astigmatism and distortion. In order to more effectively correct field dependent aberrations such as coma and distortion, the aspherical lens surface must be properly located remotely from the aperture stop. As is known in the optical art, if it is desired to only correct spherical aberration, an aspherical lens surface is most effective when placed at the aperture stop location, as in the Schmidt telescope configuration. In the present invention, the aspherical lens surface is located forward of the aperture stop **106** so that the aspherical lens surface contributes some coma correction as well as basic spherical aberration correction.

Surface **5** is a diffractive optical element surface. The diffractive optical surface is defined by the following equation that describes the phase departure of the diffractive surface: $\phi(R)=C_1R^2+C_2R^4+C_3R^6+C_4R^8+C_5R^{10}$, where the values C_1–C_5 are constants and R is defined by $R^2=X^2+Y^2$. FIG. **4** shows the graphical relationship between R, X and Y. The above equation is a radially symmetric polynomial. The value R is the radial distance from the axis represented by the z coordinate shown in FIG. **4**. The axis represented by the z coordinate coincides with the optical axis in the optical lens system in which the lens element is installed. Preferably, the diffractive optical surface is formed on a planar surface. Forming the diffractive optical surface on a planar surface is preferable because it is easier, and thus less expensive, to manufacture. The formation of a diffractive optical surface on a planar surface also allows more options for manufacturing the diffractive optical surface such as photolithography, replication, and diamond turning.

The diffractive surface **5** on the second lens element **106** is placed on the refractive element with the most optical power. As is known in the optical are, the refractive element with the most optical power is the largest contributor to axial chromatic aberration. With the diffractive surface placed on this element, axial color correction can be most beneficially performed at this location so that chromatic errors are not propagated through the remainder of the optical system. As can be appreciated, if the axial chromatic aberration is not corrected at a specific location, it will be propagated through the optical system and must be corrected by the addition of more optical lens elements before reaching the focal plane. The addition of the lens elements necessary to correct the chromatic aberrations increases the cost and complexity of the resulting optical lens system. The diffractive optical element as used in the present invention provides dispersion in the form of optical power to provide axial color correction to the overall objective lens system. Because the diffractive optical element is utilized to only introduce optical power and not to correct for spherical wavefront type aberrations, the objective lens system does not exhibit residual color dependent aberrations such as spherochromatism or chromatic coma.

In addition, the separation of the aspherical lens surface and the diffractive optical element allows the production tolerances on the individual lens elements and surfaces to be looser than if the aspherical and diffractive surfaces are on the same lens element. The more relaxed tolerances on the individual surface production, alignment and accuracy result in lower production costs. The lower production costs are achieved without a decrease in the optical performance of the objective lens system.

The diffractive optical element may be a binary optical element that is generally produced through photolithographic processes or it may be a true Fresnel phase plate produced by precision diamond machining. Generally, to produce optical power, the binary diffractive optical element is in the form of a Fresnel phase plate with stair step approximations of the true desired periodic phase altering projections. Further details about binary optical surfaces may be found in the publications: G. Swanson and W. Veldkamp, "Diffractive optical elements for use in infrared systems," Optical Engineering, Vol. 28 (6), pp. 605–608 (June 1989); and C. W. Chen and J. S. Anderson, "The Use of Diffractive Optical Element in 3–5 Micrometer Optical System," Proc. IRIS Passive Sensors 1992, Vol. 1.

A prescription table of an objective lens system in accordance with the present invention shown in FIG. **1** is shown below in Table I. In this Table it will be noted that the lens surfaces correspond to the lens surfaces shown in FIG. **1**. The radius refers to the radius of curvature of the particular surface specified in accordance with conventional practice, that is, a positive radius indicates the center of curvature is to the right and a negative radius indicates the center of curvature is to the left. All dimensions are given in millimeters. The aspherical constants are defined above as are the constants needed to manufacture the diffractive lens element. The thickness refers to the distance along the optical axis **101** from the surface for which the thickness is specified to the next highest numbered surface. Thus, the thickness from surface **1** to surface **2** of lens element **102** is 4.0000 mm and the thickness through air between surface **2** of lens element **102** and the plane of the aperture stop **104** is 32.4129 mm.

Referring to FIGS. **2A–2D** there is shown details of the structure of diffractive optical elements. FIG. **2A** shows a diffractive zone plate type of phase profile **200** having discrete 2π increments **202–208** located along a common plane **210**. This analog type surface relief profile is commonly known as a kinoform and is capable of achieving 100% diffraction efficiency at its functional wavelength. Digitized approximations to the kinoform profile can be formed as shown in FIGS. **2B–2D**. FIG. **2B** shows a 2-level approximation to the kinoform shown in FIG. **2A**. However, the 2-level approximation only has a diffraction efficiency of 40.5%. FIG. **2C** shows a 4-level approximation that has a diffraction efficiency of 81%. FIG. **2D** shows an 8-levely approximation that has a diffraction efficiency of 95%. Diffraction efficiencies of 99% or better are achievable by surface profiles containing 16 or more digitized levels.

As discussed above, a Fresnel zone plate face profile needed to achieve 100% diffraction efficiency requires

curved wedge shaped structures as shown in FIG. **2**A with a height, or phased depth, of 2π. The 2π phase depths correspond to a material etch depth of about 2 microns for mid-infrared radiation. The phase depth is proportional to the wavelength. For wavelengths in the infrared range, diamond-turned optics technology can be used to produce a continuous curved phase profile. Approximations to the kinoform profile discussed above can be produced with a diffraction efficiency of 90% or greater. Diffraction efficiencies in excess of 90% can be achieved by using, for example, integrated circuit fabrication techniques such as high-resolution lithography, mask aligning and reactive ion etching.

FIG. **3** is a front view of a diffractive Fresnel phase plate showing the concentric relationship of the diffractive rings. Each ring is numbered from **202–208** and corresponds to the numbers shown in FIG. **2**A.

FIG. **4** is a graphical representation showing the relationship of the values used to define and manufacture a diffractive optical element. The relationship is discussed above.

FIGS. **5**A–**5**E illustrate in graphical form ray aberrations in millimeters of the objective lens system shown in FIG. **1** and shows the performance of the lens system in accordance with the present invention.

FIGS. **6**A–**6**C illustrate in graphical form longitudinal spherical aberration, astigmatic field curves and distortion of the objective lens system shown in FIG. **1** and further shows the performance of the lens system in accordance with the present invention.

The foregoing description of the embodiment of the invention has been presented for purposes of illustration and description. It is not intended to be exhaustive or to limit the invention to the precise form disclosed. Obvious modifications or variations are possible in light of the above teachings. All such modifications and variations are within the scope of the invention as determined by the appended claims when interpreted in accordance with the breadth to which they are fairly, legally, and equitably entitled.

What is claimed is:

1. An objective lens system that provides complete axial color correction with no substantial residual color dependent aberrations such as spherochromatism or chromatic coma, the objective lens system comprising, in order from an object side to an image plane:

a first lens element having an aspherical surface;

an aperture stop; and

a second lens element having a diffractive optical surface, wherein the first lens element and the second lens element are located on an optical axis such that the objective lens system satisfies the following condition:

$$0.5<L_A/efl<1.25,$$

where L_A is the axial distance from a surface on the image side of the first lens element to a surface on the object side of the second lens element and efl is the effective focal length of the objective lens system.

2. The objective lens system of claim **1**, wherein the second lens element is a refractive lens element having the most optical power in the objective lens system.

3. The objective lens system of claim **2**, wherein the diffractive optical surface is optically dispersive and provides axial color correction to the objective lens system, whereby chromatic errors are not propagated to the image plane.

4. The objective lens system of claim **3**, wherein the diffractive optical surface is optically dispersive and provides axial color correction, whereby the objective lens system does not exhibit residual color dependent aberrations such as spherochromatism and chromatic coma.

5. The objective lens system of claim **4**, wherein the aspherical surface is located on the object side of the aperture stop and provides coma correction and spherical aberration correction.

6. The objective lens system of claim **5**, wherein the aspherical surface further corrects residual monochromatic aberrations such as astigmatism and distortion.

7. The objective lens system of claim **6**, wherein the diffractive surface is located on the image plane side of the aperture stop.

8. The objective lens system of claim **7**, wherein the objective lens system is designed for a wavelength in the range of 3000 to 5000 nanometers.

9. A method of providing complete axial color correction with no substantial residual color dependent aberrations such as spherochromatism or chromatic coma in an objective lens system, the method comprising:

transmission of radiation through a first lens element having an aspherical surface;

transmission of the radiation through an aperture stop; and

transmission of the radiation through a second lens element having a diffractive surface, wherein the first lens element is located on an optical axis of the objective lens system an axial distance from the second lens element by a distance that is determined by the following condition:

$$0.5<L_A/efl<1.25,$$

where L_A is the axial distance from a surface on the image side of the first lens element to a surface on the object side of the second lens element and efl is the effective focal length of the objective lens system.

10. The method of claim **9**, wherein transmission of the radiation through a second lens element having a diffractive surface further comprises transmission of the radiation through a second lens element that is a refractive lens element having the most optical power in the objective lens system.

11. The method of claim **10**, wherein transmission of the radiation through a second lens element having a diffractive surface further comprises transmission of the radiation through a second lens element that is optically dispersive and provides axial color correction whereby chromatic errors are not propagated to the image plane.

12. The method of claim **11**, wherein transmission of the radiation through a second lens element having a diffractive surface further comprises transmission of the radiation through a second lens element that is optically dispersive and provides axial color correction whereby the objective lens system does not exhibit residual color dependent aberrations such as spherochromatism and chromatic coma.

13. The method of claim **12**, wherein transmission of the radiation through an aspherical surface further comprises transmission of the radiation through an aspherical surface that is located on the object side of the aperture stop and provides coma correction and spherical aberration correction.

14. The method of claim **13**, wherein transmission of the radiation through an aspherical surface further comprises transmission of the radiation through an aspherical surface that provides correction to residual monochromatic aberrations such as astigmatism and distortion.

15. The method of claim **14**, wherein transmission of the radiation through a diffractive surface further comprises

transmission of the radiation through a diffractive surface located on the image side of the aperture stop.

16. The method of claim **15**, wherein transmission of the radiation through a first lens element, an aperture stop, and a second lens element further comprises transmission of the radiation having a wavelength in the range of 3000 nm to 5000 nm.

[57] **ABSTRACT**

An optical recording and/or reproducing apparatus having an objective lens adjusting mechanism suitable for a compact optical pickup device. The apparatus has a carriage for holding an objective lens, and a guide. The carriage is movable along the guide. The apparatus has an objective lens adjusting device for adjusting an inclination of the optical axis of the objective lens in rotational directions about two axes perpendicular to the optical axis of the objective lens and to each other.

OPTICAL RECORDING AND/OR REPRODUCING APPARATUS HAVING OBJECTIVE LENS ADJUSTING MECHANISM

This is a continuation of application Ser. No. 08/584,463, filed Jan. 11, 1996, now abandoned.

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to an optical recording and/or reproducing apparatus for recording information on an optical recording medium such as a magneto-optical disk or a compact disk and/or reproducing information recorded on such a medium, and more particularly to an optical recording and/or reproducing apparatus having an objective lens adjusting mechanism.

2. Description of the Related Art

In an optical recording and/or reproducing apparatus, light emitted from a laser beam source is focused on a signal recording surface of an optical recording medium by an objective lens to record and/or reproduce an information signal. If the optical axis of the objective lens is inclined with respect to the signal recording surface, coma is caused so that the signal cannot be recorded and/or reproduced well. Therefore, there have been used various mechanisms for adjusting the two-directional inclination of the optical axis of the objective lens with respect to the signal recording surface.

FIGS. **11** and **12** show an example of a conventional optical pickup device having an adjusting mechanism disclosed in Japanese Laid-Open Patent Application Publication Hei 5-303749.

As shown in FIG. **11**, this optical pickup device has a supporting substrate **203** movable in a radial direction of an optical disk D rotated by a motor **201**. The supporting substrate **203** has a bobbin supporting member **216**, to which a lens bobbin **206** having an objective lens R is secured via a flexible member **206***b* such as a wire.

As shown in FIG. **12**, the supporting substrate **203** is movably supported on one side A thereof by a slide guide shaft **204** arranged on a subchassis **202** and on the other side B thereof by an inner edge **205** of the subchassis **202**. Each of the one side A and the other side B of the supporting substrate **203** is provided with a height adjusting mechanism. These two sets of height adjusting mechanisms cause the one side A to move in the direction of arrow a or arrow b about the slide guide shaft **204** and the other side B to move in the direction of arrow c or arrow d about the inner edge **205**, thereby adjusting the inclination of the objective lens R in a direction parallel to the paper without changing the height of the objective lens R.

SUMMARY OF THE INVENTION

The objective lens adjusting mechanism shown in FIGS. **11** and **12** can adjust the inclination in only one direction and cannot adjust the inclination in a direction perpendicular thereto. In order to do so, it is necessary to add another adjusting mechanism. Further, the two sets of adjusting mechanisms are used in order not to change the height of the objective lens at the time of adjusting the inclination. This results in a large optical pickup device. That is, the adjusting mechanism in FIGS. **11** and **12** is not suitable for a compact optical pickup device. Moreover, although the inclination in only one direction can be adjusted, the two sets of adjusting mechanisms are used. Thus, there is also the drawback that its production costs are high.

A primary object of this invention is to provide an optical recording and/or reproducing apparatus having an objective lens adjusting mechanism suitable for a compact optical pickup device.

An optical recording and/or reproducing apparatus according to this invention comprises a carriage for supporting an objective lens, and a guide, in which the carriage is movable along the guide. In order to attain the above object, the optical recording and/or reproducing apparatus further comprises an objective lens adjusting device for adjusting the inclination of the optical axis of the objective lens in the rotational directions about two axes perpendicular to the optical axis of the objective lens and to each other.

In order to attain the above object, another feature of this invention is that a fulcrum for adjusting the inclination of a carriage in a direction perpendicular to the optical axis of an objective lens is formed by bearings below the objective lens. Thus, there is the special advantage that the Z-directional position of the objective lens is scarcely changed at the time of inclination adjustment.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a perspective view of an information recording and/or reproducing apparatus having an objective lens adjusting mechanism according to a first embodiment of this invention.

FIG. **2** is a cross-sectional view of the information recording and/or reproducing apparatus in FIG. **1**.

FIG. **3** is a perspective view of a movable portion of the information recording and/or reproducing apparatus in FIG. **1**.

FIG. **4** is an exploded perspective view of the movable portion shown in FIG. **3**.

FIG. **5** is a side view of the movable portion shown in FIG. **3**.

FIG. **6** is a perspective view of a movable portion of an information recording and/or reproducing apparatus having an objective lens adjusting mechanism according to a second embodiment of this invention.

FIG. **7** is a side view of the movable portion shown in FIG. **6**.

FIG. **8** is a perspective view of a movable portion of an information recording and/or reproducing apparatus having an objective lens adjusting mechanism according to a third embodiment of this invention.

FIG. **9** is a side view of the movable portion shown in FIG. **8**.

FIG. **10** is a perspective view of a movable portion of an information recording and/or reproducing apparatus having an objective lens adjusting mechanism according to a fourth embodiment of this invention.

FIG. **11** is a perspective view of an optical pickup device having a conventional objective lens adjusting mechanism.

FIG. **12** is a side view of the optical pickup device shown in FIG. **11**.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

Referring to the drawings, the embodiments of this invention will be described in detail.

[First Embodiment]

Referring to FIGS. **1** to **5**, a first embodiment of this invention is described. This embodiment has an objective lens adjusting device for adjusting the inclination of the optical axis of the objective lens in the rotational directions about two axes perpendicular to the optical axis of the objective lens and to each other.

FIGS. **1** to **5** show a first embodiment of this invention applied to a coarse access driving device of an objective lens of an information recording and/or reproducing apparatus using a magneto-optical disk as a recording medium.

As shown in FIG. **1** (a perspective view of the whole apparatus), a spindle motor **3** for rotating a disk **2** is fixed to a deck base **1**, and the disk **2** is positioned in a cartridge **4** having an opening **4***a* at its center (FIG. **2**). A movable portion **6** having an objective lens **5** is movably supported so as to be driven with respect to the deck base **1** in the X direction, as described below. Further, a fixed optical system **30** having a laser, a light detector and the like is fixed on the deck base **1**.

Furthermore, as shown in FIG. **3** (a perspective view of the movable portion) and FIG. **4** (an exploded perspective view of the movable portion), the movable portion **6** is provided at its center with an access coil **7** wound in the form of a square pole, and the access coil **7** mainly contributes to the rigidity of the entire movable portion **6**. A carriage **8** provided on the access coil **7** is formed of an epoxy resin including spherical silica and has a fixing portion **8***a* bonded to the Y(−) side surface of the access coil **7**, and the fixing portion **8***a* reinforces the Y(−) side surface of the access coil **7**.

A bearing portion **9** on a reference side is bonded and fixed to the Y(+) side surface of the access coil, as described below, and is provided with bearings **9***a* and **9***b*, into which a guide rail **11** (FIG. **1**) is inserted with both ends thereof fixed on the deck base **1**. The fixing portion **8***a* is provided on its Y(−) side with a fixing portion **8***b* for a mirror, to which a mirror **12** is bonded and fixed. The light reflected by the mirror enters the lens **5**.

A bearing portion **13** on a driven side is positioned under the mirror **12** of the fixing portion **8***a*, and a guide rail **14** (FIG. **1**) is inserted into a U-shaped bearing **13***a* of the bearing portion **13**. The guide rails **11** and **14** are made of silicon carbide ceramic, or stainless steel with fluoride coating. The fixing portion **8***a* and a connecting portion **8***c* are integrated into the carriage **8**, and the access coil **7** mainly contributes to the rigidity between the bearing portions **9** and **13**. The carriage **8** may be formed by inserting the access coil **7**.

A fixing portion **8***f* is formed on the Z(+) side of the fixing portion **8***a*. The X(−) side surface of a holding member **10** abuts on the X(+) side of the fixing portion **8***f* to be positioned properly and is bonded and fixed.

A spring **15** hanged between the holding member **10** and a holder **16** is formed by cutting a thin sheet of stainless steel in a substantial U-shape by a press. A pair of springs **15**, the holding member **10**, and the holder **16** are integrated by insert formation using plastic.

The lens **5** is secured at the center of the holder **16**, and a focus coil **17** wound in a rectangular shape is secured on each of both sides of the holder **16** in the Y direction.

The holding member **10**, the springs **15**, the holder **16**, the focus coils **17**, and the objective lens **5** form an objective lens supporting device.

As shown in FIG. **2** (a cross-sectional view showing magnetic circuits), in the space inside the access coil **7**, there is arranged a center yoke **19** with a short ring **18** fixed around it. A magnet **20** is arranged so as to form a magnetic gap with the center yoke **19** and is fixed inside (on the Z(−) side) of a side yoke in a substantial U-shape. Both ends of the side yoke **21** abut on respective ends of the center yoke **19** to form a magnetic circuit for access.

On the Y(−) side surface of the side yoke **21**, a magnet **22** is fixed so as to face a lower side **17***a* of the focus coil **17** on the Y(+) side. A magnet **23** is fixed to a yoke **24** so as to face a lower side **17***a* of the focus coil **17** on the Y(−) side. The yoke **24** is fixed on the deck base **1**.

Next, an operation of the first embodiment so constructed will be described. As shown in FIG. **2**, a magnetic field acts on the upper and lower sides of the focus coil **17** in opposite Y directions. When an electric current flows through the focus coil **17**, a force in the Z direction is produced in these two sides to drive the lens **5** in the Z direction. At this time, the springs **15** bend to drive the lens **5** in the Z direction.

Further, a force in the X direction is produced in the access coil **7** by the magnet **20** to drive the movable portion **6** in the X direction. At this time, the bearings **9***a*, **9***b* and **13***a* and the guide rails **11** and **14** cooperate to slide the movable portion **6** slides in the X direction.

Since the directions of magnetization of the magnets **20**, **22** and **23** are set as shown in FIG. **2**, the leakage flux from the magnets **22** and **23** near the light spot formed by the lens **5** on the optical disk **2** is in the Y(+) direction whereas the leakage flux from the magnet **20** is in the Y(−) direction, thereby cancelling each other. Thus, the leakage flux near the light spot formed by the lens **5** on the optical disk **2** is reduced a little in the Y direction. Therefore, it does not affect so much a magnetic field generating means (not shown) for generating a magnetic field near the light spot on the optical disk **2** at the time of erasing and/or recording information.

Since the side yoke **21** is positioned in the opening **4***a* of the disk cartridge **4**, the side yoke **21** can be brought near the optical disk **2** to reduce the height of the electromagnetic driving device.

As shown in FIG. **4**, since the carriage **8** is composed of the bearing portion **13**, the fixing portion **8***b* for fixing the mirror **12**, the fixing portion **8***a*, the connecting portions **8***c*, and projecting portions **8***g* and **8***h*, its structure is simple. Further, since the access coil **7** mainly contributes to the rigidity between the projecting portions **8***g* and **8***h* and the bearing portion **13**, it is sufficient for the connecting portion **8***c* to have such a dimension that a resin can flow at the time of its formation and thus the mass of this portion may be small.

When the movable portion **6** is driven in the X direction, the warping deformation in the X and Z directions, the twisting deformation about the Y axis or the like of the entire movable portion **6** is a cause of resonance. However, since the rigidity of the entire movable portion **6** is derived from the access coil **7** whose rigidity is high, there is no problem. Further, since the access coil **7** is made of an alloy of copper and aluminum, its elastic modulus is higher than plastic so that the frequency of resonance can be high.

A coil-moved electromagnetic driving device requires a coil in its movable portion. In this invention, since the coil is formed as a main structural member and contributes to the rigidity of the entire device, the carriage as another main structural member may be minimal.

Now, the main features of this invention will be explained.

As can be seen from FIGS. **2** and **3**, the bearing **13***a* of the bearing **13** on the driven side has cylindrical surfaces to

contact the guide rail **14**. Thus, the guide rail **14** point-contacts the bearing **13***a*. The guide rail **14** is at the same position as the objective lens **5** in the Y direction. The position of the bearing **13***a* in the X direction is near that of the objective lens **5**.

The connecting portions **8***c* are provided on its Y(+) side with the projections **8***g* and **8***h* protruding outward in the X direction. The projections **8***g* and **8***h* are provided in their Z(−) side surfaces with conical recesses **8***i* and **8***j* having an apex angle of about 90° to 120°.

The angle θ formed by the recess **8***i*, the bearing **13***a* and the recess **8***j* is about 90°. The angle θ may be about 60**20** to 120°. However, the more the angle θ is away from 90°, the larger the below-mentioned crosstalk at the time of inclination adjustment becomes. Thus, in order to make adjusting operation easily, it is preferable that the angle θ is near 90°.

The bearing portion **9** on the reference side is formed independently of the carriage **8** and provided with two bearings **9***a* and **9***b* spaced apart in the X direction and whose cross-section is a square tilted by 45°.

Next, the assembly and inclination adjustment of the movable portion will be described.

The bearing portion **9** and an assembly **6'** of the movable portion **6** excluding the bearing portion **9** are mounted on the deck base **1** together with the guide rails **11** and **14**.

As shown in FIG. **5**, the assembly **6'** is supported on the Y(−) side by the guide rail **14** contacting the bearing **13***a* at a point on the Z(+) side and is supported on the Y(+) side by two adjusting pins **33***a* and **33***b* having spherical tips fitted into the recesses **8***i* and **8***j*, respectively, from the Z(−) side. At this time, in order that the assembly **6'** is stable with respect to the guide rail **14** and the adjusting pins **33***a* and **33***b*, the center of the assembly **6'** is pressed from the Z(+) side by a spring or the like, as indicated by arrow **32**.

The deck base **1** is fixed to a jig (or adjusting means) base (not shown), and the adjusting pins **33***a* and **33***b* are stable in the X and Y directions and movable only in the Z direction on the jig base.

The position with respect to and rotation about the X, Y and Z axes of the assembly **6'** are determined by the two adjusting pins **33***a* and **33***b* and the guide rail **14**.

The bearing portion **9** is positioned with a small gap **35** from the access coil **7** in the Y direction and pressed to the guide rail **11** by a spring or the like from the direction indicated by arrows **34**, and its position with respect to and rotation about the X, Y and Z axes are determined.

Light is emitted from the laser of the fixed optical system **30** to enter the objective lens **5** via the mirror **12**, and the light from the objective lens **5** is made incident on a detecting optical system **31**, such as a television camera. Then, in order to correct the comatic aberration of the light from the objective lens which is detected by the detecting optical system **31**, the adjusting pin **33***a* or **33***b* is moved up and down to adjust the relative vertical position of the assembly **6'** with respect to the bearing portion **9** thereby adjusting the inclination of the objective lens **5** in two directions perpendicular to the optical axis of the objective lens **5** parallel to the Z direction and perpendicular to each other, that is, the inclination of the objective lens **5** with respect to the disk **2**. Specifically, the α and β axes in FIG. **3** are in the XY plane and displaced by 45° from the X and Y axes which are perpendicular to each other. When the adjusting pin **33***a* is moved up and down, the assembly **6'** rotates about the α axis, and when the adjusting pin **33***b* is moved up and down, the assembly **6'** rotates about the β axis.

After the comatic aberration is corrected, an adhesive **35** is injected into the gap **36** between the access coil **7** and the bearing portion **9** to fix the bearing portion **9** to the assembly **6'**.

As described above, since there is provided the objective lens adjusting mechanism in which the fixed side of the objective lens supporting member can be fixed to the bearing on the reference side (defining at least two points in the guide direction) after its inclination is adjusted in two directions perpendicular to the optical axis of the objective lens and substantially perpendicular to each other, the following advantages can be obtained:

1. The objective lens supporting device and the movable part of the optical pickup need not be provided with any spherical surface, vis, spring and the like for inclination adjustment. Therefore, the objective lens supporting device and the movable portion can be compact, thin and light, and their production costs can be low.
2. Since the center of inclination (bearing **13***a*) of the objective lens is positioned almost under the objective lens, the objective lens is scarcely moved in the Z direction even though the inclination is adjusted by one set of adjusting mechanism. Although the objective lens is moved in the X and Y directions at the time of inclination adjustment, the amount of movement in the X and Y directions can be small, that is, 0.1 mm or less with respect to an inclination adjustment of 0.5° , since the bearing **13***a* can be arranged under the objective lens at a distance of, for example, about 5 to 10 mm. Further, since the bearing **13***a* is positioned almost under the objective lens, the distance between the bearing **13***a* and the bearings **9***a* and **9***b* can be small, and the movable portion of the optical pickup can be compact especially in the Y direction and also can be light.
3. The inclination of the objective lens can be adjusted by one adjusting mechanism in two directions perpendicular to its optical axis and to each other. Thus, no other adjusting mechanisms are necessary, the movable portion of the optical pickup can be compact and light, and its production costs can be low.
4. Since the bearing **13***a* on the driven side as the center of inclination adjustment (fulcrum) is formed as cylindrical surfaces and point-contacts the guide rail **14**, even if the inclination of the assembly is adjusted in two directions, the contacting state of the bearing **13***a* and the guide rail **14** does not change although their contacting point is shifted a little. Thus, their sliding performance does not change.

If the bearing **13***a* were formed as, for example, planes parallel to the XY plane, the state of contact, such as the place and length, would change.

Since the position with respect to and rotation about the X, Y and Z axes of the assembly **6'** are determined by the two recess **8***i* and **8***j*, the assembly **6'** can be precisely positioned with respect to the guide rail even if it does not have the bearing portion **9** on the reference side.

This invention is not limited to the above embodiment, and various modifications may be made without departing from the spirit and scope thereof. For example, the following modifications are naturally covered by this invention:

Although the embodiment employs a sliding bearing, other bearings such as a radial bearing may be used.

In the embodiment, the movable portion is electromagnetically driven. However, a rack and pinion, a lead screw or the like may be employed. The guide rail may be formed integrally with the yoke or the deck base.

Although in the embodiment the laser and the like are separated from the movable portion, all the optical system such as a laser may be arranged in the movable portion **6**.

In the embodiment, the mirror **12** is arranged in the assembly **6'** whose inclination is adjusted with respect to the guide rails **11** and **14**. However, the bearing **9** remaining fixed at the time of inclination adjustment may be provided with a mounting portion, to which the mirror may be fixed.

In the embodiment, the inclination of the assembly **6'** is adjusted about two axes perpendicular to the optical axis of the objective lens and to each other. However, it may be adjusted about the X and Y axes by interlocking the two adjusting pins **33***a* and **33***b* with each other, the bearing **13***a* being the center of rotation.

Although the embodiment uses a supporting spring for supporting the objective lens in the focus direction (Z direction) only, the supporting spring and the like may be formed as movable in the focus and tracking directions.

In the embodiment, the adjusting pins **33***a* and **33***b* contact the recesses **8***i* and **8***j* of the projecting portions **8***g* and **8***h*, respectively. However, the pins may abut on the Z(−) side of the access coil **7** at two points which are on the Y(+) side and near the opposite ends in the X direction (in FIG. **3**, the points on the access coil **7** near the adjusting pins **33***a* and **33***b*) to adjust the inclination. In this case, the connecting portions **8***c* and the projecting portions **8***g* and **8***h* of the carriage **8** are not necessary and thus the carriage **8** can be further minimized.

Moreover, in the embodiment, the magnetic circuit for driving the objective lens in the focus direction is arranged on the deck base which is a fixed portion with respect to the movable portion. However, it may be arranged on the movable portion.

In this embodiment, the height can be adjusted at two points spaced apart in the direction of movement of the bearing, and the bearing on the driven side serves as the fulcrum of inclination adjustment. Thus, this embodiment can provide an adjusting mechanism in which no special fulcrum of inclination adjustment is necessary and is effective in making an optical pickup compact and light.

[Second Embodiment]

Referring to FIGS. **6** and **7**, a second embodiment of this invention will now be described. In the drawings, the same members as those already explained in the first embodiment are indicated by the same reference numerals and letters. Mainly, the features particular to this embodiment will be described below.

A carriage **8** is provided on its Y(+) side with fitting portions **8***l* and **8***k* having a cross-sectional shape of L.

A bearing portion **9** is provided with a fitting portion **9***c* protruding in the Y(−) direction and a fitting portion **9***d* protruding in the Z(−) direction.

The bearing portion **9** and the carriage **8** are pinched by a spring **40** so as to move relative to each other with the fitting portions **8***l* and **9***d* contacting to each other.

Two screws **42** are screwed through holes **8***p* into threaded holes **9***e* with compression springs **41** interposed between the fitting portions **8***k* and **9***c*. The space between the fitting portions **8***k* and **9***c* can be adjusted by rotating the two screws **42**.

The X-directional position of the bearing portion **9** with respect to the carriage **8** is defined by two bosses **8***m* contacting the insides of the fitting portions **9***c*.

The angle formed by the hole **8***p*, a bearing **13***a* and the hole **8***p* is set to be about 90°, thereby facilitating the adjustment of inclination of the optical axis of the objective lens. The angle θ may be about 60° to 120°. However, the more the angle θ is away from 90°, the larger becomes the crosstalk at the time of inclination adjustment, that is, the amount of inclination in the other adjusting direction at the time of the adjustment in one direction. Thus, in order to make adjusting operation easily, it is preferable that the angle θ is near 90°.

By rotating the two screws **52** of a movable portion **6** mounted on a deck base together with guide rails **11** and **14**, the relative vertical position of an assembly **6'** with respect to the bearing portion **9** can be adjusted to adjust the inclination of an objective lens **5** in two direction perpendicular to the optical axis of the objective lens and to each other.

In order that bearings **9***a*, **9***b* and **13***a* and the guide rails **11** and **14** remain stable at the time of assembly, the bearing portion **9** and the assembly **6'** may be press lightly in the Z(−) direction.

As described above, the fixed portion of the objective lens supporting member is coupled to the bearing on the reference side at two points whose height can be adjusted, and the two points and the bearing on the driven side form an approximately right angle.

This embodiment has the following advantages:

1. Compared with the first embodiment, while the movable portion includes the screws etc. and is heavier, the structure of the inclination adjusting jig is simpler.
2. Since the inclination adjusting mechanism is arranged in a place around the bearing and having enough space, it can be arranged in the movable portion of an optical pickup even if the objective lens supporting device is small.

b **3**.Except for advantage 1 of the first embodiment, this embodiment has the same advantages as those of the first embodiment. Also, the same modifications can be made as the first embodiment.

[Third Embodiment]

Next, referring to FIGS. **8** and **9**, a third embodiment of this invention will be described.

A carriage **8** is provided on its Y(+) side with a semi-spherical convex portion **8***n*. The convex portion **8***n* is at the same position in the X direction as a bearing **13***a*.

A bearing portion **9** is provided on its Y(−) side with a semi-spherical concave portion **9***f* in surface-engagement with the convex portion **8***n*.

The convex portion **8***n* is contacted to the concave portion **9***f*, and a screw **52** is screwed into a threaded hole of the convex portion **8***n*. A compression spring **51** is interposed between the screw **52** and the bearing portion **9**.

Thus, the carriage **8** and the bearing portion **9** are temporarily held by the spring **51** and the screw **52** with the convex portion **8***n* and the concave portion **9***f* being slidable.

In this state, a movable portion **6** is mounted on a deck base together with guide rails **11** and **14**. At this time, the X(−) side of a connecting portion **8***c'* on the X(−) side of an assembly **6'** abuts on a jig (or adjusting means) to prevent the assembly **6'** from being rotated about the Z axis.

The inclination of an objective lens **5** about the X axis is adjusted by sliding the convex portion **8***n* and the concave portion **9***f* in the Z direction to incline the assembly **6'** about the X axis, with a bearing **13***a* being the center of inclination.

The inclination of the objective lens **5** about the Y axis is adjusted by sliding the convex portion **8***n* and the concave portion **9***f* about the screw **52** to rotate the assembly **6'** about the Y axis, with the bearing **13***a* being the center of rotation.

As described above, the bearing portion **9** and the assembly **6'** with the objective lens supporting member fixed are assembled by contacting the semi-spherical portions **8***n* and

9*f* to each other, whereby the inclination of the assembly with respect to the bearing portion on the reference side can be adjusted about two axes perpendicular to the optical axis of the objective lens and to each other.

It is preferable that the X directional position of the centers of the convex portion **8***n* and the concave portion **9***f* is coincident with the bearing **13***a* and the optical axis of the objective lens **5**. In this case, there is the advantage that the Z-directional position of the objective lens **5** is scarcely changed at the time of the inclination adjustment around the Y axis.

Further, it is preferable that the Z directional position of the centers of the convex portion **8***n* and the concave portion **9***f* is coincident with a nodal point of the objective lens **5**. In this case, there is the advantage that the objective lens **5** is not moved in the Z and X axes at the time of the inclination adjustment around the Y axis.

In the first, second and third embodiments, since the bearing on the driven side serving as the fulcrum for inclination adjustment is substantially aligned with the optical axis of the objective lens, the objective lens is moved scarcely in the direction of its optical axis at the time of inclination adjustment.

According to the embodiments of this invention, the inclination of the optical axis of the objective lens can be adjusted in the rotational directions about two axes perpendicular to the optical axis of the objective lens and to each other. Thus, this invention contributes to the reduction of the size and costs of the objective lens supporting device and the movable portion of the optical pickup device.

[Fourth Embodiment]

FIG. **10** shows a fourth embodiment of this invention. In the fourth embodiment, a fulcrum for adjusting the inclination of a carriage in a direction perpendicular to the optical axis of an objective lens is formed by bearings below the objective lens. Thus, there is the special advantage that the Z-directional position of the objective lens is scarcely changed at the time of inclination adjustment. In the drawing, the same members as those of the first embodiment are assigned the same reference numerals, and the description of the common structural parts is omitted.

A carriage **8** is provided with bearings **13***a* and **13***b* on a reference side below an objective lens **5**. A bearing portion **9** is provided with a bearing **9***a* on a driven side.

An assembly **6***a* is rotated about the X axis with a guide rail **14**, that is, the bearings **13***a* and **13***b* being the center of rotation, to adjust the inclination of the objective lens **5** about the X axis. At this time, since the center of rotation is below the objective lens **5**, the objective lens **5** is not moved in the Z direction. The X(+) side surface of a fixing portion **8***f* and the X(−) side surface of a holding member **10** are formed as cylindrical surfaces whose centers are on an axis passing through a nodal point of the objective lens **5** and parallel to the Y axis. The inclination of the objective lens **5** is adjusted about the Y axis by sliding the holding member **10** with respect to the fixing portion **8***f* in the Z direction.

What is claimed is:

1. An optical recording and/or reproducing apparatus for recording information on an optical recording medium and/or reproducing information recorded on said medium, the apparatus comprising:

an objective lens having an optical axis;

a carriage for supporting the objective lens;

a base;

first and second guide members fixed to the base for supporting the carriage movably in a first direction;

the carriage having first and second bearings to be guided by the first and second guide members, the carriage comprising a first portion having at least the objective lens and the first bearing, and a second portion having at least the second bearing; and

an objective lens adjusting device on said carriage for adjusting an inclination of the optical axis of the objective lens by rotating the first portion of said carriage, including the objective lens and the first bearing, with respect to the second portion of said carriage in rotational directions about two axes perpendicular to the optical axis of the objective lens and to each other, the first portion of the carriage, including the objective lens and the first bearing, being displaceable with respect to the second portion of the carriage.

2. The apparatus of claim **1**, in which the first bearing serves as a fulcrum for the rotation of the first portion, and the first portion is substantially aligned with the optical axis of the objective lens.

3. The apparatus of claim **1** in which the position of said objective lens in a direction along the optical axis is scarcely changed at the time of the inclination adjustment around one of the two axes.

4. The apparatus of claim **1** in which the objective lens is not moved in a direction parallel to the optical axis and about a first of said two axes at the time of the inclination adjustment around a second of the two axes.

5. An optical recording and/or reproducing apparatus for recording information on an optical recording medium and/or reproducing information recorded on said medium, the apparatus comprising:

a guide including first and second guide rails; and

a carriage movable along the guide;

the carriage comprising:

an objective lens having an optical axis; and

an objective lens adjusting device for adjusting an inclination of the optical axis in rotational directions about two axes perpendicular to the optical axes of the objective lens and to each other and said carriage including a fulcrum below the objective lens for inclining the objective lens and wherein said fulcrum contacts the first guide rail, and said adjusting device is disposed at a position spaced apart from the fulcrum.

6. The apparatus of claim **5**, in which the fulcrum has a cylindrical surface perpendicular to and contacting the first guide rail.

7. The apparatus of claim **6**, in which the fulcrum is a bearing arranged in the carriage and contacting the first guide rail.

8. The apparatus of claim **5** further comprising a guide receiving portion having a spherical concave portion for contacting the carriage; a spherical convex portion provided on the carriage for contacting the guide receiving portion; and biasing means for contacting the concave portion to the convex portion.

9. The apparatus of claim **5**, in which the adjusting device has first and second adjusting pins whose height is adjustable and which contact the carriage upward to adjust the inclination of the optical axis of the objective lens in rotational directions about said two.

10. The apparatus of claim **9**, in which the first adjusting pin, the fulcrum, and the second adjusting pin form an angle of about 90°.

11. The apparatus of claim **5** further comprising a bearing on the second guide rail; and first and second height-adjustable screws for coupling the bearing to the carriage.

12. The apparatus of claim **11**, in which the first screw, the fulcrum, and the second screw form an angle of about 90°.

13. An optical recording and/or reproducing apparatus for recording information on an optical recording medium and/or reproducing information recorded on said medium, the apparatus comprising:

an objective lens having an optical axis;

a carriage for supporting the objective lens;

a base;

first and second guide members fixed to the base for supporting the carriage movably in a first direction;

the carriage having first and second bearings to be guided by the first and second guide members, the carriage comprising a first portion having at least the objective lens and the first bearing, and a second portion having at least the second bearing; and

an objective lens adjusting device on said carriage for adjusting an inclination of the optical axis of the objective lens by rotating the first portion of said carriage with respect to the second portion of said carriage in rotational directions about two axes perpendicular to the optical axis of the objective lens and to each other, wherein the first bearing serves as a fulcrum for the rotation of the first portion, and the first portion is substantially aligned with the optical axis of the objective lens.

[57] **ABSTRACT**

A method for recognizing a three-dimensional objective in which a two-dimensional image is obtained from the same viewing point as a distance image obtained by picking up the objective in a three-dimensional space and the two-dimensional image is utilized to previously limit an existence zone of the objective under detection for the distance image and to perform objective detecting operation over the partial distance image in the limited zone, thereby realizing a sufficiently high speed detection of, in particular, the three-dimensional objective.

METHOD OF UTILIZING EDGE IMAGES OF A CIRCULAR SURFACE FOR DETECTING THE POSITION, POSTURE, AND SHAPE OF A THREE-DIMENSIONAL OBJECTIVE HAVING THE CIRCULAR SURFACE PART

This application is a divisional of application Ser. No. 08/391,006, filed Feb. 21, 1995, now U.S. Pat. No. 5,692,061.

BACKGROUND OF THE INVENTION

The present invention relates to a method for recognizing an objective in a three-dimensional space and, more particularly, an objective recognition method for detecting the position, attitude or posture and shape of an objective.

DESCRIPTION OF RELATED ART

For recognizing a three-dimensional objective, there have conventionally been suggested a method in which objective position detection is carried out by extracting a cluster in a space of parameters indicative of the positional posture of an objective obtained based on correspondences between all edge segments in an image and all arris or ridge lines of an objective model as disclosed in Japanese Patent Laid-Open Publication No. 2-230478. In another method an objective to be checked is considered to be an objective model comprising a plurality of rigid bodies and joints having degrees of freedom of rotation connected to the bodies. Posture candidates for each of the rigid bodies are found based on correspondences between features (such as designated segments or designated points) in an image and the objective model. An image of the objective image is estimated from the respective posture candidates and collated with the image to thereby determined a suitable posture as disclosed in Japanese Patent Laid-Open Publication No. 4-54409.

In the former method, it is necessary to make correspondences between all the edge segments in the image and all the arris lines of the objective model. Thus, when the target objective has a complicated shape, the number of edge segments in an image and the number of arris lines in an objective model become large, which disadvantageously results in that a lot of time is required for making the correspondences, and a detection accuracy becomes bad. Even in the latter method, when an objective has a flexible structure, the numbers of rigid bodies and joints become large, so final detection of the three-dimensional posture of an objective requires lots of time.

Meanwhile, for the purpose of recognizing an objective having such a shape as a cylindrical shape, there is suggested such a method for realizing high-speed detection of an objective as shown in Japanese Patent Laid-Open Publication No. 6-29695. In this method, an objective to be checked is photographed obliquely by two image pick-up means to obtain two images. Curve edges are extracted from the two images, some of the curve edges when located within a predetermined distance range being regarded as edges in an identical elliptical line. The center of a right circle is regarded as photographed as the center of the ellipse in the images. The centers of the upper and lower ellipses are calculated and made associated with each other from the two images. The centers of right circles corresponding to the upper and lower ellipses are calculated based on the trigonometrical survey. The orientation or direction of a line segment connecting the calculated two centers is calculated to find a central line for the cylinder, thereby determining the position and posture of the cylindrical body.

However, this method has a problem that, when it is desired to recognize a ring-shaped objective or a plurality of cylindrical objectives, combinations of curve edges not in an identical circle are erroneously regarded as in the identical circle, and some edges in the lower cylindrical surface become positioned off the screen, leading to the fact that it becomes impossible to measure the direction of the central line of the cylindrical objective, i.e., its posture. Further, when the center of a circle is projected to an image, the center will be projected as offset from the circle center in the image so long as the plane containing the circle is not perpendicular to the optical axis of the image pick-up means. Furthermore, since nearly half of edges of the lower circle are hidden as unseen, the center accuracy of the circle calculated based on such edges tends to be low. Accordingly, the values of the position and posture thus obtained have been low in accuracy and reliability.

SUMMARY OF THE INVENTION

It is therefore an object of the present invention to provide an objective recognition method for realizing high-speed detection with a high accuracy.

In accordance with an aspect of the present invention, the above objective is attained by providing an objective recognition method which comprises the steps of obtaining a two-dimensional image from the same viewing point as a distance image obtained by photographing an objective in a three-dimensional space, specifying a partial image for the two-dimensional image, applying the specified two-dimensional partial image to the distance image to extract a partial image for the distance image, and subjecting the distance partial image to an objective detecting operation.

In accordance with another aspect of the present invention, there is provided an objective recognition method wherein a two-dimensional image is obtained from the same viewing point as a distance image obtained by photographing an objective in a three-dimensional space, an inertia principal axis and gravity center of a target objective image in the two-dimensional image, the distance image is projected onto a plane passing through the inertia principal axis and perpendicular to the two-dimensional image, an inertia principal axis and gravity center of a target objective image in a projected plane, and a position and posture of an inertia principal axis of the target objective in the three-dimensional space is detected from the 2 obtained inertia principal axes and the 2 obtained gravity centers.

In accordance with yet a further aspect of the present invention, there is provided an objective recognition method wherein an edge image and an intensity gradient direction image are obtained from gray images obtained by photographing an objective having a circular shape in a three-dimensional space from a plurality of directions, an edge image as a reference is created through stereo image processing and a disparity image is created from the reference image and the other edge image, only curved edges are extracted from the reference edge image, a circle is extracted from the curved edges, and a position and posture of the extracted circle are detected with use of three-dimensional information found from the disparity of edge points of the extracted circle.

In the present invention, in the objective detecting operation, the two-dimensional image is utilized to previously restrict the existence zone of the objective under detection in the distance image, and the objective detecting operation is carried out over the distance partial image of the restricted zone. Thus, the present invention can realize the

high-speed detecting operation when compared to the prior art wherein detecting operation is carried out over all zones of the distance image. In this case, the specification of the partial image of the two-dimensional image may be carried out on the basis of the shape pattern of the surface of the target objective, the statistical image feature of texture, the color or brightness classification, or the two-dimensional geometrical feature derived from the three-dimensional geometrical feature of the target objective.

While the present invention is susceptible of various modifications and alternative constructions, certain illustrated embodiments hereof have been shown in the drawings and will be described below in detail. It should be understood, however, that there is no intention to limit the invention to specific forms disclosed, but on the contrary, the intention is to cover all modifications, alternative constructions and equivalents falling within the spirit and scope of the invention.

BRIEF EXPLANATION OF THE DRAWINGS

These and other features of the present invention will become apparent from the following description, with reference to the accompanying drawings, in which:

FIG. **1** is a flowchart for explaining the operation of an embodiment of a system of the present invention:

FIG. **2** is a block diagram of the system of the embodiment of FIG. **1**;

FIG. **3** is a perspective view of an example of objectives under detection in the embodiment of FIG. **1**;

FIG. **4***a* is a diagram for explaining a two-dimensional image of the exemplary objectives in the embodiment of FIG. **1**;

FIG. **4***b* is a diagram for explaining a distance image of the exemplary objectives in the embodiment of FIG. **1**;

FIG. **5** is a flowchart for explaining the operation of a more specific variation of the embodiment of FIG. **1**;

FIG. **6** is a diagram for explaining the operation of the variation of FIG. **5**;

FIG. **7** is a flowchart for explaining the operation of another specific variation of the embodiment of FIG. **1**;

FIG. **8** is a diagram for explaining the operation of the variation of FIG. **7**;

FIG. **9** is a flowchart for explaining the operation of a further specific variation of the embodiment of FIG. **1**;

FIG. **10** is a diagram for explaining the operation of the variation of FIG. **9**;

FIG. **11** is a flowchart for explaining the operation of yet a further specific variation of the embodiment of FIG. **1**;

FIG. **12** is a front view of an example of a detection objective in the variation of FIG. **11**;

FIG. **13***a* is a diagram for explaining a two-dimensional image in the variation of FIG. **11**;

FIG. **13***b* is a diagram for explaining a distance image in the variation of FIG. **11**;

FIG. **14** is a diagram for explaining the operation of the variation of FIG. **11**;

FIG. **15** is a flowchart for explaining the operation of another embodiment of the present invention;

FIG. **16** is a diagram for explaining one operation of the embodiment of FIG. **15**;

FIG. **17** is a diagram for explaining another operation of the embodiment of FIG. **15**;

FIG. **18** is a flowchart for explaining the operation of a further embodiment of the present invention;

FIG. **19** is a flowchart for explaining the operation of yet another embodiment of the present invention;

FIG. **20***a* is a diagram for explaining a two-dimensional image in the embodiment of FIG. **19**;

FIG. **20***b* is a diagram for explaining a distance image in the embodiment of FIG. **19**;

FIG. **21***a* is a diagram for explaining the distance image after subjected to a pre-processing operation in the embodiment of FIG. **19**;

FIG. **21***b* is a diagram for explaining the two-dimensional image after subjected to a pre-processing operation in the embodiment of FIG. **19**;

FIG. **22** is a flowchart for explaining the operation of an embodiment to which the inspection method according to the present invention is applied;

FIG. **23** is a perspective view of an objective to be inspected in the embodiment of FIG. **23**;

FIG. **24***a* is a diagram for explaining a two-dimensional image in the embodiment of FIG. **22**;

FIG. **24***b* is a diagram for explaining a distance image in the embodiment of FIG. **22**;

FIG. **25** is a flowchart for explaining the operation of another embodiment of the present invention to find a position and posture of a target objective;

FIG. **26** is a perspective view of an example of the target objective in FIG. **25**;

FIG. **27** is a diagram for explaining a plane onto which the upper surface of the target objective in the embodiment of FIG. **25** is applied;

FIG. **28***a* is a diagram showing a rotated state of the plane in the embodiment of FIG. **25**;

FIG. **28***b* is a diagram for explaining a template image;

FIG. **29** is a block diagram of a system in which the present invention is employed and an objective to be detected has a cylindrical shape;

FIG. **30** shows perspective views of an example of the detection objective in the system of FIG. **29**;

FIG. **31***a* is a diagram for explaining an edge image in a stereo reference image in the system of FIG. **30**;

FIG. **31***b* is a diagram for explaining a disparity image in the system of FIG. **30**;

FIG. **32***a* is a diagram for explaining an example of an edge image in the system of FIG. **30**;

FIG. **32***b* is a diagram for explaining curve edges in the system of FIG. **30**;

FIG. **32***c* is a diagram for explaining a circular edge extracted in the system of FIG. **30**;

FIG. **33** is a flowchart for explaining the operation of a variation of the present invention;

FIG. **34** is a perspective view of other embodiment of the present invention;

FIG. **35** shows perspective views of an objective in the embodiment of FIG. **34**;

FIG. **36***a* is a diagram for explaining an edge image in the embodiment of FIG. **35**;

FIG. **36***b* is a diagram for explaining a circular edge extracted in the embodiment of FIG. **35**;

FIG. **37** is a flowchart for explaining the operation of another variation of the present invention;

FIG. **38** is a perspective view of an image acquisition state of other embodiment of the present invention;

FIG. **39** shows perspective views of an objective in the embodiment of FIG. **38**;

FIG. **40***a* is a diagram for explaining an edge image in the embodiment of FIG. **38**;

FIG. **40***b* is a diagram for explaining an extracted circular edge in the embodiment of FIG. **38**;

FIG. **41** is a flowchart for explaining the operation of another variation of the present invention;

FIG. **42** is a flowchart for explaining the operation of other embodiment of the present invention;

FIG. **43***a* is a diagram for explaining how to search edge points in the embodiment of FIG. **42**;

FIG. **43***b* is a diagram for explaining extracted edges in the embodiment of FIG. **42**;

FIG. **44** is a diagram for explaining how to extract a curved edge in the embodiment of FIG. **42**;

FIG. **45***a* is a diagram for explaining extracted curved edges in the embodiment of FIG. **42**;

FIG. **45***b* is a diagram explaining extracted curved edges in the embodiment of FIG. **42**;

FIG. **46** is a flowchart for explaining the operation of a variation of other embodiment of the present invention;

FIG. **47***a* is a diagram for explaining extracted curved edges in the embodiment of FIG. **46**;

FIG. **47***b* is a diagram for explaining a binary image of edges with disparities calculated in the embodiment of FIG. **46**;

FIG. **47***c* is a diagram for explaining extracted circular edges in the embodiment of FIG. **46**;

FIG. **48** is a flowchart for explaining the operation of a variation of other embodiment of the present invention;

FIG. **49** is a perspective view of an objective in the embodiment of FIG. **48**;

FIG. **50***a* is a diagram for explaining an edge image in the embodiment of FIG. **48**;

FIG. **50***b* is a diagram for explaining extracted curved edges in the embodiment of FIG. **48**;

FIG. **50***c* is a diagram for explaining extracted curved edges in the embodiment of FIG. **48**;

FIG. **51** is a diagram for explaining how to select curved edges in the embodiment of FIG. **48**;

FIG. **52** is a flowchart for explaining the operation of other embodiment of the present invention;

FIG. **53** shows perspective views of an objective in the embodiment of FIG. **52**;

FIG. **54***a* is a diagram for explaining edge images in the embodiment of FIG. **52**;

FIG. **54***b* is a diagram for explaining extracted circular edges in the embodiment of FIG. **52**;

FIG. **55** is a flowchart for explaining the operation of a variation of other embodiment of the present invention;

FIG. **56** is a flowchart for explaining the extracting operation of the embodiment of FIG. **55**;

FIG. **57** is a flowchart for explaining the operation of a variation of other embodiment of the present invention;

FIG. **58** is a perspective view of objectives in the embodiment of FIG. **57**;

FIG. **59***a* is a diagram for explaining edge images in the embodiment of FIG. **57**;

FIG. **59***b* is a diagram for explaining an extracted circular edge in the embodiment of FIG. **57**;

FIG. **60** is a diagram for explaining how to extract a circular edge in the embodiment of FIG. **57**;

FIG. **61** is a flowchart for explaining the operation of a variation of other embodiment of the present invention;

FIG. **62** is a diagram showing a plane of an objective when viewed from its upper side in the embodiment of FIG. **61**;

FIG. **63** is a diagram for explaining a state of the plane when rotated in the embodiment of FIG. **61**;

FIG. **64** is a flowchart for explaining the operation of a variation of other embodiment of the present invention;

FIG. **65** is a flowchart for explaining the operation of other embodiment;

FIG. **66** is a flowchart for explaining the operation of a variation of other embodiment;

FIG. **67** is a diagram for explaining a form of the operation of the embodiment of FIG. **66**;

FIG. **68** is a flowchart for explaining the operation of an embodiment of the present invention which can be applied to an assembly control system;

FIG. **69** is a perspective view of objectives in the embodiment of FIG. **68**;

FIG. **70***a* is a diagram for explaining edge images in the embodiment of FIG. **68**;

FIG. **70***b* is a diagram for explaining extracted circular edges in the embodiment of FIG. **68**; and

FIG. **71** is a diagram for explaining a Sobel operator used, for example, in the embodiments of FIGS. **29** to **31**.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

The present invention will be detailed in connection with illustrated embodiments. First and second features of the present invention involving using a distance image and a two-dimensional image photographed from the same viewing point as the distance image. Though there are various ways of creating the distance image, explanation will be made in connection with a case where the distance image is created from a stereoscopic image, i.e., from two-dimensional images. In FIG. **2**, reference symbols **10***a* and **10***b* denote television cameras for capturing stereo images. An image photographed by one **10***a* of the television cameras **10***a* and **10***b* connected to a two-dimensional image memory **4** is used as a stereo reference image. Images photographed by the television cameras **10***a* and **10***b* are associated with each other in a stereo image processor **2**, and distances calculated based on the associated result are mapped onto the stereo reference image to generate a distance image in a three-dimensional image generator **3**. The two-dimensional image acquired by one television camera **10***a* is stored in the two-dimensional image memory **4**. An objective existence zone extractor **5**, on the basis of the two-dimensional image and distance image, extracts an objective existence zone in which the objective is present, and a three-dimensional position/posture detector **6** detects a three-dimensional position or posture of the objective based on the objective existence zone and the distance image in its vicinity.

FIG. **3** shows an example of objectives to be detected. FIG. **4***a* is a two-dimensional image I**2** of the exemplary objectives, and FIG. **4***b* is a distance image I**3** thereof. Areas which are differently hatched in the distance image I**3** stand for different heights of the objectives. This representation is also applied to cases which will be described later.

Explanation will first be made as to how to extract an objective existence zone using a shape pattern present on a surface of an objective under detection undetectable from the distance image. The extraction of an objective existence zone by the objective existence zone extractor **5** is carried

out by means of pattern matching in the case of FIG. **5**. For example, when a letter "B" is present on a surface of an objective under detection, the letter "B" is used as a detection pattern. Pattern matching is carried out between the two-dimensional image **I2** and the detection pattern to extract a part corresponding to a matching score equal to or larger than a threshold value and to use as an objective existence zone **A1** a zone including the extracted part and covering a circle having a center corresponding to a gravity center **G1** of the extracted part as shown in FIG. **6**. An objective detecting operation is carried out over a partial image of the distance image **I3** corresponding to the objective existence zone **A1**. This objective detecting operation may be realized not only by the two methods already explained in connection with the prior art but also by another method which will be explained later.

For setting the objective existence zone **A2**, as shown in FIGS. **7** and **8**, edges may be extracted from the two-dimensional image **I2**, a part corresponding to an edge intensity equal to or larger than a threshold value may be extracted, an objective existence zone **A2** having a center corresponding to a gravity center **G2** of the extracted part may be set, and an objective detecting operation may be carried out over a partial image of the distance image **I3** corresponding to the objective existence zone **A2**. This objective detecting operation utilizes the fact that differences in the statistical image features of the objective texture appear as different edge densities in the two-dimensional image **I2**.

When only one of a plurality of rectangular parallelepipeds located in their center is red in color and the other rectangular parallelopipeds are blue, as shown in FIG. **9**, color extraction (red extraction in the illustrated example) may be carried out from the two-dimensional image **I2** to extract a part having a red component equal to or larger than a threshold value. And as shown in FIG. **10**, an objective existence zone **A3** having a center corresponding to a gravity center **G3** of the extracted part may be set and objective detecting operation may be performed over a partial image of the distance image **I3** corresponding to the objective existence zone **A3**. It goes without saying that a specific part may be extracted based on its brightness in place of the color. In this case, it will be noted that an objective existence zone is set on the basis of an extracted part of a two-dimensional image having a target component equal to or larger than its threshold value and an image corresponding to the set zone is used as a partial image of the two-dimensional image.

In addition to the above, the existence zone of an objective under detection may be previously limited by utilizing two-dimensional geometrical features derived from three-dimensional geometrical features. FIG. **11** shows a case where a two-dimensional geometrical feature comprised two straight lines connected in the form of a letter T is utilized. More specifically, first, an objective **120** shown in FIG. **12** is photographed to obtain such a two-dimensional image **12** as shown in FIG. **13***a* and such a distance image **I3** as shown in FIG. **13***b*. In this case, a two-dimensional geometrical feature appears as such a T-shape connection of two straight lines as shown by a reference numeral **130**. Next, edges are extracted from the two-dimensional image **I2** and subjected to a Hough transform to detect straight lines, an intersection point of the detected lines is extracted, the presence or absence of a T-shaped connection is judged, whereby an intersection point **G4** in the T-shaped connection is extracted as shown in FIG. **14**. And a zone having a predetermined range and having a center corresponding to the intersection point **G4** of the T-shaped connection is applied to a distance image **I3** to detect a three-dimensional position or posture of the objective from a distance partial image.

As shown in FIGS. **15** and **16**, an inertia principal axis **EA1** and a gravity center **G5** are detected from the two-dimensional image **I2**, and the distance image **I3** is projected onto a plane P passing through the Inertia principal axis **EA1** and perpendicular to the two-dimensional image **I2**. When an inertia principal axis **EA2** and a gravity center **G6** are detected from the projected image as shown in FIG. **17**, the posture of the inertia principal axis can be detected from the two inertia principal axes **EA1** and **EA2** and the position of the inertia principal axis can be detected from the gravity centers **G5** and **G6**.

Further, as shown in FIG. **18**, after the posture and position of the inertia principal axis are detected as mentioned above, an inertia principal axis and gravity center for the objective model are found and made to coincide with the posture and position of the detected inertia principal axis, the objective model is rotated on the inertia principal axis to find a coincidence or matching degree between the objective model and target objective, and a three-dimensional position and posture of the objective can be detected on the basis of the position and posture of the target model when the matching degree becomes maximum. In this case, since the position and posture of the inertia principle axis representative of the position and posture of the objective in the three-dimensional space are used as fixed references, that is, since 5 of 6 degrees of freedom of the objective in the three-dimensional space are restricted, the position and posture of the objective in the three-dimensional space can be accurately detected at a high speed.

As will be seen from a two-dimensional image **I2** shown in FIG. **20***a* and from a distance image **I3** shown in FIG. **20***b*, when a plurality of such objectives as shown in FIG. **12** are piled, a predicted height of an existence position of an objective to be detected is set as a pre-processing, a zone higher than the predicted height is extracted from the distance image **I3** (see FIG. **21***a*), and a zone having the same position as in the image is extracted from the two-dimensional image **I2** (see FIG. **21***b*), as shown in FIG. **19**. Thereafter, the zone restricted by the predicted height references of a two-dimensional image **I2'** and distance image **I3'** is subjected to such processing as mentioned above (in the illustrated example, which is the same as the processing shown in FIG. **11**) to detect a three-dimensional position and posture of the objective.

Such a three-dimensional objective recognition method can be applied to objective inspection situations. For example, FIG. **23** shows a case where a rectangular column **8** is inserted into a square hole **70** of a base **2** and it is desired to examine whether or not the rectangular column **8** was inserted in the square hole perpendicularly (θ=90°) to the base **2**. FIG. **22** shows a flowchart for explaining the operation when the aforementioned pattern matching is employed. That is, such a two-dimensional image **I2** as shown in FIG. **24***a* and such a distance image **I3** as shown in FIG. **24***b* are obtained from stereo images of two television cameras. In more detail, a circle **80** (which may be replaced by an opening or a screw hole) on the top surface of the rectangular column **8** is used as a detection pattern, an objective existence zone is restricted in a similar way to the foregoing embodiment, and then a position and posture of the rectangular column **8** in the three-dimensional space are detected. On the basis of the detection result, a tilt θ of the rectangular column **8** is found to judge whether the inserted state is good or not.

FIGS. **25** to **28** show an example of a detection method in which a position and posture of an objective are detected based on a distance partial image extracted by utilizing the aforementioned texture. More specifically, when such an objective **8** as shown in FIG. **26** is present, a partial image corresponding to the top surface of the objective **8** is extracted from a distance image obtained by photographing the objective **8** and based on the texture, and three-dimensional information obtained from the partial image is applied to find a plane Pa containing the top surface of the objective **8** in the three-dimensional space as shown in FIG. **27**. The plane Pa can be obtained by calculating coefficients a, b and c in the following equation by the least squares method.

$$ax+by+cz+1=0$$

Next, as shown in FIG. **27**, three-dimensional positions of points on the top surface of the objective are rotated on an origin Po of a camera image coordinate system so that a normal Paz of the plane Pa coincides with a Z axis of the image coordinate system as shown in FIG. **28***a*, and the positions are then projected onto a plane (in this case, an X-Y plane Pxy of the above image coordinate system) of a reference coordinate system with use of x and y coordinate values of the points on the top surface of the objective after rotated. A projected image thus obtained and a previously-registered template image M (such as shown in FIG. **28***b*) are subjected to a pattern matching therebetween to find a position and posture of the objective of the projected image. The found objective position is subjected to an inverse transformation to find a position and posture of the top surface of the objective before the above rotation. In order to detect the position and posture of the objective on the two-dimensional image, the pattern matching with the template image has been employed in the illustrated example, but it goes without saying that another method such as a generalized Hough transform can be employed.

In the foregoing embodiment, the two-dimensional image has been obtained from the same viewing point as the distance image obtained by picking up the objective in the three-dimensional space, the zone to be subjected to the detecting operation of the position and posture of the target objective has been extracted and restricted, and the inertia principal axis and gravity center of the target objective have been extracted on the basis of two-dimensional image. However, when the target objective has such a shape as a circular cylinder, a circular part is extracted by utilizing an edge image, and a position, posture and radius of the circle are measured to realize higher speed recognition of the objective.

In this case, such a system as shown in FIG. **29** comprises two cameras **11** and **12** for photographing an objective **18** illuminated by an illuminator **19**, A/D converters **13** and **14** for converting analog image signals from the both cameras **11** and **12** into digital image signals, frame memories **15** and **16** for storing the digital image signals therein, and a processor **17** connected to the frame memories **15** and **16**. With this system, parallel stereo conversion is carried out through the stereo image processing of an edge image, that is, the two cameras **11** and **12** are matched in their orientation and focal distance, the image signals are converted into images so that the corresponding pixels of the two images coincide with each other in the Y coordinate value to thereby realize efficient corresponding point search, and a disparity corresponding to a difference between the X coordinate values of the two calculated images is photographed by the camera **11** and mapped onto an extracted edge image (stereo reference image) to create a disparity image. When a distance image is required, conversion from disparity to distance is added. For example, in the case where circular cylindrical objectives **18***a*, **18***b* and **18***c* having different heights are located as shown in FIG. **30**, when the objectives are photographed from their upper side by the two cameras, such an edge image IE for the stereo reference image as shown in FIG. **31***a* and such a disparity image ID as shown in FIG. **31***b* are obtained. In FIG. **31***b*, a thicker line indicates a higher objective.

The images stored in the frame memories **15** and **16** through the image acquisition are subjected to the parallel stereo conversion to obtain an edge image and a gradient direction image based on the converted image. In order to extract edges from the images, a Sobel operator as shown in FIG. **71** is used. Upon application of this operator, the center of the operator is moved to a target pixel, the intensity values of pixels adjacent to the target pixel are multiplied by the values of the operator, whereby gradient magnitudes Gx and Gy in the X and Y directions, gradient intensity |G| and gradient direction θ are calculated with respect to all the pixels. When I(x,y) denotes the intensity of a pixel at a coordinate point [x,y], the gradient magnitudes Gx and Gy in the X and Y directions are expressed by the following equations.

$$Gx(x,y)=\{I(x+1,y-1)+2I(x+1,y)+I(x+1,y+1)\}-\{I(x-1,y-1)+2I(x-1,y)+I(x-1,y+1)\}$$

$$Gy(x,y)=\{I(x-1,y-1)+2I(x,y-1)+I(x+1,y-1)\}-\{I(x-1,y+1)+2I(x,y+1)+I(x+1,y+1)\}$$

Using Gx and Gy, the gradient intensity |G| and the gradient direction θ at each pixel position are found as follows. Images of pixels having such values are referred to as gradient intensity image and gradient direction image, respectively.

$$|G|=(Gx^2+Gy^2)^{1/2}$$

$$\theta=\tan^{-1}(Gy/Gx)$$

After a threshold value is provided for the value of the gradient intensity |G| and the gradient intensities for pixels having gradient intensities lower than the threshold value are set at 0, points having the highest gradient intensities in the vicinity, i.e., the gradient intensities in the form of a ridge line are extracted as edge points, such an edge image IE as shown in FIG. **32***a* is obtained. And only curved components **321** and **322** are extracted from the edge image of the stereo reference image as shown in FIG. **32***b*, and a circular component **322** is extracted from the extracted curved components as shown in FIG. **32***c*.

A disparity is calculated in the aforementioned manner on the basis of the two stereo edge images through the stereo image processing, the calculated disparity is mapped onto the edge image of the stereo reference image to create a disparities image, three-dimensional positions at points on the circular edge are calculated from the corresponding parts of the circular disparities image extracted in the aforementioned manner, and a central position and posture of a circle of the top surface of the circular cylindrical objective **18** are measured based on the calculated three-dimensional position information to thereby recognize a position and posture of the objective **18**.

The extraction of only the curved components from the edge image of the stereo reference image can be carried out, for example, by extracting straight lines through Hough transform and by erasing edges present within a predeter-

mined distance from the extracted straight lines. Explanation will be made as to the case where three types of such objectives **18***a*. **18***b* and **18***c* as shown in FIG. **35** are conveyed along a conveyor **92** and the target objective **18** is one of three types of such objectives, and as to how to select the target objective from the three types of objectives. As shown in FIG. **37**, an edge image is created through parallel stereo conversion and creation of a gradient magnitude image and a gradient direction image. In this case, a camera **11** for photographing an image to be used as a stereo reference image acquires the image of the objective **18** nearly right from its top, whereupon such an edge image as shown in FIG. **36***a* is obtained. When the edge image is subjected to a Hough transform to extract straight lines therefrom and edges present within a predetermined distance from extracted straight lines **126** and **127** are erased, edges **122** to **125** resulting from the conveyor **92** can be erased. Thus only a circular edge **121** of the top surface of the objective **18** can be extracted. And when three-dimensional positions at points on the circular edge are calculated from the disparity of the extracted circle and when a central position and radius of the circle of the top surface of the objective **18** are measured from the calculated three-dimensional position information, the objective **18** can be specified as one of the three types of objectives shown in FIG. **35** on the basis of the measured central position (height) and radius.

Meanwhile, when the circular cylindrical objectives **18**, **18***a*, **18***b* and **18***c* have straight line components in the edges of their top surface as shown in FIGS. **38** and **39**, mere erasing of edges present within a predetermined distance from the extracted straight lines also causes part of curved lines to be erased. To avoid such disadvantage, as shown in FIGS. **40** and **41**, it is arranged to erase edges which are present within a predetermined distance from extracted straight lines **177**, **178**, **179**, **17***a*, **17***b* and **17***c* and which have values within a predetermined value from 90 degrees in the angle between their gradient direction and straight line direction vector. This enables realization of erasure of straight line edges while preventing partial erasing of a circular edge **171** as shown in FIG. **40***b*.

The erasure of straight line components from the edge image while leaving curve components may be realized by such a method as shown in FIGS. **42** to **45**. That is, edge points are found from an edge image of a stereo reference image for storage, points surrounded by a found target edge point **201** are searched clockwise from its right side to find the presence of another edge point as shown in FIG. **43***a*, storing operation of an edge point which gradient direction is different from the gradient direction of the previously-stored edge point **201** by a predetermined value or less as the next target edge point is continued, in the presence of the edge point, until no edge point is found at the points around the target edge point **201**. When the number of such edge points stored exceeds a predetermined value, such edge points are assembled into edge groups **431** to **435** as shown in FIG. **43***b*. For each edge group, as shown in FIG. **44**, an angle **224** made between a segment connecting an edge start point **221** and a middle point **222** and a segment connecting the edge start point **221** and an end point **223** is examined so that, when only such an edge that has the angle exceeding a predetermined value is left, only curved edges **431**, **434** and **435** can be extracted as shown in FIG. **45***a* and such circular edges **434** and **435** as shown in FIG. **45***b* can be extracted from the edges of FIG. **45***a*.

The extraction of circular edges from curved edges may be carried out in the following manner. First, a method shown in FIG. **46** utilizes the fact that the objective **18** has in its lower side substantially no corresponding parts in its left and right side images and thus its disparity detection ratio becomes considerably low. When the calculated disparities of curved edges **261**, **262** and **263** are examined from such an edge image having only curved edges as shown in FIG. **47***a*, the curved edges **262** and **263** are almost calculated in their disparity as shown by a binary image of edge points with the disparities calculated in FIG. **47***b*. Since the curved edge **261** has no corresponding parts in the left and right side images and its disparity is not calculated yet, when curved edges whose already-calculated disparity ratios are smaller than a predetermined value are deleted, the curved edge **261** is deleted, which results in that only the curved edges **262** and **263** on the top surface of the objective can remain left as shown in FIG. **47***c*, from which the edges **262** and **263** can be extracted to form a circle.

When the objective **18** has such a ring shape as shown in FIG. **49**, since the top surface of the objective has two circular edges, only one (the outer circular edge in FIG. **49**) of the circular edges is extracted. More specifically, an edge image IE for the objective **18** is as shown in FIG. **50***a* and, when straight line components are erased from the edge image, such an edge image IE**2** as shown in FIG. **50***b* is obtained. When the objective **18** is seen bright on the background, and a gradient direction **335** of an edge **331** for the outer ring is directed inwardly of the circle while a gradient direction **336** of an edge **332** for the outer ring is directed outwardly of the circle as shown in FIG. **51**, coefficients a and b and constant r can be found by the least squares method in accordance with a right-circle application equation which follows.

$$X^2+Y^2+ax+by+r=0$$

When the right-circle application equation is applied to the single edge **332** of the top surface to calculate a center (−a/2,−b/2) **334** of the circle, any one **339** of points of the right-circle edge is selected, a direction toward the calculated center **334** of the circle from the selected point **339** is found, and such an edge of the top surface is extracted that a difference between the direction **338** and the gradient direction **336** of the selected point is a predetermined value (90°) or less. Even with respect to edges **331**, **33***a*, **33***b*, **33***c*, **33***d*, **33***e* and **33***f* of the top surface other than the edge **332**, when the aforementioned operation is carried out to calculate a difference between the direction of gradient of a point of each edge and the direction from the point toward the center of the right circle, and when edges of the top surface having such differences of a predetermined value (90°) or less are extracted, such an edge image IE**3** of a stereo reference image with the inner-side circular edges **332**, **33***a*, **33***c* and **33***e* removed as shown in FIG. **50***c* can be obtained. In this connection, when the predetermined value for the difference is selected to be higher than 90°, the outer-side circular edges **331**, **33***b*, **33***d* and **33***f* are erased while the inner-side circular edges **332**, **33***a*, **33***c* and **33***e* are left.

An embodiment of FIG. **52** is designed so that, when such circular cylindrical objectives **18** as shown in FIG. **53** are piled and thus its edge image IE is as shown in FIG. **54***a* a highest-level one of the piled objectives is detected to measure its position and posture. Among a plurality of curved edges present in the edge image, an edge having the maximum disparity because of its highest-level location is selected and the selected edge is set to be a reference edge **381** as shown in FIG. **54***a*, and it is examined whether or not the reference edge **381** forms part of a circle. When the reference edge cannot be regarded as part of the circle, the

edge having a disparity larger next to the edge **381** is selected as a reference edge and it is examined whether or not the edge forms part of the circle. The above operation is repeated until the reference edge capable of forming part of the circle is found. Thereafter, the other edges are denoted by reference numerals **382**, **383**, . . . in an increasing order of the distance from the reference edge **381** and it is examined in the above numeral order whether or not the other edges form part of the same circle. Those of the edges judged to form part of the same circle as the reference edge are contained in the same group as the reference edge. Such processing is also carried out over other edges having distances of a predetermined value or less from the reference edge so that edges **381**, **383**, **384** and **386** having the same circle are assembled as shown in FIG. **54***b*, on the basis of which a position and posture of the highest-level objective **18** can be detected.

In an embodiment of FIG. **55**, an edge having the largest disparity due to the highest-level location of the target objective is selected from the edge image of FIG. **54***a*. The selected edge is used as a reference edge **381**, and the other edges are denoted by reference numerals **382**, **383**, . . . in an increasing order of the distance from the reference edge **381**. Thereafter, coefficients a, b, h, g and f are found by the least squares method in accordance with an equation (to be applied to ellipse) which follows.

$$ax^2+by^2+2hxy+2gx+2fy=1$$

An ellipse is applied to the reference edge **381** to calculate its center coordinate point (xo,yo). As shown in FIG. **56**, a straight line **413** passing through a point **417** of the reference edge and a center **412** of an ellipse **411** intersects the ellipse at two intersection points **414** and **415**, and, when a distance **416** of one **414** of the two intersection points closer to the edge point **417** therefrom exceeds a predetermined value at any points of the reference edge, the reference edge is not regarded as a circle component and a next reference edge is arbitrarily selected. When the distance does not exceed the predetermined value, on the other hand, the reference edge is regarded as a circle component, the reference edge **381** is combined with the edge **382** in the vicinity thereof, and the coefficients a, b, h, g and f are found in the above equation by the least squares method, whereby the ellipse is applied to the reference edge to calculate its center coordinate point (xo,yo). And distances between the points of the reference edge **381** and edge **382** in its vicinity and the found ellipse are found. When the found distances are all less than a predetermined value, the reference edge **381** and the edge **382** in its vicinity are judged to form part of the same circle. When even a single one of the distances is not less than the predetermined value, the edges are judged not to form part of the same circle and the reference edge **381** is combined with the next edge **383** in its vicinity to perform the aforementioned operation. When a series of operations is repeated until edges to be combined become null, edges belonging to the same circle can be combined into one. In this conjunction, the center coordinate point (xo,yo) of the above ellipse is expressed as follows.

$$xo=(hf/bg)/(ab-h^2)$$

$$yo=(hg/af)/(ab-h^2)$$

An embodiment shown in FIG. **57** is also intended to detect a highest-level one of a plurality of circular cylindrical objectives **18** piled as shown in FIG. **58**. FIG. **59***a* shows an edge image IE of such objectives of FIG. **58**. In FIG. **59***a*, a reference edge **441** corresponds to the highest-level edge having the maximum disparity. In this case, according to the method of the above embodiment, when the edge **442** to be detected as part of the same circle as the reference edge **441** cannot be detected due to the tilted objective or the like, it may be erroneously judged that the edge **443** is to be combined with the reference edge **441**. In the illustrated example, in order to avoid such error, when the reference edge **441** and the edge **443** are judged to form part of the same circle according to the method of the above embodiment, final judgement of the same circle is carried out only when a difference is within a predetermined range between the direction of a normal of a plane **453** made with use of three-dimensional information found based on the disparity of any two points of the reference edge **441** and any one point of the other edge **443** and the direction of a normal of a plane **454** made with use of three-dimensional information found based on the disparity of any two points of the edge **443** and any one point of the reference edge **441** except for the selected two points, as shown in FIG. **60**. Through the above operation, the circular edge **441** of the top surface of the highest-level objective can be extracted as shown in FIG. **59***b*.

Explanation will be directed to the operation after the extraction of the circular edges of the top surface of the circular cylindrical objective. In an embodiment of FIGS. **61** to **63**, as in the case of FIG. **25**, three-dimensional positions of points are calculated based on the disparity of the extracted circle edges, and coefficients a, b and c are calculated by the least squares method in accordance with the following equation (to be applied to plane).

$$ax+by+cz+1=0$$

Then, a plane Pa containing the top surface of the objective **18** is found as shown in FIG. **62**, three-dimensional positions of points in the top surface of the objective are rotated on an origin po of a camera coordinate system so that a normal Paz of the plane Pa coincides with the Z axis of the camera coordinate system as shown in FIG. **63**, and coefficients a, b and constant r are found by the least squares method in accordance with the following equation (to be applied to right circle) to calculate a center position **491** and radius **492** of the right circle after the rotation.

$$x^2+y^2+ax+by+r=0$$

In the illustrated example, the camera coordinate system is employed as a reference coordinate system. A center position **486** of the right circle of the top surface of the objective **18** is calculated through inverse transformation (to before the rotation) of the center position **491** of the calculated right circle to obtain a position, posture and radius of the objective **18**. In the calculation of the right circle after the coordinate system rotation, coefficients a, b, h, g and f are found in the above ellipse application equation by the least squares method and conversion to a standard ellipse is carried out to obtain a position and posture of the elliptical cylinder as well as a major and minor radii thereof.

In an embodiment of FIG. **64**, three-dimensional positions of points on the top surface of the objective are rotated on the origin po of the above image coordinate system as mentioned above so that the normal Paz of the plane Pa coincides with the Z axis of the coordinate system, after which certain edge points are removed so that a distance **493** (difference from the Z coordinate value) of the found plane Pa from the edge points of the circle after the rotation in the three-dimensional space exceeds a predetermined value. With use of the x and y coordinate values of edge points of

the top surface of the objective **18** after the rotation except for the above edge points, coefficients a and b and constant r are found by the least squares method in accordance with the right-circle application equation to calculate a center position **491** and radius **492** of the right circle after the rotation. In this connection, the camera coordinate system is used as a reference coordinate system. And a center position **486** of the right circle of the top surface of the objective **18** is calculated through inverse transformation (to before the rotation) of the center position **491** of the calculated right circle to obtain a position, posture and radius of the objective **18** after the coordinate system rotation. In the calculation of the right circle after the coordinate system rotation, further, coefficients a, b, h, g and f are found by the least squares method in accordance with the aforementioned ellipse application equation, and a position and posture of the elliptical cylinder as well as a major and minor radii thereof are obtained through conversion to standard ellipse.

In an embodiment of FIG. **65**, three-dimensional positions of points on the top surface of the objective are rotated on the origin po of the above image coordinate system as mentioned above so that the normal Paz of the plane Pa coincides with the Z axis of the coordinate system, after which certain edge points are so removed that a distance (difference from the Z coordinate value) of the found plane Pa from the edge points of the circle after the rotation in the three-dimensional space exceeds a predetermined value, a plane Pa in the three-dimensional space containing the edge of the top surface of the circular cylindrical objective **18** is again found by the least squares method, and three-dimensional positions of points of the top surface of the objective are rotated on the origin po of the camera coordinate system so that the normal Paz of the found plane Pa coincides with the Z axis of the coordinate system. Thereafter, with use of the x and y coordinate values of edge points of the top surface of the objective **18** after the rotation except for the above edge points, coefficients a and b and constant r are found by the least squares method in accordance with the right-circle application equation to calculate a center position **491** and radius **492** of the right circle after the rotation. And a center position **486** of the right circle of the top surface of the objective **18** is calculated through inverse transformation (to before the rotation) of the center position **491** of the calculated right circle to obtain a position, posture and radius of the objective **18** after the coordinate system rotation. Even in this case, in the calculation of the right circle after the coordinate system rotation, further, coefficients a, b, h, g and f are found by the least squares method in accordance with the aforementioned ellipse application equation, and a position and posture of the elliptical cylinder as well as a major and minor radii thereof are obtained through conversion to standard ellipse.

In an embodiment of FIG. **66**, three-dimensional positions of points are calculated based on the disparity of the extracted circle edges as mentioned above, and coefficients a, b and c are calculated by the least squares method in accordance with the aforementioned plane applying equation to find a plane Pa containing the top surface of the objective **18**. Further, as shown in FIG. **67**, a sphere **531** containing the right circle of the top surface of an objective **18** in a three-dimensional space is found by the least squares method. When a sphere is applied, since the right circle of the top surface is present on the same plane, the sphere is not uniquely determined. However, the center of the sphere is restricted to the extent that the center is present on a straight line perpendicular to the above plane Pa and passing through the center of the right circle present on the plane. Further, since the found sphere may be any sphere so long as its radius is larger than the right circle of the top surface and the sphere contains the right circle of the top surface, when any one value of any one of center coordinate axes of the sphere is fixed, the sphere can be determined. In the present embodiment, the Z coordinate value of the center of the sphere was fixed to a Z coordinate value c_o different by more than the radius of the right circle from the Z coordinate values of the objective existence zone. In other words, an equation for the sphere was expressed as follows to find coefficients a and b and constant R by the least squares method.

$$x^2+y^2+z^2+ax+by-2c_oz+R=0$$

A center **533** of the right circle of the top surface of the circular cylindrical objective **18** is found by calculating an intersection point between the plane Pa and a straight line passing through a center **532** of the sphere and having the same direction vector as a normal vector **537** of the plane Pa. A radius **534** is found by subtracting a square of a distance **536** between the center of the sphere and the center of the right circle from a square of a radius **535** of the sphere to find a subtraction and then by finding a square root of the subtraction. Accordingly, even in this case, a position, posture and radius of the objective **18** can be found.

An embodiment of FIGS. **68** to **70** shows an example where the present invention is applied to automatic assembling work. More in detail, as shown in FIG. **69**, when it is desired to assemble a part **541** having two holes and a part **542** having two projections by means of robot, positions and posture of the holes and projections are detected to detect positions and postures of the parts **541** and **542**.

More specifically, an edge image IE (see FIG. **70***a*) of a stereo reference image, a gradient direction image and a disparity image are created and curved edges are extracted from the edge image. That is, such 4 circular edges **701** to **704** as shown in FIG. **70***b* are extracted. When the direction of a segment connecting the middle point and centers of corresponding 4 circles **543** to **546** in a three-dimensional space as well as the direction of a normal of a plane defined by the 2 circles are calculated from the 4 circle edges, the position and posture of the part **542** having the two projections are determined. When the similar operation is carried out for the remaining 2 circles, the position and posture of the part having the two holes are determined.

In accordance with the present invention, as has been explained in the foregoing, a two-dimensional image is obtained from the same viewing point as a distance image obtained by photographing an objective in a three-dimensional space, a partial image in the two-dimensional image is specified, the specified two-dimensional partial image is applied to the distance image to extract a partial image from the distance image, and an objective detecting operation is carried out over the distance partial image. That is, upon performing the objective detecting operation, an existence zone of the objective under detection in the distance image is previously restricted by utilizing the two-dimensional image, and the objective detecting operation is carried out over a distance partial image of the restricted zone. As a result, it will be appreciated that from the present invention a relatively high detecting operation can be realized when compared with the prior art for performing a detecting operation over all the zones of the distance image.

What is claimed is:

1. A method of utilizing edge images of a circular surface part for detecting the position, posture and shape of a

three-dimensional objective having the circular surface part, wherein at least two gray images are obtained by photographing the three-dimensional object having the circular surface part from at least first and second positions of different angles on the same coordinate with respect to the objective, an edge image and a concentration gradient directional image are obtained from each of the two gray images obtained, a disparity image is prepared through a stereo image processing in which, with the edge image obtained for the first position made as a reference edge image, the correspondence is taken between respective edge points on the reference edge image and respective edge points on the other edge image obtained for the second position and a disparity is obtained with respect to each edge point on the reference edge image, only edges of curves including circles are extracted from the reference edge image, the edges of a circle only are extracted from the edges of curves, and a position and posture of the circular surface part of the objective are detected with use of three-dimensional information obtained from the disparity at parts of the disparity image corresponding to the edge points of the extracted circle.

2. The method as set forth in claim **1**, wherein straight lines are extracted from the reference edge image, and edges in the vicinity of the extracted straight lines are erased to extract only the edges of curves.

3. The method as set forth in claim **1**, wherein straight lines are extracted from the reference edge image, and edges which are located close to the extracted straight lines and which have angles of nearly 90° between their gradient direction and straight line direction vector are erased to extract only the edges of curves.

4. The method as set forth in claim **1**, wherein, upon extraction of only the edges of curves including circles from the reference edge image, an optional one of the edge points forming the edge in the reference edge image is set as a target edge point, other edge points adjacent to and surrounding the target edge point are sequentially searched for determining a next target edge point, the adjacent edge point searched and satisfying conditions that a difference in the direction of concentration gradient of the adjacent edge points searched from the target edge point is below a predetermined value is registered as the next target edge point, such search and registration are continued until failure of determination of the edge point satisfying the conditions in the adjacent edge points to group the edge points into the edges of curves and of straight line, and only the edges of curves are extracted from a distribution of the edge points in an identical group.

5. The method as set forth in claim **1**, wherein, upon extraction of the circle from the extracted edges of curves, one of the extracted edges of curves having a predetermined number or percentage of edge points with disparities calculated are extracted as the circle.

6. The method as set forth in claim **1**, wherein the circle is applied to extracted edges of curves by the least squares method to calculate a center of the circle, ones of the edges of curves having values in a predetermined range in a difference between a direction from an edge point of the respective curve edge toward the center of the circle and a direction of gradient of the edge point are extracted, and the circle is extracted from the extracted edges of curves.

7. The method as set forth in claim **1**, wherein, upon combination of extracted edges of curves to form the circle, the edges of curves are combined in an increasing order of a distance between the edges of curves to form the circle in an image, and ones of the edges of curves having distances of a predetermined value or more therebetween are not used for forming the circle.

8. The method as set forth in claim **7**, wherein, when the circle is found by the least square method from two-dimensional data of the combined edges of curves and only when respective points on the combined edges of curves are within a predetermined distance range from the found circle, the combined edges of curves are judged as present on the same circle and form the circle.

9. The method as set forth in claim **1**, wherein two edges of curves judged as able to form a circle are judged as present in the same circle and form the circle, only when a difference between a normal of a plane defined with use of three-dimensional information found based on disparities between two points of a first curve edge and a point of a second curve edge and a normal of a plane defined with use of three-dimensional information found based on disparities between two points of the second curve edge and a point of the first curve edge except for the selected two points is within a predetermined value range.

10. The method as set forth in claim **1**, wherein a plane to which circle edges are applied is found with use of three-dimensional information of points on the extracted circle edges, the three-dimensional information is rotated on an origin of a camera coordinate system to cause a normal of the found plane to coincide with a Z axis of the camera coordinate system, a center and radius of the circle are calculated by the least squares method with use of X and Y coordinate values of the circle edges after the rotation, the calculated coordinate values are subjected to an inverse transformation to detect a position and posture of the objective before the rotation.

11. The method as set forth in claim **10**, wherein a plane to which circle edges are applied is found, circle edge points corresponding to points spaced by a predetermined distance or more in a three-dimensional space are removed from the found plane, and a center and radius of the circle are calculated.

12. The method as set forth in claim **10**, wherein a plane to which circle edges are applied is found, circle edge points corresponding to points spaced by a predetermined distance or more in a three-dimensional space are removed from the found plane, a plane to which circle edges defined by remaining circle edge points are applied is again found, and the found plane is rotated.

13. The method as set forth in claim **1**, wherein extracted circle edges are applied to a plane and a sphere in a three-dimensional space to calculate a center position and radius of a right circle of a cross section of the sphere defined by an intersection plane between the plane and sphere.

14. The method as set forth in claim **1**, wherein a position and posture of the objective are detected and recognized based on a magnitude of the detected circle and on a positional relationship thereof in a three-dimensional space.

[57] **ABSTRACT**

An objective unit in which illumination light is applied through an annular illumination light path surrounding lenses for guiding observation light coming from an object of observation, and which includes a shared lens for guiding the illumination light from the illumination light path to the object of observation and for guiding the observation light to the lenses.

OBJECTIVE UNIT

BACKGROUND OF THE INVENTION

The present invention relates to an objective unit which is for use in an optical microscope and which performs incident lighting, and more particularly to an objective unit which uses a space outside the observation light path to perform lighting for accomplishing dark-field observation or for generating evanescent waves to achieve incident-light fluorescent observation.

FIG. **7** is a sectional view of the illumination system of an optical microscope. The microscope comprises an objective unit **3**, a focusing lens **4**, and eye lens (not shown), a lamp **7**, a collector lens **9**, and mirror **10**. To obtain a magnified image of a sample **1** (i.e., an object of observation), the objective unit **3**, focusing lens **4** and eye lens are arranged in the axis **2** of observation light. The objective unit **3** contains an objective lens system **6**.

The lamp **7** is located at a predetermined distance from the observation-light axis **2**. The lamp **7** emits light for incident lighting, which has an illumination-light axis **8** extending at right angles to the observation-light axis **2**. Arranged in the illumination-light axis **8** are the collector lens **9** and the mirror **10**. The collector lens **9** is semi-spherical, while the mirror **10** is shaped like a ring. The mirror **10** is inclined at 45° to the observation-light axis **2** and the illumination-light axis **8**. The mirror **10** has an annular reflecting surface.

The collector lens **9** collects the light emitted from the lamp **7** for incident lighting, converting the light to a light beam having a circular cross section. The light beam reaches the mirror **10**. Part of the light beam passes through the opening of the mirror **10**. The remaining part of the light beam is reflected downwards from the reflecting surface of the mirror **10**. It is used as an illumination light (incident illumination light) **11** which is suitable for incident lighting. The light beam has an annular cross section and is coaxial with the observation-light axis **2**. The illumination light **11** passes surrounding the observation light path and is guided into objective unit **3**.

The illumination light **11** for incident lighting passes through the objective unit **3**, surrounding the lens system **6**. The illumination light **11** is then reflected by a mirror **12** and converged onto the sample **1**. The observation light beam **5** reflected from the sample **1** passes through the lens system **6** of the unit **3**. The light beam **5** then passes through the focusing lens **4**. Eventually the light beam **5** is guided to the eye lens (not shown), whereby an observer can see a magnified image of the sample **1**.

The objective unit **3** will be described in detail, with reference to FIG. **8** which is a sectional view. The objective unit **3** is a dry objective unit. As seen from FIG. **8**, the unit **3** comprises lens-holding frames **20***a* to **20***g*, a hollow cylinder **21**, and a lens-holding ring **22**, besides the lens system **6**. The lens system **6** consists of seven lenses **6***a* to **6***g* which are arranged in the observation-light axis **2**. The lenses **6***a* to **6***g* are held by the lens-holding frames **20***a* to **20***g*, respectively. The frames **20***a* to **20***g* are provided in the hollow cylinder frame **21** and held in place once the lens-holding ring **22** has been fitted into one end of the hollow cylinder frame **21**.

As shown in FIG. **8**, a ring **25** is mounted on the objective unit **3**. The ring **25** will be described with reference to FIG. **9**, which is a part of a sectional view taken along line IX—IX in FIG. **8**. As FIG. **9** shows, the ring **25** has two arcuate elongated holes **23** and **24**. Thus, the ring has two parts in which no holes are made. The holes **23** and **24** are arranged in the same circle and separated from each other. The ring **25** has a screw thread **26** on its outer circumferential surface.

As seen from FIG. **8**, a hollow cylindrical cover **27** is mounted on the mirror **12** and also on the ring **25**. The cover **27** is set in screw engagement with the ring **25** at the screw **26** thereof, positioned coaxial with the hollow cylinder **21**. Hence, an annular space is provided between the hollow cylinder **21** and the hollow cylindrical cover **27** by holes **23** and **24**. The annular space serves as illumination light path. The mirror **12**, which is fitted in the distal end of the cover **27**, reflects the illumination light **11** at its reflecting surface **12***a*, applying the light **11** onto the sample **1**.

As illustrated in FIG. **8**, a cover glass **30** is located below the objective unit **3**. The cover glass **30** has a sample-mounting surface **29**. The hollow cylindrical cover **27** has a screw **27***a* on its proximal end. At the screw **27***a* the objective unit **3** is removably attached to the body of the microscope.

In the illumination system shown in FIG. **7**, the lamp **7** is the illumination light source, and the illumination light **11** is applied into the objective unit **3** by using the collector lens **9** and the mirror **10**.

The illumination light **11** is applied to the sample **1**, with a numerical aperture (NA) larger than that of the observation light. The 0th-order light totally reflected from the sample **1** does not enter the observation light path provided in the objective unit **3**. The high-order light diffracted and scattered from the sample **1** enters the lens **6***a* set in the observation light path and passes through the lens **6***b* to **6***g* set also in the observation light path. The high-order light is applied to the focusing lens **4**, which focuses the light. The light thus focused is guided to the eye lens (not shown) or a video camera (not shown), etc. Dark-field observation of the sample **1** is thereby accomplished.

The objective lens **3** may be an oil immersion objective. In this case, assume that the cover glass **30**, the oil and the sample **1** have refractive indices of 1.5, 1.5 and 1.3, respectively. Then, the illumination light applied with NA of 1.3 or more is totally reflected at the interface between the cover glass **30** and the sample **1**. In this case, evanescent light is generated on the side of the sample **1**. The evanescent light may be used as excitation light in the oil immersion objective unit. Fluorescent observation can then be achieved by use of the illumination path independent of the observation system even if the objective unit comprises lenses having great NAs. This is utilized when objective lenses designed for mono-molecular fluorescent observation are employed in order to reduce auto-fluorescent light and attain a high S/N ratio.

Being a dry system, not a liquid-immersion system, the objective unit **3** shown in FIG. **8** has a small NA and a long working distance (WD), i.e., the distance between its distal end and the cover glass **30**. Therefore, the unit **3** has a sufficient space for the illumination light path. On the other hand, most liquid immersion objective units, particularly oil immersion ones, comprises lenses having a large NA of about 1 to about 1.45 and have a short working distance of about 0.1 mm. In such a liquid immersion objective unit, the distal end, the lens-holding frames and the hollow cylinder make it difficult to provide a space large enough for an illumination light path.

To enable the objective unit **3** to apply as much illumination light as possible to the sample, it is necessary to increase the NA of the illumination light **11**. If the light **11** has an NA as large as that of the observation light beam, i.e.

it has a large marginal ratio, the peripheral part of the light **11** will be blocked by the lens-holding frames. Hence, the illumination light **11** cannot have a large NA.

To increase the NA of the illumination light **11**, the wall thickness of the lens-holding frames **20***a* to **20***g* may be decreased, making it possible to broaden the annular space for passing the illumination light **11**. If the frames **20***a* to **20***g* have less wall thickness, however, they will become less rigid than is required to hold the lenses **6***a* to **6***g* in a completely coaxial relationship. And, it is difficult to ensure a high degree of precision with respect to the dimensions of the frames. In addition, the size of the objective unit **3** is limited; its overall length should be 45 mm or less. The lenses cannot be made thicker and the lens-holding frames cannot be made longer, in order to increase the working distance so as to provide a space sufficient for an illumination light path.

BRIEF SUMMARY OF THE INVENTION

The object of the present invention is to provide an objective unit which has a large numerical aperture (NA) and a short working distance (WD) as an oil immersion objective unit, and which has an illumination light path outside the observation light path which guides an illumination light such that the light is not blocked by lenses or lens-holding frames.

According to the invention, there is provided an objective unit in which illumination light is applied through an annular illumination light path surrounding lenses for guiding observation light coming from an object of observation, the unit comprising: a shared lens for guiding the illumination light from the illumination light path to the object of observation and for guiding the observation light to the lenses.

Additional objects and advantages of the invention will be set forth in the description which follows, and in part will be obvious from the description, or may be learned by practice of the invention.

BRIEF DESCRIPTION OF THE SEVERAL VIEWS OF THE DRAWING

The accompanying drawings, which are incorporated in and constitute a part of the specification, illustrate presently preferred embodiments of the invention, and together with the general description given above and the detailed description of the preferred embodiments given below, serve to explain the principles of the invention.

FIG. **1** is a longitudinal sectional view of an objective unit according to a first embodiment of the invention, taken along a plane containing the axis of the observation light;

FIG. **2** is a longitudinal sectional view of an objective unit according to a second embodiment of the invention, taken along a plane containing the observation light axis;

FIG. **3**A is a perspective view of the prism incorporated in the second embodiment of the invention;

FIG. **3**B is a perspective view of one of prism pieces which may be used in the second embodiment;

FIG. **4**A is a diagram explaining a method of coupling a shared lens to the prism shown in FIG. **3**A;

FIG. **4**B is a diagram explaining an another of coupling a shared lens to the prism shown in FIG. **3**A;

FIG. **4**C is a diagram explaining still another method of coupling a shared lens to the prism shown in FIG. **3**A;

FIG. **5**A is a diagram representing an angle defined between the illumination light and an observation light;

FIG. **5**B is a diagram representing a different angle defined between the illumination light and an observation light;

FIG. **6** is a longitudinal sectional view of an objective unit according to a third embodiment of the invention, taken along a plane containing the axis of the observation light;

FIG. **7** is a sectional view of the illumination system of an optical microscope;

FIG. **8** which is a sectional view of the dry system objective unit incorporated in the conventional microscope; and

FIG. **9** is a sectional view of the ring mounted on the objective unit shown in FIG. **8**, taken along line IX—IX in FIG. **8**.

DETAILED DESCRIPTION OF THE INVENTION

Embodiments of the present invention will be described, with reference to the accompanying drawing.

FIG. **1** is a longitudinal sectional view of the objective unit **31**, or the first embodiment of the invention, taken along a plane containing the axis of the observation light. The objective unit **31** is located on the position on which there is located on the objective unit **3** incorporated in the illumination system of the conventional optical microscope, which is shown in FIG. **7**. In FIG. **1**, the same components as those of the conventional objective unit shown in FIG. **8** are designated at the same reference numerals.

The objective unit **31** is an oil immersion type wherein oil **40** is filled in the space between a cover glass **30** and the distal end of the unit **31**. The unit **31** has a working distance (WD) of about 0.1 mm. A sample **1** is placed on an object glass **70**. The sample **1** is covered with a cover glass **30**.

Fitted in the distal end of the objective unit **31** are a shared lens **41** and a lens-holding frame **42**. The frame **42** is a hollow cylinder closed at the lower end, in which a circular hole is made. The frame **42** has a path hole **42***a* for guiding an illumination light **11**. The path hole **42***a* is a through hole that extends between the outer and inner circumferential surfaces of the frame **42** and opens in both circumferential surfaces thereof. In other words, the frame **42** has a through hole between the outer and inner circumferential surfaces. The path hole **42***a* opens, but not all around the lens-holding frame **42**. In other words, the frame **42** has one part in which the path hole **42***a* is not formed at all.

The lens-holding frame **42** may have two or more paths, instead of one. In other words, the frame has some through holes between the outer and inner circumferential surfaces. In this case, the paths are spaced apart in the circumferential direction of the frame **42**.

It suffices for the path hole **42***a* to extend from the outer surface of the frame **42** to the inner surface thereof. It may be made in the lower part of the frame **42**, in the form of either a groove or a hole.

The shared lens **41** is fitted in the circular hole made in the lower end of the lens-holding frame **42**. The frame **42** is snap-fitted in the lower end of a hollow cylinder **21**, by virtue of an annular projection **211** of the hollow cylinder **21**. Provided in the hollow cylinder **21** are lenses **6***a* to **6***g* and lens-holding frames **20***a* to **20***g*. The lenses **6***a* to **6***g* are held in the frames **20***a* to **20***b*, respectively. The frames **20***a* to **20***g* are fitted in the cylinder **21** and held in place once a lens-holding ring **22** has been fitted into one end of the hollow cylinder **21**.

A hollow cylindrical mirror **43** is fitted into one end of the hollow cylindrical cover **27**. The mirror **43** has a conical

inner surface, i.e, an inclined reflecting surface **43***a*. The reflecting surface **43***a* reflects the illumination light **11** having an annular cross section, applying the light **11** onto the sample **1** through the path hole **42***a* provided in the lens-holding frame **42**.

The shared lens **41** and the frame **42** will be described in detail. As mentioned above, the objective unit **31** is an oil immersion type and therefore has a large NA. The shared lens **41** is a sphere with a part cut off, having a cross section larger than half the sphere. The lens **41** therefore has a flat circular face whose diameter is shorter than the diameter of the sphere. The circular hole made in the lower end of the lens-holding frame **42** has the same diameter as that of the flat circular face of the shared lens **41**. The lens **41** is fitted in the circular hole of the frame **42**. As indicated above, the frame **42** has a path hole **42***a*. The path hole **42***a* extends between the outer circumferential surface of the frame **42** and the inner circumferential surface thereof (i.e., the lens-holding surface).

How the objective unit **31** works will be explained, with reference to FIG. **7**. As shown in FIG. **7**, the light emitted from the lamp **7** is focused by the collector lens **9**, forming a light beam which has a circular cross section. Part of the light beam passes through the opening of the mirror **10**. The remaining part of the light beam is reflected downwards from the reflecting surface of the mirror **10**. It is used as an illumination light **11** which is suitable for incident lighting. The light has an annular cross section and is coaxial with the observation-light axis **2**. The illumination light **11** is guided through an annular space located outside the observation light path and is applied into the objective unit **31**.

In the objective unit **31**, the illumination light **11** passes through the illumination light path which has an annular cross section. This light path is provided between the cylinder **21** and the hollow cylindrical cover **27** and, hence, surrounds the lens system **6** or the lenses **6***a* to **6***g*. The illumination light **11** reaches the hollow cylindrical mirror **43**. The inclined surface **43***a* of the mirror **43** reflects the illumination light **11**, applying the light **11** to the path hole **42***a* made in the lens-holding frame **42**. The light **11** is applied through the path hole **42***a* to the shared lens **41**. The lens **41** refracts the light **11**. The light **11** thus refracted passes through the oil **40** and the cover glass **30**. The light **11** is therefore applied to the sample **1** mounted on the object glass **70**.

The light reflected from the sample **1**, or the observation light **5**, passes through the cover glass **30**, the oil **40**, the shared lens **41**, the lenses **6***a* to **6***g* and the focusing lens **4**. The observation lights reaches the eye lens (not shown), etc, which provides a magnified image of the sample **1**.

As indicated by the two dash-dotted lines **1** in FIG. **1**, the frame **42** may have a through hole in the part in which the path hole **42***a* is not formed. The hole can guide a part of the light **11** into the illumination light path, said part of the light **11** having been diffracted at the outer surface of the shared lens **41** and then totally reflected from the interface between the sample **1** and cover glass **30**.

Since the objective unit **31** is an oil immersion type, it has a large NA and a short working distance, so that it is difficult for the unit **31** to include in its distal end portion a space for guiding the illumination light **11**. Nonetheless, the lens-holding frame **42** does not block the illumination light **11** because it has the light-guiding path hole **42***a*. The light **11** passes through the path hole **42***a* provided outside the observation light path and reaches, in its entirety, to the sample **1** through the shared lens **41**, oil **40** and cover glass **30**.

Furthermore, the shared lens **41** serves not only to apply the illumination light **11** onto the sample **1** but also to guide the observation light toward the focusing lens **4**. An incident-lighting only lens for guiding the observation need not be used, and a space for accommodating such a lens need not be provided in the objective unit **31**. The unit **31** can be manufactured at lower cost than otherwise. Still further, the shared lens **41** can easily apply the illumination light **11** onto the sample **1** because the lens **41** is designed to guide the light reflected from the sample **1**, along the axis **2** of observation light.

As described above, the path hole **42***a* opens, but not all around the lens-holding frame **42**. Hence, the frame **42** has an inner circumferential surface large enough to hold the shared lens **41** firmly. The path hole **42***a* almost does not reduce that surface of the frame **42** which contacts the shared lens **41**. Since the frame **42** has one part in which the path hole **42***a* is not formed at all, it is rigid enough to maintain its shape even while being machined. In addition, the frame **42** can have dimensions of high precision.

As indicated by the two dash-dotted lines **1**, the frame **42** has a through hole. The hole guide a part of the light **11** into the illumination light path, said part of the light **11** having been totally reflected from the interface between the sample **1** and cover glass **30**. Thus guided through the hole, the part of the light **11** would not be scattered at the frame **42**. It would not enter the observation light path, as noise known as "flare.", etc. Hence, the microscope can provide a high-contrast, high SN ratio image of the sample **1**.

An objective unit **32** according to the second embodiment of the invention will be described, with reference to FIG. **2**. FIG. **2** is a longitudinal sectional view of the objective unit **32** taken along a plane containing the axis of the observation light. The objective unit **32** is located on the position on which there is located on the objective unit **3** incorporated in the illumination system of the conventional optical microsope, which is shown in FIG. **7**. In FIG. **2**, the same components as those of the conventional lens unit shown in FIG. **8** are designated at the same reference numerals. The objective unit **32** is an oil immersion type wherein oil **40** is filled in the space between a cover glass **30** and the distal end of the unit **32**. The unit **32** has a working distance (WD) of about 0.1 mm.

Fitted in the distal end of the objective unit **32** are a shared lens **41** and a lens-holding frame **50**. The frame **50** is a hollow cylinder closed at the lower end, in which a circular hole is made. The frame **50** has a path hole **50***a* for guiding an illumination light. The path hole **50***a* is a through hole that extends between the outer and inner circumferential surfaces of the frame **50** and opens in both circumferential surfaces thereof. In other words, the frame **50** has a through hole between the outer and inner circumferential surfaces. The path hole **50***a* opens, but not all around the lens-holding frame **50**. Namely, the frame **50** has one part in which the path hole **50***a* is not formed at all. Inserted in the path hole **50***a* is a prism **51**, which will be described later in detail. The lens-holding frame **50** may have two or more through holes, instead of one. In this case, the through holes are spaced apart in the circumferential direction of the frame **50**.

It suffices for the path **50***a* to extend from the outer surface of the frame **50** to the inner surface thereof. It may be made in the lower part of the frame **50**, in the form of either a groove or a hole.

The shared lens **41** is fitted in the circular hole made in the lower end of the lens-holding frame **50**. The frame **50** is snap-fitted in the lower end of a hollow cylinder **21**, by

virtue of an annular projection **211** of the hollow cylinder **21**. Provided in the hollow cylinder **21** are lenses **6***a* to **6***g* and lens-holding frames **20***a* to **20***g*. The lenses **6***a* to **6***g* are held in the frames **20***a* to **20***b*, respectively. The frames **20***a* to **20***g* are fitted in the cylinder **21** and held in place once a lens-holding ring **22** has been fitted into one end of the hollow cylinder **21**.

A hollow cylindrical mirror **52** is fitted into one end of the hollow cylindrical cover **27**. The mirror **52** has a closed lower end, in which circular opening is made. It has a conical inner surface, i.e, an inclined reflecting surface **52***a*. The reflecting surface **52***a* reflects the illumination light **11** having an annular cross section, applying the light **11** onto a sample **1** through the path hole **50***a* provided in the lens-holding frame **50**.

The share lens **41**, the frame **50** and the prism **51** will be described in detail.

FIG. **3**A is a perspective view of the prism **51**. As FIG. **3**A shows, the prism **51** is a truncated cone having a circular through hole in its center part. It has a cylindrical inner surface **511** in its lower end and a conical outer surface **512** at its top. The prism **51** is made of material which exhibits a refractive index higher than that of the shared lens **41**. The shared lens **41** has its lower part fitted in the cylindrical inner surface **511** of the prism **51** and the inner surface of the frame **50**. The inner surface of the frame **50** is flush with the cylindrical inner surface **511** of the prism **51**. As indicated above, the path hole **50***a* extends between the outer and inner circumferential surfaces of the lens-holding frame **50**. The inner circumferential surface holds the shared lens **41**.

FIG. **3**B shows one of prism pieces obtained by dividing the prism **51** shown in FIG. **3**A into eight. The prism **51** is not limited to a 8-piece type but may consist of an arbitrary number of pieces. One or more of the pieces of the prism **51** can be buried in the through hole or holes **50***a* formed at the predetermined locations of the lens holding frame **50**. The number of through holes *51*a is determined in accordance with the number of prism pieces used, and the size of each through hole **50** is determined in such a manner that one prism piece can be fitted therein.

The shared lens **41** and the prism **51** can be coupled in various methods, as will be explained with reference to FIGS. **4**A, **4**B and **4**C.

As shown in FIG. **4**A, the lower part of the lens **41** is placed in the cylindrical inner surface **511** of the prism **51** and adhered thereto with adhesive c which has the same refractive index as the prism **51**.

Alternatively, as shown in FIG. **4**B, the lower part of the lens **41** may set in optical contact with the inner surface **511** which is curved in the same way as the surface of the shared lens **41**.

Further, as illustrated in FIG. **4**C, the lower part of the lens **41** may placed in the cylindrical inner surface **511** which is curved in the same way as the surface of the lens **41**. And the gap between the lens **41** and the surface **511** of the prism **51** may be filled with adhesive c which has the same refractive index as the prism **51**.

How the objective unit **32** works will be explained, with reference to FIG. **7**. As shown seen from FIG. **7**, the light emitted from the lamp **7** is focused by the collector lens **9**, forming a light beam which has a circular cross section. Part of the light beam passes through the opening of the mirror **10**. The remaining part of the light beam is reflected downwards from the reflecting surface of the mirror **10** and is used as an illumination light **11**. The illumination light **11** has an annular cross section and is coaxial with the observation-light axis **2**. The light **11** is guided through an annular space located outside the observation path and is applied into the objective unit **32**.

In the objective unit **32**, the illumination light **11** passes through the illumination light path which has an annular cross section. This light path is provided between the cylinder **21** and the hollow cylindrical cover **27** and, hence, surrounds the lenses **6***a* to **6***g*. The illumination light **11** reaches the hollow cylindrical mirror **52**. The inclined surface **52***a* of the mirror **52** reflects the illumination light **11**, applying the light **11** to the path hole **50***a* made in the lens-holding frame **50**. The light **11** is applied through the path hole **50***a* to the shared lens **41**.

Since the prism **51** has a higher refractive index than the shared lens **41**, the illumination light **11** is refracted at the interface between the lens **41** and the prism **51**, away from the observation-light axis **2**. The light **11** is then refracted by the shared lens **41**. Thus refracted, the light **11** passes through the oil **40** and the cover glass **30** and is applied to the sample **1** mounted on the object glass **70**.

The light reflected from the sample **1**, or the observation light **5**, passes through the cover glass **30**, the oil **40**, the shared lens **41**, the lenses **6***a* to **6***g* and the focusing lens **4**. The observation light **5** reaches the eye lens (not shown), etc, which provides a magnified image of the sample **1**.

The second embodiment attain the same advantage as the first embodiment. Moreover, it is advantageous in that the illumination light **11** is refracted at a greater angle to the observation-light axis **2** as will be described below, even if the light **11** has the same NA as the light **11** used in the first embodiment. This is because the prism **51** is held in the lens-holding frame **50** has a higher refractive index than the shared lens **41**.

In the first embodiment, the angle α between the light **11** and the observation light **5** can be reduced but to a certain degree as shown in FIG. **5**A, due to the positions of the hollow cylinder **21** and lens-holding frame **42**. In the second embodiment, the angle α can be reduced as much as is illustrated in FIG. **5**B. The angle α can be reduced so that the diameter of the illumination light beam **11** has a large value, and so that the path for the light **11** is located farther from the hollow cylinder **21** and the lenses **6***a* to **6***g* than in the first embodiment. A larger space is therefore available in the distal end of the second embodiment. Since the illumination light **11** has a larger cross section than the light **11** applied to the sample **1** in the first embodiment, the sample **1** can be illuminated more than in the case the first embodiment is used.

As shown in FIG. **4**A, the shared lens **41** and the prism **51** are connected by adhesive. The adhesive has the same refractive index as the prism **51**. Therefore, the prism **51** can apply the light **11** to the lens **41** at a desired incident angle, even if it has not been processed with high precision at the surface contacting the lens **41**. Optically connected together, the shared lens **41** and the prism **51** prevent the light scattered by the adhesive, from entering the observation light path. This enables the microscope to provide a high SN-ratio (i.e., observation light/scattered light) image of the sample **1**.

The illumination light **11** is scarcely refracted at the conical outer surface **512** of the prism **51**, to which the light **11** is applied. The prism **51** may be re-designed to incline the surface **512** to increase the incidence angle of the beam **11**. The surface **512** may be a part of the surface of a sphere. Further, the prism **51** may have the same refractive index as the shared lens **41** or may be made of the same glass as the

lens **41**, in order to decrease the aberration resulting from the refraction of the light **11** at the interface between the lens **41** and the prism **51**.

An objective unit **33** which is the third embodiment of the invention will be describe, with reference to FIG. **6**. FIG. **6** is a longitudinal sectional view of the objective unit **33**, taken along a plane containing the axis of the observation light. The objective unit **33** is located on the position on which there is located on the objective unit **3** incorporated in the illumination system of the conventional optical microscope, which is shown in FIG. **7**. In FIG. **6**, the same components as those of the conventional lens unit shown in FIG. **8** are designated at the same reference numerals. The objective unit **33** is an oil immersion one. Oil **40** is filled in the space between a cover glass **30** and the distal end of the unit **33**. The unit **33** has a working distance (WD) of about 0.1 mm.

Fitted in the distal end of the objective unit **33** are a shared lens **41** and a lens-holding frame **60**. The frame **60** is a hollow cylinder closed at the lower end, in which a circular hole is made. The frame **60** is made of material which is greatly transparent to light. The frame **60** therefore acts as a prism.

The shared lens **41** is a sphere with a part cut off, having a cross section larger than half the sphere and a flat circular face whose diameter is shorter than the diameter of the sphere. The lower part of the lens **41** is fitted in the circular hole made in the lower end of the lens-holding frame **60**. The frame **60** is snap-fitted in the lower end of a hollow cylinder **21**, by virtue of an annular projection **211** of the hollow cylinder **21**. Provided in the hollow cylinder **21** are lenses **6***a* to **6***g* and lens-holding frames **20***a* to **20***g*. The lenses **6***a* to **6***g* are held in the frames **20***a* to **20***b*, respectively. The frames **20***a* to **20***g* are fitted in the cylinder **21** and held in place once a lens-holding ring **22** has been fitted into one end of the hollow cylinder **21**.

A hollow cylindrical mirror **43** is fitted into one end of the hollow cylindrical cover **27**. The mirror **43** has a conical inner surface, i.e, an inclined reflecting surface **43***a*. The reflecting surface **43***a* reflects the illumination light **11** having an annular cross section, applying the light **11** onto the sample **1** through the the lens-holding frame **60**.

How the objective unit **33** works will be explained, with reference to FIG. **7**. As shown seen from FIG. **7**, the light emitted from the lamp **7** is focused by the collector lens **9**, forming a light beam which has a circular cross section. Part of the light beam passes through the opening of the mirror **10**. The remaining part of the light beam is reflected downwards from the reflecting surface of the mirror **10** and is used as an illumination light **11**. The illumination light **11** has an annular cross section and is coaxial with the observation-light axis **2**. The light **11** is guided through an annular space located outside the observation path and is applied into the objective unit **33**.

In the objective unit **33**, the illumination light **11** passes through the illumination light path which has an annular cross section. This light path is provided between the cylinder **21** and the hollow cylindrical cover **27** and, hence, surrounds the lenses **6***a* to **6***g*. The illumination light **11** reaches the hollow cylindrical mirror **43**. The inclined surface **43***a* of the mirror **43** reflects the illumination light **11**, applying the light **11** to the lens-holding frame **60**. The light **11** passes through the frame **60** which acts as a prism, reaching the shared lens **41**.

The lens **41** refracts the light **11**. The light **11** thus refracted passes through the oil **40** and the cover glass **30**. The light **11** is therefore applied to the sample **1** mounted on the object glass **70**.

The light reflected from the sample **1**, or the observation light **5**, passes through the cover glass **30**, the oil **40**, the shared lens **41**, the lenses **6***a* to **6***g* and the focusing lens **4**. The observation light reaches the eye lens (not shown), etc, which provides a magnified image of the sample **1**.

The third embodiment attain the same advantage as the first embodiment. Further, the lens-holding frame **60** does not block the illumination light **11** at all because it is made of material transparent to light. The light **11** is therefore applied, in its entirety, onto the sample **1**. Moreover, since frame **60** need not have path hole to guide the illumination light **11**, the frame **60** is rigid enough to hold the lens **41** firmly. In addition, since the frame **60** is transparent, the light **11** is applied to the sample **1** at an angle β with respect to the observation light **5**, as shown in FIG. **5**B. The illumination light beam **11** is thus far from the axis **2** of observation light, and this helps to illuminate the sample **1** more brightly.

The lens-holding frame **60** may be replaced by a plurality of segments which forms a hollow cylinder when combined together.

The present invention is not limited to the embodiments described above. Various changes and modifications can be made. For example, the illumination light **11** may be guided by the lens **6***a* and the frame **20***a* holding the lens **6***a*, not by the shared lens **41** and the frame holding the lens **41** as in the first to third embodiments.

Further, the shared lens **41** may be used to guide only the observation light, not both the observation light and the illumination light **11** as in the first to third embodiments. In this case, the illumination light **11** is replaced by dark-field illumination light such as evanescent illumination light. Still further, the present invention is not limited to oil immersion (liquid immersion system) objective units only. It can also be applied to dry system objective units. Specifically, the first to third embodiments can be converted to dry system type objective units merely by draining the oil **40**. Moreover, the components of the first to third embodiments may be used in various combinations, providing various modified objective units.

Furthermore, the embodiments described above can be modified so long as an illumination light is guided parallel to the observation-light axis **2** through the annular space provided between the hollow cylinder **21** and the hollow cylindrical cover **27**. For example, an annular optical fiber may be located above the annular space, and a laser beam may be applied directly from the optical fiber into the space from above.

As has been described, the objective unit according to the invention is simple in structure and makes good use of an internal space, thanks to the shared lens which guides both the illumination light and the observation light. No lens for applying the illumination light only need not be used, and the illumination light can easily focused on the object of observation. Further, the frame holding the shared lens does not block the illumination light at all; rather it guides the illumination light to the object of observation. Since the frame holding the shared lens has a greater refractive index than the shared lens, it can refracts the illumination light at a large angle to the axis of the observation light. Hence, the illumination light path can be located remote from the other lenses used in the unit and from the frames holding these lenses, whereby a larger space is available in the distal end of the objective unit. A thick beam of illumination light can

therefore be applied, achieving effective incident lighting to illuminate the object brightly.

Thus, the present invention achieves an objective unit which has a large numerical aperture (NA) and a short working distance (WD) as an oil immersion objective unit and which has an illumination light path outside the observation light path which guides an illumination light such that the light is not blocked by lenses or lens-holding frames.

Additional advantages and modifications will readily occur to those skilled in the art. Therefore, the invention in its broader aspects is not limited to the specific details and representative embodiments shown and described herein. Accordingly, various modifications may be made without departing from the spirit or scope of the general inventive concept as defined by the appended claims and their equivalents.

I claim:

1. An objective unit comprising:

a plurality of lenses for guiding observation light reflected from a sample;

an inner frame surrounding and holding said plurality of lenses;

an outer frame surrounding said inner frame;

an annular path provided between said inner frame and said outer frame along which illumination light passes; and

a deflecting member for deflecting the illumination light passing along said annular path to thereby guide the illumination light to the sample;

wherein said plurality of lenses includes a shared lens for allowing passage of the observation light and the illumination light, and

wherein said inner frame includes at least one through hole for guiding the illumination light deflected by said deflecting member to the sample through said shared lens, and at least one transparent member inserted in said at least one through hole.

2. The objective unit according to claim **1**, wherein said at least one transparent member has a greater refractive index than said shared lens.

3. The objective unit according to claim **1**, wherein said inner frame includes a plurality of through holes for guiding the illumination light, and a plurality of transparent members provided in a same number as the plurality of through holes, said plurality of transparent members being inserted in respective ones of said plurality of through holes.

4. The objective unit according to claim **1**, wherein said shared lens and said at least one transparent member are coupled by an adhesive which is transparent to light.

5. The objective unit according to claim **1**, wherein said shared lens and said at least one transparent member are optically coupled.

6. An objective unit comprising:

a plurality of lenses for guiding observation light reflected from a sample;

an inner frame surrounding and holding said plurality of lenses;

an outer frame surrounding said inner frame;

an annular path provided between said inner frame and said outer frame along which illumination light passes; and

a deflecting member for deflecting the illumination light passing along said annular path to thereby guide the illumination light to the sample;

wherein said plurality of lenses includes a shared lens for allowing passage of the observation light and the illumination light, and

wherein said inner frame includes at least one transparent portion for guiding the illumination light deflected by said deflecting member to the sample through said shared lens.

7. The objective unit according to claim **6**, wherein said at least one transparent portion of said inner frame has a greater refractive index than said shared lens.

8. The objective unit according to claim **6**, wherein said shared lens and said at least one transparent portion of said inner frame are coupled by an adhesive which is transparent to light.

9. The objective unit according to claim **6**, wherein said shared lens and said at least one transparent portion of said inner frame are optically coupled.

10. The objective unit according to claim **6**, wherein said inner frame includes an additional through hole for guiding reflected beams of the illumination light reflected from the sample to return the reflected beams to said annular path.

11. An objective unit comprising:

a plurality of lenses for guiding observation light reflected from a sample;

an inner frame surrounding and holding said plurality of lenses;

an outer frame surrounding said inner frame;

an annular path provided between said inner frame and said outer frame along which illumination light passes; and

a deflecting member for deflecting the illumination light passing along said annular path to thereby guide the illumination light to the sample;

wherein said plurality of lenses includes a shared lens for allowing passage of the observation light and the illumination light, and

wherein said inner frame includes a through hole for guiding the illumination light deflected by said deflecting member to the sample through said shared lens.

12. The objective unit according to claim **11**, wherein said inner frame includes an additional through hole for guiding reflected beams of the illumination light reflected from the sample to return the reflected beams to said annular path.

[57] **ABSTRACT**

An objective lens for an endoscope includes a front lens of negative power, an aperture stop, and a rear lens group of positive power in this order from the object side. At least one surface of the front lens group and/or the rear lens group is a compound aspherical lens made of a glass lens and a transparent layer applied to the glass lens surface. A surface of the transparent layer farther from the glass lens is an aspherical surface. The refractive index n of the glass lens to which the transparent layer is applied is more than 1.65 (n>1.65).

OBJECTIVE LENS OF ENDOSCOPE

This application is a continuation of application Ser. No. 08/547,339, filed Oct. 24, 1995, now abandoned.

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to an objective lens for an endoscope or a rigid endoscope.

2. Description of Related Art

In general, an endoscope or a rigid endoscope has a wide angle of view from 90° to 120°. Consequently, distortion caused in the objective lens tends to become large. Generally speaking, the distortion is approximately −36% or −50% when the angle of view is 100° or 120°, respectively. To reduce this distortion, it is known to use an aspherical lens, as disclosed for example, in Japanese Unexamined Patent Publication No. 61-162021.

However, since the diameter of an objective lens for an endoscope must be as small as possible, it is more difficult to treat or polish the aspherical surface, than in a lens for a 35 mm camera. Moreover, in general such a small aspherical lens is produced by a glass molding process which is, however, only applicable to a glass material whose transition temperature is relatively low and which can be easily made soft. An endoscope or rigid endoscope needs a fast objective lens, due to the low quantity of illuminating light used in a human body.

However, a fast objective lens tends to be large in diameter and long in length. In view of this, it is possible to make each lens element of a glass material having a high refractive index, to increase the power thereof, to thereby reduce the number of lens elements. Thus, a short and small diameter objective lens having a wide angle of view can be produced. However, many glass materials having a high refractive index have a high transition temperature, and accordingly, the glass molding process is not suitable. Nevertheless, if the glass molding process is applied, the amount of heat necessary to melt the glass is increased, and hence, energy consumption is increased. This results in an increased time for heating and annealing, the service life of molding dies is shortened, and production costs are increased. In addition, the degree of freedom of design of an objective lens made of a glass which can be easily molded is restricted, and it is difficult to obtain a desired optical performance.

Usually in an objective lens for an endoscope, the power mainly relies upon a front lens group located closer to an object to be observed than an aperture-stop. If a front lens group is eliminated, the overall length of the lens can be reduced. However, if there is no front lens group, the power of the rear lens group must be increased accordingly. This leads to a deterioration in optical performance, for example distortions occur. In order to increase the power of the rear lens group, it is necessary to increase the refractive index thereof. An aspherical lens can advantageously be used to effectively compensate aberrations.

However, glass materials having a high refractive index which can be easily molded to form an aspherical surface are limited, as has already been mentioned above. Consequently, it is difficult to produce an aspherical lens by the molding process with a glass having a high refractive index. Therefore, in practice, it is very difficult to produce a short objective lens for an endoscope, in which little or no distortion occurs.

SUMMARY OF THE INVENTION

It is an object of the present invention to provide a short and simple objective lens for an endoscope, which can be easily produced, has little or no distortion and includes fewer lens elements than conventional objective lenses for endoscopes.

In the basic concept of the present invention, the main lens power is made mainly of a glass and includes an aspherical surface layer made of transparent resin, or the like, which can be easily machined or processed and applied to the glass to form a compound aspherical lens.

According to one aspect of the present invention, there is provided an objective lens for an endoscope comprising a front lens group of negative power, an aperture stop, and a rear lens group of positive power in this order from the object side, wherein at least one lens of one of the front lens group or rear lens group is a compound aspherical lens made of a glass lens having a transparent layer applied to a surface of the glass lens, a surface of the transparent layer farthest from the glass lens being an aspherical surface, and the refractive index n of the glass lens to which the transparent layer is applied is more than 1.65 (n>1.65).

According to another aspect of the present invention, there is provided an objective lens for an endoscope comprising: a front lens group of negative power; an aperture stop; and, a rear lens group of positive power in this order from the object side; wherein at least one lens of each of the front and rear lens groups is a compound aspherical lens made of a glass lens and a transparent layer applied to a surface of the glass lens, a surface of the transparent layer farthest from the glass lens being an aspherical surface, and the refractive index n of the glass lens to which the transparent layer is applied is more than 1.65 (n>1.65).

In the arrangements mentioned above, the front lens group of negative power is provided on the object side of the diaphragm (stop) and the rear lens group of positive power is provided on the image side of the diaphragm.

Consequently, a wide angle of view can be easily obtained with fewer lenses (lens elements).

Moreover, the degree of freedom to select the number of lens surfaces, to which the aspherical surfaces can be applied to correct distortion, is increased, and hence, distortion can be appropriately compensated, taking into account the balance with other aberrations.

According to a modification of the present invention, there is provided an objective lens for an endoscope comprising: a glass cover; an aperture stop; and, a rear lens group of positive power in this order from the object side; wherein at least one lens of the rear lens group is a compound aspherical lens made of a glass lens and a transparent layer applied to a surface of the glass lens, a surface of the transparent layer farthest from the glass lens being an aspherical surface, and the refractive index n of the glass lens of the compound aspherical lens being more than 1.65 (n>1.65).

According to another aspect of the present invention, there is provided an objective lens for an endoscope comprising: an aperture stop; and, a rear lens group of positive power in this order from the object side; wherein at least one lens of said rear lens group is a compound aspherical lens made of a glass lens and a transparent layer applied to a surface of the glass lens, a surface of the transparent layer farthest from the glass lens being an aspherical surface, and the refractive index n of the glass lens of the compound aspherical lens being more than 1.65 (n>1.65).

According to the present invention, the lens is comprised of an aperture stop and a rear lens group of positive power in this order from the object side, with an absence of a front lens group, wherein at least one lens of the rear lens group is made of a compound aspherical lens comprised of a glass lens and a transparent member applied to the surface of the glass lens; the surface of the transparent member that is not adhered to the glass lens is an aspherical surface; and, the glass lens of the compound aspherical lens is made of a glass material having a refractive index n of more than 1.65 (n>1.65).

Thus, a short and small diameter objective lens for an endoscope can be provided.

In addition, according to the present invention, the aspherical surface effectively reduces various aberrations including spherical aberration, axial chromatic aberration, lateral chromatic aberration, astigmatism, and distortion.

The present disclosure relates to subject matter contained in Japanese patent application Nos. 06-260702 (filed on Oct. 25, 1994) and 06-283811 (filed on Nov. 17, 1994) which are expressly incorporated herein by reference in their entireties.

BRIEF DESCRIPTION OF THE DRAWINGS

The present invention will be discussed below in detail with reference to the accompanying drawings, in which:

FIG. **65** shows diagrams of various aberrations of the objective lens shown in FIG. **64**.

DESCRIPTION OF THE PREFERRED EMBODIMENT

FIGS. **1** and **2** show a first embodiment of the present invention; FIGS. **3** and **4** show a 2nd embodiment; FIGS. **5** and **6** show a 3rd embodiment; FIGS. **7** and **8** show a 4th embodiment; FIGS. **9** and **10** show a 5th embodiment; FIGS. **11** and **12** show a 6th embodiment; FIGS. **13** and **14** show a 7th embodiment; FIGS. **15** and **16** show an 8th embodiment; FIGS. **17** and **18** show a 9th embodiment; FIGS. **19** and **20** show a 10th embodiment; FIGS. **21** and **22** show an 11th embodiment; FIGS. **23** and **24** show a 12th embodiment; FIGS. **25** and **26** show a 13th embodiment; FIGS. **27** and **28** show a 14th embodiment; FIGS. **29** and **30** show a 15th embodiment; FIGS. **31** and **32** show a 16th embodiment; FIGS. **33** and **34** show a 17th embodiment; FIGS. **35** and **36** show an 18th embodiment; FIGS. **37** and **38** show a 19th embodiment; FIGS. **39** and **40** show a 20th embodiment; FIGS. **41** and **42** show a 21st embodiment; FIGS. **43** and **44** show a 22nd embodiment; FIGS. **45** and **46** show a 23rd embodiment; FIGS. **47** and **48** show a 24th embodiment; FIGS. **49** and **50** show a 25th embodiment; FIGS. **51** and **52** show a 26th embodiment; FIGS. **54** and **55** show a 27th embodiment; FIGS. **56** and **57** show a 28th embodiment; FIGS. **58** and **59** show a 29th embodiment; FIGS. **60** and **61** show a 30th embodiment; FIGS. **62** and **63** show a 31st embodiment; and, FIGS. **64** and **65** show a 32nd embodiment, respectively.

In the 1st to 26th embodiments, the front lens group is comprised of a first lens group I; and, the rear lens group is comprised of either only a second lens group II, or a second lens group II and a third lens group III.

In the first (FIG. **1**) and second (FIG. **3**) embodiments, the terminal surfaces of the glass lenses of the first lens group I and the third lens group III are provided with aspheric resin layers. Namely, the glass lens **11** (FIG. **1**) or **21** (FIG. **3**) is located closest to an object to be photographed, and the second surface No. **2** thereof on the image side is provided with a transparent resin layer **12** (or **22**) applied thereto, which is formed by pressing a transparent synthetic resin material. The third surface No. **3**, belonging to the transparent resin layer, on the image side is an aspherical surface. The glass lenses **15** (FIG. **1**) and **25** (FIG. **3**) of the third lens group III, that are located furthest from the object (i.e. on the image side), are provided on the terminal surfaces (eighth surfaces) No. **8**, with transparent resin layers **16** (FIG. **1**) and **26** (FIG. **3**) formed by pressing a transparent synthetic resin material. The ninth surfaces No. **9**, belonging to the transparent resin layers **16** and **26**, on the image side are aspherical surfaces. The aperture stop **13S** (**23S**) is provided between the first lens group I and the second lens group II.

In the third embodiment (FIG. **5**), the terminal surface of the glass lens of the first lens group I is provided with an aspherical resin layer. Namely, the glass lens **31** is located closest to the object and is provided, on the second surface No. **2** thereof on the image side, with a transparent resin layer **32** formed by pressing a synthetic resin material. The surface No. **3**, belonging to the transparent resin layer, on the image side is an aspherical surface. The aperture stop **33S** is provided between the first lens group I and the second lens group II.

In the fourth (FIG. **7**), fifth (FIG. **9**), and sixth (FIG. **11**) embodiments, the terminal surfaces of the glass lenses of the third lens group III furthest from the object are provided with aspherical resin layers. Namely, the glass lenses **44** (FIG. **7**), **54** (FIG. **9**), and **64** (FIG. **11**) are located closest to the image side, and the seventh (terminal) surfaces No. **7** thereof furthest from the object are each provided with a transparent resin layer **45** (**55** or **65**) applied thereto, which is formed by pressing a transparent synthetic resin material. The eighth surfaces No. **8**, belonging to the transparent resin layers, on the image side are aspherical surfaces. The

aperture stop **42S** (**52S** or **62S**) is provided between the first lens group I and the second lens group II.

In the seventh embodiment (FIG. **13**), the terminal surfaces of the glass lenses of the first and third lens groups I and III are provided with aspherical resin layers. Namely, the glass lens **71** is located closest to the object, and the second surface No. **2** thereof on the image side is provided with a transparent resin layer **72** applied thereto, which is formed by pressing a transparent synthetic resin material. The third surface No. **3**, belonging to the transparent resin layer, on the image side is an aspherical surface. The glass lens **75** of the third lens group III that is located furthest from the object (i.e., on the image side) is provided on the terminal surface (eighth surface) No. **8**, with a transparent resin layer **76** formed by pressing a transparent synthetic resin material. The ninth surface No. **9**, belonging to the transparent resin layer **76**, on the image side is an aspherical surface. The aperture stop **73S** is provided between the first lens group I and the second lens group II.

In the eighth embodiment (FIG. **15**), the terminal surface of the glass lens of the first lens group I is provided with an aspherical resin layer. Namely, the glass lens **81** is located closest to the object and is provided, on the second surface No. **2** thereof on the image side, with a transparent resin layer **82** formed by pressing a synthetic resin material. The surface No. **3**, belonging to the transparent resin layer **82**, on the image side is an aspherical surface. The aperture stop **83S** is provided between the first lens group I and the second lens group II.

In the ninth (FIG. **17**) and eleventh (FIG. **21**) embodiments, the terminal surface of the glass lens of the third lens group III furthest from the object is provided with an aspherical resin layer. Namely, the glass lenses **94** and **114** are located closest to the image and are provided, on the seventh surfaces No. **7** thereof on the image side, with transparent resin layers **95** and **115** which are formed by pressing a synthetic resin material. The eighth surfaces No. **8**, belonging to the transparent resin layers, on the image side are aspherical surfaces. The aperture stops **92S** and **112S** are respectively provided between the first lens group I and the second lens group II.

In the tenth embodiment (FIG. **19**), the terminal, surface of the glass lens of the second lens group II is provided with an aspherical resin layer. Namely, the glass lens **102** of the second lens group II is provided, on the fourth surface No. **4** thereof on the image side, with a transparent resin layer **103** formed by pressing a synthetic resin material. The fifth surface No. **5**, belonging to the transparent resin layer, on the image side is an aspherical surface. The aperture stop **102S** is provided between the first lens group I and the second lens group II.

In the twelfth embodiment (FIG. **23**), the lens of the first lens group I on the object side is made of a glass lens **121** which is provided on the surface thereof on the image side with a transparent resin layer **122** formed by pressing a synthetic resin material. The third surface No. **3**, belonging to the transparent resin layer, on the image side is an aspherical surface. The aperture stop **124S** is provided between the first lens group I and the second lens group II.

In the thirteenth embodiment (FIG. **25**), the lens of the third lens group III on the image side is a glass lens **135** which is provided on the surface thereof on the image side with a transparent resin layer **136** formed by pressing a synthetic resin material. The tenth surface No. **10**, belonging to the transparent resin layer **136**, on the image side is an aspherical surface. The aperture stop **133S** is provided between the first lens group I and the second lens group II.

The fourteenth to twentieth embodiments are all applied to an electronic endoscope. In these embodiments, an image sensor, such as a CCD image pickup device (not shown) is used instead of an optical fiber bundle. To this end, a glass cover (flat plate) is provided just in front of the image surface and is closely adhered to the image sensor by an adhesive. In the illustrated embodiments, the rearmost two optical elements are glass covers. Thus, the back focal distance fB is 0 (zero).

In the fourteenth embodiment (FIG. **27**), the first lens group I is comprised of a single glass lens **141** which is provided on the surface thereof on the image side with a transparent resin layer **142** formed by pressing a synthetic resin material. The third surface No. **3**, belonging to the transparent resin layer, on the image side is an aspherical surface. The aperture stop **143S** is provided between the first lens group I and the second lens group II.

In the fifteenth embodiment (FIG. **29**), the lens of the first lens group I on the image side is a glass lens **152** which is provided, on the surface thereof on the image side, with a transparent resin layer **153** formed by pressing a synthetic resin material. The fifth surface No. **5**, belonging to the transparent resin layer, on the image side is an aspherical surface. The aperture stop **154S** is provided between the first lens group I and the second lens group II.

In the sixteenth embodiment (FIG. **31**), the lens of the first lens group I on the object side is made of a glass lens **161** which is provided, on the surface thereof on the image side, with a transparent resin layer **162** formed by pressing a synthetic resin material. The third surface No. **3**, belonging to the transparent resin layer **162**, on the image side is an aspherical surface. The aperture stop **164S** is provided between the first lens group I and the second lens group II.

In the seventeenth embodiment (FIG. **33**), the lens of the first lens group I on the image side is made of a glass lens **172** which is provided, on the surface thereof on the image side, with a transparent resin layer **173** formed by pressing a synthetic resin material. The fifth surface No. **5**, belonging to the transparent resin layer **173**, on the image side is an aspherical surface. The aperture stop **174S** is provided between the first lens group I and the second lens group II.

In the eighteenth embodiment (FIG. **35**), the lens of the first lens group I on the image side is made of a glass lens **181** which is provided, on the surface thereof on the image side, with a transparent resin layer **182** formed by pressing a synthetic resin material. The third surface No. **3**, belonging to the transparent resin layer **182**, on the image side is an aspherical surface. The aperture stop **183S** is provided between the first lens group I and the second lens group II.

In the nineteenth embodiment (FIG. **37**), the lens of the first lens group I on the image side is made of a glass lens **192** which is provided on the surface thereof on the image side with a transparent resin layer **193** formed by pressing a synthetic resin material. The fifth surface No. **5**, belonging to the transparent resin layer **193**, on the image side is an aspherical surface. The aperture stop **194S** is provided between the first lens group I and the second lens group II.

In the twentieth embodiment (FIG. **39**), the lens of the first lens group I on the object side is made of a glass lens **201** which is provided, on the surface thereof on the image side, with a transparent resin layer **202** formed by pressing a synthetic resin material. The third surface No. **3**, belonging to the transparent resin layer **202**, on the image side is an aspherical surface. The aperture stop **204S** is provided between the first lens group I and the second lens group II.

In the twenty first (FIG. **41**) and twenty second (FIG. **43**) embodiments, the lens of the second lens group II on the

object side is made of a glass lens **213** (or **223**) which is provided, on the surfaces thereof on the image side, with a transparent resin layer **214** (or **224**) formed by pressing a synthetic resin material. The surfaces of the transparent resin layers **214** and **224** on the image side are aspherical surfaces. The aperture stops **213**S and **223**S are respectively provided between the first lens group I and the second lens group II.

In the twenty third embodiment (FIG. **45**), the lens of the third lens group III on the image side is made of a glass lens **235** which is provided, on the surface thereof on the image side, with a transparent resin layer **236** formed by pressing a synthetic resin material. The tenth surface No. **10**, belonging to the transparent resin layer **236**, on the image side is an aspherical surface. The aperture stop **233**S is provided between the first lens group I and the second lens group II.

In the twenty fourth embodiment (FIG. **47**), the lens of the second lens group II on the object side is made of a glass lens **242** which is provided, on the surface thereof on the image side, with a transparent resin layer **243** formed by pressing a synthetic resin material. The fifth surface No. **5**, belonging to the transparent resin layer **243**, on the image side is an aspherical surface. The aperture stop **242**S is provided between the first lens group I and the second lens group II. In the twenty fifth (FIG. **49**) and twenty sixth (FIG. **51**) embodiments, the lens of the third lens group III on the image side is made of a glass lens **255** (or **265**) which is provided, on the surfaces thereof on the image side, with a transparent resin layer **256** (or **266**) formed by pressing a synthetic resin material. The tenth surfaces, belonging to the transparent resin layers **256** and **266**, on the image side are aspherical surfaces. The aperture stops **253**S and **263**S are respectively provided between the first lens group I and the second lens group II.

In the above mentioned embodiments, the angle of view **2**w is **2**w=90° (in the 23rd embodiment), **2**w=100° (in the 1st–5th, and 7th–22nd embodiments), **2**w=110° (in the 24th embodiment), **2**w=120° (in the 6th, 11th, 25th, and 26th embodiments), respectively. The F-number is F=2.9 (in the 1st–14th, 21st–23rd, and 25th embodiments), F=5.6 (in the 15th–20th embodiments), F=1.8 (in the 24th embodiment), and F=3.6 (in the 26th embodiment), respectively. The F-number F refers to a value corresponding with an object at infinite, and the angle of view **2**w refers to a value corresponding with a predetermined object distance (design value) which is 10.0 mm (in the 1st–13th, 23rd, 25th and 26th embodiments), 6.0 mm (in the 14th–20th embodiments), or 8.0 mm (in the 21st, 22nd, and 24th embodiments).

The 27th to 31st embodiments are applied to an objective lens for a fiber scope, and the 32nd embodiment is applied to an objective lens for an electronic scope, respectively. The 27th embodiment includes a glass cover (lens group I), but there is no glass cover in the 28th to 32nd embodiments. In the 27th and 28th embodiments, the rear lens group is comprised of a single lens group II, I, respectively. In the 29th through 32nd embodiments, the rear lens group is comprised of two lenses. Namely, the rear lens group is comprised of two positive lens groups I, II (in the 29th–31st embodiments), and a positive lens group and a negative lens group in combination, in this order from the object side in the 32nd embodiment, respectively. Note that although only the optical elements are shown in the drawings, the optical elements are secured to or held by a lens barrel, etc., at the front end of an associated endoscope or rigid endoscope, etc.

In the twenty seventh and twenty eighth embodiments, the rear lens groups **272** and **281** are each made of a glass lens group II, I whose refractive index n is larger than 1.65 (n>1.65). The glass lenses are provided, on the fourth and second surfaces No. **4** and No. **2** thereof on the image side, with transparent resin layers **273** and **282**, respectively formed by pressing a synthetic resin material. The fifth and third surfaces No. **5** and No. **3**, belonging to the transparent resin layers **273** and **282**, on the image side (that are not adhered to the lens surfaces No. **4** and No. **2** of the glass lenses **272** and **281**) are both aspherical surfaces to form compound aspherical lenses comprised of the rear lens group **272** and the transparent layer **273**; and, the rear lens group **281** and the transparent layer **282**, respectively. The aperture stops **272**S and **281**S are respectively provided in the space located closer to the object than the rear lens groups **272** and **281**, respectively.

In the twenty ninth embodiment, at least the second lens **292**, of the two rear lenses (lens elements) **291** and **292**, is made of a glass lens whose refractive index n is more than 1.65 (n>1.65). The glass lens is provided, on the fourth surface No. **4** thereof on the image side, with a transparent resin layer **293** formed by pressing a synthetic resin material. The fifth surface No. **5**, belonging to the transparent resin layer **293**, on the image side (that is not adhered to the lens surface No. **4** of the second lens **292**) is an aspherical surface to form a compound aspherical lens comprised of the second lens **292** and the transparent layer **293**. The aperture stop **291**S is provided in the space located closer to the object than the first lens **291**.

In the thirtieth embodiment, among the first lens **301** of positive power, the second lens **302** of negative power, and the third lens **303** of positive power, of the rear lens group, at least the third lens **303** is made of a glass lens whose refractive index n is more than 1.65 (n>1.65). The glass lens **303** is provided, on the fifth surface No. **5** thereof on the image side, with a transparent resin layer **304** formed by pressing a synthetic resin material. The sixth surface No. **6**, belonging to the transparent resin layer **304**, on the image side (that is not adhered to the lens surface No. **5** of the third lens **303**) is an aspherical surface to form a compound aspherical lens comprised of the third lens **303** and the transparent layer **304**. The aperture stop **301**S is provided in the space located closer to the object than the first lens **301**.

In the thirty first embodiment, among the first lens **311** of positive power, the second lens **313** of negative power, and the third lens **314** of positive power, of the rear lens group, the first lens **311** is made of a glass lens whose refractive index n is more than 1.65 (n>1.65). The glass lens **311** is provided, on the second surface No. **2** thereof on the image side, with a transparent resin layer **312** formed by pressing a synthetic resin material. The third surface No. **3**, belonging to the transparent resin layer **312**, on the image side (that is not adhered to the lens surface No. **2** of the first lens **311**) is an aspherical surface to form a compound aspherical lens comprised of the first lens **311** and the transparent layer **312**. The aperture stop **311**S is provided in the space located closer to the object than the first lens **311**.

In the thirty second embodiment, among the first lens **321** of positive power, the second lens **323** of negative power, and the third lens **324** of positive power, of the rear lens group, at least the first lens **321** is made of a glass lens whose refractive index n is more than 1.65 (n>1.65). The glass lens **321** is provided, on the second surface No. **2** thereof on the image side, with a transparent resin layer **322** formed by pressing a synthetic resin material. The third surface No. **3**, belonging to the transparent resin layer **322**, on the image side (that is not adhered to the lens surface No. **2** of the first lens) is an aspherical surface to form a compound aspherical

lens comprised of the first lens **321** and the transparent layer **322**. The aperture stop **321S** is provided in the space located closer to the object than the first lens **321**. Note that numerals **325** and **326** designate the glass cover and the adhesive layer for a CCD image pickup device used in an electronic endoscope.

In the embodiments mentioned above, a glass product under the trade name "LAH58" marketed by OHARA K. K., can be used as the glass lens, in view of a chemical resistance, a demand for correction of aberrations, polishing efficiency and machinability, etc. The LAH58 has a high transition point (transition temperature) equal to 730° C. and accordingly no molding process can be effectively applied to the LAH58.

Moreover, no glass material having the substantially same refractive index and Abbe number as those of the LAH58 and having a transition point low enough to apply the glass molding process exists. Although the transparent aspherical surface layer is made of thermosetting resin in the above-mentioned embodiments, it is possible to use other resin materials, such as optically setting resin, etc. The refractive index of resin material to be used is not limited to a specific value.

Numerical data of the 1st–32nd embodiments are shown in Tables below and aberrations thereof are shown in FIGS. **2**, **4**, **6**, **8**, **10**, **12**, **14**, **16**, **18**, **20**, **22**, **24**, **26**, **28**, **30**, **32**, **34**, **36**, **38**, **40**, **42**, **44**, **46**, **48**, **50**, **52**, **55**, **57**, **59**, **61**, **63**, and **65**. In the drawings and tables, "SA" designates the spherical aberration; "SC" the sine condition; "d-line", "g-line" and "C-line" the chromatic aberrations represented by the spherical aberrations, and the transverse chromatic aberrations, at the respective wavelengths; and "S" and "M" the sagittal ray and meridional ray, respectively.

Furthermore, "F_{NO}" designates the f-number; "f" the focal length (mm); "M" the lateral magnification, "W" the half angle of view (degree); "f_B" the back focal distance (mm); "r" the radius of curvature of each lens surface (mm); "d" the distance between the surfaces (mm); "n_d" the refractive index of the d-line; and "vd" the Abbe number of the d-line, respectively.

The distortion in the 1st–11th, 25th and 26th embodiments is around −25% to −8%, and the distortion in the 12th–19th, 21st, 22nd, and 24th embodiments, is around −34% to −14%. If this distortion is corrected to be almost 0%, the quantity of light at the peripheral portion of the lens is reduced. FIG. **53**, shows a relationship between the distortion and the ratio (%) of the quantity of light (ratio of the quantity of paraxial light to the quantity of light at the peripheral portion) when the angle of view is 100°. It can be seen from FIG. **53** that, even at the same angle of view, if the distortion is reduced, the quantity ratio is reduced so that the peripheral portion becomes dark. Therefore, in the embodiments mentioned above, the distortion remains to prevent the quantity of light at the peripheral portion from decreasing.

However, in the 20th and 23rd embodiments, the distortion is almost 0%, but nevertheless, the quantity of light at

the peripheral portion is about 30%. Namely, there is a sufficient quantity of light at the peripheral portion. This effect is achieved by the fact that, in the 20th embodiment in which the lens has a wide angle of view, the first lens has a large negative power, so that the aperture efficiency at the peripheral portion is improved owing to the aspherical terminal surface; and in the 23rd embodiment, the lens surfaces of the first lens group I are concentric with respect to the aperture stop **233**S, and hence, the aperture efficiency is improved.

It can be also seen that in the 27th and 28th embodiments, astigmatism, curvature of the field, and distortion are effectively compensated, in comparison with a lens having no aspherical surface.

In the 29th embodiment, the rear lens group II is split into the first lens **291** and the second lens **292**, so that the radius of curvature r of each of the first and second lenses can be increased in comparison with the 1st and 2nd embodiments. Thus, not only can the lens be more easily produced, but also spherical aberrations can be reduced. Moreover, a comparison with a corresponding lens having no aspherical surface, distortion can be reduced from −27% to −19%.

In the 30th and 31st embodiments, the lenses **302** and **313** of the rear lens group II on the object side are cemented to the lenses **303** and **314** thereof on the image side, respectively, and hence, chromatic aberrations can be reduced.

Moreover, since the surfaces of the transparent layers **304** and **312** that are not adhered to the glass lenses are aspherical surfaces, distortion can be reduced in the 30th embodiment and astigmatism can be reduced in the 31st embodiment, respectively.

In the 32nd embodiment (FIGS. **64** and **65**) which is applied to an objective lens for an electronic endoscope, an image pickup device such as a CCD (not shown) is closely connected to the adhesive layer **326** located furthest from the object. In the 32nd embodiment in which the image height is greater than, for example, that of the 31st embodiment at the same angle of view, the focal length becomes longer than that in the 31st embodiment, if the lens arrangement is identical. This results in an increase in the overall length of the lens. To prevent this, the lens group furthest from the object has a negative power, and thus, the overall length of the lens can be reduced. The length of the lens is reduced by about 20% in comparison with the 31st embodiment. Furthermore, the distortion can be reduced.

As can be understood from the above discussion, according to the present invention, since the transparent resin layer is formed on the surface of the glass lens and the surface of the transparent resin layer is an aspherical surface, an objective lens for an endoscope having an appropriate distortion can be obtained.

Moreover, since the surfaces of the glass lens can be aspherical surfaces in the present invention, not only can the glass lens be easily produced, but also the glass to be used is not limited to a specific material. Consequently, according to the present invention, even a glass material of which it is difficult to produce an aspherical surface by the molding process can be used, thus increasing the degree of freedom of design and production process.

What is claimed is:

1. An objective lens for an endoscope comprising:

a front lens group of negative power;

an aperture stop; and,

a rear lens group of positive power in this order from the object side;

wherein at least one lens of one of said front lens group or rear lens group is a compound aspherical lens comprising a glass lens and a transparent resin layer applied to a surface of said glass lens, a surface of said transparent resin layer farthest from said glass lens being an aspherical surface, and a refractive index n of said glass lens to which said transparent resin layer is applied being more than 1.65 (n>1.65)

wherein a thickness of said glass lens on which said transparent resin layer is formed is larger on an optical axis of said objective lens than a thickness of said transparent resin layer.

2. An objective lens for an endoscope according to claim **1**, wherein said front lens group is comprised of said compound aspherical lens.

3. An objective lens for an endoscope according to claim **1**, wherein said front lens group is comprised of a first lens group having negative power, and said rear lens group is comprised of a second lens group having positive power and a third lens group having positive power.

4. An objective lens for an endoscope according to claim **1**, wherein said rear lens group is comprised of said compound aspherical lens.

5. An objective lens for an endoscope according to claim **1**, wherein said front lens group is comprised of a first lens group having negative power, and said rear lens group is comprised of a second lens group having positive power and a third lens group having negative power.

6. An objective lens of an endoscope comprising:

a front lens group of negative power;

an aperture stop; and,

a rear lens group of positive power in this order from the object side;

wherein at least one lens of said each of said front and rear lens groups is a compound aspherical lens group is a compound aspherical lens comprising a glass lens and a transparent resin layer applied to a surface of said glass lens, a surface of said transparent resin layer farthest from said glass lens being an aspherical surface, and a refractive index n of said glass lens to which said transparent resin layer is applied being more than 1.65 (n>1.65);

wherein a thickness of said glass lens on which said transparent resin layer is formed is larger on an optical axis of said objective lens than a thickness of said transparent resin layer.

7. An objective lens for an endoscope according to claim **6**, wherein said front lens group is comprised of a first lens group having negative power, and said rear lens group is comprised of a second lens group having positive power and a third lens group having positive power.

8. An objective lens of an endoscope comprising:

a glass cover;

an aperture stop; and,

a rear lens group of positive power in this order from the object side;

wherein at least one lens of said rear lens group is a compound aspherical lens comprising a glass lens and a transparent resin layer applied to a surface of said glass lens, a surface of said transparent resin layer farthest from said glass lens being an aspherical surface, and a refractive index n of said glass lens of said compound aspherical lens being more than 1.65 (n>1.65);

wherein a thickness of said glass lens on which said transparent resin layer is formed is larger on an optical

axis of said objective lens than a thickness of said transparent resin layer.

9. An objective lens for an endoscope according to claim **8**, wherein said rear lens group is made of a single compound aspherical lens.

10. An objective lens of an endoscope comprising:

an aperture stop; and

a rear lens group of positive power in this order from the object side;

wherein at least one lens of said rear lens group is a compound aspherical lens comprising a glass lens and a transparent resin layer applied to a surface of said glass lens, a surface of said transparent resin layer farthest from said glass lens being an aspherical surface, and a refractive index n of said glass lens of said compound aspherical lens being more than 1.65 (n>1.65);

wherein a thickness of said glass lens on which said transparent resin layer is formed is larger on an optical axis of said objective lens than a thickness of said transparent resin layer.

11. An objective lens for an endoscope according to claim **10**, wherein said rear lens group is made of a single compound aspherical lens.

12. An objective lens for an endoscope according to claim **10**, wherein said rear lens group is comprised of a first lens group having positive power and a second lens group having positive power, at least one of said first and second lens groups being provided with said compound aspherical lens.

13. An objective lens for an endoscope according to claim **10**, wherein said rear lens group is comprised of a first lens group having positive power and a second lens group having negative power, at least one of said first and second lens groups being provided with said compound aspherical lens.

14. An objective lens for an endoscope according to claim **12**, wherein said first lens group is constituted by said compound aspherical lens.

15. The objective lens for an endoscope according to claim **1**,

wherein a radius of curvature of said surface of said glass lens on which said transparent resin layer is formed, and a paraxial curvature of an aspherical surface of said transparent resin layer, have the same sign.

16. The objective lens for an endoscope according to claim **1**,

wherein said transparent resin layer is formed by pressing a transparent synthetic resin material.

17. The objective lens for an endoscope according to claim **6**,

wherein a radius of curvature of said surface of said glass lens on which said transparent resin layer is formed, and a paraxial curvature of an aspherical surface of said transparent resin layer, have the same sign.

18. The objective lens for an endoscope according to claim **6**,

wherein said transparent resin layer is formed by pressing a transparent synthetic resin material.

19. The objective lens for an endoscope according to claim **8**,

wherein a radius of curvature of said surface of said glass lens on which said transparent resin layer is formed, and a paraxial curvature of an aspherical surface of said transparent resin layer, have the same sign.

20. The objective lens for an endoscope according to claim **8**,

wherein said transparent resin layer is formed by pressing a transparent synthetic resin material.

21. The objective lens for an endoscope according to claim **10**,

wherein a radius of curvature of said surface of said glass lens on which said transparent resin layer is formed, and a paraxial curvature of an aspherical surface of said transparent resin layer, have the same sign.

22. The objective lens for an endoscope according to claim **10**,

wherein said transparent resin layer is formed by pressing a transparent synthetic resin material.

[57] **ABSTRACT**

A method for designing an objective lens apparatus formed by at least two lenses, a first lens and a second lens, which includes the steps of: measuring aberration which occurs when a light beam is converged by the first lens; setting the first lens is set such that the aberration occurring in the first lens satisfies Maréchal's criterion, in accordance with the measurement results; measuring aberration which occurs when a light beam is converged by the first lens and the second lens; and setting the second lens such that the aberrations occurring in the first lens and the second lens satisfy Maréchal's criterion, in accordance with the measurement results. Accordingly, an objective lens apparatus with a small aberration and a large numerical aperture NA can be designed by this method.

LENS DESIGNING METHOD AND OBJECTIVE LENS APPARATUS WITH TWO LENSES

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention broadly relates to a lens designing method, and, more particularly, to a lens designing method for separately determining the aberrations of a first lens and a second lens forming a two lens assembly which allows the numerical aperture NA to be increased and records or reproduces information of two recording media having different substrate thicknesses.

2. Description of the Related Art

In recent years, the moving picture expert group (MPEG) system has put into practical use a technique for performing recording and reproducing operations on a recording medium by compressing image signals and audio signals to a high density. In the audio visual (AD) field, the digital video disk (DVD) is drawing attention as the next generation optical disk recording medium, while in the computer field, the optical disk for high-capacity recording by opto-magnetic recording method or phase change method is drawing attention as the next generation optical disk recording medium. A DVD for recording thereon image signals and audio signals based on MPEG and an optical disk for recording thereon a large quantity of data than was previously possible have been proposed.

Accordingly, in order to record digital data at a high density onto, for example, a DVD or other recording media allowing high capacity recording, it is necessary to decrease the size of the spot formed by the light beam compared to the sizes of spots formed on conventional recording media such as compact disks (CD).

When the spot size of the light beam has radius R, the objective lens has an exit angle θ, and the light beam has a wavelength λ., the radius R of the spot size of the light beam is roughly:

$$R=0.32\lambda/\mathrm{SIN}\ \theta \quad (1)$$

From Formula (1), the spot size of the light beam is reduced by decreasing the wavelength λ of the light beam and increasing the numerical aperture NA of the objective lens (SIN θ (=n*SIN θ: In air, the index of refraction N is 1).

Although the numerical aperture NA can be made larger by increasing the diameter of the objective lens, this not only results in a larger optical head which records or reproduces information on and from a disk, but also makes it difficult to perform focusing control and tracking control operations due to a larger mass.

To overcome the above-described problems, the use of a solid immersion lens has been proposed, which is disclosed, for example, in U.S. Pat. No. 5,125,750, to irradiate a recording light beam or a reproducing light beam onto a disk.

In the proposal, as illustrated for example in FIG. **16**, a light beam is converged by an objective lens L1 and impinges upon a solid immersion lens having a spherical light-entering surface and a planar light-exiting surface. From the objective lens L1, the light beam impinges perpendicular to the spherical surface of the solid immersion lens L2, so that the light beam converges at the center of the planar light-exiting surface. Accordingly, when the index of refraction of the solid immersion lens L2 is n, the numerical aperture NA of the objective lens L1 can be made substantially n times the original value.

However, since it is actually necessary to converge the light beam from the solid immersion lens L2 onto a disk (not shown), the thickness of the solid immersion lens L2 is set at a value which is smaller by an amount corresponding to the thickness of the substrate of the disk, such that the light beam actually converges on the disk.

In order to obtain a large NA, the light beam from the objective lens L1 is slightly refracted at the spherical surface of the solid immersion lens L2, as shown in FIG. **17**.

In order to produce an objective lens apparatus with, for example, a single lens in order to converge the light beam on the disk, it is necessary to form the spherical surface of the objective lens apparatus into a perfectly spherical surface to correct wave aberration of the objective lens apparatus. Therefore, it is difficult to precisely produce the die used to produce a glass molded objective lens.

Therefore, accurate production of an objective lens is ordinarily achieved by repeating the processes of measuring the aberration occurring in the objective lens formed by a predetermined die using, for example, an interferometer, modifying the die of the objective lens based on the measurement results, and producing an objective lens using the modified die, when necessary.

However, when the lens apparatus for converging the light beam is formed by a two lens assembly as described above, it becomes necessary to produce each lens such that no aberration occurs when these two lenses are combined. The individual lenses obviously have predetermined aberrations, so that it is difficult to use the conventional producing method which consists in using, for example, an interferometer to measure the aberrations occurring in the two combined lenses and modifying the dies used for producing the lenses, based on the measurement results. In addition, since the individual lenses have predetermined aberrations when an aberration occurs in the produced two lens assembly, it becomes difficult to judge which lens needs to be corrected for aberration and the manner in which the lens needs to be corrected. As a result, the aberration of the produced two lens assembly cannot be easily corrected, thus making it difficult to produce the two lens assembly based exactly on the design values.

SUMMARY OF THE INVENTION

Accordingly, in view of the above-described problems, an object of the present invention is to make it possible to separately determine the aberration of each lens of a two lens assembly, and separately produce each lens, thereby facilitating production of a two lens assembly having no aberration.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a block diagram showing the construction of an embodiment of a recording medium reproducing apparatus **1** to which a lens designing method in accordance with the present invention is applied;

FIG. **2** is a diagram showing the construction of the optical pickup **23** of an embodiment in accordance with the present invention.

FIG. **3** is an enlarged view of the actuating portion of the two lenses of the optical pickup **23**.

FIG. **4** is a diagram showing the construction of a two lens assembly in Embodiment 1 of the present invention.

FIG. **5** is a diagram showing the first lens LA-1 of the two lens assembly of FIG. **4** moved out of an optical path.

FIG. **6** is a diagram showing the construction of a two lens assembly in Embodiment 2 of the present invention.

FIG. **7** is a diagram showing the second lens LB-2 of the two lens assembly of FIG. **6** moved out of an optical path.

FIG. **8** is a diagram showing the optical path when the two lens assembly of FIG. **4** is used.

FIG. **9** is a diagram showing the aberration of the second lens LB-1 of FIG. **8** with respect to the substrate **63** being measured.

FIG. **10** is a diagram illustrating the aberration of the first lens LA-1 alone.

FIG. **11** is a diagram showing the aberration of the first lens LA-1 of FIG. **8** being measured.

FIG. **12** is a diagram showing the optical path when the two lens assembly of FIG. **6** is used.

FIG. **13** is a diagram showing the aberration of the first lens LA-2 of FIG. **12** with respect to the substrate **63** being measured.

FIG. **14** is a diagram illustrating the aberration of the second lens LB-2 alone.

FIG. **15** is a diagram showing the aberration of the second lens LB-2 of FIG. **12** being measured.

FIG. **16** is a diagram illustrating the principle of a solid immersion lens.

FIG. **17** is a diagram showing the solid immersion lens being in actual use.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

FIG. **1** is a block diagram showing the construction of an embodiment of a recording medium reproducing apparatus **1** to which a lens designing method in accordance with the present invention is applied.

The spindle motor **21** is such as to rotate a disk **2** in accordance with a command generated from a rotation control circuit **22** which drives the spindle motor **21** in accordance with a command generated from a control circuit **28**.

The optical pickup **23** causes convergence of a light beam onto an information recording layer of the disk **2** in order to convert the light beam reflected from the information recording layer of the disk **2** into a reproduction signal which is output to a signal processing circuit **27**.

The thread motor **24** causes the optical pickup **23** to move to the position of the desired track of the information recording layer of the disk **2**.

The thread motor control circuit **25** causes the thread motor **24** to be driven in accordance with a command from the control circuit **28**.

The pickup control circuit **26** controls the focusing actuator and the tracking actuator in the optical pickup **23** in accordance with a command from the control circuit **28**.

The signal processing circuit **27** demodulates the reproduction signal from the optical pickup **23** and handles any signal errors. In addition, the signal processing circuit **27** detects, for example, the thickness (or type) of the substrate of the disk **2** from the RF signal level, and the detection signal is output to the control circuit **28**.

The control circuit **28** is constructed so as to output a command to the rotation control circuit **22**, the thread motor control circuit **25**, the pickup control circuit **26**, and the signal processing circuit **27**, in accordance with the command signal input through an external interface **29**. The control circuit **28** is also constructed so as to output the reproduction signal, input from the signal processing circuit **27** through the external interface **29**, to an external device.

FIG. **2** is a diagram showing the construction of the optical pickup **23** of an embodiment in accordance with the present invention.

In the optical pickup **23**, the light beam emitted from a laser diode **38** is collimated by a collimator lens **39**. The collimated light beam passes through a polarization beam splitter **33** and a ¼ wavelength plate **32**, and then impinges upon a two lens assembly comprising a first lens LA and a second lens LB having the surface facing the disk **2** formed into a planar or aspherical surface and the other surface formed into a curved, but aspherical, surface. From the two lens assembly, the light beam converges on an information recording surface of the disk **2**. In this case, a large numerical aperture NA can be obtained compared to the case where an objective lens is used singly, since the light beam is converged by the two lens assembly. In addition, recording and reproducing operations can be performed on a high-density disk.

The aforementioned light beam, reflected from the information recording surface of the disk **2** and which has passed through the two lens assembly (the second lens LB and the first lens LA) and the ¼ wavelength plate **32**, impinges upon the polarization beam splitter **33** and is reflected thereby. The reflected light passes through a focusing lens **35** and a multi-lens **36** and converges on a photodetector **37** disposed at a conjugate point in order to be converted into a reproduction signal.

The electromagnetic actuator assembly **31** comprises a focusing actuator which moves the two lens assembly in the axial direction and a tracking actuator which moves the two lens assembly so as to follow the center of a track. Therefore, the assembly **31** performs focusing servo and tracking servo operations.

FIG. **3** is an enlarged view of the actuating portion of the two lens assembly of the optical pickup **23** of FIG. **2**. In FIG. **3**, corresponding or similar parts to those of FIG. **2** are given the same reference numerals, so that descriptions thereof will be given when required.

The light beam, converged by the first lens LA, passes through the second lens LB which converges it onto a information recording surface **2***a* of the disk **2** having a substrate **2***b* formed from a light-transmitting material, such as polycarbonate, into a predetermined thickness.

The second lens LB is connected to a bobbin **101** of the first lens LA by means of an electromagnetic actuator **40**. The distance between the first lens LA and the second lens LB is controlled by the electromagnetic actuator **40** to a predetermined value, when the optical axes coincide.

A description will now be given of performing reproducing operations on two types of disks, disks **2-1** and **2—2**, having different substrate (formed from a light-transmitting material such as polycarbonate) thicknesses and numerical aperture specifications, with reference to FIGS. **4** to **7**.

FIG. **4** is a diagram showing the construction of the two lens assembly in Embodiment 1 of the present invention.

In the two lens assembly of FIG. **4**, the second lens LB-1 produces no aberration with respect to the disk **2—2** (of FIG. **5**) having a light-transmitting substrate **2—2***b* thickness of d2 and a lens numerical aperture specification of NA2, and is designed to have the numerical aperture specification value of NA2. When the first lens LA-1 is used in combination with the second lens LB-1, the first lens LA-1

produces no aberration with respect to the disk **2-1** having a light-transmitting substrate **2-1***b* thickness of d1 (where d1≦d2) and a lens numerical aperture specification value of NA1, and is designed to have the numerical aperture specification value of NA1. In the specification, "no aberration" means an aberration value which satisfies Marechal's criterion. In the present embodiment, numerical aperture NA1>numerical aperture NA2.

The change-over device **41** causes the first lens LA-1 to move in and out of the optical path, in accordance with the type of disk **2** specified by the information supplied from the pickup control circuit **26**.

More specifically, the signal processing circuit **27** detects the thickness of the substrate of the disk **2** (or type of disk **2**) from the RF signal level, and outputs the detected thickness to the control circuit **28**. In accordance with the detected thickness, the control circuit **28** supplies a predetermined control command to the change-over device **41** through the pickup control circuit **26**. As shown in FIG. **4**, the change-over device **41** causes the first lens LA-1 to move into the optical path, so that the first lens LA-1 and the second lens LB-2 of the two lens assembly are used to converge the light beam onto an information recording surface **2-1***a* of the disk **2-1** having light-transmitting substrate **2-1***b* thickness d1 and numerical aperture specification value NA1. In this case, no aberration occurs and numerical aperture specification value of NA1 is realized.

A description will now be given of the case where reproduction operations are performed on the disk **2—2**, instead of on the disk **2-1**.

In this case, the signal processing circuit **27** detects the thickness of the light-transmitting substrate of the disk **2** (or the type of disk **2**) from the RF signal level, and the detected thickness is output to the control circuit **28**. In accordance with the detected thickness, the control circuit **28** sends a predetermined control command to the change-over device **41** through the pickup control circuit **26**. In accordance with the control command, the change-over device **41** causes the first lens LA-1 to move out of the optical path, so that the optical pickup **23** is set in correspondence with the disk **2—2**, as shown in FIG. **5**.

More specifically, as shown in FIG. **5**, only the second lens LB-1 is used to converge the light beam onto the information recording surface **2—2***a* of the disk **2—2** having substrate thickness d2 and numerical aperture specification value NA2. In this case, the no aberration occurs and numerical aperture specification value of NA2 is realized.

Accordingly, it is possible to properly reproduce data on different types of disk **2** by moving the first lens LA-1 into and out of the optical path, in accordance with the disk **2** type.

FIG. **6** is a diagram showing the construction of the second lens assembly in Embodiment 2.

In the two lens assembly of FIG. **6**, the first lens LA-2 produces no aberration with respect to the disk **2—2** having substrate **2—2***b* thickness d2 and numerical aperture specification value NA2, and is designed to have numerical aperture specification value NA2 (FIG. **7**). When the second lens LB-2 is used in combination with the first lens LA-2, it produces no aberration with respect to the disk **2-1** having substrate **2-1***b* thickness d1 and numerical aperture specification value NA1, and is designed to have numerical aperture specification value NA1.

The change-over device **42** causes the second lens LB-2 to move in and out of the optical path, in accordance with the type of disk **2** specified by the information supplied from the pickup control circuit **26**.

More specifically, when the disk **2-1** is detected, the control circuit **28** controls the change-over circuit **42** through the pickup control circuit **26**, causing the second lens LB-2 to move into the optical path, as shown in FIG. **6**, so that the first lens LA-2 and the second lens LB-2 of the two lens assembly are used to converge the light beam onto the information recording surface **2-1***a* of the disk **2-1** having substrate **2-1***b* thickness d1 and numerical aperture specification value NA1. This produces no aberration and allows the numerical aperture specification of NA1 to be realized.

It will now be assumed that reproducing operations are started and performed on the disk **2—2**, instead of the disk **2-1**.

Here, in accordance with the control signal from the pickup control circuit **26**, the change-over device **42** causes the second lens LB-2 to move out of the optical path, so that the optical pickup **23** is set in correspondence with the disk **2—2**, as shown in FIG. **7**.

More specifically, as shown in FIG. **7**, only the first lens LA-2 alone is used to converge the light beam onto the information recording surface **2—2***a* of the disk **2—2** having substrate **2—2***b* thickness d2 and numerical aperture specification value NA2. This produces no aberration and allows numerical aperture specification value of NA2 to be achieved.

Accordingly, it is possible to selectively reproduce data on different disk types with the optical pickup **23** by moving the second lens LB-2 in and out of the optical path.

Although in the foregoing description, the two lens assembly comprising one second lens and one first lens was used to reproduce data on two disk types having different substrate thicknesses and numerical aperture specification values, the lens assembly may be an N lens assembly having an N number of lenses. In such a case, it is possible to reproduce data on an N number of disks having different numerical aperture specification values and substrate thicknesses with the optical pickup **23** using the lens designing method described below.

A description will now be given of the method of designing individual lenses of an N lens assembly, with reference to FIGS. **8** to **15**. FIGS. **8** to **15** illustrate the case where a two lens assembly is used to simplify the description.

A description will first be given of the method of designing the first lens LA-1 and the second lens LA-2 of the two lens assembly in the embodiments illustrated in FIGS. **4** and **5**, with reference to FIGS. **8** to **11**.

FIG. **8** shows the exact shape of a curved surface of each lens of the two lens assembly and the optical path in Embodiment 1. As shown in FIG. **8**, the light beam, which has passed through a stop **51**, passes through the first lens LA-1 and the second lens LB-1, which converge the light beam upon the disk **2-1** having numerical aperture specification value NA1 and substrate **2-1***b* thickness d1.

When the second lens LB-1 is used singly, as shown in FIG. **5**, the lens LB-1 is formed in correspondence with the disk **2—2**. Therefore, the second lens LB-1 can be designed and produced by the above-described methods involving measurement of aberration using an interferometer and modification of the die.

FIG. **9** is a diagram showing the aberration of the second lens LB-1 with respect to the thickness of the substrate **2—2***b* of the disk **2—2**, being measured with an interferometer **61**.

The light beam emitted from a light source (not shown) of the interferometer **61** passes through a reference plane **64**

and impinges upon the second lens LB-1 which converges the light beam. The converged light beam then passes through a light-transmitting substrate **63** made of the same material as that of the disk **2—2** and having substrate thickness d2, whereby an image is formed on the optical axis of the second lens LB-1. Here, the thickness d2 of the substrate **63** includes 0 thickness.

A reference spherical surface **62** whose center is defined by the imaging point located in opposing relation to the substrate **63** reflects, for example, about 4% of the total amount of the light beam. The reflected light beam travels back again through the imaging point, the substrate **63**, and the second lens LB-1, and impinges upon the reference plane **64**. The interference image on the reference plane **64** is taken by a CCD camera (not shown) of the interferometer **61**. Therefore, the aberration which occurs in the second lens LB-1 with respect to the substrate **63** can be measured in terms of the tilting of the interference image on the CCD camera.

In this way, the aberration of the second lens LB-1 with respect to the disk **2—2** (substrate **63**) is measured to modify the die of the second lens LB-1 in accordance with the measurement results. The modified die is used to repeat the step of producing the second lens LB-1 into one having a predetermined curved (aspherical) surface which sufficiently reduces aberration.

In the same way, it is possible to relatively easily produce the second lens LB-1 whose aberration is corrected with respect to the disk **2—2**.

As shown in FIG. **8**, in the case where the aberration of the first lens LA-1 alone is measured with an interferometer (with the substrate having 0 thickness) in order to form the first lens LA-1 such that it does not produce aberration when a light beam is converged onto the disk **2-1** using the two lens assembly formed by the first lens LA-1 and the second lens LB-1, it is obvious that the predetermined aberration is obtained. The aberration which occurs in such a case is illustrated in FIG. **10** showing the amount of aberration three-dimensionally in terms of height.

The aberration of the first lens LA-1 with respect to the substrate having thickness d1, is measured, while the first lens LA-1 is arranged in combination with the second lens LB-1 corrected for aberration with respect to the disk **2—2**.

FIG. **11** is a diagram showing the aberration with respect to a light-transmitting substrate **71** with a thickness of d1, being measured using the two lens assembly which is a combination of the first lens LA-1 and the second lens LB-1 previously corrected for aberration with respect to the disk **2—2**. In FIG. **11**, corresponding or similar parts to those of FIG. **9**.are given the same reference numerals, and unnecessary descriptions thereof will be omitted. Here, the thickness d1 of the substrate **71** includes zero thickness.

The substrate **71** is made of the same material and is of the same thickness as the substrate **2-1***b* of the disk **2-1**. The light beam emitted from the light source passes through the reference plane **64**, the first lens. LA-1, the second lens LB-1, and the substrate **71**, and converges on a point on the optical axis of the first lens LA-1 and the second lens LB-1. A portion of the converged light beam is reflected back by the reference spherical surface **62** through the same optical path, whereby an interference image is formed on the reference plane **64**.

In this case, the second lens LB-1 is one sufficiently corrected for aberration with respect to the substrate having thickness d2, so that the tilting of the interference image can be used to indicate the aberration of the first lens LA-1. Therefore, the die for forming a curved surface of the first lens LA-1 is modified, based on the tilting of the interference image.

Accordingly, since the aberrations of the first lens LA-1 and the second lens LB-1 of the two lens assembly can be separately determined and corrected, it is possible to easily produce the two lens assembly satisfying the specifications illustrated in FIGS. **4** and **5**. In the specifications, the first lens LA-1 and the second lens LB-1 are used to reproduce data on the disk **2-1**, while the second lens LB-1 is used to reproduce data on the disk **2—2**.

A description will now be given of the method for producing the first lens LA-2 and the second lens LB-2 of the two lens assembly in Embodiment 2 illustrated in FIGS. **6** and **7**, with reference to FIGS. **12** to **15**.

FIG. **12** is a diagram showing the exact shape of a curved surface of each lens of the two lens assembly and the optical path in Embodiment 2. As shown in FIG. **12**, the light beam, which has passed through the stop **81**, passes through the first lens LA-2 and the second lens LB-2, which converge the light beam on the disk **2-1**.

Similarly, as previously described with reference to FIG. **9**, the conventional methods are used to correct the first lens LA-2 such that it does not produce aberration with respect to the substrate with thickness d2.

More specifically, as shown in FIG. **13**, the interferometer **61** is used to measure the aberration occurring in the first lens LA-2 alone with respect to the light-transmitting substrate **63** made of the same material and having the same thickness as those of the substrate of the disk **2—2**.

The light beam, emitted from the light source, passes through the reference plane **64** and impinges upon the first lens LA-2 which converges the light beam. The converged light beam passes through the substrate **63** with thickness d2 to form an image on the optical axis of the first lens LA-2. Part of the light beam is then reflected back by the reference spherical surface **62** through the same optical path to form an interference image on the reference plane **64**.

Accordingly, the aberration occurring in the first lens LA-1 with respect to the disk **2—2** (substrate **63**), is measured in order to modify the die for forming the first lens LA-2, based on the measurement results.

As with the case illustrated in FIG. **8**, in the case where the aberration of the second lens LB-2 alone is measured with the interferometer **61** (with the substrate thickness being 0) such that the second lens LB-2 does not produce aberration when a light beam is converged onto the disk **2-1** using the two lens assembly comprising the first lens LA-2 and the second lens LB-2, the predetermined aberration is obviously obtained. The aberration which occurs in this case is illustrated in FIG. **14**.

Accordingly, the aberration of the second lens LB-2 with respect to the substrate thickness d1, is measured, while the second lens LB-2 is arranged in combination with the first lens LA-2 corrected for aberration with respect to the disk **2—2**.

FIG. **15** is a diagram illustrating the aberration of the second lens LB-2 with respect to the substrate with thickness d1, being measured using the two lens assembly which is combination of the second lens LB-2 and the first lens LA-2 previously corrected for aberration with respect to the disk **2—2**.

The light-transmitting substrate **71** is made of the same material and is of the same thickness as the substrate of the disk **2-1**. The light beam emitted from the light source

travels through the reference plane **64**, the first lens LA-2, the second lens LB-2, and the substrate **71** and converges on a point on the optical axis of the first lens LA-2 and the second lens LB-2. Then, part of the light beam is reflected back by the reference spherical surface **62** through the same path to form an interference image on the reference plane **64** in correspondence with the aberration.

In this case, the first lens LA-2 is one which has been sufficiently corrected for aberration with respect to the thickness d2 of the substrate, so that the tilting of the interference image can be used to indicate the aberration of the second lens LB-2. Therefore, the die used for forming a curved surface of the second lens LB-2 is modified based on the tilting of the interference image. Although the substrate **63** and the substrate **71** were used in the description, the same substrate may be used. In such a case, only one type of substrate is used.

Accordingly, since the aberrations of the first lens LA-2 and the second lens LB-2 of the two lens assembly can be separately determined and corrected, it is possible to easily produce the two lens assembly satisfying the specifications illustrated in FIGS. **6** and **7**. In the specifications, the first lens LA-2 and the second lens LB-2 are used to reproduce data on the disk **2-1**, while the first lens LA-2 is used to reproduce data on the disk **2—2**.

Although in the foregoing description, the lens designing method was used for a two lens assembly, the designing method may similarly be used for an N lens assembly consisting of an N number of lenses. In such a case, for example, the Nth lens opposing the disk has no aberration with respect to a predetermined substrate thickness, when it is combined with a previously corrected (N-1)th lens.

Accordingly, it is possible to separately determine the aberrations of the first lens and second lens of the two lens assembly, and easily correct the aberrations. In addition, using one pickup including the two lenses makes it possible to achieve a large numerical aperture NA in correspondence with a high-density optical disk, and moving one of the lenses in and out of the optical path allows reproducing operations to be performed on disks with different numerical aperture specification values and substrate thicknesses.

In addition, it is possible to realize a recording medium reproducing apparatus in correspondence with an N number of disks by designing the N lens assembly formed by an N number of lenses as described above.

The present invention can be applied to information recording as well as information recording or reproduction of information of recording media other than disks. In addition, the present invention can be applied to an infinite optical system as well as to a finite optical system.

What is claimed is:

1. A method for designing an objective lens apparatus including at least two lenses, a first lens and a second lens, said method comprising the steps of:

measuring aberration which occurs when a light beam is converged by said first lens;

setting said first lens such that the aberration occurring in said first lens satisfies Maréchal's criterion, in accordance with the measurement results;

measuring aberration which occurs when a light beam is converged by said first lens and said second lens; and

setting said second lens such that the aberrations occurring in said first lens and said second lens satisfy Maréchal's criterion, in accordance with the measurement results.

2. A method according to claim **1**, wherein the light beam converged by said first lens irradiates a first medium having a light-transmitting substrate with a first thickness, wherein the light beam converged by said first lens and said second lens irradiates a second medium having a light-transmitting substrate with a second thickness, and wherein the light-transmitting substrate of at least one of the first and second media has a thickness of 0.

3. A method according to claim **1**, wherein the light beam converged by said first lens irradiates a first medium having a light-transmitting substrate with a first thickness, wherein the light beam converged by said first lens and said second lens irradiates a second medium having a light-transmitting substrate with a second thickness, and wherein the light-transmitting substrates of each of the first and second media have the same thickness.

4. A method according to claim **1**, wherein the light beam converged by said first lens and the light beam converged by said first lens and said second lens irradiate the same common medium.

5. A method according to claim **1**, wherein said first lens and said second lens are arranged along the direction in which the light beam impinges upon said lenses, and wherein said second lens has the surface facing said first lens formed into an aspherical surface and the opposite surface thereof formed into a planar surface or an aspherical surface.

6. A method according to claim **5**, wherein said second lens has a smaller diameter than that of said first lens.

7. A method according to claim **1**, wherein said second lens and said first lens are arranged in the direction in which the light beam impinges upon said lenses, and wherein said first lens has the surface facing said second lens formed into an aspherical surface and the surface facing said medium formed into a planar surface or an aspherical surface.

8. A method according to claim **7**, wherein said first lens has a smaller diameter than that of said second lens.

9. A method according to claim **1**, wherein the aberration is measured with an interferometer.

10. A method according to claim **1**, wherein the aberrations of said first lens and said second lens are corrected by producing dies for molding each of said lenses.

11. An objective lens apparatus including at least two lenses, said apparatus comprising:

a first lens which is set such that aberration, occurring when light converges on a first medium having a light-transmitting substrate with a first thickness, satisfies Maréchal's criterion; and

a second lens which is set such that aberration, occurring when light converges on a second medium having a light-transmitting substrate with a second thickness by said first lens and said second lens, satisfies Maréchal's criterion.

12. An apparatus according to claim **11**, wherein said second lens is disposed between said first lens and said second medium, and wherein said first lens has the surface facing said first lens formed into an aspherical surface and the surface facing said medium formed into a planar surface or an aspherical surface.

13. An apparatus according to claim **12**, wherein said second lens has a smaller diameter than said first lens.

14. An apparatus according to claim **11**, wherein said first lens is disposed between said second lens and said second medium, and wherein said second lens has the surface facing said second lens formed into an aspherical surface and the opposite surface thereof formed into a planar surface or an aspherical surface.

15. An apparatus according to claim **14**, wherein said first lens has a smaller diameter than that of said second lens.

16. An apparatus according to claim 11, further comprising change-over means for selectively changing over optical paths, where the light beam from a light source is converged onto said medium, between a first light path where the light beam is converged by said first lens and a second light path where the light beam is converged by said first lens and said second lens.

17. An apparatus according to claim 11, further comprising moving means for moving either one of said first lens and said second lens away from the optical path where the light beam from the light source is converged on said medium.

18. An apparatus according to claim 11, further comprising actuating means for allowing said first lens and said second lens to be movably supported in the axial direction of said first lens and said second lens and in a direction perpendicular to the axial direction.

19. An apparatus according to claim 11, wherein said first lens and said second lens are supported so as to be movable relative to each other.

[57] **ABSTRACT**

A compound objective lens is composed of a hologram lens or transmitting a part of incident light without any diffraction to form a beam of transmitted light and diffracting a remaining part of the incident light to form a beam of first-order diffracted light, and an objective lens for converging the transmitted light to form a first converging spot on a front surface of a thin type of first information medium and converging the diffracted light to form a second converging spot on a front surface of a thick type of second information medium. Because the hologram selectively functions as a concave lens for the diffracted light, a curvature of the transmitted light differs from that of the diffracted light. Therefore, even though the first and second information mediums have different thicknesses, the transmitted light incident on rear surface of the first information medium is converged on the its front surface, and the diffracted light incident on a rear surface of the second information medium is converged on the its front surface. That is, the compound objective lens has two focal points.

COMPOUND OBJECTIVE LENS HAVING TWO FOCAL POINTS

CROSS-REFERENCE TO RELATED APPLICATIONS

This application is a continuation-in-part of U.S. Pat. application Ser. No. 08/190,520, filed Feb. 1, 1994 now U.S. Pat. No. 5,446,565.

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to a compound objective lens composed of an objective lens and a hologram lens which has two focal points, an imaging optical system for converging light on two converging spots placed at different depths of an information medium with the compound objective lens, an optical head apparatus for recording, reproducing or erasing information on or from an information medium such as an optical medium or a magneto-optical medium like an optical disk or an optical card with the imaging optical system, an optical disk in which a series of high density recording pits and a series of comparatively low density recording pits are provided, an optical disk apparatus for recording or reproducing information on or from the optical disk with the compound objective lens, a binary focus microscope having two focal points in which two types of images drawn at different depths are simultaneously observed, and an alignment apparatus for aligning two types of images drawn at different depths with the binary focus microscope.

2. Description of the Related Art

An optical memory technique has been put to practical use to manufacture an optical disk in which a pit pattern formed of a series of pits is drawn to record information. The optical disk is utilized as a high density and large capacity of information medium. For example, the optical disk is utilized for a digital audio disk, a video disk, a document file disk, and a data file disk. To record information on the optical disk and to reproduce the information from the optical disk, a light beam radiated from a light source is minutely converged in an imaging optical system, and the light beam minutely converged is radiated to the optical disk through the imaging optical system. Therefore, the light beam is required to be reliably controlled in the imaging optical system with high accuracy.

The imaging optical system is utilized for an optical head apparatus in which a detecting system is additionally provided to detect the intensity of the light beam reflected from the optical disk. Fundamental functions of the optical head apparatus are classified into a converging performance for minutely converging a light beam to form a diffraction-limited micro-spot of the light beam radiated on the optical disk, a focus control in a focus servo system, a tracking control in a tracking serve system, and the detection of pit signals (or information signals) obtained by radiating the light beam on a pit pattern of the optical disk. The fundamental function of the optical head apparatus is determined by the combination of optical sub-systems and a photoelectric transfer detecting process according to a purpose and a use. Specifically, an optical head apparatus in which a holographic optical element (or hologram) is utilized to minimize and thin the optical head apparatus has been recently proposed.

2.1. Previously Proposed Art

FIG. **1** is a constitutional view of a conventional optical head apparatus proposed in Japanese Patent Application No. 46630 of 1991 which is applied by inventors of the present invention.

As shown in FIG. **1**, a conventional optical head apparatus **11** for recording or reproducing information on or from an information medium **12** such as an optical disk is provided with a light beam source **13** such as a semiconductor laser, a transmission type of blazed hologram **14** for transmitting a light beam L1 radiated from the light beam source **12** without any diffraction in an outgoing optical path and diffracting a light beam L2 reflected on the information medium **12** in a returning optical path, an objective lens **15** for converging the light beam L1 transmitting through the hologram **13** on the information medium **14** to read the information, an actuator **16** for integrally moving the objective lens **15** with the blazed hologram **13** to focus the light beam L1 on the information medium **12** with the objective lens **15**, and a photo detector **17** for detecting the intensity of the light beam L2 reflected on the information medium **12** to reproduce the information.

As shown in FIG. **2**A, a relative position between the blazed hologram **14** and the objective lens **15** is fixed by a fixing means **18**. Or, as shown in FIG. **2**B, a blazed pattern is formed on a side of the objective lens **15** to integrally form the blazed hologram **14** with the objective lens **15**.

In the above configuration, a light beam L1 (or a laser beam) radiated from the light beam source **13** is radiated to the blazed hologram **14**, and the light beam L1 mainly transmits through the blazed hologram **14** without any diffraction in an outgoing optical path. The light beam L1 transmitting through the blazed hologram **14** is called zero-order diffracted light. Thereafter, the zero-order diffracted light L1 is converged on the information medium **12** by the objective lens **15**. In the information medium **12**, information indicated by a series of patterned pits is recorded and read by the zero-order diffracted light L1. Thereafter, a beam light L2 having the information is reflected toward the objective lens **15** in a returning optical path and is incident to the blazed hologram **14**. In the blazed hologram **14**, the light L2 is mainly diffracted. The light L2 diffracted is called first-order diffracted light. Thereafter, the first-order diffracted light L2 is received in the photo detector **17**.

In the photo detector **17**, the intensity distribution of the first-order diffracted light L2 is detected. Therefore, a servo signal for adjusting the position of the objective lens **15** by the action of the actuator **16** is obtained. Also, the intensity of the first-order diffracted light L2 is detected in the photo detector **17**. Because the information medium **12** is rotated at high speed, the patterned pits radiated by the light **17** are changed so that the intensity of the first-order diffracted light L2 detected is changed. Therefore, an information signal indicating the information recorded in the information medium **12** is obtained by detecting the change in intensity of the first-order diffracted light L2.

In the above operation, a part of the light beam L1 is necessarily diffracted in the blazed hologram **14** when the light beam L1 is radiated to the blazed hologram **14** in the outgoing optical path. Therefore, unnecessary diffracted light such as first-order diffracted light and minus first-order diffracted light necessarily occurs. In cases where the hologram **14** is not blazed, the unnecessary diffracted light in the outgoing optical path also reads the information recorded in the information medium **12**, and the unnecessary light is undesirably received in the photo detector **17**. To prevent the unnecessary light from transmitting to the information medium **12**, the blazed hologram **14** is manufactured to form a blazed hologram pattern on the surface thereof, so that the intensity of the unnecessary light received in the photo detector **17** is decreased.

Also, because an objective lens of a conventional microscope has only a focal point, images placed within a focal

depth of the objective lens can be only observed with the conventional microscope.

Also, a minute circuit is formed on a semiconductor such as a group III-V compound semiconductor to form a microwave circuit, an opto-electronic detector or a solid state laser. In this case, a photo-sensitive material is coated on a sample made of the semiconductor. Thereafter, a relative position between the sample and a photo mask covering the sample is adjusted by utilizing an alignment apparatus, and the photo-sensitive material is exposed by a beam of exposure light through the photo mask to transfer a circuit pattern drawn on the photo mask to the photo-sensitive material in an exposure process by utilizing an exposure apparatus. For example, an alignment pattern is drawn on a reverse side of the sample, and a relative position between the sample and the photo mask is adjusted with high accuracy while simultaneously observing the alignment pattern of the sample and the circuit pattern of the photo mask with the conventional microscope. Thereafter, the circuit pattern of the photo mask is transferred to a front side of the sample.

In this case, because images placed within a focal depth of an objective lens utilized in the conventional microscope can be only observed with the conventional microscope, it is required to utilize the conventional microscope having a deep focal depth in the alignment apparatus in cases where the alignment pattern and the circuit pattern are simultaneously observed with the conventional microscope. Therefore, the magnification of the conventional microscope having a deep focal depth is lowered.

2.2. Problems to be Solved by the Invention

An optical disk having a high density memory capacity has been recently developed because of the improvement in a design technique of an optical system and the shortening of the wavelength of light radiated from a semiconductor laser. For example, a numerical aperture at an optical disk side of an imaging optical system in which a light beam converged on an optical disk is minutely narrowed in diameter is enlarged to obtain the optical disk having a high density memory capacity. In this case, the degree of aberration occurring in the imaging optical system is increased because an optical axis of the system tilts from a normal line of the optical disk. As the numerical aperture is increased, the degree of the aberration is enlarged. To prevent the increase of the numerical aperture, it is effective to thin the thickness of the optical disk. The thickness of the optical disk denotes a distance from a surface of the optical disk (or an information medium) radiated by a light beam to an information recording plane on which a series of patterned pits are formed.

FIG. **3** shows a relationship between the thickness of the optical disk and the numerical aperture on condition that the tilt of the optical axis is constant.

As shown in FIG. **3**, because the numerical aperture is 0.5 when the thickness of the optical disk is 1.2 mm, it is effective to thin the optical disk to 0.6 mm in thickness when the numerical aperture is increased to 0.6. In this case, even though the numerical aperture is increased on condition that the tilt of the optical axis is not changed, the degree of the aberration is not increased. Therefore, it is preferred that the thickness of the optical disk be thinned to obtain the optical disk having a high density memory capacity.

Accordingly, it is expected that the thickness of a prospective optical disk having a high density memory capacity becomes thinner than that of a present optical disk such as a compact disk appearing on the market now. For example, the thickness of the compact disk is about 1.2 mm, and the thickness of the prospective optical disk is expected to range from 0.4 mm to 0.8 mm. In this case, it is required to record or reproduce information on or from an optical disk with an optical head system regardless of whether the optical disk is the present optical disk or the prospective optical disk having a high density memory capacity. That is, an optical head apparatus having an imaging optical system in which a light beam is converged on an optical disk within the diffraction limit regardless of whether the optical disk is thick or thin is required.

However, in a conventional optical head apparatus, a piece of information is only recorded or reproduced on or from an optical disk having a fixed thickness. For example, in cases where the thickness of the information medium **12** is off a regular range by about ±0.1 mm or more, an aberration such as a spherical aberration occurs when the optical head apparatus **11** is operated. Therefore, the recording or the reproduction of the information is impossible. Accordingly, there is a drawback that an optical head apparatus in which a piece of information is recorded or reproduced on or from an optical disk regardless of whether the optical disk is the present optical disk or the prospective optical disk having a high density memory capacity cannot be manufactured in a conventional technique.

Also, there is a problem in the conventional microscope. That is, because an objective lens of the conventional microscope has only a focal point and images placed within a focal depth of the objective lens can be only observed with the conventional microscope, the magnification of the conventional microscope and an observed range in an optical axis direction are in a trade-off relationship. Therefore, there is a drawback that it is impossible to observe the images over a wide observed range in the optical axis direction at high magnification

Also, there is a problem in the alignment apparatus. That is, when a circuit pattern drawn on the photo mask is transferred to the front side of the sample after an alignment pattern is drawn on the reverse side of the sample, the alignment of the photomask and the sample is performed by simultaneously observing the circuit pattern of the photo mask and the alignment pattern of the sample with the conventional microscope having a deep focal depth and a low magnification. Therefore, because the conventional microscope has a low magnification, there is a drawback that it is impossible to align the photo mask with the sample at a high accuracy ranging within 5 μm.

SUMMARY OF THE INVENTION

A first object of the present invention is to provide, with due consideration to the drawbacks of such a conventional objective lens having a focal point, a compound objective lens having two focal points.

A second object of the present invention is to provide an imaging optical system having the compound objective lens in which light transmitting through the compound objective lens is converged at a diffraction limit on two converging spots placed at different depths of an information medium.

A third object of the present invention is to provide an optical head apparatus having the imaging optical system in which information is recorded, reproduced or erased on or from one of the converging spots of the information medium at which light is converged by the action of the imaging optical system.

A fourth object of the present invention is to provide a high density optical disk in which a series of first recording pits is formed to record pieces of information at high density on a thin substrate.

A fifth object of the present invention is to provide an optical disk apparatus in which information is recorded or reproduced on or from the optical disk with the compound objective lens regardless of whether a series of recording pits expressing pieces of information is recorded or reproduced on or from the high density optical disk having a thin thickness or a conventional compact disk having an ordinary thickness.

A sixth object of the present invention is to provide a binary focus microscope having two focal points in which two types of images drawn at different depths are simultaneously observed.

A seventh object of the present invention is to provide an alignment apparatus in which two types of images drawn at different depths are aligned with the binary focus microscope.

An eighth object of the present invention is to provide a focusing method for focusing light on an information medium with the optical head apparatus.

A ninth embodiment of the present invention is to provide an information reproducing method for reproducing a piece of recording information recorded on a high density optical disk having a thin thickness.

The first object is achieved by the provision of a compound objective lens having two focal points, comprising:

hologram means for transmitting a part of incident light without any diffraction to form a beam of transmitted light and diffracting a remaining part of the incident light to form a beam of diffracted light, the hologram means functioning as a lens for the diffracted light to diverge the diffracted light from the hologram means or converge the diffracted light; and

lens means for converging the transmitted light formed in the hologram means to form a first converging spot at a first focal point and converging the diffracted light formed in the hologram means to form a second converging spot at a second focal point, the second focal point differing from the first focal point.

In the above configuration, a part of incident light transmits through the hologram means without any diffraction. Therefore, a beam of transmitted light not diverged from the hologram means or not converging is formed. Thereafter, the transmitted light is refracted and converged by the lens means, so that the transmitted light is focused on a first converging spot positioned at a first focal point.

In contrast, a remaining part of incident light is diffracted by the hologram means. Therefore, a beam of diffracted light such as a beam of first-order diffracted light which is diverged from the hologram lens or converges is formed. Thereafter, the diffracted light is refracted and converged by the lens means, so that the diffracted light is focused on a second converging spot positioned at a second focal point.

In this case, because a propagation direction of the transmitted light differs from that of the diffracted light, the first focal point of the compound objective lens for the transmitted light differs from the second focal point of the compound objective lens for the diffracted light. Therefore, the compound objective lens has two focal points, and the incident light transmitting through the compound objective lens are converged on two converging points.

Accordingly, the incident light transmitting through the compound objective lens can be reliably converged on an information medium regardless whether the information medium has a first thickness or a second thickness.

It is preferred that a grating pattern be drawn in the hologram means in a concentric circle shape, the grating pattern of the hologram means be formed in relief to concentrically form alternating rows of bottom portions and top portions, a height H of relief in the grating pattern be set to $H < \lambda/(n(\lambda)-1)$ where a symbol λ denotes a wavelength of the incident light and a symbol $n(\lambda)$ denotes a refractive index of the hologram means made of a glass material for the incident light having the wavelength λ, and a difference in phase modulation degree between the incident light transmitting through a bottom portion of the grating pattern and the incident light transmitting through a top portion of the grating pattern be lower than 2π radians to set a diffraction efficiency of the hologram means to a value lower than 100%.

In the above configuration, because the height of the relief in the grating pattern is lower than a value $\lambda/(n(\lambda)-1)$, the difference in phase modulation degree is induced to be lower than 2π radians. Therefore, the diffraction efficiency of the hologram means is set to a value lower than 100% over the entire grating pattern, so that the transmitted light and the diffracted light are simultaneously formed in the hologram lens.

The first object is also achieved by the provision of a compound objective lens, comprising:

lens means for converging a beam of first incident light on a front surface of a first information medium having a first thickness T1 and converging a beam of second incident light on a front surface of a second information medium having a second thickness T2 (T2<T1), the first incident light passing through the first information medium from its rear surface, and the second incident light passing through the second information medium from its rear surface; and

aperture limiting means for selectively limiting an aperture of the lens means for the second incident light which is incident on the lens means, a second numerical aperture of the lens means for the second incident light which is incident on the lens means being lower than a first numerical aperture of the lens means for the first incident light which is incident on the lens means.

In the above configuration, an aperture of the lens means for the second incident light is limited by the aperture limiting means, and another aperture of the lens means for the first incident light is limited. Thereafter, the first incident light is converged by the lens means on the first information medium at a high numerical aperture, and the second incident light is converged by the lens means on the second information medium at a low numerical aperture. Accordingly, the compound objective lens has two focal points. Also, the intensity of the first incident light can be larger than that of the second incident light.

The first object is also achieved by the provision of a compound objective lens, comprising:

lens means for converging a beam of first incident light on a front surface of a first information medium having a first thickness and converging a beam of second incident light on a front surface of a second information medium having a second thickness, the first incident light passing through the first information medium from its rear surface, and the second incident light passing through the second information medium from its rear surface; and

curvature changing means for changing a curvature of spherical waves of a part of incident light to form the first incident light which is incident on the lens means and not changing a curvature of spherical waves of a remaining part of incident light to form the second incident light which is incident on the lens means.

In the above configuration, a curvature of spherical waves of a part of incident light is changed by the curvature changing means to form a beam of first incident light, and a curvature of spherical waves of a remaining part of incident light is not changed to form a beam of second incident light. Thereafter, the first incident light is converged on the first information medium, and the second incident light is converged on the second information medium.

Accordingly, the compound objective lens has two focal points.

The second object is achieved by the provision of an imaging optical system, comprising:

a light source for radiating a beam of incident light of which a far field pattern is distributed to decrease intensity of the incident light toward a peripheral portion of the beam;

hologram means for transmitting a part of the incident light radiated from the light source without any diffraction to form a beam of transmitted light and diffracting a remaining part of the incident light to form a beam of diffracted light, a grating pattern being formed in relief in the hologram means to concentrically form alternating rows of bottom portions and top portions on condition that a height H of relief in the grating pattern is set to $H < \lambda/(n(\lambda)-1)$ where a symbol λ denotes a wavelength of the incident light and a symbol $n(\lambda)$ denotes a refractive index of the hologram means made of a glass material for the incident light having the wavelength λ, a difference in phase modulation degree between the incident light transmitting through the bottom portions of the grating pattern and the incident light transmitting through the top portions of the grating pattern being lower than 2π radians to set a diffraction efficiency of the hologram means to a value lower than 100%, the height H of the relief in the grating pattern being gradually lowered toward an outer direction of a pattern region in which the grating pattern is drawn, and the diffraction efficiency of the hologram means for the incident light being gradually lowered toward the outer direction of the pattern region to distribute intensity of the transmitted light in a gently-sloping shape; and

lens means for converging the transmitted light formed in the hologram means to form a first converging spot at a first focal point and converging the diffracted light formed in the hologram means to form a second converging spot at a second focal point.

In the above configuration, a beam of incident light is radiated from a light source. A far field pattern of the incident light is distributed to decrease intensity of the incident light toward a peripheral portion of the beam. For example, the light source is a semiconductor laser, the far field pattern of the incident light is distributed in the Gaussian distribution. Thereafter, the incident light transmits through the hologram means. In this case, because a grating pattern is drawn in relief in the hologram means and because the height of the relief is lower than a value $\lambda/(n(\lambda)-1)$, the difference in phase modulation degree between the incident light transmitting through a bottom portion of the grating pattern and the incident light transmitting through a top portion of the grating pattern is induced to be lower than 2π radians. Therefore, the diffraction efficiency of the hologram means for the incident light is set to a value lower than 100% over the entire grating pattern, so that the transmitted light and the diffracted light are simultaneously formed in the hologram lens. In addition, because the height H of the relief in the grating pattern is gradually lowered toward the outer direction of the pattern region, the diffraction efficiency of the hologram means for the incident light is gradually lowered toward the outer direction of the pattern region. Therefore, the incident light positioned at a center portion of its beam are mainly changed to the diffracted light, and the incident light positioned at a peripheral portion of its beam are mainly changed to the transmitted light.

Thereafter, the transmitted light is refracted and converged by the lens means, so that the transmitted light is focused on a first converging spot positioned at a first focal point. Also, the diffracted light is refracted and converged by the lens means, so that the diffracted light is focused on a second converging spot positioned at a second focal point. In this case, because a propagation direction of the transmitted light differs from that of the diffracted light, the first focal point for the transmitted light differs from the second focal point for the diffracted light.

Accordingly, even though the far field pattern of the incident light is distributed in the Gaussian distribution, the far field pattern of the transmitted light is distributed in a gently-sloping shape. Therefore, secondary maxima (or side lobes) of the transmitted light can be prevented from occurring at the first converging spot.

Also, because the height H of the relief in the grating pattern is gradually lowered over the entire pattern region, a numerical aperture of the lens means for the diffracted light can be sufficiently heightened.

The second object is also achieved by the provision of an imaging optical system, comprising:

a light source for radiating a beam of incident light of which a far field pattern is distributed to decrease intensity of the incident light toward a peripheral portion of the beam;

hologram means for transmitting a part of the incident light radiated from the light source without any diffraction to form a beam of transmitted light and diffracting a remaining part of the incident light to form a beam of diffracted light, a grating pattern being formed in relief in the hologram means to concentrically form alternating rows of bottom portions and top portions on condition that a height H of relief in the grating pattern is set to $H < \lambda/(n(\lambda)-1)$ where a symbol λ denotes a wavelength of the incident light and a symbol $n(\lambda)$ denotes a refractive index of the hologram means made of a glass material for the incident light having the wavelength λ, a difference in phase modulation degree between the incident light passing through the bottom portions of the grating pattern and the incident light passing through the top portions of the grating pattern being lower than 2π radians to set a diffraction efficiency of the hologram means to a value lower than 100%, the height H of the relief in the grating pattern being gradually lowered toward an inner direction of a pattern region in which the grating pattern is drawn, and the diffraction efficiency of the hologram means for the incident light being gradually lowered toward the inner direction of the pattern region to distribute intensity of the diffracted light in a gently-sloping shape; and

lens means for converging the transmitted light formed in the hologram means to form a first converging spot at a first focal point and converging the diffracted light formed in the hologram means to form a second converging spot at a second focal point.

In the above configuration, the transmitted light and the diffracted light are simultaneously formed in the hologram lens in the same manner. Also, because the height H of the relief in the grating pattern is gradually lowered toward the

inner direction of the pattern region, the diffraction efficiency of the hologram means for the incident light is gradually lowered toward the inner direction of the pattern region. Therefore, the incident light positioned at a center portion of its beam are mainly changed to the transmitted light, and the incident light positioned at a peripheral portion of its beam are mainly changed to the diffracted light.

Accordingly, even though the far field pattern of the incident light is distributed in the Gaussian distribution, the far field pattern of the diffracted light is distributed in a gently-sloping shape. Therefore, secondary maxima (or side lobes) of the diffracted light can be prevented from occurring at the second converging spot.

Also, because the height H of the relief in the grating pattern is gradually lowered over the entire pattern region, a numerical aperture of the lens means for the transmitted light can be sufficiently heightened.

The third object is achieved by the provision of an optical head apparatus for recording or reproducing a piece of information on or from a thin type of first information medium having a first thickness or a thick type of second information medium having a second thickness larger than the first thickness, comprising:

a light source for radiating a beam of incident light;

hologram means for transmitting a part of the incident light radiated from the light source without any diffraction on an outgoing path to form a beam of transmitted light and diffracting a remaining part of the incident light radiated from the light source on the outgoing path to form a beam of diffracted light, the hologram means functioning as a lens for the diffracted light to diverge the diffracted light from the hologram means or converge the diffracted light;

lens means for converging the transmitted light formed in the hologram means at a first focal length on the outgoing path to form a first converging spot at a front surface of the first information medium or converging the diffracted light formed in the hologram means at a second focal length on the outgoing path to form a second converging spot at a front surface of the second information medium, the transmitted light being incident on a rear surface of the first information medium and being converged at the front surface of the first information medium, the transmitted light being reflected at the rear surface of the first information medium and again passing through the lens means and the hologram means on an incoming path, the diffracted light being incident on a rear surface of the second information medium and being converged at the front surface of the second information medium, and the diffracted light being reflected at the rear surface of the first information medium and again passing through the lens means and the hologram means on the incoming path;

wavefront changing means for changing a wavefront of the transmitted light or the diffracted light passing through the lens means and the hologram means on the incoming path to form one or more beams of information light; and

detecting means for detecting intensities of the information light formed by the wavefront changing means and generating an information signal according to the intensities of the information light, the information signal expressing a piece of information recorded on the first information medium or the second information medium.

In the above configuration, a beam of incident light is radiated from the light source, and a part of the incident light transmits through the hologram lens to form a beam of transmitted light. Also, a remaining part of the incident light is diffracted by the hologram lens to form a beam of diffracted light. Thereafter, the transmitted light and the diffracted light are converged by the converging means. In cases where a piece of information is recorded or reproduced on or from the first information medium, the transmitted light is incident on the rear surface of the first information medium and is converged at the front surface of the first information medium to form the first converging spot. Thereafter, the transmitted light is reflected at the rear surface of the first information medium and again passes through the lens means and the hologram means without any diffraction. In contrast, in cases where a piece of information is recorded or reproduced on or from the second information medium, the diffracted light is incident on the rear surface of the second information medium and is converged at the front surface of the second information medium to form the second converging spot. Thereafter, the diffracted light is reflected at the rear surface of the second information medium and again passes through the lens means. Thereafter, the diffracted light is again diffracted by the hologram means.

Thereafter, a wavefront of the transmitted light or the diffracted light is changed by the wavefront changing means to form a plurality of beams of reflected light, and the intensities of the reflected light is detected by the detecting means. Therefore, an information signal expressing the information recorded on the first or second information medium is generated according to the intensities of the reflected light.

Accordingly, because the first converging spot of the transmitted light differs from the second converging spot of the diffracted light. a compound objective lens composed of the hologram lens and the lens means has two focal points. Therefore, a piece of information can be recorded or reproduced on or from an information medium regardless of whether the information medium has the first thickness or the second thickness.

The third object is also achieved by the provision of an optical head apparatus for recording or reproducing a piece of information on or from a first information medium having a first thickness **T1** or a second information medium having a second thickness **T2** (**T1<T2**), comprising:

lens means for converging a beam of first incident light on a front surface of a first information medium having a first thickness **T1** or converging a beam of second incident light on a front surface of a second information medium having a second thickness **T2** (**T2<T1**), the first incident light passing through the first information medium from its rear surface, and the second incident light passing through the second information medium from its rear surface;

aperture limiting means for selectively limiting an aperture of the lens means for the second incident light which is incident on the lens means, a second numerical aperture of the lens means for the second incident light which is incident on the lens means being lower than a first numerical aperture of the lens means for the first incident light which is incident on the lens means, the first incident light being reflected at the front surface of the first information medium and again passing through the lens means and the aperture limiting means on an incoming path, and the second incident light being reflected at the front surface of the second information

medium and again passing through the lens means and the aperture limiting means on the incoming path;

a light source for radiating the first incident light and the second incident light to the aperture limiting means;

wavefront changing means for changing a wavefront of the first or second incident light passing through the lens means and the aperture limiting means on the incoming path to form one or more beams of information light; and

detecting means for detecting intensities of the information light formed by the wavefront changing means and generating an information signal according to the intensities of the information light, the information signal expressing a piece of information recorded on the first information medium or the second information medium.

In the above configuration, a compound objective lens composed of the lens means and the aperture limiting means has two focal points, and the intensity of the first incident light is larger than that of the second incident light.

Accordingly, a piece of information can be recorded or reproduced on or from an information medium regardless of whether the information medium has the first thickness or the second thickness. Also, a piece of information can be efficiently recorded on the first information medium with the first incident light having a high intensity, and a piece of information can be efficiently reproduced from the second information medium with the second incident light having a comparatively low intensity.

The third object is also achieved by the provision of an optical head apparatus for recording or reproducing a piece of information on or from a first information medium having a first thickness or a second information medium having a second thickness, comprising:

lens means for converging a beam of first incident light on a front surface of the first information medium and converging a beam of second incident light on a front surface of the second information medium, the first incident light passing through the first information medium from its rear surface, and the second incident light passing through the second information medium from its rear surface; and

curvature changing means for changing a curvature of spherical waves of a part of incident light to form the first incident light which is incident on the lens means and not changing a curvature of spherical waves of a remaining part of incident light to form the second incident light which is incident on the lens means, the first incident light being reflected at the front surface of the first information medium and again passing through the lens means and the curvature changing means on an incoming path, and the second incident light being reflected at the front surface of the second information medium and again passing through the lens means and the curvature changing means on the incoming path;

a light source for radiating the incident light to the curvature changing means;

wavefront changing means for changing a wavefront of the first or second incident light passing through the lens means and the curvature changing means on the incoming path to form one or more beams of information light; and

detecting means for detecting intensities of the information light formed by the wavefront changing means and generating an information signal according to the intensities of the information light, the information signal expressing a piece of information recorded on the first information medium or the second information medium.

In the above configuration, because a compound objective lens is composed of the lens means and the curvature changing means, the compound objective lens has two focal points. Accordingly, a piece of information can be recorded or reproduced on or from an information medium regardless of whether the information medium has the first thickness or the second thickness.

The fourth object is achieved by the provision of an optical disk, comprising:

an information recording substrate partitioned into a first region and a second region, the first region having a first thickness, and the second region having a second thickness smaller than the first thickness;

a plurality of first recording pits placed at the first region of the information recording substrate for recording pieces of recording information at a high recording density, the first recording pits being formed at narrow intervals; and

a plurality of second recording pits placed at the second region of the information recording substrate for recording pieces of distinguishing information at an ordinary recording density of a compact disk, the distinguishing information informing that the recording information are recorded on the information recording substrate having the first thickness, and the recording density of the recording information being higher than that of the distinguishing information.

In the above configuration, a substrate of a conventional compact disk has the same second thickness as that of the second region of the information recording substrate in the optical disk according to the present invention. Therefore, in cases where a beam of reproducing light is incident on a prescribed region of an unknown disk selected from a group of the conventional compact disk and the optical disk, the reproducing light is focused on a recording pit of the conventional compact disk or one of the second recording pits of the optical disk regardless of whether the unknown disk is the conventional compact disk or the optical disk.

In cases where the unknown disk is the optical disk, a piece of distinguishing information is read by the reproducing light. Because the distinguishing information informs that pieces of recording information are recorded on the information recording substrate having the first thickness, a curvature of the reproducing light is automatically changed to focus the reproducing light on the information recording substrate having the first thickness, and the reproducing light is automatically focused on one of the first recording pits. Therefore, a piece of recording information is reproduced.

In contrast, in cases where the unknown disk is the conventional compact disk, a piece of recording information is read by the reproducing light in the same manner as in a prior art.

Accordingly, a piece of recording information formed on an information recording substrate can be reliably reproduced even though the thickness of the information recording substrate is unknown.

The fourth object is also achieved by the provision of an optical disk, comprising:

an information recording substrate having a thin thickness, the thin thickness of the information recording substrate being thinner than that of a compact disk;

a plurality of first recording pits placed at a first region of the information recording substrate for recording

pieces of recording information at a high recording density, the first recording pits being formed at narrow intervals; and

a plurality of second recording pits placed at a second region of the information recording substrate for recording pieces of distinguishing information at a low recording density, the distinguishing information informing that the recording information are recorded on the information recording substrate having the thin thickness, the recording density of the recording information being higher than that of the distinguishing information, each of the second recording pits being larger than that of a recording pit in the compact disk, and a converging spot of a beam of reproducing light, which is converged to focus on an ordinary recording pit formed on a substrate having an ordinary thickness of the compact disk, being formed in one of the second recording pits to read the distinguishing information.

In the above configuration, a beam of reproducing light, of which a curvature is adjusted to focus the reproducing light on a recording pit formed on an information recording substrate of the compact disk, is incident on a prescribed region of an unknown disk selected from a group of the compact disk having an ordinary thickness and the optical disk according to the present invention. In cases where the unknown disk is the optical disk, the reproducing light is converged on one of the second recording pits in defocus because the information recording substrate of the optical disk has the thin thickness. However, because each of the second recording pits is large in size, a converging spot of the reproducing light is formed in the second recording pit. Therefore, a piece of distinguishing information is read by the reproducing light. Because the distinguishing information informs that pieces of recording information are recorded on the information recording substrate having the thin thickness, a curvature of the reproducing light is automatically changed to focus the reproducing light on the information recording substrate having the thin thickness, and the reproducing light is automatically focused on one of the first recording pits. Therefore, a piece of recording information is reproduced.

In contrast, in cases where the unknown disk is the compact disk, a piece of recording information is read by the reproducing light in the same manner as in a prior art.

Accordingly, a piece of recording information formed on an information recording substrate can be reliably reproduced even though the thickness of the information recording substrate is unknown.

The fifth object is achieved by the provision of an optical disk apparatus for recording or reproducing pieces of recording information on or from an optical disk in which the recording information are recorded or reproduced at a high density on or from a first substrate having a first thickness and a piece of distinguishing information informing that the recording information are recorded or reproduced on or from the first substrate having the first thickness is recorded at an ordinary density on a second substrate having a second thickness larger than the first thickness, comprising:

rotating means for rotating the optical disk at a regular speed;

a light source for radiating a beam of incident light;

hologram means for transmitting a part of the incident light radiated from the light source without any diffraction on an outgoing path to form a beam of transmitted light and diffracting a remaining part of the incident light radiated from the light source on the outgoing path to form a beam of diffracted light, the hologram means functioning as a lens for the diffracted light to diverge the diffracted light from the hologram means;

lens means for converging the transmitted light formed in the hologram means on the first substrate of the optical disk rotated by the rotating means to record or reproduce a piece of recording information on or from the optical disk and converging the diffracted light formed in the hologram means on the second substrate of the optical disk rotated by the rotating means to reproduce the distinguishing information from the optical disk, the transmitted light being reflected by the first substrate of the optical disk and again passing through the lens means and the hologram means on an incoming path, and the diffracted light being reflected by the second substrate of the optical disk and again passing through the lens means and the hologram means on the incoming path;

wavefront changing means for changing a wavefront of the transmitted light passing through the lens means and the hologram means on the incoming path to form one or more beams of recording information light and changing a wavefront of the diffracted light passing through the lens means and the hologram means on the incoming path to form one or more beams of distinguishing information light;

detecting means for detecting intensities of the recording information light formed by the wavefront changing means to generate a recording information signal according to the intensities of the recording information light and detecting intensities of the distinguishing information light formed by the wavefront changing means to generate a distinguishing information signal according to the intensities of the distinguishing information light, the distinguishing information signal expressing the distinguishing information recorded on the second substrate of the optical disk, and the recording information signal expressing the recording information recorded on the first substrate of the optical disk; and

moving means for moving an optical head apparatus comprising the light source, the hologram means, the lens means and the detecting means to converge the diffracted light formed in the hologram means on the second substrate of the optical disk and moving the optical disk, in which the diffracted light formed in the hologram means is converged on the second substrate of the optical disk, to converge the transmitted light formed in the hologram means on the first substrate of the optical disk in cases where the distinguishing information is detected in the detecting means.

In the above configuration, an optical head apparatus comprising the light source, the hologram means, the lens means and the detecting means has the same configuration as that described before. Initially, the optical head apparatus is moved by the moving means to converge in focus the diffracted light formed in the hologram means on the second substrate of the optical disk rotated by the rotating means. Therefore, the distinguishing information recorded on the second substrate is reproduced in the detecting means, and it is informed that pieces of recording information are recorded or reproduced on or from the first substrate having the first thickness. Thereafter, the optical head apparatus is moved by the moving means to converge in focus the transmitted light formed in the hologram means on the first substrate of the optical disk rotated by the rotating means. Therefore, a piece of recording information is recorded or reproduced on or from the first substrate of the optical disk.

Accordingly, even though a high density type of optical disk, in which pieces of recording information is recorded or reproduced on or from the substrate having the first thickness smaller than the second thickness of a conventional optical disk, is utilized, the recording information can be reliably recorded or reproduced.

The fifth object is also achieved by the provision of an optical disk apparatus for recording or reproducing pieces of recording information on or from an optical disk in which the recording information are recorded or reproduced at a high density on or from a first substrate having a thin thickness thinner than that of a compact disk and a piece of distinguishing information informing that the recording information are recorded or reproduced on or from the first substrate having the thin thickness is recorded at a low density on a second substrate having the thin thickness, comprising:

rotating means for rotating the optical disk at a regular speed;

a light source for radiating a beam of incident light;

hologram means for transmitting a part of the incident light radiated from the light source without any diffraction on an outgoing path to form a beam of transmitted light and diffracting a remaining part of the incident light radiated from the light source on the outgoing path to form a beam of diffracted light, the hologram means functioning as a lens for the diffracted light to diverge the diffracted light from the hologram means;

lens means for converging in focus the transmitted light formed in the hologram means on the first substrate of the optical disk rotated by the rotating means to record or reproduce a piece of recording information on or from the optical disk and converging in defocus the diffracted light formed in the hologram means on the second substrate of the optical disk rotated by the rotating means to reproduce the distinguishing information from the optical disk, the transmitted light being reflected by the first substrate of the optical disk and again passing through the lens means and the hologram means on an incoming path, and the diffracted light being reflected by the second substrate of the optical disk and again passing through the lens means and the hologram means on the incoming path;

wavefront changing means for changing a wavefront of the transmitted light passing through the lens means and the hologram means on the incoming path to form one or more beams of recording information light and changing a wavefront of the diffracted light passing through the lens means and the hologram means on the incoming path to form one or more beams of distinguishing information light;

detecting means for detecting intensities of the recording information light formed by the wavefront changing means to generate a recording information signal according to the intensities of the recording information light and detecting intensities of the distinguishing information light formed by the wavefront changing means to generate a distinguishing information signal according to the intensities of the distinguishing information light, the distinguishing information signal expressing the distinguishing information recorded on the second substrate of the optical disk, and the recording information signal expressing the recording information recorded on the first substrate of the optical disk; and

moving means for moving an optical head apparatus comprising the light source, the hologram means, the lens means and the detecting means, to converge the diffracted light formed in the hologram means in defocus on the second substrate of the optical disk and moving the optical disk, in which the diffracted light formed in the hologram means is converged on the second substrate of the optical disk in defocus, to converge the transmitted light formed in the hologram means on the first substrate of the optical disk in focus in cases where an intensity of the distinguishing information signal generated in the detecting means is larger than a threshold value.

In the above configuration, an optical head apparatus comprising the light source, the hologram means, the lens means and the detecting means has the same configuration as that described before. Initially, the optical head apparatus is moved by the moving means to converge in defocus the diffracted light formed in the hologram means on the second substrate of the optical disk rotated by the rotating means. In this case, because the distinguishing information is recorded at a low density, a plurality of recording pits expressing the distinguishing information are respectively large in size. Therefore, even though the diffracted light is converged on each of the recording pits in defocus, a converging spot of the diffracted light is formed in each of the recording pits. Therefore, the distinguishing information recorded on the second substrate is reproduced in the detecting means, and it is informed that pieces of recording information are recorded or reproduced on or from the first substrate having the thin thickness. Thereafter, the optical head apparatus is moved by the moving means to converge in focus the transmitted light formed in the hologram means on the first substrate of the optical disk rotated by the rotating means. Therefore, a piece of recording information is recorded or reproduced on or from the first substrate of the optical disk.

Accordingly, even though a high density type of optical disk, in which pieces of recording information are recorded or reproduced on or from the substrate having the thin thickness smaller than an ordinary thickness of a conventional optical disk, is utilized, the recording information can be reliably recorded or reproduced.

The sixth object is achieved by the provision of a binary focus microscope for simultaneously observing a first image put on a first image plane and a second image put on a second image plane, comprising:

an objective lens for refracting a beam of first light diverging from the first image and a beam of second light diverging from the second image, a first distance between the objective lens and the first image of the first image plane differing from a second distance between the objective lens and the second image of the second image plane;

a hologram lens for transmitting the first light refracted by the objective lens without any diffraction to form a beam of transmitted light and diffracting the second light refracted by the objective lens to form a beam of diffracted light, the hologram lens functioning as a lens for the second light to pass the diffracted light through the same optical path as the transmitted light passes through, and a beam of superposed light being formed of the transmitted light and the diffracted light;

an inner lens for converging the superposed light formed by the hologram lens at an image point of a third image plane to simultaneously form the first image and the second image enlarged on the third image plane; and

an ocular lens for converging the superposed light which is converged by the inner lens and diverges from the

image point to simultaneously form the first image and the second image moreover enlarged.

In the above configuration, a beam of first light diverging from the first image and a beam of second light diverging from the second image are refracted together by the objective lens. In this case, because a first distance between the objective lens and the first image of the first image plane differs from a second distance between the objective lens and the second image of the second image plane, a curvature of the first light refracted differs from another curvature of the second light refracted. Thereafter, the first light refracted transmits through the hologram lens without any diffraction to form a beam of transmitted light, and the second light refracted is diffracted by the hologram lens to form a beam of diffracted light. In this case, because the hologram lens functions as a lens for the diffracted light, a curvature of the diffracted light agrees with that of the transmitted light. In other words, the diffracted light passes through the same optical path as the transmitted light passes through. Therefore, a beam of superposed light is formed of the transmitted light and the diffracted light. Thereafter, the superposed light is converged by the inner lens at an image point of a third image plane, so that the first image and the second image enlarged are simultaneously formed on the third image plane. Thereafter, the superposed light diverging from the image point is converged by the ocular lens, so that the first image and the second image moreover enlarged are simultaneously formed.

Accordingly, an operator can observe the first image and the second image sufficiently enlarged.

The sixth object is also achieved by the provision of a binary focus microscope for simultaneously observing a first image put on a first image plane and a second image put on a second image plane, comprising:

an objective lens for refracting a beam of first light diverging from the first image and a beam of second light diverging from the second image, a first distance between the objective lens and the first image of the first image plane differing from a second distance between the objective lens and the second image of the second image plane;

a hologram lens for transmitting the first light refracted by the objective lens without any diffraction to form a beam of transmitted light and diffracting the second light refracted by the objective lens to form a beam of diffracted light, the hologram lens functioning as a lens for the second light to pass the diffracted light through the same optical path as the transmitted light passes through, and a beam of superposed light being formed of the transmitted light and the diffracted light;

an inner lens for converging the superposed light formed by the hologram lens at an image point of a third image plane to simultaneously form the first image and the second image enlarged on the third image plane; and

photographing means for photographing a superposed image formed of the first and second images enlarged on the third image plane by converging the superposed light in the inner lens.

In the above configuration, the first image and the second image enlarged are simultaneously formed on the third image plane in the same manner. Thereafter, the first image and the second image enlarged are photographed by the photographing means as a superposed image.

Accordingly, the first image and the second image enlarged can be observed.

The seventh embodiment is achieved by the provision of an alignment apparatus for aligning a first reference image drawn on a photomask with a second reference image drawn on a sample, comprising:

a light source for radiating beams of alignment light to illuminate the first and second reference images;

an objective lens for refracting both a beam of first alignment light diverging from the first reference image and a beam of second alignment light diverging from the second reference image which are illuminated with the alignment light radiated from the light source, a first distance between the objective lens and the first reference image of the photomask differing from a second distance between the objective lens and the second reference image of the sample;

a hologram lens for transmitting the first alignment light refracted by the objective lens without any diffraction to form a beam of transmitted light and diffracting the second alignment light refracted by the objective lens to form a beam of diffracted light, the hologram lens functioning as a lens for the second alignment light to pass the diffracted light through the same optical path as the transmitted light passes through, and a beam of superposed light being formed of the transmitted light and the diffracted light;

an inner lens for converging the superposed light formed by the hologram lens at an image point of an image plane to simultaneously form the first and second reference images enlarged on the image plane, an optical axis passing through centers of the objective lens, the hologram lens and the inner lens;

photographing means for photographing a superposed image formed of the first and second images enlarged on the image plane by converging the superposed light in the inner lens; and

moving means for moving the photomask or the sample according to the superposed image photographed by the photographing means to align the first reference image with the second reference image along the optical axis.

In the above configuration, the objective lens, the hologram lens and the inner lens are the same as those in the binary focus microscope. Therefore, the first and second images enlarged on the image plane is photographed by the photographing means as a superposed image. Thereafter, the photomask or the sample is moved in a direction perpendicular to the optical axis by the moving means to align the first reference image with the second reference image along the optical axis.

Accordingly, because the superposed image formed of the first and second reference images enlarged is photographed by the photographing means, a relative position between the first and second reference images can be accurately observed. Therefore, the first reference image can be accurately aligned with the second reference image.

The eighth embodiment is achieved by the provision of a focusing method for focusing light on a first information medium having a first thickness or a second information medium having a second thickness to record or reproduce a piece of information on or from the first information medium or the second information medium, comprising the steps of:

moving an optical head apparatus in a direction to decrease or increase the distance between the optical head apparatus and the first or second information medium, the optical head apparatus comprising

a light source for radiating a beam of incident light,

hologram means for transmitting a part of the incident light radiated from the light source without any dif-

fraction on an outgoing path to form a beam of transmitted light and diffracting a remaining part of the incident light radiated from the light source on the outgoing path to form a beam of diffracted light, the hologram means functioning as a lens for the diffracted light to diverge the diffracted light from the hologram means or converge the diffracted light,

lens means for converging the transmitted light formed in the hologram means at a first focal length on the outgoing path to form a first converging spot at a front surface of the first information medium or converging the diffracted light formed in the hologram means at a second focal length on the outgoing path to form a second converging spot at a front surface of the second information medium, the transmitted light being incident on a rear surface of the first information medium and being converged at the front surface of the first information medium, the transmitted light being reflected at the rear surface of the first information medium and again passing through the lens means and the hologram means on an incoming path, the diffracted light being incident on a rear surface of the second information medium and being converged at the front surface of the second information medium, and the diffracted light being reflected at the rear surface of the first information medium and again passing through the lens means and the hologram means on the incoming path,

wavefront changing means for changing a wavefront of the transmitted light or the diffracted light passing through the lens means and the hologram means on the incoming path to form one or more beams of information light, and

detecting means for detecting intensities of the information light formed by the wavefront changing means and generating an information signal and a focus error signal according to the intensities of the information light, the information signal expressing a piece of information recorded on the first information medium or the second information medium;

judging whether or not an intensity of the focus error signal generated in the detecting means is larger than a threshold value; and

adjusting the position of the optical head apparatus to decrease the intensity of the focus error signal to zero when the intensity of the focus error signal becomes larger than the threshold value.

In the above steps, the focusing method is performed by utilizing the optical head apparatus described above. The intensity of the focus error signal is largely increased when the distance between the lens means and the first or second information medium is near to a focal length of the lens means. Therefore, when the intensity of the focus error signal becomes larger than a threshold value, the lens means is placed near to a just-focus point in which the transmitted light or the diffracted light is converged on the first or second information medium in focus.

Accordingly, in cases where the position of the optical head apparatus is adjusted to decrease the intensity of the focus error signal to zero when the intensity of the focus error signal becomes larger than the threshold value, the transmitted light or the diffracted light can be focused on the first or second information medium.

The ninth embodiment is achieved by the provision of an information reproducing method for reproducing a piece of recording information from an optical disk in which the recording information are recorded at a high density on a first substrate having a first thickness and a piece of distinguishing information informing that the recording information are recorded on the first substrate is recorded at an ordinary density on a second substrate having a second thickness larger than the first thickness, comprising the step of:

moving an optical disk apparatus under the second substrate of the optical disk, the optical disk comprising

rotating means for rotating the optical disk at a regular speed,

a light source for radiating a beam of incident light;

hologram means for transmitting a part of the incident light radiated from the light source without any diffraction on an outgoing path to form a beam of transmitted light and diffracting a remaining part of the incident light radiated from the light source on the outgoing path to form a beam of diffracted light, the hologram means functioning as a lens for the diffracted light to diverge the diffracted light from the hologram means,

lens means for converging the transmitted light formed in the hologram means on the first substrate of the optical disk rotated by the rotating means to record or reproduce a piece of recording information on or from the optical disk and converging the diffracted light formed in the hologram means on the second substrate of the optical disk rotated by the rotating means to reproduce the distinguishing information from the optical disk, the transmitted light being reflected by the first substrate of the optical disk and again passing through the lens means and the hologram means on an incoming path, and the diffracted light being reflected by the second substrate of the optical disk and again passing through the lens means and the hologram means on the incoming path,

wavefront changing means for changing a wavefront of the transmitted light passing through the lens means and the hologram means on the incoming path to form one or more beams of recording information light and changing a wavefront of the diffracted light passing through the lens means and the hologram means on the incoming path to form one or more beams of distinguishing information light, and

detecting means for detecting intensities of the recording information light formed by the wavefront changing means to generate a recording information signal according to the intensities of the recording information light and detecting intensities of the distinguishing information light formed by the wavefront changing means to generate a distinguishing information signal according to the intensities of the distinguishing information light, the distinguishing information signal expressing the distinguishing information recorded on the second substrate of the optical disk, and the recording information signal expressing the recording information recorded on the first substrate of the optical disk; and

converging the diffracted light on the second substrate of the optical disk to reproduce the distinguishing information;

moving the optical disk apparatus to a position under the first substrate of the optical disk to converge the transmitted light on the first substrate of the optical disk when the distinguishing information is detected in the detecting means; and

reproducing the recording information by generating the recording information signal in the detecting means.

In the above steps, the information reproducing method is performed by utilizing the optical disk apparatus described above. The distinguishing information placed on the second substrate of the optical disk is reproduce with the diffracted light. In this case, because the second substrate has the second thickness, the diffracted light is just focused on the second substrate. Thereafter, when the distinguishing information is detected, the optical disk apparatus is moved to a position under the first substrate of the optical disk, and the transmitted light is converged on the first substrate of the optical disk. In this case, because the first substrate has the first thickness, the diffracted light is just focused on the first substrate.

Accordingly, the recording information can be reliably reproduced.

BRIEF DESCRIPTION OF THE DRAWINGS

The objects, features and advantages of the present invention will be apparent from the following description taken in conjunction with the accompanying drawings, in which:

FIG. **1** is a constitutional view of a conventional optical head apparatus proposed in Japanese Patent Application No. 46630 of 1991;

FIGS. **2**A, **2**B are respectively a cross sectional view of a set of an objective lens and a blazed hologram shown in FIG. **1**;

FIG. **3** shows a relationship between the thickness of an optical disk and a numerical aperture of an objective lens on condition that the tilt of the optical axis is constant;

FIG. **4**A is a constitutional view of an imaging optical system having a compound objective lens according to a first embodiment of the present invention, a beam of transmitted light not diffracted being converged on a thin type of information medium;

FIG. **4**B is a constitutional view of the imaging optical system shown in FIG. **4**A, a beam of first-order diffracted light being converged on a thick type of information medium;

FIG. **5** is a plan view of a hologram lens shown in FIGS. **4**A, **4**B, a grating pattern of the hologram lens being depicted;

FIG. **6** is a cross sectional view of the hologram lens shown in FIG. **5**, the grating pattern formed in relief on the hologram lens being shown;

FIG. **7** is an explanatory diagram showing an intensity distribution of transmitted light L4 converged on a converging spot S1 of a first information medium, a primary maximum and secondary maxima suppressed occurring in the converging spot S1;

FIG. **8**A is a cross sectional view of the hologram lens shown in FIG. **5**, the grating pattern approximating to a stepwise shape composed of four stairs being shown;

FIG. **8**B is a cross sectional view of the hologram lens shown in FIG. **5**, the grating pattern approximating to a stepwise shape composed of a plurality of stairs being shown;

FIG. **9**A is a constitutional view of an imaging optical system having a compound objective lens according to a modification of the first embodiment, a beam of first-order diffracted light being converged on a thin type of information medium;

FIG. **9**B is a constitutional view of the imaging optical system shown in FIG. **9**A, a beam of transmitted light not diffracted being converged on a thick type of information medium;

FIG. **10**A is a constitutional view of an imaging optical system having a compound objective lens according to a second embodiment of the present invention, a beam of transmitted light not diffracted being converged on a thin type of information medium;

FIG. **10**B is a constitutional view of the imaging optical system shown in FIG. **10**A, a beam of first-order diffracted light being converged on a thick type of information medium;

FIG. **11** shows a change of a diffraction efficiency of a hologram lens shown in FIGS. **10**A, **10**B;

FIGS. **12**A to **12**E are respectively a cross sectional view of the hologram lens shown in FIGS. **10**A, **10**B, the grating pattern of the hologram lens approximating to a step-wise shape;

FIG. **13**A shows an intensity distribution of incident light utilized in the second embodiment, a far field pattern of the incident light being distributed in a Gaussian distribution;

FIG. **13**B shows an intensity distribution of transmitted light transmitting through a hologram lens shown in FIGS. **10**A, **10**B, a far field pattern of the incident light being distributed in a gently-sloping shape;

FIGS. **14**A to **14**C show intensity distributions of transmitted light and diffracted light transmitting through a hologram lens shown in FIGS. **10**A, **10**B;

FIG. **15**A is a plan view of a hologram lens according to a modification of the second embodiment, a grating pattern of the hologram lens being depicted;

FIGS. **15**B, **15**C are respectively a constitutional view of an imaging optical system having a compound objective lens according to another modification of the second embodiment;

FIG. **16**A is a constitutional view of an imaging optical system having a compound objective lens according to a third embodiment of the present invention, a beam of first-order diffracted light being converged on a thin type of information medium;

FIG. **16**B is a constitutional view of the imaging optical system shown in FIG. **16**A, a beam of transmitted light not diffracted being converged on a thick type of information medium;

FIG. **17** shows a change of a diffraction efficiency of a hologram lens shown in FIGS. **16**A, **16**B;

FIGS. **18**A to **18**C show intensity distributions of transmitted light and diffracted light transmitting through a hologram lens shown in FIGS. **16**A, **16**B;

FIG. **19**A is a cross sectional view of a compound objective lens according to a fourth embodiment of the present invention;

FIG. **19**B is a cross sectional view of a compound objective lens according to a modification of the fourth embodiment of the present invention;

FIG. **20** is a cross sectional view of a compound objective lens according to a fifth embodiment of the present invention;

FIG. **21** is a constitutional view of an optical head apparatus according to a sixth embodiment of the present invention;

FIG. **22** is a plan view of a wavefront changing device utilized in the six, ninth and twelfth embodiments, a grating pattern of a hologram lens utilized as the wavefront changing device being depicted;

FIG. **23** shows a positional relation between focal points of diffracted light occurring in the wavefront changing device shown in FIG. **22** and a photo detector;

FIG. **24** is a plan view of a photo detector utilized in the six, ninth, tenth, twelfth, thirteenth and seventeenth embodiments;

FIG. **25**A and **25**C respectively show a converging spot of first-order diffracted light radiated to detecting sections SE**1**, SE**2** and SE**3** of a sextant photo-detector shown in FIG. **24** and another converging spot of minus first-order diffracted light radiated to detecting sections SE**4**, SE**5** and SE**6** of the sextant photo-detector on condition that an objective lens shown in FIG. **21** is defocused on an information medium;

FIG. **25**B shows a converging spot of first-order diffracted light radiated to the detecting sections SE**1**, SE**2** and SE**3** of the sextant photo-detector and another converging spot of minus first-order diffracted light radiated to the detecting sections SE**4**, SE**5** and SE**6** of the sextant photo-detector on condition that the objective lens is just focused on the information medium;

FIG. **26** shows a relationship between beams of diffracted light occurring in the wavefront changing device shown in FIG. **22** and the photo detector shown in FIG. **24**;

FIG. **27** is a constitutional view of an optical head apparatus according to a seventh embodiment;

FIG. **28** is a plan view of a photo detector utilized in the seven, ninth, tenth, twelfth and thirteenth embodiments;

FIGS. **29**A, **29**B, **29**C show various shapes of converging spots converged on the photo detector shown in FIG. **28**;

FIG. **29**D shows a radial direction Dr and a tangential direction Dt;

FIG. **30** is a constitutional view of an optical head apparatus according to a first modification of the seventh embodiment;

FIG. **31** is a constitutional view of an optical head apparatus according to a second modification of the seventh embodiment;

FIG. **32** is a constitutional view of an optical head apparatus according to a third modification of the seventh embodiment;

FIG. **33** is a constitutional view of an optical head apparatus according to a forth modification of the seventh embodiment;

FIG. **34** shows a beam of transmitted light not diffracted on an incoming optical path and a beam of transmitted light diffracted on the incoming optical path, the beams being utilized to detect an information signal;

FIG. **35**A graphically shows a change of a focus error signal obtained by detecting the intensity of transmitted light, the strength of the focus error signal depending on a distance between an objective lens and a first information medium;

FIG. **35**B graphically shows a change of a focus error signal obtained by detecting the intensity of diffracted light, the strength of the focus error signal depending on a distance between an objective lens and a second information medium.

FIG. **36**A graphically shows a change of a focus error signal obtained by detecting the intensity of diffracted light, the strength of the focus error signal depending on a distance between an objective lens and a first information medium;

FIG. **36**B graphically shows a change of a focus error signal obtained by detecting the intensity of transmitted light, the strength of the focus error signal depending on a distance between an objective lens and a second information medium;

FIG. **37** is a constitutional view of an optical head apparatus according to a ninth embodiment;

FIG. **38** is a constitutional view of an optical head apparatus according to a tenth embodiment;

FIG. **39** is a plan view of a beam splitter having a reflection type of hologram utilized in the optical head apparatus shown in FIG. **38**;

FIGS. **40**A, **40**B are respectively a constitutional view of an optical head apparatus according an eleventh embodiment;

FIG. **41** is a plan view of a beam splitter having a reflection type of hologram utilized in the optical head apparatus shown in FIG. **38**;

FIG. **42**A and **42**C respectively show a converging spot of first-order diffracted light radiated to detecting sections SE**1**, SE**2** and SE**3** of a sextant photo-detector shown in FIG. **24** and another converging spot of minus first-order diffracted light radiated to detecting sections SE**4**, SE**5** and SE**6** of the sextant photo-detector on condition that diffracted light is converged in defocus on a second information medium;

FIG. **42**B shows a converging spot of first-order diffracted light radiated to the detecting sections SE**1**, SE**2** and SE**3** of a sextant photo-detector shown in FIG. **24** and another converging spot of minus first-order diffracted light radiated to the detecting sections SE**4**, SE**5** and SE**6** of the sextant photo-detector on condition that diffracted light is converged in focus on a second information medium;

FIG. **43** is a constitutional view of an optical head apparatus according to a twelfth embodiment;

FIG. **44** is a constitutional view of an optical head apparatus according to a thirteenth embodiment;

FIG. **45** is a constitutional view of an optical head apparatus according to a fourteenth embodiment;

FIG. **46** is a plan view of a hologram lens utilized in the optical head apparatus shown in FIG. **45**;

FIG. **47** is a constitutional view of an optical head apparatus according to a fifteenth embodiment;

FIG. **48** is a plan view of a hologram lens utilized in the optical head apparatus shown in FIG. **47**;

FIGS. **49**A, **49**B respectively show a positional relation between unnecessary light occurring in the hologram lens shown in FIG. **48** and a photo detector shown in FIG. **47**;

FIG. **50** is a constitutional view of an optical head apparatus according to a sixteenth embodiment;

FIG. **51** is a diagonal view of a light source and photo detectors utilized in the optical head apparatus shown in FIG. **50**;

FIG. **52** is a constitutional view of an optical head apparatus according to a seventeenth embodiment;

FIG. **53** is a diagonal view of a high density optical disk according to an eighteenth embodiment, a cross sectional view of the disk being partially shown;

FIG. **54** is a diagonal view of a high density optical disk according to a nineteenth embodiment, a cross sectional view of the disk being partially shown;

FIG. **55** is a block diagram of an optical disk apparatus with one of the optical head apparatuses shown in FIGS. **21**, **27**, **30**, **31**, **32**, **33**, **37**, **38**, **40**A, **43**, **44**, **50** and **52** according to a twentieth embodiment;

FIG. **56** is a flow chart showing the operation of the optical disk apparatus shown in FIG. **55**;

FIG. **57** is a block diagram of an optical disk apparatus with one of the optical head apparatuses shown in FIGS. **21**, **27**, **30**, **31**, **32**, **33**, **37**, **38**, **40**A, **43**, **44**, **50** and **52** according to a twenty-first embodiment;

FIG. **58** is a flow chart showing the operation of the optical disk apparatus shown in FIG. **57**;

FIG. **59** is a constitutional view of a binary focus microscope according to a twenty-second embodiment;

FIG. **60** is a partial view of the binary focus microscope shown in FIG. **59** in cases where first and second samples are located at bottoms of sample holders;

FIG. **61** is a constitutional view of a binary focus microscope according to a modification of the twenty-second embodiment;

FIG. **62** is a constitutional view of an alignment apparatus according to a twenty-third embodiment;

Fig. **63** is a constitutional view of the optical disk apparatus of which the block diagram is shown in FIG. **55**;

FIG. **64** is a constitutional view of an exposure apparatus in which the alignment apparatus is included;

FIG. **65** is a diagonal view of an image reproducing apparatus for which the optical disk apparatus **176** is provided;

FIG. **66** is a diagonal view of a voice reproducing apparatus for which the optical disk apparatus **176** is provided;

FIG. **67** is a diagonal view of an information processing apparatus for which the optical disk apparatus **176** is provided; and

FIG. **68** is a diagonal view of another information processing apparatus for which the optical disk apparatus **176** is provided.

DETAIL DESCRIPTION OF THE PREFERRED EMBODIMENTS

Preferred embodiments of a compound objective lens, an imaging optical system, an optical head apparatus, an optical disk, an optical disk apparatus, a binary focus microscope and an alignment apparatus according to the present invention are described with reference to drawings.

(First Embodiment)

FIG. **4**A is a constitutional view of an imaging optical system having a compound objective lens according to a first embodiment of the present invention, a beam of transmitted light not diffracted being converged on a thin type of information medium. FIG. **4**B is a constitutional view of the imaging optical system shown in FIG. **4**A, a beam of first-order diffracted light being converged on a thick type of information medium. FIG. **5** is a plan view of a hologram lens shown in FIGS. **4**A, **4**B, a grating pattern of the hologram lens being depicted.

As shown in FIGS. **4**A, **4**B, an imaging optical system **21** for converging light on a first substrate **22** of a thin type of first information medium **23** (a thickness T1) or a second substrate **24** of a thick type of second information medium **25** (a thickness T2) to form a diffraction-limited converging spot comprises a blazed hologram lens **26** for transmitting a part of incident light **L3** radiated from a light source without any diffraction to form a beam of transmitted light **L4** and diffracting a remaining part of the incident light **L3** to form a beam of first-order diffracted light **L5**, and an objective lens **27** for converging the transmitted light **L4** on the first information medium **23** or converging the first-order diffracted light **L5** on the second information medium **25**.

The first information medium **23** represents a prospective optical disk having a high density memory capacity, and the thickness T1 of the first information medium **23** ranges from 0.4 mm to 0.8 mm. The second information medium **25** represents a compact disk or a laser disk appearing on the market now, and the thickness T2 of the second information medium **25** is about 1.2 mm.

The term "convergence" denotes in this specification that divergent light or collimated light is focused to form a diffraction-limited micro spot.

In the above configuration, a part of incident light **L3** collimated transmits through the hologram lens **26** without any diffraction, and a beam of transmitted light **L4** (that is, a beam of zero-order diffracted light **L4**) is formed. Thereafter, the transmitted light **L4** is converged by the objective lens **27**. Also, a remaining part of the incident light **L3** is diffracted and refracted by the hologram lens **26**, and a beam of first-order diffracted light **L5** is formed. In this case, the hologram lens **26** selectively functions as a concave lens for the first-order diffracted light **L5**, so that the first-order diffracted light **L5** diverges from the hologram lens **26**. Thereafter, the first-order diffracted light **L5** is converged by the objective lens **27**.

In cases where the thin type of first information medium **23** is utilized to record or reproduce pieces of information on or from a front surface of the medium **23**, as shown in FIG. **4**A, the transmitted light **L4** is incident on a rear surface of the first information medium **23** and is focused on its front surface by the objective lens **27** to form a diffraction-limited converging spot **S1** on the first information medium **23**. In contrast, in cases where the thick type of second information medium **25** is utilized to record or reproduce pieces of information on or from a front surface of the medium **25**, the diffracted light **L5** is incident on a rear surface of the second information medium **25** and is focused on its front surface to form a diffraction-limited converging spot **S2** on the second information medium **25**. Because the hologram lens **26** functions as a concave lens to diverge the first-order diffracted light **L5**, the diffraction-limited converging spots **S1**, **S2** are formed even though the thickness T1 of the first information medium **23** differs from the thickness T2 of the second information medium **25**. Therefore, a compound objective lens **29** composed of the hologram lens **26** and the objective lens **27** has substantially two focal points.

As shown in FIG. **5**, the hologram lens **26** is formed by drawing a grating pattern **P1** in a pattern region **26**A of a transparent substrate **28** in a concentric circle shape. The pattern region **26**A is positioned in a center portion of the transparent substrate **28**, and a no-pattern region **26**B is positioned in a peripheral portion of the transparent substrate **28** to surround the pattern region **26**A. An optical axis of the imaging optical system **21** passes through a central point of the grating pattern **P1** and a central axis of the objective lens **27**.

In addition, as shown in FIG. **6**, the grating pattern **P1** of the hologram lens **26** is formed in relief to produce a phase modulation type of hologram lens. That is, blocks which each are composed of a bottom portion and a top portion are concentrically formed in the grating pattern **P1**. The height H of the relief in the grating pattern **P1** is set to:

$$H < \lambda/(n(\lambda)-1), \quad (1)$$

where the symbol λ denotes a wavelength of the incident light **L3** and the symbol $n(\lambda)$ denotes a refractive index of the transparent substrate **28** for the incident light **L3**. In this case, a difference in phase modulation degree between the incident light **L3** transmitting through a bottom portion of the grating pattern **P1** and the incident light **L3** transmitting through a top portion of the grating pattern **P1** is lower than 2π radians. Therefore, a diffraction efficiency of the holo-

gram lens **26** for the incident light L3 transmitting through the grating pattern P1 is less than 100% to generate the light L4 transmitting through the grating pattern P1. Also, the incident light L3 transmitting through the no-pattern region **26**B is not diffracted. As a result, the intensity of the transmitted light L4 can be sufficient to record or reproduce pieces of information on or from the first information medium **23**.

Also, because the intensity of the transmitted light L4 is sufficient over the entire surface of the hologram lens **26**, secondary maxima (side lobes) of the transmitted light L4 undesirably occurring in the converging spot S1 can be suppressed. In detail, as an intensity distribution of the transmitted light L4 converged on the converging spot S1 is shown in FIG. **7**, a primary maximum (a main lobe) of the transmitted light L4 positioned in a center of the converging spot S1 is utilized to record or reproduce a piece of information on or from the first information medium **23**, and secondary maxima positioned around the primary maximum are unnecessary because the secondary maxima deteriorate a recording pit or a reproducing signal formed by the primary maximum.

The grating pattern P1 of hologram lens **26** formed in relief is blazed as shown in FIG. **6**, so that the occurrence of minus first-order diffracted light is considerably suppressed. Therefore, the intensity sum of the transmitted light L4 and the first-order diffracted light L5 is maximized. In other words, a utilization efficiency of the incident light L3 is enhanced.

The numerical aperture NA of the objective lens **27** is equal to or more than 0.6. Also, when the transmitted light L4 is converged by the objective lens **27**, the diffraction-limited converging spot S1 is formed on the first information medium **23** having a thickness T1.

A diameter of the hologram lens **26** is almost the same as an aperture of the objective lens **27**, so that a diameter of the pattern region **26**A is smaller than the aperture of the objective lens **27**. Because the incident light L3 transmitting through the no-pattern region **26**B is not diffracted, not only the light L4 transmitting through the pattern region **26**A but also the light L4 transmitting through the no-pattern region **26**B are converged on the first information medium **23** by the objective lens **27** having a high numerical aperture. Therefore, the intensity of the transmitted light L4 converged at the converging point S1 can be increased. In contrast to the transmitted light L4, only the incident light L3 transmitting through the pattern region **26**A of the hologram lens **26** is changed to the first-order diffracted light L5, and the first-order diffracted light L5 is converged on the second information medium **25** by the objective lens **27** having substantially a low numerical aperture.

The phase of the light L4 transmitting through the grating pattern P1 of the pattern region **26**A is determined by an average value of the phase modulation degrees in the light L4 transmitting through the bottom and top portions of the grating pattern P1. In contrast, because the height of the no-pattern region **26**B is constant, the phase of the light L4 transmitting through the no-pattern region **26**B is modulated at a phase modulation degree. Therefore, as shown in FIG. **6**, the height of the no-pattern region **26**B is set even with an average height of the grating pattern P1 to enhance the convergence function of the objective lens **27**.

For example, as shown in FIG. **8**A, in cases where each block of the grating pattern P1 in the hologram lens **26** shown in FIG. **6** approximates to a step-wise shape composed of four stairs, a first step is etched at a depth h1+h2 and a width W1, a second step is etched at a depth hi and a width W2, a third step is etched at a depth h2 and a width W2, and a fourth step is etched at a width W1. Therefore, the grating pattern P1 approximating to the step-wise shape is formed in the pattern region **26**A. Thereafter, a peripheral portion of the transparent substrate **28** is etched by a depth h1 or h2 to form the no-pattern region **26**B. Therefore, the height of the no-pattern region **26**B is almost the same as an average height of the pattern region **26**A, so that the phase of the light L4 transmitting through the pattern region **26**A is almost the same as that of the light L4 transmitting through the no-pattern region **26**B.

In addition, as shown in FIG. **8**B, an ideal blazed shape of the hologram lens **26** shown in FIG. **6** can approximate to a step-wise shape which is obtained by etching a center portion of the transparent substrate **28** many times. In this case, the height H0 of the step-wise shape is set to satisfy an equation $H0<\lambda/(n(\lambda)-1)$ so that the difference in phase modulation degree is set to a value lower than 2π radians. Specifically, in cases where the step-wise shape of the hologram lens **26** is composed of a flight of N stairs having the same difference n_o in level, the difference n_o in level is set to satisfy an equation $n_o<\lambda/\{(n(\lambda)-1)*N\}$ to set the difference in phase modulation degree of each stairs to a value lower than $2\pi/N$ radians. A peripheral portion of the transparent substrate **28** is etched to set the thickness of the no-pattern region **26**B to a thickness of the pattern region **26**A at one of the N stairs which is not the top stair or the bottom stair. Therefore, the height of the no-pattern region **26**B is almost the same as an average height of the pattern region **26**A, so that the phase of the light L4 transmitting through the pattern region **26**A is almost the same as that of the light L4 transmitting through the no-pattern region **26**B.

The grating pattern P1 of the hologram lens **26** is designed to correct any aberration occurring in the objective lens **27** and the second information medium **25**, so that the first-order diffracted light L5 transmits through the second information medium **25** having a thickness T2 and is converged on the medium **25** to form the diffraction-limited converging spot S2 without any aberration. A method for designing the hologram lens **26** having an aberration correcting function is described.

After the first-order diffracted light L5 is converged on the second information medium **25**, spherical waves diverge from the converging spot S2 and transmit through the second substrate **24** and the objective lens **27**. Thereafter, the spherical waves transmit through the transparent substrate **28** and optically interfere with the incident light L3. Therefore, an interference pattern is formed by the interference between the spherical waves and the incident light L3. The interference pattern can be calculated by subtracting the phase of the spherical waves from an inverted phase obtained by inverting the phase of the incident light L3. Accordingly, the grating pattern P1 of the hologram lens **26** which agrees with the interference pattern calculated can be easily formed according to a computer generated hologram technique.

Accordingly, because the compound objective lens **29** is composed of the objective lens **27** and the hologram lens **26** in which a part of the incident light L3 is diffracted and refracted, a diffraction-limited converging spot can be reliably formed on an information medium regardless of whether the information medium has a thickness T1 or a thickness T2. Also, two diffraction-limited converging spots can be simultaneously formed on an information medium at difference depths. In other words, the compound objective lens has substantially two focal points.

Also, because the diffraction efficiency of the hologram lens **26** is less than 100% and the intensity of the light L4

transmitting through the hologram lens **26** is sufficient to record or reproduce information on or from the first information medium **23**, the secondary maxima of the transmitted light **L4** converged on the converging spot **S1** can be suppressed.

Also, because the hologram lens **26** is blazed, the occurrence of minus first-order diffracted light can be considerably suppressed. Therefore, the intensity sum of the transmitted light **L4** and the first-order diffracted light **L5** can be maximized, and a utilization efficiency of the incident light **L3** can be enhanced.

Also, because the hologram lens **26** functions as a lens only for the first-order diffracted light, the position of the converging point **S1** formed by the transmitted light **L4** differs from that of the converging point **S2** formed by the first-order diffracted light **L5** in an optical axis direction. Therefore, when the transmitted light **L4** is converged in focus on an information recording plane of the information medium **23** to record or read a piece of information, the first-order diffracted light **L5** converged on the information medium **23** is out of focus at the information recording plane. In the same manner, when the first-order diffracted light **L5** is converged in focus on an information recording plane of the information medium **25**, the transmitted light **L4** converged on the information medium **25** is out of focus at the information recording plane. Accordingly, when the light **L4** (or **L5**) is converged on the converging spot **S1** (or **S2**) in focus to record or read the information, the light **L5** (or **L4**) not converged on the converging spot **S1** (or **S2**)in focus does not adversely influence on the recording or reading of the information. To reliably prevent the adverse influence on the recording or reading of the information, a difference in the optical axis direction between the converging spots **S1**, **S2** is required to be equal to or more than 50 μm. That is, when the difference is equal to or more than 50 μm, the light **L5** (or **L4**) largely diverges to reduce the intensity of the light **L5** (or **L4**) at an information recording plane when the light **L4** (or **L5**) is converged on the converging spot **S1** (or **S2**) of the information recording plane at a high intensity.

Also, because the thickness **T2** of the second information medium **25** representing the compact disk or the laser disk is about 1. 2 mm and because the thickness **T1** of the first information medium **23** representing a prospective optical disk ranges from 0.4 mm to 0.8 mm, the difference in the optical axis direction between the converging points **S1**, **S2** is required to be equal to or less than 1.0 mm by considering a moving range of an actuator with which the position of the compound objective lens **29** composed of the objective lens **27** and the hologram lens **26** is adjusted according to a focus servo signal. Because the hologram lens **26** functions as a concave lens for the first-order diffracted light, the difference between the converging points **S1**, **S2** can be increased to about 1 mm.

Accordingly, even though the transmitted light **L4** and the first-order diffracted light **L5** are simultaneously converged by the objective lens **27**, no adverse influence is exerted on the recording or reproduction of the information on condition that the difference between the converging points **S1**, **S2** ranges from 50 μm to 1 mm.

Examples of the utilization of the imaging optical system **21** for various types of optical disks are described.

In cases where the image optical system **21** is utilized for an optical disk device in which pieces of information recorded in a thin type of high density optical disk and a thick type of compact disk are exclusively reproduced, the diffraction efficiency of the hologram lens **26** for changing the incident light **L3** to the diffracted light **L5** is set in a range from about 20% to 70%. In this case, the intensity of the transmitted light **L4** converged on the high density optical disk is almost the same as that of the first-order diffracted light **L5** converged on the compact disk. Therefore, the output power of the incident light **L3** can be minimized.

Also, in cases where the image optical system **21** is utilized for an optical disk device in which pieces of information recorded in a thin type of high density optical disk are recorded or reproduced and pieces of information recorded in a thick type of optical disk are exclusively reproduced, the diffraction efficiency of the hologram lens **26** for changing the incident light **L3** to the first-order diffracted light **L5** is set to a value equal to or lower than 30%. In this case, even though a high intensity of transmitted light **L4** is required to record a piece of information on the high density optical disk, the recording of the information can be reliably performed without increasing the intensity of the incident light **L3** because a transmission efficiency of the hologram lens **26** for the incident light **L3** is high. In other words, a utilization efficiency of the incident light **L3** can be enhanced when a piece of information is recorded on the high density optical disk, so that the output power of the incident light **L3** can be minimized.

In the first embodiment, the hologram lens **26** functions as a concave lens for the first-order diffracted light **L5**. However, it is applicable that a hologram lens **26M** functioning as a convex lens for the first-order diffracted light **L5** be utilized in place of the hologram lens **26**. That is, as shown in FIGS. **9A**, **9B**, the diffracted light **L5** is converged on the first information medium **23** by the objective lens **27** to form the diffraction limited converging spot **S1**, and the transmitted light **L4** is converged on the second information medium **25** by the objective lens **27** to form the diffraction limited converging spot **S2**. In this case, the difference between the converging points **S1**, **S2** is required to be equal to or less than 0.5 mm by considering the moving range of the actuator. However, the occurrence of a chromatic aberration can be prevented in an imaging optical system **21M** in which the hologram lens **26M** functioning as a concave lens for the diffracted light **L5** is utilized. The achromatization function in the imaging optical system is described in detail.

When a focal length of the hologram lens **26M** for the incident light **L3** having a wavelength λ_o is represented by f_{Ho} and another focal length of the hologram lens **26M** for the incident light **L3** having a wavelength λ_l is represented by f_{Hl}, an equation (2) is satisfied.

$$f_{Hl}=f_{Ho}\times\lambda_o/\lambda_l \tag{2}$$

The focal length f_H of the hologram lens **22** is shortened as the wavelength λ of the incident light **L3** becomes longer. Also, when a refractive index of the objective lens **27** for the incident light **L3** having a wavelength λ_o is represented by $n(\lambda_o)$ and another refractive index of the objective lens **27** for the incident light **L3** having a wavelength λ_l is represented by $n(\lambda_l)$, a focal length $f_D(\lambda)$ of the objective lens **27** for the incident light **L3** having a wavelength λ is formulated by an equation (3).

$$f_D(\lambda_1)=f_D(\lambda_o)\times(n(\lambda_o)-1)/(n(\lambda_l)-1) \tag{3}$$

The focal length $f_D(\lambda)$ of the objective lens **27** is lengthened as the wavelength λ of the incident light **L3** becomes longer. That is, the dependence of the focal length $f_D(\lambda)$ on the wavelength λ in the objective lens **27** is opposite to that of the focal length f_H on the wavelength λ in the hologram lens **26M**. Therefore, a condition that the compound objective lens **29M** composed of the objective lens **27** and the

hologram lens **26**M functions as an achromatic lens is formulated by an equation (4).

$$1/f_{Ho}+1/f_D(\lambda_o)=1/f_{Hf}+1/f_D(\lambda_f)=1/(f_{Ho}\times\lambda_o/\lambda_f)+(n(\lambda_f)-1)/\{f_D(\lambda_o)\times(n(\lambda_o)-1)\} \quad (4)$$

Accordingly, because the dependence of the focal length $f_D(\lambda)$ on the wavelength λ in the objective lens **27** is opposite to that in the hologram lens **22**, the compound objective lens **29**M having an achromatic function can be formed by the combination of the lenses **26**M, **27**, and the occurrence of the chromatic aberration can be prevented. Also, even though the equation (4) is not strictly satisfied, the occurrence of the chromatic aberration can be largely suppressed.

Also, a curvature of the objective lens **27** can be small because the hologram lens **26**M functions as a convex lens for the first-order diffracted light L**5**. Also, because the hologram lens **26**M is a plane type of element, a lightweight type of compound objective lens having an achromatic function can be made in large scale manufacture. A principal of the achromatization has been proposed in a first literature (D. Faklis and M. Morris, Photonics Spectra(1991), November p.205 & December p.131), a second literature (M. A. Gan et al., S.P.I.E.(1991), Vol.1507, p.116), and a third literature (P. Twardowski and P. Meirueis, S.P.I.E.(1991), Vol.1507, p.55).

(Second Embodiment)

FIG. **10**A is a constitutional view of an imaging optical system having a compound objective lens according to a second embodiment of the present invention, a beam of transmitted light not diffracted being converged on a thin type of information medium. FIG. **10**B is a constitutional view of the imaging optical system shown in FIG. **10**A, a beam of first-order diffracted light being converged on a thick type of information medium.

As shown in FIGS. **10**A, **10**B, an imaging optical system **31** for converging light on the first substrate **22** of the first information medium **23** (the thickness T**1**) or the second substrate **24** of the second information medium **25** (the thickness T**2**) to form a diffraction-limited converging spot, comprises a blazed hologram lens **32** for transmitting a part of incident light L**3** without any diffraction to form a beam of transmitted light L**4** and diffracting a remaining part of incident light L**3** to form a beam of first-order diffracted light L**5**, and the objective lens **27** for converging the transmitted light L**4** on the first information medium **23** or converging the first-order diffracted light L**5** on the second information medium **25**.

The hologram lens **32** is formed by drawing a grating pattern P**2** in a pattern region **32**A of the transparent substrate **28** in a concentric circle shape. The pattern region **32**A is positioned in a center portion of the transparent substrate **28**. An diameter of the grating pattern P**2** is equal to or larger than an aperture of the objective lens **27**. Also, a diffraction efficiency of the hologram lens **32** for the incident light L**3** transmitting through the grating pattern P**2** is less than 100% in the same manner as in the first embodiment, so that the intensity of the transmitted light L**4** is sufficient to record or reproduce a piece of information on or from the first information medium **23**.

In addition, as shown in FIG. **11**, the diffraction efficiency in a central portion of the pattern region **32**A is high, and the diffraction efficiency is gradually decreased toward an outer direction of the pattern region **32**A. In other words, in cases where the grating pattern P**2** of the hologram lens **32** is formed in relief, the height H of the relief in the grating pattern P**2** is gradually lowered toward the outer direction of the pattern region **32**A. Or, in cases where an ideal blazed shape of the hologram lens **26** approximates to a step-wise shape, each block of the grating pattern P**2** positioned in the central portion of the transparent substrate **28** is formed in a step-wise shape shown in FIG. **12**A in which an inclined angle θ_1 of stairs is large and a relationship W**1** >W**2** between a first etching width W**1** and a second etching width W**2** is satisfied, and the grating pattern P**2** formed in the step-wise shape shown in FIG. **12**A is gradually changed by decreasing the first etching width W**1** and increasing the second etching width W**2** toward the outer direction of the pattern region **32**A while the height H of the grating pattern P**2** is gradually decreased. Therefore, each block of the grating pattern P**2** positioned in a peripheral portion of the transparent substrate **28** is formed in a step-wise shape shown in FIG. **12**B in which an inclined angle θ_2 of stairs is small and a relationship W**1**<W**1** between the etching widths is satisfied. Also, each block of the grating pattern P**2** positioned in a middle portion between the central and peripheral portions is formed in a step-wise shape shown in FIG. **12**C in which the etching widths W**1**, W**2** is the same.

In the above configuration of the imaging optical system **31**, a part of the incident light L**3** transmits through the hologram lens **32** without any diffraction to form a beam of transmitted light L**4**, and the transmitted light L**4** is converged by the objective lens **27**. Also, a remaining part of the incident light L**3** is diffracted and refracted by the hologram lens **32**. In this case, the hologram lens **32** functions as a concave lens for the incident light L**3**, so that a first-order diffracted light L**5** diverges from the hologram lens **32**. Thereafter, the first-order diffracted light L**5** is converged by the objective lens **27**.

In cases where the thin type of first information medium **23** is utilized to record or reproduce pieces of information on or from a front surface of the medium **23**, as shown in FIG. **10**A, the transmitted light L**4** is incident on a rear surface of the first information medium **23** and is focused on its front surface by the objective lens **27** to form a diffraction-limited converging spot S**3** on the first information medium **23**. In this case, because the diffraction efficiency in the central portion of the grating pattern P**2** is high and because the diffraction efficiency is gradually decreased toward the outer direction of the grating pattern P**2**, a diffraction probability of the incident light L**3** is lowered in the peripheral portion of the grating pattern P**2**. Therefore, the light L**4** transmits through the objective lens **27** on condition that the numerical aperture NA of the objective lens **27** is high.

In contrast, in cases where the thick type of second information medium **25** is utilized to record or reproduce pieces of information on or from a front surface of the medium **25**, the diffracted light L**5** is incident on a rear surface of the second information medium **25** and is focused on its front surface to form a diffraction-limited converging spot S**5** on the second information medium **25**. In this case, because the hologram lens **32** functions as a concave lens to diverge the first-order diffracted light L**5**, the diffraction-limited converging spots S**3**, S**4** are formed even though the thickness T**1** of the first information medium **23** differs from the thickness T**2** of the second information medium **25**. Therefore, a compound objective lens **34** composed of the hologram lens **32** and the objective lens **27** has substantially two focal points.

Accordingly, because the light L**4** transmits through the objective lens **27** on condition that the numerical aperture NA of the objective lens **27** is high, the intensity of the transmitted light L**4** converged on the first information medium **23** can be high.

Also, in cases where the incident light L3 is radiated from a semiconductor laser, a far field pattern of the incident light L3 is distributed in a Gaussian distribution as shown in FIG. 13A. Therefore, because the diffraction efficiency is gradually decreased toward the outer direction of the grating pattern P2, a far field pattern of the transmitted light L4 is distributed in a gently-sloping shape as shown in FIG. 13B. In contrast to the second embodiment, because the incident light L3 is not diffracted in the no-pattern region 26*b* of the hologram lens 26 in the first embodiment, the intensity of the transmitted light L4 is suddenly increased at the peripheral portion of the hologram lens 26.

Accordingly, secondary maxima of the transmitted light L4 converged on the converging spot S3 can be moreover suppressed in the second embodiment as compared with in the first embodiment. That is, the recording and reproducing of the information can be performed without any deterioration of the information by utilizing the imaging optical system 31.

In addition, in cases where the first-order diffracted light L5 is converged on the second information medium 25 to form the diffraction-limited converging spot S4, a numerical aperture of the objective lens 27 for the first-order diffracted light L5 is low because the diffraction efficiency of the hologram lens 32 is decreased toward an outer direction of the pattern region 32A. As a result, the intensity of the first-order diffracted light L5 becomes lowered. In cases where the diffraction efficiency of the hologram lens 32 is heightened to increase the intensity of the first-order diffracted light L5, the intensity of the transmitted light L4 at its inner beam portion is largely decreased, and secondary maxima (or side lobes) of the transmitted light L4 at the converging spot S3 is undesirably increased. Therefore, the incident light L3 of which the far field pattern is distributed in the Gaussian distribution is radiated to the hologram lens 32 to increase the intensity of the first-order diffracted light L5 without any increase of the second maxima. In detail, as shown in FIG. 14A, the incident light L3 distributed not only in a central portion of the Gaussian distribution but also in a peripheral portion of the Gaussian distribution transmits through the hologram lens 32 and is refracted by the objective lens 27 because the diameter of the grating pattern P2 is equal to or larger than the aperture of the objective lens 27. Therefore, a numerical aperture NA of the objective lens 27 at a light source side for the incident light L3 becomes higher than that in the first embodiment, and the diffraction efficiency of the hologram lens 32 is heightened. As a result, the intensity of the first-order diffracted light L5 converged on the second information medium 25 can be increased, as shown in FIG. 14B. Also, because the intensity of the incident light L3 at the peripheral portion of the Gaussian distribution is low and because the diffraction efficiency of the hologram lens 32 is increased toward the inner direction of the grating pattern region 32A, intensity of the transmitted light L4 is distributed in a gently-sloping shape as shown in FIG. 14C. Accordingly, secondary maxima of the transmitted light L4 at the converging spot S3 can be suppressed.

Examples of the utilization of the imaging optical system 31 for various types of optical disks are described.

In cases where the image optical system 31 is utilized for an optical disk device in which pieces of information recorded in a thin type of high density optical disk and a thick type of compact disk are exclusively reproduced, the diffraction efficiency of the hologram lens 32 for the incident light L3 is set in a range from about 20% to 70%. In this case, the intensity of the transmitted light L4 converged on the high density optical disk is almost the same as that of the first-order diffracted light L5 converged on the compact disk. Therefore, the output power of the incident light L3 can be minimized.

Also, in cases where the image optical system 31 is utilized for an optical disk device in which pieces of information recorded in a thin type of high density optical disk are recorded or reproduced and pieces of information recorded in a thick type of optical disk are exclusively reproduced, the diffraction efficiency of the hologram lens 32 for the incident light L3 is set to a value equal to or lower than 30%. In this case, even though a high intensity of transmitted light L4 is required to record a piece of information on the high density optical disk, the recording of the information can be reliably performed without increasing the intensity of the incident light L3 because a transmission efficiency of the hologram lens 32 for the incident light L3 is high. In other words, a utilization efficiency of the incident light L3 can be enhanced when a piece of information is recorded on the high density optical disk, so that the output power of the incident light L3 can be minimized.

In the second embodiment, the grating pattern P2 positioned in the central portion of the transparent substrate 28 is gradually changed toward the outer direction of the pattern region 32A from the step-wise shape shown in FIG. 12A to the step-wise shape shown in FIG. 12B through the step-wise shape shown in FIG. 12C. However, because the occurrence of unnecessary diffracted light such as minus first-order diffracted light can be effectively prevented in the middle portion of the transparent substrate 28 in which the grating pattern P2 is formed in the step-wise shape shown in FIG. 12C, it is preferred that the middle portion occupy a large part of the pattern region 32A of the hologram lens 32. In this case, the intensity sum of the transmitted light L4 and the first-order diffracted light L5 can be maximized, so that a utilization efficiency of the incident light L3 can be enhanced.

Also, because the first etching width W1 of the grating pattern P2 is gradually decreased toward the outer direction of the pattern region 32A, it is applicable that the grating pattern P2 formed in the step-wise shape shown in FIG. 12B be changed to a step-wise shape shown in FIG. 12D when the first width W1 is decreased to a value lower than about 1 μm. That is, a flight of four stairs shown in FIG. 12B is changed to a flight of two stairs. In this case, the grating pattern P2 formed in the step-wise shape shown in FIG. 12D can be easily made. In addition, in cases where a height H4 of the grating pattern P2 formed in the step-wise shape shown in FIG. 12D is moreover decreased toward the outer direction of the pattern region 32A, it is preferred that the grating pattern P2 be formed in a step-wise shape shown in FIG. 12E. That is, a third etching width W3 is gradually decreased toward the outer direction of the pattern region 32A while decreasing a height H5 of the grating pattern P2. Therefore, the diffraction efficiency of the hologram lens 32 can be gradually decreased toward the outer direction of the pattern region 32A without any manufacturing difficulty of the grating pattern P2.

In addition, as shown in FIG. 15A, it is applicable that a hologram lens 33 be formed, in place of the hologram lens 32, by placing the grating pattern P1 of the pattern region 32A in a central portion of the transparent substrate 28 and placing four types of diffraction regions 33A, 33B, 33C and 33D which surround the grating pattern P1. A part of the incident light L3 transmitting through each of the diffraction regions 33A to 33D is diffracted to control a transmission efficiency of the hologram lens 33. In this case, the intensity of the transmitted light L4 at its peripheral portion is

decreased, so that secondary maxima occurring in the converging spot S3 can be suppressed. Also, it is applicable that the grating pattern P1 of the hologram be replaced with the grating pattern P2. Also, it is applicable that grating directions of the diffraction regions 33A to 33D differ from each other. In this case, even though the first-order diffracted light L5 diffracted in the diffraction region 33A is, for example, incident on the diffraction region 33c after the diffracted light L5 is reflected by the second information medium 25, the diffracted light L5 again diffracted in the diffraction region 33c does not pass in parallel to the optical axis. Therefore, in cases where a piece of information read from the second information medium 25 is detected in a detector to reproduce the information, the first-order diffracted light L5 diffracted in the diffraction regions 33A to 33D is not detected by the detector as stray light. Accordingly, the reproduction of the information does not deteriorate.

Also, as shown in FIG. 15B, it is applicable that the hologram lens 32 function as a convex lens. In this case, the diffracted light L5 is converged on the first information medium 23, and the transmitted light L4 is converged on the second information medium 25, as shown in FIG. 15C.

(Third Embodiment)

FIG. 16A is a constitutional view of an imaging optical system having a compound objective lens according to a third embodiment of the present invention, a beam of first-order diffracted light being converged on a thin type of information medium. FIG. 16B is a constitutional view of the imaging optical system shown in FIG. 16A, a beam of transmitted light not diffracted being converged on a thick type of information medium.

As shown in FIGS. 16A, 16B, an imaging optical system 41 for converging light on the first substrate 22 of the first information medium 23 (the thickness T1) or the second substrate 24 of the second information medium 25 (the thickness T2) to form a diffraction-limited converging spot comprises a blazed hologram lens 42 for transmitting a part of incident light L3 without any diffraction to form a beam of transmitted light L4 and diffracting a remaining part of incident light L3 to form a beam of first-order diffracted light L6, and the objective lens 27 for converging the first-order diffracted light L6 on the first information medium 23 or converging the transmitted light L4 on the second information medium 25.

The hologram lens 42 is formed by drawing a grating pattern P3 in a pattern region 42A of the transparent substrate 28 in a concentric circle shape. The pattern region 42A is positioned in a center portion of the transparent substrate 28. An diameter of the grating pattern P3 is equal to or larger than an aperture of the objective lens 27. Also, a diffraction efficiency of the hologram lens 42 for the incident light L3 transmitting through the grating pattern P3 is less than 100% in the same manner as in the first embodiment, so that the intensity of the transmitted light L4 is sufficient to record or reproduce a piece of information on or from the second information medium 25.

In addition, as shown in FIG. 17, the diffraction efficiency of the hologram lens 42 is high in a peripheral portion of the pattern region 42A, and the diffraction efficiency is gradually decreased toward an inner direction of the pattern region 42A. In other words, in cases where the grating pattern P3 of the hologram lens 42 is formed in relief, the height H of the relief in the grating pattern P3 is gradually lowered toward the inner direction of the pattern region 42A. Or, in cases where an ideal blazed shape of the hologram lens 26 approximates to a step-wise shape, each pitch of the grating pattern P3 positioned in the peripheral portion of the transparent substrate 28 is formed in a step-wise shape shown in FIG. 12A in which the inclined angle θ_1 of stairs is large and the relationship W1>W2 between the first and second etching widths W1, W2 is satisfied, and the grating pattern P3 formed in the step-wise shape shown in FIG. 12A is gradually changed by decreasing the first etching width W1 and increasing the second etching width W2 toward the inner direction of the pattern region 42A while the height H of the grating pattern P3 is gradually decreased. Therefore, each pitch of the grating pattern P3 positioned in a central portion of the transparent substrate 28 is formed in a stepwise shape shown in FIG. 12B in which the inclined angle θ_2 of stairs is small and the relationship W1<W2 is satisfied. Also, each pitch of the grating pattern P3 positioned in a middle portion between the central and peripheral portions is formed in a step-wise shape shown in FIG. 12C in which the etching widths W1, W2 is the same.

In the above configuration of the imaging optical system 41, as shown in FIG. 16B, a part of the incident light L3 transmits through the hologram lens 42 without any diffraction to form a beam of transmitted light L4, and the transmitted light L4 is converged by the objective lens 27. Also, a remaining part of the incident light L3 is diffracted by the hologram lens 42 to form a beam of first-order diffracted light L6. In this case, the hologram lens 42 functions as a convex lens for the incident light L3, so that a first-order diffracted light L6 formed in the hologram lens 42 converges. Thereafter, the diffracted light L6 is converged by the objective lens 27.

In cases where the thin type of first information medium 23 is utilized to record or reproduce pieces of information on or from a front surface of the medium 23, as shown in FIG. 16A, the diffracted light L6 is incident on a rear surface of the first information medium 23 and is focused on its front surface to form a diffraction-limited converging spot S5 on the first information medium 23. In contrast, in cases where the thick type of second information medium 25 is utilized to record or reproduce pieces of information on or from a front surface of the medium 25, the transmitted light L4 is incident on a rear surface of the second information medium 25 and is focused on its front surface to form a diffraction-limited converging spot S6 on the second information medium 25.

In this case, because the hologram lens 42 functions as a convex lens to converge the diffracted light L6, the diffraction-limited converging spots S5, S6 are formed even though the thickness T1 of the first information medium 23 differs from the thickness T2 of the second information medium 25. Therefore, a compound objective lens 43 composed of the hologram lens 42 and the objective lens 27 has substantially two focal points.

Also, because the hologram lens 42 functions as a convex lens for the diffracted light L6, the diffracted light L6 transmits through the objective lens 27 on condition that the numerical aperture NA of the objective lens 27 is substantially high.

In addition, because the diffraction efficiency in the peripheral portion of the grating pattern P3 is high and because the diffraction efficiency is gradually decreased toward the inner direction of the grating pattern P3, a diffraction probability of the incident light L3 is higher in the peripheral portion of the grating pattern P3.

The grating pattern P3 of the hologram lens 42 is designed to correct any aberration occurring in the objective lens 27 and the first information medium 23, so that the diffracted light L6 transmits through the first information medium 23 having the thickness T1 and is converged on the medium 23

to form the diffraction-limited converging spot S5 without any aberration. A method for designing the hologram lens **42** having an aberration correcting function is described.

After the diffracted light L6 is converged on the first information medium **23**, spherical waves diverge from the converging spot S5 and transmit through the first substrate **22** and the objective lens **27**. Thereafter, the spherical waves transmit through the transparent substrate **28** and optically interfere with the incident light L3. Therefore, an interference pattern is formed by the interference between the spherical waves and the incident light L3. The interference pattern can be calculated by adding the phase of the spherical waves to an inverted phase obtained by inverting the phase of the incident light L3. Accordingly, the grating pattern P3 of the hologram lens **42** which agrees with the interference pattern calculated can be easily formed according to a computer generated hologram technique.

Accordingly, because the hologram lens **42** functions as a convex lens for the first-order diffracted light L6, a curvature of the objective lens **27** can be lowered. Also, a glass material having a high refractive index is not required to produce the objective lens **27**.

Also, because the first-order diffracted light L6 formed in the hologram lens **42** converges before the diffracted light L6 is incident on the objective lens **27**, the distance in an optical axis direction between the converging spots S5, S6 can be lengthened to about 1 mm. Therefore, even though the transmitted light L4 (or the first-order diffracted light L6) is converged on the converging spot S6 (or S5) in focus to record or read a piece of information, the light L6 (or L4) is not converged on the converging spot S6 (or S5) in focus to reduce the intensity of the light L6 (or L4) at the converging spot S6 (or S5). Accordingly, no adverse influence is exerted on the recording or reproduction of the information

Also, because the hologram lens **42** functions as a convex lens for the first-order diffracted light L6, the occurrence of a chromatic aberration can be prevented in the imaging optical system **41**. In detail, the focal length of the hologram lens **42** is shortened as the wavelength of the incident light L3 becomes longer. In contrast, the focal length of the objective lens **27** is lengthened as the wavelength of the incident light L3 becomes longer. That is, the dependence of the focal length on the wavelength in the objective lens **27** is opposite to that of the focal length on the wavelength in the hologram lens **42**. Therefore, the compound objective lens **43** having an achromatic function can be formed by the combination of the lenses **27**, **42**, and the occurrence of the chromatic aberration can be prevented.

Also, because the hologram lens **42** is a plane type of element, a lightweight type of compound objective lens can be made in large scale manufacture.

Also, because the diffraction efficiency of the hologram lens **42** is gradually decreased toward an inner direction of the pattern region **42**A, the numerical aperture of the objective lens **27** for the first-order diffracted light L6 becomes substantially enlarged. Therefore, the intensity of the first-order diffracted light L6 can be enlarged to record or reproduce a piece of information on or from the first information medium **23**.

Also, in cases where the incident light L3 is radiated from a semiconductor laser, a far field pattern of the incident light L3 is distributed in a Gaussian distribution as shown in FIG. **13**A. Therefore, because the diffraction efficiency of the hologram lens **42** is gradually decreased toward the inner direction of the grating pattern P2, a far field pattern of the first-order diffracted light L6 is distributed in a gently-sloping shape. Accordingly, secondary maxima of the first-order diffracted light L6 converged on the converging spot S5 can be moreover suppressed in the third embodiment as compared with in the first embodiment. That is, the recording and reproducing of the information can be performed without any deterioration of the information by utilizing the imaging optical system **41**.

In addition, in cases where the transmitted light L4 is converged on the second information medium **25** to form the diffraction-limited converging spot S6, a numerical aperture of the objective lens **27** for the transmitted light L4 is low because the diffraction efficiency of the hologram lens **42** is increased toward an outer direction of the grating pattern **42**A. As a result, the intensity of the transmitted light L4 becomes lowered. In cases where a transmission efficiency of the hologram lens **42** is heightened to increase the intensity of the transmitted light L4, the intensity of the first-order diffracted light L6 at its inner beam portion is largely decreased, and secondary maxima (or side lobes) of the first-order diffracted light L6 at the converging spot S6 is undesirably increased. Therefore, the incident light L3 of which the far field pattern is distributed in the Gaussian distribution is radiated to the hologram lens **42** to increase the intensity of the transmitted light L4 without any increase of the second maxima. In detail, as shown in FIG. **18**A, the incident light L3 distributed in not only a central portion of the Gaussian distribution but also a peripheral portion of the Gaussian distribution transmits through the hologram lens **42** and is refracted by the objective lens **27** because the diameter of the grating pattern P3 is equal to or larger than the aperture of the objective lens **27**. Therefore, a numerical aperture NA of the objective lens **27** at a light source side for the incident light L3 becomes higher than that in the first embodiment, and a transmission efficiency of the hologram lens **42** is heightened. As a result, the intensity of the transmitted light L4 converged on the second information medium **25** can be increased, as shown in FIG. **18**B. Also, because the intensity of the incident light L3 at the peripheral portion of the Gaussian distribution is low and because the diffraction efficiency of the hologram lens **42** is decreased toward the inner direction of the grating pattern **42**A, the first-order diffracted light L6 is distributed in a gently-sloping shape as shown in FIG. **18**C. Accordingly, secondary maxima of the first-order diffracted light L6 at the converging spot S5 can be suppressed.

Examples of the utilization of the imaging optical system **41** for various types of optical disks are described.

In cases where the image optical system **41** is utilized for an optical disk device in which pieces of information recorded in a thin type of high density optical disk and a thick type of compact disk are exclusively reproduced. the diffraction efficiency of the hologram lens **42** for the incident light L3 is set in a range from about 20% to 70%. In this case, the intensity of the transmitted light L4 converged on the compact disk is almost the same as that of the first-order diffracted light L6 converged on the high density optical disk. Therefore, the output power of the incident light L3 can be minimized.

Also, in cases where the image optical system **41** is utilized for an optical disk device in which pieces of information recorded in a thin type of high density optical disk are recorded or reproduced and pieces of information recorded in a thick type of optical disk are exclusively reproduced, the diffraction efficiency of the hologram lens **42** for the incident light L3 is set to a value equal to or higher than 55%. In this case, even though a high intensity of the first-order diffracted light L6 is required to record a piece of information on the high density optical disk, the recording of

the information can be reliably performed without increasing the intensity of the incident light L3 because the diffraction efficiency of the hologram lens **42** for changing the incident light L3 to the first-order diffracted light L6 is high. In other words, a utilization efficiency of the incident light L3 can be enhanced when a piece of information is recorded on the high density optical disk, so that the output power of the incident light L3 can be minimized. Also, because the diffraction efficiency of the hologram lens **42** is gradually decreased toward an inner direction of the pattern region **42**A, the numerical aperture of the objective lens **27** for the first-order diffracted light L6 becomes substantially enlarged. Therefore, the intensity of the first-order diffracted light L6 can be enlarged to record or reproduce a piece of information on or from the high density optical disk.

In the third embodiment, the grating pattern P3 positioned in the pattern region **42**A of the transparent substrate **28** is gradually changed toward the outer direction of the pattern region **42**A from the step-wise shape shown in FIG. **12**B to the step-wise shape shown in FIG. **12**A through the step-wise shape shown in FIG. **12**C while increasing the height H of the grating pattern P3. However, because the occurrence of unnecessary diffracted light such as minus first-order diffracted light can be effectively prevented in the middle portion of the transparent substrate **28** in which the grating pattern P3 is formed in the step-wise shape shown in FIG. **12**C, it is preferred that the middle portion occupy a large part of the pattern region **42**A of the hologram lens **42**. In this case, the intensity sum of the transmitted light L4 and the first-order diffracted light L6 can be maximized, so that a utilization efficiency of the incident light L3 can be enhanced.

Also, because the first etching width W1 of the grating pattern P3 is gradually decreased toward the inner direction of the pattern region **42**A, it is applicable that the grating pattern P3 formed in the step-wise shape shown in FIG. **12**B be changed to a step-wise shape shown in FIG. **12**D when the first width W1 is decreased to a value lower than about 1 μm. In this case, the grating pattern P3 formed in the step-wise shape shown in FIG. **12**D can be easily made. In addition, in cases where a height H4 of the grating pattern P3 formed in the step-wise shape shown in FIG. **12**D is moreover decreased toward the inner direction of the pattern region **42**A, it is preferred that the grating pattern P3 be formed in a step-wise shape shown in FIG. **12**E. In this case, a third etching width W3 is gradually decreased toward the inner direction of the pattern region **42**A while decreasing a height H5 of the grating pattern P3. Therefore, the diffraction efficiency of the hologram lens **42** can be gradually decreased toward the inner direction of the pattern region **42**A without any manufacturing difficulty of the grating pattern P3.

In the first to third embodiments of the image optical systems **21**, **31** and **41**, the grating patterns P1, P2 and P3 of the hologram lenses **26**, **32** and **42** are respectively formed on a front side of the transparent substrate **28** not facing the objective lens **27**. Therefore, a beam of light reflected at the front side of the transparent substrate **28** does not adversely influence as stray light on the recording or reproduction of the information. In detail, because the reflected light is diffracted by the hologram lens, the reflected light is scattered. Also, even though the first-order diffracted light L5 or L6 is reflected at a reverse side of the transparent substrate **28**, the diffracted light reflected is again diffracted by the hologram lens and is scattered. Therefore, the light reflected at the front or reverse side of the hologram lens does not adversely influence on the recording or reproduction of the information.

However, in cases where an anti-reflection film is coated on a front side of the hologram lens **28** at which the grating pattern is not formed, it is applicable that the grating patterns P1, P2 and P3 of the hologram lenses **26**, **32** and **42** be respectively formed on a reverse side of the transparent substrate **28** facing the objective lens **27**. In this case, because the first-order diffraction light L5, L6 is not refracted at the front side of the hologram lens **28**, the design of the image optical systems **21**, **31** and **41** can be simplified.

Also, in the first to third embodiments, the grating patterns P1, P2 and P3 of the hologram lenses **26**, **32** and **42** are respectively formed in relief to produce a phase modulation type of hologram lens. However, as is described in Provisional Publication No. 189504/86 (S61-189504) and Provisional Publication No. 241735/88 (S63-241735), the phase modulation type of hologram lens can be produced by utilizing a liquid crystal cell. Also, the phase modulation type of hologram lens can be produced by utilizing a birefringece material such as lithium niobate. For example, the phase modulation type of hologram lens can be produced by proton-exchanging a surface part of a lithium niobate substrate.

(Fourth Embodiment)

Also, in the first to third embodiments, the compound objective lens **29**, **34** or **43** having two focal points is composed of the objective lens **27** and the hologram lens **26**, **32** or **42**. However, as a compound objective lens according to a fourth embodiment is shown in FIG. **19**A, it is preferred that each of the hologram lenses **26**, **32** and **42** and the objective lens **27** be unified with a packaging means **44** to form a compound objective lens **45** in which a relative position between each of the hologram lenses **26**, **32** and **42** and the objective lens **27** is fixed. In this case, the transmitted light L4 and the first-order diffracted light L5, L6 can be easily converged on the first or second information medium **23**, **25** by adjusting the position of the packing means **44** with an actuator. Also, as another compound objective lens according to a modified fourth embodiment is shown in FIG. **19**B, it is preferred that each of the grating patterns P1, P2 and P3 be directly drawn on a curved side of the objective lens **27** facing a light source side to form a compound objective lens **46** in which each of the hologram lenses **26**, **32** and **42** is integrally formed with the objective lens **27**.

Accordingly, the central axis of the objective lens **27** can always agree with that of each of the hologram lenses **26**, **32** and **42**, so that abaxial aberrations of each of the hologram lenses **26**, **32** and **42** such as a coma aberration and an astigmatic aberration occurring in the first-order diffracted light can be prevented in the fourth embodiment. Also, because the hologram lens **26**, **32** or **42** is placed on a lens surface of the objective lens **27** of which a curvature is higher than those of other lens surfaces of the objective lens **27**, a sine condition for the hologram lens treated as a lens can be easily satisfied. Therefore, the degree of aberrations resulting from a constitutional error of an optical head apparatus can be sufficiently reduced.

(Fifth Embodiment)

Also, as a compound objective lens according to a fifth embodiment is shown in FIG. **20**, it is preferred that each of the grating patterns P1, P2 and P3 be directly drawn on a side of the objective lens **27** facing the information medium **23** or **25** to form a compound objective lens **47** in which each of the hologram lenses **26**, **32** and **42** is integrally formed with the objective lens **27**. In this case, a curvature at the side of the objective lens **27** can be small or in a plane shape. Therefore, each of the grating patterns P1, P2 and P3 can be made at a low cost. Also, in cases where an aberration is

caused by tilting the hologram lens from the optical axis, the aberration can be prevented by fixing the hologram lens and a light source of the incident light L3 on the same base.

(Sixth Embodiment)

An optical head apparatus with one of the compound objective lenses **29**, **29M**, **34**, **43**, **45**, **46** and **47** shown in the first to fifth embodiments is described with reference to FIGS. **21** to **26** according to a sixth embodiment of the present invention. X, Y and Z co-ordinates shown in FIGS. **21** to **26** are utilized in common.

FIG. **21** is a constitutional view of an optical head apparatus according to a sixth embodiment.

As shown in FIG. **21**, an optical head apparatus **51** for recording or reproducing pieces of information on or from the information medium **23** or **25**, comprises a light source **52** such as a semiconductor laser for radiating the incident light L3, a collimator lens **53** for collimating the incident light L3, a beam splitter **54** for transmitting the incident light L3 on an outgoing optical path and reflecting a beam of transmitted light L4 R formed by reflecting the transmitted light L4 on the information medium **23** or **25** or a beam of diffracted light L5R (or L6R) formed by reflecting the diffracted light L5 (or L6) on the information medium **23** or **25** on an incoming optical path, the compound objective lens **29** (or **29M**, **34**, **43**, **45**, **46** or **47**) composed of the hologram lens **26** (or **26M**, **32**, **33** or **42**) and the objective lens **27**, a converging lens **55** for converging the transmitted light L4R or the diffracted light L5R reflected by the beam splitter **54**, a wavefront changing device **56** such as a hologram for changing a wavefront of the transmitted light L4R or the diffracted light L5R to form a plurality of converging spots of the transmitted light L4R or the diffracted light L5R, a photo detector **57** for detecting intensities of the converging spots of the transmitted light L4R or the diffracted light L5R of which the wavefront is changed by the wavefront changing device **56** to obtain an information signal recorded on the information medium **23** or **25** and servo signals such as a focus error signal and a tracking error signal, and an actuating unit **58** for moving the compound objective lens composed of the hologram lens **26** and the objective lens **27** according to the servo signals.

In the above configuration, a beam of incident light L3 radiated from the light source **52** is collimated in the collimator lens **53** and transmits through the beam splitter **54**. Thereafter, a part of the incident light L3 transmits through the compound objective lens **29** without any diffraction, and a remaining part of the incident light L3 is diffracted.

Thereafter, in cases where a piece of information is recorded or reproduced on or from the first information medium **23**, the transmitted light L4 is converged on the first information medium **23** to form the first converging spot S1. That is, the transmitted light L4 is incident on a rear surface of the first information medium **23**, and the first converging spot S1 is formed on a front surface of the first information medium **23**. Thereafter, a beam of transmitted light L4R reflected at the front surface of the first information medium **23** passes through the same optical path in the reverse direction. That is, a part of the transmitted light L4R again transmits through the compound objective lens **29** without any diffraction and is reflected by the beam splitter **54**. In this case, the transmitted light L4R is collimated. Thereafter, the transmitted light L4R is converged by the converging lens **55**, and the wavefront of a large part of the transmitted light L4R is changed to form a plurality of converging spots on the photo detector **57**. Thereafter, the intensities of the converging spots of the transmitted light L4R are detected in the photo detector **57**. Therefore, an information signal and servo signals such as a focus error signal and a tracking error signal are obtained. The actuating unit **58** are operated according to the servo signals to move the compound objective lens **29** at high speed, so that the transmitted light L4 is converged on the first information medium **23** in focus.

Also, in cases where a piece of information is recorded or reproduced on or from the second information medium **25**, the diffracted light L5 is converged on the second information medium **25** to form the second converging spot S2. That is, the diffracted light L5 is incident on a rear surface of the second information medium **25**, and the second converging spot S2 is formed on a front surface of the second information medium **25**. Thereafter, a beam of diffracted light L5R reflected at the front surface of the second information medium **25** passes through the same optical path in the reverse direction. That is, a part of the diffracted light L5R is again diffracted by the hologram lens **26** and is reflected by the beam splitter **54**. In this case, the diffracted light L5R is collimated. Thereafter, the diffracted light L5R is converged by the converging lens **55**, and the wavefront of a large part of the diffracted light L5R is changed to form a plurality of converging spots on the photo detector **57**. In this case, the diffracted light L5R incident on the converging lens **55** is collimated in the same manner as the transmitted light L4R incident on the converging lens **55**, the converging spots of the diffracted light L5R are formed at the same positions as those of the transmitted light L4R. Thereafter, the intensities of the converging spots of the diffracted light L5R are detected in the photo detector **57**. Therefore, an information signal and servo signals such as a focus error signal and a tracking error signal are obtained. The actuating unit **58** are operated according to the servo signals to move the compound objective lens **29** at high speed, so that the diffracted light L5 is converged on the second information medium **25** in focus.

In this case, because the transmitted light L4R again transmits through the compound objective lens without any diffraction and the diffracted light L5R is again diffracted by the hologram lens **26**, the outgoing optical path agrees with the incoming optical path in a range between the information medium **23** or **25** and the beam splitter **54** even though the converging spot S1 differs from the converging spot S2. Therefore, a converging spot S7 on the photo detector **57** at which the light L4R or L5R not diffracted by the wavefront changing device **56** is converged relates to a radiation point of the light source **52** in a mirror image, so that the light L4R and L5R not diffracted by the wavefront changing device **56** are converged at the same converging point S7. In the same manner, the light L4R and L5R diffracted by the wavefront changing device **56** are converged at the same other converging points.

Accordingly, even though the compound objective lens has two focal points, the wavefront changing unit **56** and the photo detector **57** required to detect the intensity of the transmitted light L4R can be utilized to detect the intensity of the diffracted light L5R. Therefore, the number of parts required to manufacture the optical head apparatus **51** can be reduced, and a small sized optical head apparatus can be manufactured at a low cost and in light weight even though pieces of information are recorded or reproduced on or from an information medium by utilizing the optical head apparatus **51** regardless of whether the information medium is thick or thin.

In cases where the hologram lens **26** (or **32**, **33**, **42**) is integrally formed with the objective lens **27** as shown in FIG. **19A**, **19B** or **20**, each of the compound objective lenses

45, 46 and 47 can be manufactured in light weight because the hologram lens 26 (or 32, 33, 42) is a plane type of optical device. For example, the hologram lens 26 (or 32, 33, 42) is less than several tens mg in weight. Therefore, the hologram lens 26 integrally formed with the objective lens 27 can be easily moved by the actuating unit 58.

Next, a detecting method of the servo signals is described. FIG. 22 is a plan view of the wavefront changing unit 56. FIG. 23 is an enlarged view of first-order diffracted light and transmitted light detected in the photo detector 57. As shown in FIG. 22, the wavefront changing unit 56 is partitioned into as diffracted light generating region 56*a* in which a grating pattern P4 is drawn and a pair of diffracted light generating regions 55*b*, 56*c* in which a pair of grating patterns P5, P6 are drawn. The light L4R or L5R incident on the diffracted light generating region 56*a* is diffracted to obtain a focus error signal. The light L4R or L5R incident on each of the diffracted light generating regions 56*b*, 56*c* is diffracted to obtain a tracking error signal.

Initially, a spot size detection method utilized to detect a focus error signal is described as an example of a detecting method of a focus error signal. The method is proposed in Japanese Patent Application No. 185722 of 1990. In short, in cases where the method is adopted, an allowable assembly error in an optical head apparatus can be remarkably enlarged, and the servo signal such as a focus error signal can be stably obtained to adjust the position of the compound objective lens even though the wavelength of the incident light L3 varies.

In detail, as shown in FIG. 23, the grating pattern P4 is designed to change the transmitted light L4R (or the diffracted light L5R) transmitting through the diffracted light generating region 56*a* of the wavefront changing unit 56 to a beam of first-order diffracted light L7 and a beam of minus first-order diffracted light L8. The diffracted light L7, L8 are expressed by two types of spherical waves having different curvatures. That is, interference fringes are produced by actually interfering a spherical wave having a focal point FP1 in the front of the photo detector 57 with another spherical wave diverging from the converging spot S7 according to a two-beam interferometric process, so that the grating pattern P4 agreeing with the interference fringes is formed. In other case, the interference fringes are calculated according to a computer generated hologram method. As a result, the transmitted light L4R (or the diffracted light L5R) transmitting through the diffracted light generating region 56*a* of the wavefront changing unit 56 is diffracted and changed to beams of conjugate diffracted light such as a beam of first-order diffracted light L7 and a beam of minus first-order diffracted light L8. The beam of first-order diffracted light L7 has the focal point FP1 at the front surface of the photo detector 57, and the beam of minus first-order diffracted light L8 has a focal point FP2 in the rear of the photo detector 57.

As shown in FIG. 24, the photo detector 57 comprises a sextant photo-detector 59 (or a six-division photo detector) in which six detecting sections SE1, SE2, SE3, SE4, SE5 and SE6 are provided. The intensity of the first-order diffracted light L7 is detected by each of the detecting sections SE1, SE2 and SE3 of the sextant photo-detector 59 and is changed to electric current signals SC1, SC2 and SC3. Also, the intensity of the minus first-order diffracted light L8 is detected by each of the detecting sections SE4, SE5 and SE6 of the sextant photo-detector 59 and is changed to electric current signals SC4, SC5 and SC6.

FIG. 25A and 25C respectively show a converging spot of the first-order diffracted light L7 radiated to the detecting sections SE1, SE2 and SE3 of the sextant photo-detector 59 and another converging spot of the minus first-order diffracted light L8 radiated to the detecting sections SE4, SE5 and SE6 of the sextant photo-detector 59 on condition that the objective lens 27 is defocused on the information medium 23 or 25. FIG. 25B shows a converging spot of the first-order diffracted light L7 radiated to the detecting sections SE1,′ SE2 and SE3 of the sextant photo-detector 59 and another converging spot of the minus first-order diffracted light L8 radiated to the detecting sections SE4, SE5 and SE6 of the sextant photo-detector 59 on condition that the objective lens 27 is just focused on the information medium 23 or 25.

As shown in FIGS. 25A to 25C, in cases where the transmitted light L4 (or the diffracted light L5) is converged on the information medium 23 (or 25) on condition that the objective lens 27 is defocused on the information medium 23 (or 25), a converging spot S8 of the diffracted light L7 shown at the left side of FIGS. 25A, 25C is formed on the sextant photo-detector 59, and another converging spot S9 of the diffracted light L8 shown at the right side of FIG. 25A or 25C is formed on the sextant photo-detector 59. In contrast, in cases where the transmitted light L4 (or the diffracted light L5) is converged on the information medium 23 (or 25) on condition that the objective lens 27 is just focused on the information medium 23 (or 25), a converging spot S8 of the diffracted light L7 shown at the left side of FIG. 25B is formed on the sextant photo-detector 59, and another converging spot S9 of the diffracted light L8 shown at the right side of FIG. 25B is formed on the sextant photo-detector 59. The intensity of the diffracted light L7 is detected in each of the detecting sections SE1, SE2 and SE3 of the sextant photo-detector 59 and is changed to electric current signals SC1, SC2, SC3. Also, the intensity of the diffracted light L8 is detected in the detecting sections SE4, SE5 and SE6 of the sextant photo-detector 59 and is changed to electric current signals SC4, SC5 and SC6. Thereafter, a focus error signal $S_{f\theta}$. is obtained according to the spot size detection method by calculating an equation (5).

$$S_{f\theta}=(SC1+SC3-SC2)-(SC4+SC6-SC5) \quad (5)$$

Thereafter, the position of the compound objective lens is moved in a direction along an optical axis at high speed so as to minimize the absolute value of the focus error signal $S_{f\theta}$.

In the spot size detection method, the diffracted light L7, L8 are expressed by two types of spherical waves having different curvatures to detect the focus error signal $S_{f\theta}$. However, two beams of diffracted light L7, L8 radiated to the photo detector 57 are not limited to the spherical waves. That is, because the change of the diffracted light L7, L8 in a Y-direction is detected by the photo detector 57 according to the spot size detection method, it is required that a one-dimensional focal point of the diffracted light L7 is positioned in the front of the photo detector 57 and a one-dimensional focal point of the diffracted light L8 is positioned in the rear of the photo detector 57. Therefore, it is applicable that diffracted light including astigmatic aberration be radiated to the photo detector 57.

In addition, an information signal S_{in} is obtained by adding all of the electric current signals according to an equation (6).

$$S_{in}=SC1+SC2+SC3+SC4+SC5+SC6 \quad (6)$$

Because the information medium 23 or 25 is rotated at high speed, a patterned track pit radiated by the converging

spots S8, S9 of the diffracted light L7,L8 is rapidly changed one after another, so that the intensity of the information signal S_{in} is changed. Therefore, the information stored in the information medium **23** or **25** can be reproduced according to the information signal S_{in}.

Next, the detection of a tracking error signal depending on a relative position between a converging spot and a patterned track pit on the information medium **23** or **25** is described.

The grating pattern P5 drawn in the diffracted light generating region **56***b* shown in FIG. **22** is designed to change the transmitted light LR (or the diffracted light L5R) transmitting through the diffracted light generating region **56***b* of the wavefront changing unit **56** to a beam of first-order diffracted light L9 and a beam of minus first-order diffracted light L10. Also, the grating pattern P6 drawn in the diffracted light generating region **56***c* shown in FIG. **22** is designed to change the transmitted light L4R (or the diffracted light L5R) transmitting through the diffracted light generating region **56***c* of the wavefront changing unit **56** to a beam of first-order diffracted light L11 and a beam of minus first-order diffracted light L12.

As shown in FIG. **24**, the photo detector **57** further comprises four tracking photo-detectors **60***a* to **60***d* for detecting intensities of the diffracted light L9 to L12. As shown in FIG. **26**, the intensity of the diffracted light L9 is detected by the tracking photo-detector **60***a* and is changed to an electric current signal SC7, the intensity of the diffracted light L10 is detected by the tracking photo-detector **60***d* and is changed to an electric current signal SC10, the intensity of the diffracted light L11 is detected by the tracking photo-detector **60***b* and is changed to an electric current signal SC8, and the intensity of the diffracted light L12 is detected by the tracking photo-detector **60***c* and is changed to an electric current signal SC **9**. A tracking error signal $S_{t\Theta}$ is calculated according to an equation (7).

$$S_{t\Theta}=SC7-SC8-SC9+SC10 \quad (7)$$

Therefore, the asymmetry of the intensity distribution of the transmitted light L4R (or the diffracted light L5R) incident on the wavefront changing unit **56**, which changes in dependence on the positional relation between the converging spot S1 (or S2) and a patterned track pit radiated by the light L4 or L5, is expressed by the tracking error signal $S_{t\Theta}$.

Thereafter, the objective lens **27** is moved in a radial direction so as to reduce a tracking error indicated by the tracking error signal $S_{t\Theta}$. The radial direction is defined as a direction perpendicular to both the optical axis and a series of patterned track pits. Therefore, the converging spot S1 (or S2) of the transmitted light L4 (or the diffracted light L5) on the information medium **23** (or **25**) can be formed in the middle of the patterned track pit, so that the tracking error becomes zero.

Accordingly, focus and tracking servo characteristics can be stably obtained in the optical head apparatus **51**. That is, because the wavefront changing unit **56** has a wavefront changing function, a focus error signal can be easily obtained. Also, because the diffracted light generating regions **56***b*, **56***c* are provided in the wavefront changing unit **56**, a tracking error signal can be easily obtained. Therefore, the number of parts required to manufacture the optical head apparatus **51** can be reduced, and the number of manufacturing steps can be reduced. In addition, the optical head apparatus can be manufactured at a low cost and in light weight.

Also, because the compound objective lens having two focal points is utilized in the optical head apparatus **51**, pieces of information can be reliably recorded or reproduced from an information medium by utilizing the optical head apparatus **51** regardless of whether the information medium is thick or thin.

(Seventh Embodiment)

Next, an optical head apparatus in which servo signals such as a focus error signal and a tracking error signal are detected according to an astigmatic aberration method is described according to a seventh embodiment of the present invention.

FIG. **27** is a constitutional view of an optical head apparatus according to a seventh embodiment.

As shown in FIG. **27**, an optical head apparatus **61** for recording or reproducing pieces of information on or from the information medium **23** or **25**, comprises the light source **52**, the collimator lens **53**, the beam splitter **54**, the compound objective lens **29** (or **29**M, **34**, **43**, **45**, **46** or **47**) composed of the hologram lens **26** (or **26**M, **32**, **33** or **42**) and the objective lens **27**, the actuating unit **58**, the converging lens **55**, an astigmatic aberration generating unit **62** such as a plane parallel plate for generating an astigmatic aberration in the transmitted light L4R or the diffracted light L5 R converged by the converging lens **55**, and a photo detector **63** for detecting the intensity of the transmitted light L4R or the diffracted light L5R in which the astigmatic aberration is generated to obtain an information signal and servo signals such as a focus error signal and a tracking error signal.

The astigmatic aberration generating unit **62** is classified into one of the wavefront changing unit **56** because a wavefront of the transmitted light L4R or the diffracted light L5R is changed by the generating unit **62** to generate the astigmatic aberration in the light L4R or L5R. Also, a normal line of the unit **62** is tilted from an optical axis.

As shown in FIG. **28**, the photo detector **63** comprises a quadrant photo-detector **64** in which four detecting sections SE7, SE8, SE9 and SE10 are provided.

In the above configuration, the transmitted light L4R (or the diffracted light L5R) reflected by the information medium **23** (or **25**) is converged by the converging lens **55** in the same manner as in the sixth embodiment. Thereafter, the transmitted light L4R (or the diffracted light L5R) transmits through the astigmatic aberration generating unit **62** and is converged on the photo detector **57** to form a converging spot S10 on the detecting sections SE7, SE8, SE9 and SE10 of the quadrant photo-detector **64**. In this case, because the transmitted light L4R (or the diffracted light L5R) converged by the converging lens **55** is a spherical wave, an astigmatic aberration is generated in the transmitted light L4R (or the diffracted light L5R) by the astigmatic aberration generating unit **62**. Therefore, as shown in FIGS. **29**A to **29**C, the shape of the converging spot S10 considerably changes depending on a distance between the compound objective lens **29** and the information medium **23** (or **25**).

For example, in cases where the transmitted light L4 (or the diffracted light L5) is converged on the information medium **23** (or **25**) on condition that the objective lens **27** is defocused on the information medium **23** (or **25**), the converging spot S10 of the transmitted light L4R (or the diffracted light L5R) is formed on the quadrant photo-detector **64** as shown in FIGS. **29**A, **29**C. In contrast, in cases where the transmitted light L4 (or the diffracted light L5) is converged on the information medium **23** (or **25**) on condition that the objective lens **27** is just focused on the information medium **23** (or **25**), the converging spot S10 of the transmitted light L4R (or the diffracted light L5R) is formed on the quadrant photo-detector **64** as shown in FIG. **25**B.

The intensity of the transmitted light L4R (or the diffracted light L5R) is detected in the detecting sections SE7, SE8, SE9 and SE10 of the quadrant photo-detector **64** and is changed to electric current signals SC11, SC12, SC13 and SC14. Thereafter, a focus error signal $S_{f\theta}$ is obtained according to an astigmatic aberration method by calculating an equation (8).

$$S_{f\theta}=(SC11+SC14)-(SC12+SC13) \quad (8)$$

Thereafter, the position of the compound objective lens **29** is moved in a direction parallel to an optical axis at high speed so as to minimize the absolute value of the focus error signal $S_{f\theta}$.

Also, a tangential direction Dt agreeing with an extending direction of patterned recording pits and a radial direction Dr perpendicular to both the optical axis and the patterned recording pits are defined as shown in FIG. **29**D. In this case, when the quadrant photo-detector **64** is directed as shown in FIGS. **29**A to **29**C, a tracking error signal $S_{t\theta}$ is calculated according to an equation (9) by utilizing an intensity distribution change of the transmitted light L4R (or the diffracted light L5R) which depends on a positional relation between the converging spot S10 and a recording pit radiated by the light L4 or L5.

$$S_{t\theta}=SC11+SC13-(SC12+SC14) \quad (9)$$

Thereafter, the objective lens **27** is moved in the radial direction so as to reduce a tracking error indicated by the tracking error signal $S_{t\theta}$. Therefore, the converging spot S1, (or S2) of the transmitted light L4 (or the diffracted light L5) on the information medium **23** (or **25**) can be formed in the middle of the recording pit, so that the tracking error becomes zero.

In other case, the tracking error signal $S_{t\theta}$ is obtained according to a phase difference method by utilizing the result calculated in the equation (8).

In addition, an information signal S_{in} is obtained by adding all of the electric current signals according to an equation (10).

$$S_{in}=SC11+SC12+SC13+SC14 \quad (10)$$

Accordingly, focus and tracking servo characteristics can be stably obtained in the optical head apparatus **61**. That is, because an astigmatic aberration is generated in the transmitted light L4R (or the diffracted light L5R) by the astigmatic aberration generating unit **62** made of a plane parallel plate, the servo signals such as a focus error signal and a tracking error signal can be easily obtained. Therefore, the number of parts required to manufacture the optical head apparatus **61** can be reduced, and the number of manufacturing steps can be reduced. In addition, the optical head apparatus **61** can be manufactured at a low cost and in light weight.

Also, because the compound objective lens having two focal points is utilized in the optical head apparatus **61**, pieces of information can be reliably recorded or reproduced from an information medium by utilizing the optical head apparatus **61** regardless of whether the information medium is thick or thin.

In the seventh embodiment, the astigmatic aberration generating unit **62** formed out of the plane parallel plate is arranged between the converging lens **55** and the photo detector **63**. However, as an optical head apparatus **65** is shown in FIG. **30**, it is applicable that a cylindrical lens **66** integrally formed with the converging lens **55** be arranged in place of the plane parallel plate to generate an astigmatic aberration in the transmitted light L4R (or the diffracted light L5R). In this case, because the cylindrical lens **66** is integrally formed with the converging lens **55**, the optical head apparatus can be moreover manufactured at low cost. In addition, as shown in FIG. **30**, it is applicable that a normal line of the hologram lens **26** (or **32**, **33**, **42**) be tilted from an optical axis passing through the center of the objective lens **27** by about one degree to prevent stray light reflected in a surface of the hologram lens **26** from being incident on the photo detector **57** or **63**. Also, it is applicable that the hologram lens **26** (or **32**, **33**, **42**) be coated with an anti-reflection coating to prevent the occurrence of stray light.

Also, as an optical head apparatus **67** is shown in FIG. **31**, it is applicable that a polarized beam splitter **68** be arranged in place of the beam splitter **54** to perfectly transmit the incident light L3 and a ¼–λ plate **69** be additionally placed between the hologram lens **26** (or **32**, **33**, **42**) and the polarized beam splitter **68**. In this case, because the incident light L3 transmits through the ¼–λ plate **69** in an outgoing optical path and because the transmitted light L4R (or the diffracted light L5) again transmits through the ¼–λ plate **69** in an incoming optical path, the transmitted light L4R (or the diffracted light L5R) is perfectly reflected by the polarized beam splitter **68**. Accordingly, a utilization efficiency of the incident light L3 can be enhanced. Also, a signal-noise ratio of each of the servo signals and the information signal can be enhanced.

Also, as an optical head apparatus **70** is shown in FIG. **32**, it is applicable that the polarized beam splitter **68** be arranged in place of the beam splitter **54** to perfectly transmit the incident light L3 and the ¼–λ plate **69** be additionally placed between the hologram lens **26** (or **32**, **33**, **42**) and the objective lens **27**. In this case, the transmitted light L4R (or the diffracted light L5R) is perfectly reflected by the polarized beam splitter **68** in the same manner as the optical head apparatus shown in FIG. **31**. In addition, because stray light reflected from the hologram lens **26** (or **32**, **33**, **42**) transmits through the polarized beam splitter **68**, the stray light is not incident on the photo detector **63**. Accordingly, a signal-noise ratio of each of the servo signals and the information signal can be moreover enhanced.

Also, as an optical head apparatus **71** is shown in FIG. **33**, it is applicable that a wedge-like prism **72** for reshaping the incident light L3 radiated from the light source **52** be additionally placed between the collimator lens **53** and the polarized beam splitter **68**. In this case, an elliptic wavefront of the incident light L3 is reshaped to a circular wavefront by the wedge-like prism **72**. Accordingly, a utilization efficiency of the incident light L3 can be enhanced.

In the sixth and seventh embodiments, when the transmitted light L4 (that is, zero-order diffracted light L4) converged on the first information medium **23** is reflected toward the compound objective lens to reproduce a piece of information recorded on the first information medium **23**, a part of the transmitted light L4R is diffracted in the hologram lens **26** (or **32**, **33**, **42**) on the incoming optical path, so that the part of the transmitted light L4R is changed to a beam of first-order diffracted light L13. Therefore, the first-order diffracted light L13 diverges from the hologram lens **26**, and a converging spot S11 of the diffracted light L13 is formed on the photo detector **57** or **63** in a relatively large size, as shown in FIG. **34**. The size of the converging spot S11 is larger than those of the sextant photo-detector **59** and the quadrant photo-detector **64**. Therefore, there is a drawback that a signal-noise ratio in the information signal deteriorates.

To solve the drawback, it is preferred that the photo detector **57** (or **63**) further comprise an information photo-

detector **73** surrounding the sextant photo-detector **59** (or the quadrant photo-detector **64**). The size of the information photo-detector **73** is equal to or larger than a 1 mm square. Therefore, in cases where the information signal is determined by the sum of the intensity of the transmitted light L**4** detected in the sextant photo-detector **59** (or the quadrant photo-detector **64**) and the intensity of the diffracted light L**13** detected in the information photo-detector **73**, the signal-noise ratio in the information signal can be enhanced, and frequency characteristics of the information signal can be enhanced.

(Eighth Embodiment)

Next, a method of focusing performed in the optical head apparatuses **51**, **61**, **65**, **67**, **70** and **71** is described according to an eighth embodiment of the present invention.

FIG. **35**A graphically shows a change of the focus error signal obtained by detecting the intensity of the transmitted light L**4** formed in the hologram lens **26**, **32** or **33**, the strength of the focus error signal depending on a distance between the objective lens **27** and the first information medium **23**. FIG. **35**B graphically shows a change of the focus error signal obtained by detecting the intensity of the diffracted light L**5** formed in the hologram lens **26**, **32** or **33**, the strength of the focus error signal depending on a distance between the objective lens **27** and the second information medium **25**.

The intensity of the transmitted light L**4** is high because the numerical aperture of the objective lens **27** for the transmitted light L**4** is large. Therefore, as shown in FIG. **35**A, a change of a focus error signal FE**1** obtained in cases where the objective lens **27** is almost focused on the first information medium **23** is considerably large as compared with a change of an unnecessary focus error signal FE**2** obtained in cases where the objective lens **27** is defocused on the first information medium **23**. In addition, in cases where the hologram lens **26**, **32** or **33** is utilized in each of the optical head apparatuses **51**, **61**, **65**, **67**, **70** and **71**, the unnecessary focus error signal FE**2** is generated when the distance between the objective lens **27** and the first information medium **23** is larger than the focal length of the objective lens **27** for the transmitted light L**4**.

In contrast, the intensity of the diffracted light L**5** is comparatively low because the numerical aperture of the objective lens **27** for the diffracted light L**5** is comparatively small. Therefore, as shown in FIG. **35**B, a change of a focus error signal FE**3** obtained in cases where the objective lens **27** is almost focused on the second information medium **25** is almost the same as that of an unnecessary focus error signal FE**4** obtained in cases where the objective lens **27** is defocused on the second information medium **25**. In addition, in cases where the hologram lens **26**, **32** or **33** is utilized in each of the optical head apparatuses **51**, **61**, **65**, **67**, **70** and **71**, the unnecessary focus error signal FE**4** is generated when the distance between the objective lens **27** and the second information medium **25** is smaller than the focal length of the objective lens **27** for the diffracted light L**5**.

Therefore, in cases where the focusing of the transmitted light L**4** on the first information medium **23** is performed, the objective lens **27** placed far from the first information medium **23** is gradually brought near to the first information medium **23**. Thereafter, when the strength of the focus error signal reaches a threshold value, a focus servo loop provided in the photo detector **57** or **63** is set to an operation condition, so that the objective lens **27** is set to be focused on the first information medium **23**. Also, in cases where the focusing of the diffracted light L**5** on the second information medium **25** is performed, the objective lens **27** placed far from the second information medium **25** is gradually brought near to the second information medium **25** in the same manner. Thereafter, when the strength of the focus error signal reaches a threshold value, a focus servo loop provided in the photo detector **57** or **63** is set to an operation condition, so that the objective lens **27** is set to be focused on the second information medium **25**.

Accordingly, the inverse influence of the unnecessary focus error signal FE**4** on the focusing of the diffracted light L**5** can be prevented. Also, because the objective lens **27** placed far from the information medium **23** or **25** is gradually brought near to the information medium **23** or **25** regardless of whether the information medium is T**1** or T**2** in thickness, a focusing operation in each of the optical head apparatuses **51**, **61**, **65**, **67**, **70** and **71** with the hologram lens **26**, **32** or **33** can be performed according to a common procedure by changing the threshold value or performing an auto gain control in which the focus error signal is normalized by detecting the total intensity of the transmitted light L**4**R or the diffracted light L**5**R. Therefore, a control circuit required to perform the focusing operation can be made at a low cost.

FIG. **36**A graphically shows a change of the focus error signal obtained by detecting the intensity of the diffracted light L**6** formed in the hologram lens **42**, the strength of the focus error signal depending on a distance between the objective lens **27** and the first information medium **23**. FIG. **36**B graphically shows a change of the focus error signal obtained by detecting the intensity of the transmitted light L**4** formed in the hologram lens **42**, the strength of the focus error signal depending on a distance between the objective lens **27** and the second information medium **25**.

As shown in FIG. **36**A, a change of a focus error signal FE**5** obtained in cases where the objective lens **27** is almost focused on the first information medium **23** is considerably large as compared with a change of an unnecessary focus error signal FE**6** obtained in cases where the objective lens **27** is defocused on the first information medium **23**. In addition, in cases where the hologram lens **42** is utilized in each of the optical head apparatuses **51**, **61**, **65**, **67**, **70** and **71**, the unnecessary focus error signal FE**6** is generated when the distance between the objective lens **27** and the first information medium **23** is smaller than the focal length of the objective lens **27** for the diffracted light L**6**.

In contrast, as shown in FIG. **36**B, a change of a focus error signal FE**7** obtained in cases where the objective lens **27** is almost focused on the second information medium **25** is almost the same as that of an unnecessary focus error signal FE**8** obtained in cases where the objective lens **27** is defocused on the second information medium **25**. In addition, in cases where the hologram lens **42** is utilized in each of the optical head apparatuses **51**, **61**, **65**, **67**, **70** and **71**, the unnecessary focus error signal FE**8** is generated when the distance between the objective lens **27** and the second information medium **25** is larger than the focal length of the objective lens **27** for the transmitted light L**4**.

Therefore, in cases where the focusing of the diffracted light L**6** on the first information medium **23** is performed, the objective lens **27** placed near to the first information medium **23** is gradually moved away from the first information medium **23**. Thereafter, when the strength of the focus error signal reaches a threshold value, a focus servo loop provided in the photo detector **57** or **63** is set to an operation condition, so that the objective lens **27** is set to be focused on the first information medium **23**. Also, in cases where the focusing of the transmitted light L**4** on the second

information medium **25** is performed, the objective lens **27** placed near to the second information medium **25** is gradually moved away from the second information medium **25** in the same manner. Thereafter, when the strength of the focus error signal reaches a threshold value, a focus servo loop provided in the photo detector **57** or **63** is set to an operation condition, so that the objective lens **27** is set to be focused on the second information medium **25**.

Accordingly, the inverse influence of the unnecessary focus error signal FE**8** on the focusing of the transmitted light L**4** can be prevented. Also, because the objective lens **27** placed near to the information medium **23** or **25** is gradually moved away from the information medium **23** or **25** regardless of whether the information medium is T**1** or T**2** in thickness, a focusing operation in each of the optical head apparatuses **51**, **61**, **65**, **67**, **70** and **71** with the hologram lens **42** can be performed according to a common procedure by changing the threshold value or performing the auto gain control. Therefore, a control circuit required to perform the focusing operation can be made at a low cost.

(Ninth Embodiment)

An optical head apparatus with the compound objective lens **29**, **34**, **45**, **46** or **47** in which the incident light L**3** is efficiently utilized to obtain an information signal and servo signals is described with reference to FIGS. **29**, **37** according to a ninth embodiment of the present invention.

FIG. **37** is a constitutional view of an optical head apparatus according to a ninth embodiment.

As shown in FIG. **37**, an optical head apparatus **81** for recording or reproducing pieces of information on or from the information medium **23** or **25**, comprises the light source **52**, the collimator lens **53**, the beam splitter **54**, the compound objective lens the compound objective lens **29** (**34**, **45**, **46** or **47**) composed of the hologram lens **26** (or **32** or **33**) and the objective lens **27**, the actuating unit **58**, the converging lens **55**, a beam splitter **82** for transmitting a beam of diffracted light L**5**R or reflecting a beam of transmitted light L**4**R, the photo detector **63** for detecting the intensity of the diffracted light L**5**R transmitting through the beam splitter **82** to obtain servo signals and an information signal recorded on the second information medium **25**, the wavefront changing device **56** such as a hologram for changing a wavefront of the transmitted light L**4**R reflected by the beam splitter **82**, and the photo detector **57** for detecting the intensity of the transmitted light L**4**R to obtain servo signals and an information signal recorded on the first information medium **23**. The beam splitter **82** is made of a plane parallel plate of which a normal line is tilted from an optical path, so that an astigmatic aberration is generated in the diffracted light L**5**R passing through the beam splitter **82**. Also, a coating is applied on a surface of the plane parallel plate.

In the above configuration, the transmitted light L**4** (or the diffracted light L**5**) are converged by the converging lens **27** in the same manner as in the sixth embodiment. Thereafter, in cases where a piece of information is recorded or reproduced on or from the first information medium **23**, the transmitted light L**4** is converged on the first information medium **23** to form the first converging spot S**1**. Thereafter, a beam of transmitted light L**4**R reflected by the first information medium **23** passes through the same optical path in the reverse direction. That is, a great part of the transmitted light L**4**R again transmits through the compound objective lens without any diffraction and is reflected by the beam splitter **54**. Thereafter, the transmitted light L**4**R is converged by the converging lens **55**, and a part of the transmitted light L**4**R is reflected by the beam splitter **82**. Thereafter, the wavefront of a great part of the transmitted light L**4**R is changed by the wavefront changing unit **56**, and the great part of the transmitted light L**4**R is converged on the photo detector **57** to form the converging spots S**8**, S**9**. Therefore, an information signal and servo signals such as a focus error signal and a tracking error signal are obtained in the same manner as in the sixth embodiment. Also, a remaining part of the transmitted light L**4**R not changed its wavefront is converged on the photo detector **57** to form the converging spot S**7**.

In contrast, in cases where a piece of information is recorded or reproduced on or from the second information medium **25**, the diffracted light L**5** is converged on the second information medium **25** to form the second converging spot S**2**. Thereafter, a beam of diffracted light L**5**R reflected by the second information medium **25** passes through the same optical path in the reverse direction, and a great part of the diffracted light L**5**R transmits through the hologram lens **26** without any diffraction. Therefore, the diffracted light L**5**R passes through the incoming optical path differing from the outgoing optical path. Thereafter, the diffracted light L**5**R is reflected by the beam splitter **54** and is converged by the converging lens **55**. Thereafter, a part of the diffracted light L**5**R transmits through the beam splitter **82**. In this case, an astigmatic aberration is generated in the diffracted light L**5**R. Thereafter, the diffracted light L**5**R is converged on the photo detector **63** to form a converging spot S**12** of which the shape is the same as the converging spot S**10** shown in FIGS. **29**A to **29**C, and the intensity of the diffracted light L**5**R is detected in the photo detector **63**. Therefore, an information signal and servo signals such as a focus error signal and a tracking error signal are obtained in the same manner as in the seventh embodiment.

In this case, though a remaining part of the transmitted light L**4**R transmits through the beam splitter **82**, the remaining part of the transmitted light L**4**R is not converged at the converging spot S**12** because the transmitted light L**4**R passes through the same optical path. Also, though a remaining part of the diffracted light L**5**R is reflected the beam splitter **82**, the remaining part of the diffracted light L**5**R is not converged at the converging spot S**7**, S**8** or S**9** because the diffracted light L**5**R passes through the incoming optical path differing from the outgoing optical path.

In the ninth embodiment, because the diffracted light L**5**R transmits through the hologram lens **26** without any diffraction, the converging spot S**12** formed on the photo detector **63** does not relate to a radiating point of the light source **52** in a mirror image, while the converging spot S**7** formed on the photo detector **57** relates to the radiating point of the light source **52** in the mirror image. In other words, a focal point of the diffracted light L**5**R converged by the converging lens **55** differs from that of the transmitted light L**4**R converged by the converging lens **55**. Therefore, the photo detector **57** for detecting the intensity of the transmitted light L**4**R and the photo detector **63** for detecting the intensity of the diffracted light L**5**R are required.

Accordingly, because the compound objective lens having two focal points is utilized in the optical head apparatus **81**, pieces of information can be reliably recorded or reproduced on or from an information medium regardless of whether the information medium is thick or thin.

An example of the utilization of the optical head apparatus **81** for various types of optical disks is described.

In cases where the optical head apparatus **81** is utilized for an optical disk device in which pieces of information recorded in a thin type of high density optical disk **23** are recorded or reproduced and pieces of information recorded in a thick type of optical disk **25** are exclusively reproduced,

the diffraction efficiency of the hologram lens **26**, **32** or **33** in the compound objective lens **29**, **34**, **45**, **46** or **47** for changing a beam of light to a beam of first-order diffracted light is set to a value equal to or lower than 30%. Therefore, in cases where a piece of information recorded on the thick type of optical disk **25** is reproduced in the photo detector **63**, a signal-noise ratio of each of the servo signals and the information signal obtained in the photo detector **63** can be enhanced because the diffracted light L5R transmitting through the hologram lens **26**, **32** or **33** at a high transmission efficiency is utilized to obtain the servo signals and the information signal. In other words, a utilization efficiency of the incident light L3 can be enhanced when a piece of information recorded on the thick type of optical disk **25** is reproduced, so that the output power of the incident light L3 can be minimized. Also, even though a high intensity of the transmitted light L4 is required to record a piece of information on the high density optical disk **23**, the recording of the information can be reliably performed without increasing the intensity of the incident light L3 because a transmission efficiency of the hologram lens **26**, **32** or **33** for the incident light L3 is high. Also, in cases where a piece of information recorded on the high density optical disk **23** is reproduced in the photo detector **57**, a signal-noise ratio of each signal obtained in the photo detector **57** can be enhanced because the transmission efficiency of the hologram lens **26**, **32** or **33** for the light L3, L4R is high.

(Tenth Embodiment)

An optical head apparatus with the compound objective lens **29**, **34**, **45**, **46** or **47** in which the incident light L3 is efficiently utilized to obtain an information signal and servo signals is described with reference to FIGS. **38**, **39** according to a tenth embodiment of the present invention. X1 and Y1 coordinates shown in FIGS. **38**, **39** are utilized in common.

FIG. **38** is a constitutional view of an optical head apparatus according to a tenth embodiment. FIG. **39** is a plan view of a beam splitter having a reflection type of hologram utilized in the optical head apparatus shown in FIG. **38**.

As shown in FIG. **38**, an optical head apparatus **91** for recording or reproducing pieces of information on or from the information medium **23** or **25**, comprises the light source **52**, the collimator lens **53**, the beam splitter **54**, the compound objective lens **29** (or **34**, **45**, **46** or **47**) composed of the hologram lens **26** (or **32** or **33**) and the objective lens **27**, the actuating unit **58**, the converging lens **55**, a beam splitter **92** having a reflection type of hologram **93** for transmitting a large part of the transmitted light L4R or reflecting all of the diffracted light L5R incident on the hologram **93**, the photo detector **63** for detecting the intensity of the transmitted light L4R transmitting through the beam splitter **92** to obtain servo signals and an information signal recorded in the first information medium **23**, and the photo detector **57** for detecting the intensity of the diffracted light L5R to obtain servo signals and an information signal recorded in the second information medium **25**.

The beam splitter **92** is made of a plane parallel plate inclined to an optical path, so that an astigmatic aberration is generated in the transmitted light L4R passing through the beam splitter **92**. Also, as shown in FIG. **39**, the reflection type of hologram **93** is arranged at a center portion of the beam splitter **92**, and a light transmitting region **92***a* is arranged at a peripheral portion of the beam splitter **92** to surround the hologram **93**. Light incident on the light transmitting region **92***a* transmits without any diffraction. The hologram **92** is partitioned into a diffracted light generating region **93***a* in which a grating pattern P7 is drawn and a pair of diffracted light generating regions **93***b*, **93***c* in which a pair of grating patterns P8, P9 are drawn. The diffracted light L5R incident on the diffracted light generating region **93***a* is diffracted to obtain a focus error signal in the photo detector **57**. The diffracted light L5R incident on each of the diffracted light generating regions **93***b*, **93***c* is diffracted to obtain a tracking error signal in the photo detector **57**.

In the above configuration, the transmitted light L4 and the diffracted light L5 are converged by the converging lens **27** in the same manner as in the sixth embodiment. Thereafter, in cases where a piece of information is recorded or reproduced on or from the first information medium **23**, the transmitted light L4 is converged on the first information medium **23** to form the first converging spot S1. Thereafter, a beam of transmitted light L4R reflected by the first information medium **23** passes through the same optical path in the reverse direction. That is, a large part of the transmitted light L4R again transmits through the compound objective lens **29** without any diffraction and is reflected by the beam splitter **54**. Thereafter, the transmitted light L4R is converged by the converging lens **55**, and a large part of the transmitted light L4R transmits through the beam splitter **92**. In this case, an astigmatic aberration is generated in the transmitted light L4R. Thereafter, the transmitted light L4R is converged on the photo detector **63** to form a converging spot S13 of which the shape is the same as the converging spot S10 shown in FIGS. **29**A to **29**C, and the intensity of the transmitted light L4R is detected in the photo detector **63**. Therefore, an information signal and servo signals such as a focus error signal and a tracking error signal are obtained in the same manner as in the seventh embodiment.

In contrast, in cases where a piece of information is recorded or reproduced on or from the second information medium **25**, the diffracted light L5 is converged on the second information medium **25** to form the second converging spot S2. Thereafter, a beam of diffracted light L5R reflected by the second information medium **25** passes through the same optical path in the reverse direction, and a large part of the diffracted light L5R transmits through the hologram lens **26** without any diffraction. Therefore, the diffracted light L5R transmits on the incoming optical path differing from the outgoing optical path in the same manner as in the ninth embodiment. Thereafter, the diffracted light L5R is reflected by the beam splitter **54** and is converged by the converging lens **55** on the beam splitter **92** to form a converging spot on the reflection type of hologram **93** of the beam splitter **92**. Therefore, all of the diffracted light L5R is diffracted and reflected by the hologram **93** to be converged on the photo detector **57**. That is, the diffracted light L5R diffracted and reflected in the diffracted light generating region **93***a* of the hologram **93** is splitted into two beams and is converged on the detecting sections SE1 to SE6 of the sextant photo-detector **59** in the photo detector **57** in the same manner as in the sixth embodiment. Also, the diffracted light L5R diffracted and reflected in the diffracted light generating region **93***b* of the hologram **93** is splitted into two beams, and the intensity of the diffracted light L5R is detected in the tracking photo-detectors **60***a* and **60***d*. Also, the diffracted light L5R diffracted and reflected in the diffracted light generating region **93***c* of the hologram **93** is splitted into two beams, and the intensity of the diffracted light L5R is detected in the tracking photo-detectors **60***b* and **60***c*. Therefore, an information signal and servo signals such as a focus error signal and a tracking error signal are obtained in the same manner as in the sixth embodiment.

In the tenth embodiment, because the transmitted light L4R transmits through the hologram lens **26** without any

diffraction, the converging spot S13 formed on the photo detector 63 does not relate to a radiating point of the light source 52 in a mirror image. Therefore, the photo detector 57 for detecting the intensity of the diffracted light L5R and the photo detector 63 for detecting the intensity of the transmitted light L4R are required.

Accordingly, because the compound objective lens having two focal points is utilized in the optical head apparatus 91, pieces of information can be reliably recorded or reproduced on or from an information medium regardless of whether the information medium is thick or thin.

Also, because all of the diffracted light L5R is completely diffracted and reflected by the hologram 93 of the beam splitter 92, the diffracted light L5R can be utilized at high efficiency. Therefore, a signal-noise ratio of the signals obtained in the photo detector 57 can be enhanced.

An example of the utilization of the optical head apparatus 91 for various types of optical disks is described.

In cases where the optical head apparatus 91 is utilized for an optical disk device in which pieces of information recorded in a thin type of high density optical disk 23 are recorded or reproduced and pieces of information recorded in a thick type of optical disk 25 are exclusively reproduced, the diffraction efficiency of the hologram lens 26, 32 or 33 in the compound objective lens 29, 34, 45, 46 or 47 for changing a beam of light to a beam of first-order diffracted light is set to a value equal to or lower than 30%. Therefore, in cases where a piece of information recorded on the thick type of optical disk 25 is reproduced in the photo detector 57, a signal-noise ratio of each of the servo signals and the information signal obtained in the photo detector 57 can be enhanced because the diffracted light L5R transmitting through the hologram lens 26, 32 or 33 at a high transmission efficiency is utilized to obtain the servo signals and the information signal. In other words, a utilization efficiency of the incident light L3 can be enhanced when a piece of information recorded on the thick type of optical disk 25 is reproduced, so that the output power of the incident light L3 can be minimized. Also, even though a high intensity of the transmitted light L4 is required to record a piece of information on the high density optical disk 23, the recording of the information can be reliably performed without increasing the intensity of the incident light L3 because a transmission efficiency of the hologram lens 26, 32 or 33 for the incident light L3 is high. Also, in cases where a piece of information recorded on the high density optical disk 23 is reproduced in the photo detector 63, a signal-noise ratio of each signal obtained in the photo detector 63 can be enhanced because the transmission efficiency of the hologram lens 26, 32 or 33 for the light L3, L4R is high.

(Eleventh Embodiment)

An optical head apparatus with the compound objective lens 29, 34, 45, 46 or 47 in which the incident light L3 is efficiently utilized to obtain an information signal and servo signals is described with reference to FIGS. 40 to 42 according to an eleventh embodiment of the present invention. X1 and Y1 co-ordinates shown in FIGS. 40, 41 are utilized in common, and X, Y and Z co-ordinates shown in FIGS. 40, 42 are utilized in common.

FIGS. 40A, 40B are respectively a constitutional view of an optical head apparatus according an eleventh embodiment. FIG. 41 is a plan view of a beam splitter having a reflection type of hologram utilized in the optical head apparatus shown in FIG. 38.

As shown in FIGS. 40A, 40B, an optical head apparatus 101 for recording or reproducing pieces of information on or from the information medium 23 or 25, comprises the light source 52, the collimator lens 53, the beam splitter 54, the compound objective lens 29 (or 34, 45, 46 or 47) composed of the hologram lens 26 (or 32 or 33) and the objective lens 27, the actuating unit 58, the converging lens 55, a beam splitter 102 having a transmission type of hologram 103 for transmitting the transmitted light L4R converged on the first information medium 23 and the diffracted light L5R converged on the second information medium 25 and diffracting the transmitted light L4R which is converged on the second information medium 25 in defocus, a photo detector 104 for detecting the intensity of the transmitted light L4R converged on the first information medium 23 to obtain servo signals and an information signal recorded in the first information medium 23, detecting in defocus the intensity of the diffracted light L5R to obtain an information signal recorded in the second information medium 25, and detecting the intensity of the transmitted light L4R converged on the second information medium 25 in defocus to obtain a focus error signal.

The beam splitter 102 is made of a plane parallel plate inclined to an optical path, so that an astigmatic aberration is generated in the light L4R, L5R passing through the beam splitter 102. Also, as shown in FIG. 41, the transmission type of hologram 103 is arranged at a center portion of the beam splitter 102, and a light transmitting region 102*a* is arranged at a peripheral portion of the beam splitter 102 to surround the hologram 103. The transmitted light L4R incident on the light transmitting region 102*a* transmits without any diffraction. The hologram 102 is partitioned into diffracted light generating regions 103*a*, 103*b* alternately arranged to detect a focus error signal according to the spot size detection method described in the sixth embodiment. That is, a grating pattern P10 is drawn in each of the diffracted light generating regions 103*a*, and a converging spot is formed by the transmitted light L4R diffracted in the regions 103*a*. Also, a grating pattern P11 is drawn in each of the diffracted light generating regions 103*b*, and another converging spot is formed by the transmitted light L4R diffracted in the regions 103*b*.

The photo detector 104 comprises the sextant photodetector 59 in which the detecting sections SE1, SE2, SE3, SE4, SE5 and SE6 are provided in the same manner as the photo detector 57.

In the above configuration, the transmitted light L4 and the diffracted light L5 are converged by the converging lens 27 in the same manner as in the sixth embodiment. Thereafter, in cases where a piece of information is recorded or reproduced on or from the first information medium 23, as shown in FIG. 40A, the transmitted light L4 is converged on the first information medium 23 to form the first converging spot S1. Thereafter, a beam of transmitted light L4R reflected by the first information medium 23 passes through the same optical path in the reverse direction. That is, the transmitted light L4R again transmits through the compound objective lens without any diffraction and is reflected by the beam splitter 54. Thereafter, the transmitted light L4R is converged by the converging lens 55, and a major part of the transmitted light L4R transmits through the beam splitter 103. In this case, an astigmatic aberration is generated in the transmitted light L4R. Thereafter, the transmitted light L4R is converged on the photo detector 104 to form a converging spot S14 of which the shape is the same as the converging spot S10 shown in FIGS. 29A to 29C, and the intensity of the transmitted light L4R is detected in the photo detector 104. Therefore, an information signal and servo signals such as a focus error signal and a tracking error signal are obtained in the same manner as in the seventh embodiment. In this case,

because the position of the photo detector **104** detecting the transmitted light L4R relates to a radiation point of the light source **52** in a mirror image, the transmitted light L4R is converged on the photo detector **104** just in focus.

In contrast, in cases where a piece of information is recorded or reproduced on or from the second information medium **25**, as shown in FIG. **40**B, the diffracted light L5 is converged on the second information medium **25** to form the second converging spot S2. Thereafter, a beam of diffracted light L5R reflected by the second information medium **25** passes through the same optical path in the reverse direction and transmits through the hologram lens **26** without any diffraction. Therefore, the diffracted light L5R transmits on the incoming optical path differing from the outgoing optical path in the same manner as in the ninth embodiment. Thereafter, the diffracted light L5R is reflected by the beam splitter **54** and is converged by the converging lens **55**. Thereafter, a major part of the diffracted light L5R transmits through the beam splitter **102**, and the diffracted light L5R is converged on the photo detector **57**. In this case, an astigmatic aberration is generated in the diffracted light L5R. Also, because the diffracted light L5R is not diffracted by the hologram lens **26** on the incoming optical path, the position of the photo detector **104** detecting the diffracted light L5R does not relate to the radiation point of the light source **52** in the mirror image. Therefore, the diffracted light L5R is converged on the photo detector **104** in defocus. However, because the entire intensity of the diffracted light L5R converged in defocus is detected in the photo detector **104**, an information signal is obtained in the same manner as in the seventh embodiment.

Also, the transmitted light L4 is converged on the second information medium **25** in defocus as shown in FIG. **40**B. That is, the transmitted light L4 incident on the rear surface of the second information medium **25** is converged at the front surface of the second information medium **25**. Thereafter, a beam of transmitted light L4R reflected at the front surface of the second information medium **25** again transmits through the compound objective lens without any diffraction and is reflected by the beam splitter **54**. Thereafter, the transmitted light L4R is converged by the converging lens **55** on the beam splitter **102** to form a converging spot on the of hologram **103** of the beam splitter **102**. Therefore, all of the transmitted light L4R is diffracted by the hologram **103** and is converged on the photo detector **104**. That is, the transmitted light L4R diffracted in the diffracted light generating regions **103***a* of the hologram **103** is changed to a first spherical wave SW1 of which a focal point is placed at the front of the photo detector **104**, and the transmitted light L4R diffracted in the diffracted light generating regions **103***b* of the hologram **103** is changed to a second spherical wave SW2 of which a focal point is placed at the rear of the photo detector **104**. Thereafter, as shown in FIGS. **42**A to **42**C, the first spherical wave SW1 is converged on the detecting sections SE1 to SE3 of the sextant photo-detector **59** in the photo detector **104** to form a converging spot S15A, and the second spherical wave SW2 is converged on the detecting sections SE4 to SE6 of the sextant photo-detector **59** to form a converging spot S15B. Because the regions **103***a*, **103***b* are divided into many pieces, the converging spots S15A, S15B are respectively divided into many pieces.

In cases where the diffracted light L5 is converged on the information medium **25** in defocus, the converging spots S15A, S15B of the transmitted light L4R shown in FIGS. **42**A, **42**C are formed on the sextant photo-detector **59**. In contrast, in cases where the diffracted light L5 is converged on the information medium **25** in focus, the converging spots S15A, S15B of the transmitted light L4R shown in FIG. **42**B are formed on the sextant photo-detector **59**. The intensity of the transmitted light L4R is detected in each of the detecting sections SE1 to SE6 of the sextant photo-detector **59** and is changed to electric current signals SC15 to SC20. Thereafter, a focus error signal $S_{f\theta}$ is obtained according to the spot size detection method by calculating an equation (11).

$$S_{f\theta}=(SC15+SC17-SC16)-(SC18+SC20-SC19) \quad (11)$$

Thereafter, the position of the compound objective lens is moved in a direction along an optical axis at high speed so as to minimize the absolute value of the focus error signal $S_{f\theta}$. Therefore, the focus error signal is obtained in the same manner as in the sixth embodiment.

Accordingly, because the compound objective lens having two focal points is utilized in the optical head apparatus **101**, pieces of information can be reliably recorded or reproduced on or from an information medium regardless of whether the information medium is thick or thin.

Also, because all of the transmitted light L4R reflected by the second information medium **25** is completely diffracted by the hologram **103** of the beam splitter **102** to detect the focus error signal, the transmitted light L4R can be utilized at high efficiency. Therefore, a signal-noise ratio of the focus error signal obtained in the photo detector **104** can be enhanced.

Also, the information signal and the servo signals can be obtained in the photo detector **104** regardless of whether the information medium **23** or **25** is thin or thick. Therefore, the number of parts required to manufacture the optical head apparatus **101** can be reduced, and a small sized optical head apparatus can be manufactured at a low cost and in light weight even though pieces of information are recorded or reproduced on or from an information medium by utilizing the optical head apparatus **101** regardless of whether the information medium is thick or thin.

An example of the utilization of the optical head apparatus **101** for various types of optical disks is described.

In cases where the optical head apparatus **101** is utilized for an optical disk device in which pieces of information recorded in a thin type of high density optical disk **23** are recorded or reproduced and pieces of information recorded in a thick type of optical disk **25** are exclusively reproduced, the diffraction efficiency of the hologram lens **26**, **32** or **33** in the compound objective lens **29**, **34**, **45**, **46** or **47** is set to a value equal to or lower than 30%. Therefore, in cases where a piece of information recorded on the thick type of optical disk **25** is reproduced in the photo detector **104**, a signal-noise ratio of each of the servo signals and the information signal obtained in the photo detector **104** can be enhanced because the diffracted light L5R transmitting through the hologram lens **26**, **32** or **33** at a high transmission efficiency is utilized to obtain the information signal. In other words, a utilization efficiency of the incident light L3 can be enhanced when a piece of information recorded on the thick type of optical disk **25** is reproduced, so that the output power of the incident light L3 can be minimized. Also, even though a high intensity of the transmitted light L4 is required to record a piece of information on the high density optical disk **23**, the recording of the information can be reliably performed without increasing the intensity of the incident light L3 because a transmission efficiency of the hologram lens **26**, **32** or **33** for the incident light L3 is high. Also, in cases where a piece of information recorded on the high density optical disk **23** is reproduced in the photo

detector **63**, a signal-noise ratio of each signal obtained in the photo detector **63** can be enhanced because the transmission efficiency of the hologram lens **26**, **32** or **33** for the light L**3**, L**4**R is high.

(Twelfth Embodiment)

An optical head apparatus with the compound objective lens **29**M, **43**, **45**, **46** or **47** in which the incident light L**3** is efficiently utilized to obtain an information signal and servo signals is described with reference to FIG. **43** according to a twelfth embodiment of the present invention.

FIG. **43** is a constitutional view of an optical head apparatus according to a twelfth embodiment.

As shown in FIG. **43**, an optical head apparatus **111** for recording or reproducing pieces of information on or from the information medium **23** or **25**, comprises the light source **52**, the collimator lens **53**, the beam splitter **54**, the compound objective lens **29**M (or **43**, **45**, **46** or **47**) composed of the hologram lens **42** (or **26**M or **32**) and the objective lens **27**, the actuating unit **58**, the converging lens **55**, the beam splitter **82**, the photo detector **63**, the wavefront changing device **56**, and the photo detector **57**.

In the above configuration, a beam of incident light L**3** radiated from the light source **52** is collimated in the collimator lens **53** and transmits through the beam splitter **54**. Thereafter, a part of the incident light L**3** transmits through the compound objective lens **29** without any diffraction, and a remaining part of the incident light L**3** is diffracted.

Thereafter, in cases where a piece of information is recorded or reproduced on or from the first information medium **23**, the diffracted light L**6** is converged on the first information medium **23** to form the converging spot S**5**. That is, the diffracted light L**6** is incident on the rear surface of the first information medium **23**, and the converging spot S**5** is formed on the front surface of the first information medium **23**. Thereafter, a beam of diffracted light L**6**R reflected at the front surface of the first information medium **23** passes through the same optical path in the reverse direction, and a great part of the diffracted light L**6**R is again diffracted by the hologram lens **42**. Therefore, the diffracted light L**6**R transmits on the incoming optical path agreeing with the outgoing optical path. Thereafter, the diffracted light L**6**R is reflected by the beam splitter **54** and is converged by the converging lens **55**. Thereafter, a part of the diffracted light L**6**R transmits through the beam splitter **82**. In this case, an astigmatic aberration is generated in the diffracted light L**6**R. Thereafter, the diffracted light L**6**R is converged on the photo detector **63** to form the converging spot S**10** of which the shape is shown in FIGS. **29**A to **29**C, and the intensity of the diffracted light L**6**R is detected in the photo detector **63**. Therefore, an information signal and servo signals such as a focus error signal and a tracking error signal are obtained in the same manner as in the seventh embodiment.

In contrast, in cases where a piece of information is recorded or reproduced on or from the second information medium **25**, the transmitted light L**4** is converged on the second information medium **25** to form the converging spot S**6**. That is, the transmitted light L**4** is incident on the rear surface of the second information medium **25**, and the converging spot S**6** is formed on the front surface of the second information medium **25**. Thereafter, a beam of transmitted light L**4**R reflected at the front surface of the second information medium **25** passes through the same optical path in the reverse direction. That is, the transmitted light L**4**R is collimated by the objective lens **27** on the incoming optical path. Thereafter, a great part of the transmitted light L**4**R is diffracted by the hologram lens **42**. Therefore, the transmitted light L**4**R transmits on the incoming optical path differing from the outgoing optical path. Thereafter, the transmitted light L**4**R is reflected by the beam splitter **54** and is converged by the converging lens **55**. Thereafter, a part of the transmitted light L**4**R is reflected by the beam splitter **82**. Thereafter, the wavefront of a great part of the transmitted light L**4**R is changed by the wavefront changing unit **56**, and the great part of the transmitted light L**4**R is converged on the photo detector **57** to form converging spots S**16**, S**17**. Therefore, an information signal and servo signals such as a focus error signal and a tracking error signal are obtained in the same manner as in the sixth embodiment. Also, a remaining part of the transmitted light L**4**R not changed its wavefront by the wavefront changing unit **56** is converged on the photo detector **57** to form the converging spot S**18**.

In the twelfth embodiment, because the transmitted light L**4**R is diffracted by the hologram lens **42** on the incoming optical path, the converging spot S**18** formed on the photo detector **57** does not relate to a radiation point of the light source **52** in a mirror image, while the converging spot S**10** formed on the photo detector **63** relates to the radiation point of the light source **52** in the mirror image. In other words, a focal point of the transmitted light L**4**R converged by the converging lens **55** differs from that of the diffracted light L**6**R converged by the converging lens **55**. Therefore, the photo detector **57** for detecting the intensity of the transmitted light L**4**R and the photo detector **63** for detecting the intensity of the diffracted light L**6**R are required.

Accordingly, even though pieces of information are recorded or reproduced on or from an information medium, the information can be reliably recorded or reproduced on or from the information medium regardless of whether the information medium is thick or thin.

Also, because the diffracted light L**6** formed in the hologram lens **42** converges before the diffracted light L**6** is incident on the objective lens **27**, the distance in an optical axis direction between the converging spots S**5**, S**6** can be lengthened to about 1 mm. Therefore, even though the transmitted light L**4** (or the diffracted light L**6**) is converged on the converging spot S**6** (or S**5**) in focus to record or read a piece of information, the light L**6** (or L**4**) is not converged on the converging spot S**6** (or S**5**) in focus to reduce the intensity of the light L**6** (or L**4**) at the converging spot S**6** (or S**5**). Accordingly, no adverse influence is exerted on the recording or reproduction of the information

Also, because the hologram lens **42** functions as a convex lens for the first-order diffracted light L**6**, the occurrence of a chromatic aberration can be prevented in the optical head apparatus **111**.

An example of the utilization of the optical head apparatus **111** for various types of optical disks is described.

In cases where the optical head apparatus **111** is utilized for an optical disk device in which pieces of information recorded in a thin type of high density optical disk **23** are recorded or reproduced and pieces of information recorded in a thick type of optical disk **25** are exclusively reproduced, the diffraction efficiency of the hologram lens **26**M or **42** in the compound objective lens **29**M, **43**, **45**, **46** or **47** for changing a beam of light to a beam of first-order diffracted light is set to a value equal to or higher than 55%. Therefore. in cases where a piece of information recorded on the thick type of optical disk **25** is reproduced in the photo detector **57**, a signal-noise ratio of each of the servo signals and the information signal obtained in the photo detector **57** can be enhanced because the transmitted light L**4**R diffracted by the

hologram lens **26**M or **42** at a high diffraction efficiency is utilized to obtain the servo signals and the information signal. In other words, a utilization efficiency of the incident light **L3** can be enhanced when a piece of information recorded on the thick type of optical disk **25** is reproduced, so that the output power of the incident light **L3** can be minimized. Also, even though a high intensity of the diffracted light **L6** is required to record a piece of information on the high density optical disk **23**, the recording of the information can be reliably performed without increasing the intensity of the incident light **L3** because the diffraction efficiency of the hologram lens **26**M or **42** for the incident light **L3** and the diffracted light **L6**R is high. Also, in cases where a piece of information recorded on the high density optical disk **23** is reproduced in the photo detector **63**, a signal-noise ratio of each signal obtained in the photo detector **63** can be enhanced because the diffraction efficiency of the hologram lens **26**M or **42** for the light **L3**, **L6**R is high.

(Thirteenth Embodiment)

An optical head apparatus with the compound objective lens **29**M, **43**, **45**, **46** or **47** in which the incident light **L3** is efficiently utilized to obtain an information signal and servo signals is described with reference to FIG. **44** according to a thirteenth embodiment of the present invention.

FIG. **44** is a constitutional view of an optical head apparatus according to a thirteenth embodiment.

As shown in FIG. **44**, an optical head apparatus **121** for recording or reproducing pieces of information on or from the information medium **23** or **25**, comprises the light source **52**, the collimator lens **53**, the beam splitter **54**, the compound objective lens **43** (or **29**M, **45**, **46** or **47**) composed of the hologram lens **42** (or **26**M or **32**) and the objective lens **27**, the actuating unit **58**, the converging lens **55**, the beam splitter **92** having the reflection type of hologram **93**, the photo detector **63**, and the photo detector **57**.

In the above configuration, the transmitted light **L4** and the diffracted light **L6** are converged by the converging lens **27** in the same manner as in the twelfth embodiment. Thereafter, in cases where a piece of information is recorded or reproduced on or from the first information medium **23**, the diffracted light **L6** is converged on the first information medium **23** to form the converging spot **S5**. Thereafter, a beam of diffracted light **L5**R reflected by the first information medium **23** passes through the same optical path in the reverse direction, and a large part of the diffracted light **L6**R is diffracted by the hologram lens **42**. Therefore, the diffracted light **L6**R transmits on the incoming optical path agreeing with the outgoing optical path in the same manner as in the twelfth embodiment. Thereafter, the diffracted light **L6**R is reflected by the beam splitter **54** and is converged by the converging lens **55** on the beam splitter **92** to form a converging spot on the reflection type of hologram **93** of the beam splitter **92**. Therefore, all of the diffracted light **L6**R is diffracted and reflected by the hologram **93** to be converged on the photo detector **57** in the same manner as in the tenth embodiment. Therefore, an information signal and servo signals such as a focus error signal and a tracking error signal are obtained in the same manner as in the sixth embodiment.

In contrast, in cases where a piece of information is recorded or reproduced on or from the second information medium **25**, the transmitted light **L4** is converged on the second information medium **25** to form the converging spot **S6**. Thereafter, a beam of transmitted light **L4**R reflected by the second information medium **25** passes through the same optical path in the reverse direction. That is, a large part of the transmitted light **L4**R is collimated by the objective lens **27** on the incoming optical path. Thereafter, a great part of the transmitted light **L4**R is diffracted by the hologram Lens **42**. Therefore, the transmitted light **L4**R transmits on the incoming optical path differing from the outgoing optical path in the same manner as in the twelfth embodiment. Thereafter, the transmitted light **L4**R is reflected by the beam splitter **54** and is converged by the converging lens **55**. Thereafter, a large part of the transmitted light **L4**R transmits through the beam splitter **92**. In this case, an astigmatic aberration is generated in the transmitted light **L4**R. Thereafter, the transmitted light **L4**R is converged on the photo detector **63** to form a converging spot **S19** of which the shape is the same as the converging spot **S10** shown in FIGS. **29**A to **29**C, and the intensity of the transmitted light **L4**R is detected in the photo detector **63**. Therefore, an information signal and servo signals such as a focus error signal and a tracking error signal are obtained in the same manner as in the seventh embodiment.

In the thirteenth embodiment, because the transmitted light **L4**R is diffracted by the hologram lens **42**, the converging spot **S19** formed on the photo detector **63** does not relate to a radiation point of the light source **52** in a mirror image. Therefore, the photo detector **57** for detecting the intensity of the diffracted light **L6**R and the photo detector **63** for detecting the intensity of the transmitted light **L4**R are required.

Accordingly, because the compound objective lens having two focal points is utilized in the optical head apparatus **121**, pieces of information can be reliably recorded or reproduced on or from an information medium regardless of whether the information medium is thick or thin.

Also, because the diffracted light **L6** formed in the hologram lens **42** converges before the diffracted light **L6** is incident on the objective lens **27**, the distance in an optical axis direction between the converging spots **S5**, **S6** can be lengthened to about 1 mm. Therefore, even though the transmitted light **L4** (or the diffracted light **L6**) is converged on the converging spot **S6** (or **S5**) in focus to record or read a piece of information, the light **L6** (or **L4**) is not converged on the converging spot **S6** (or **S5**) in focus to reduce the intensity of the light **L6** (or **L4**) at the converging spot **S6** (or **S5**). Accordingly, no adverse influence is exerted on the recording or reproduction of the information

Also, because the hologram lens **42** functions as a convex lens for the first-order diffracted light **L6**, the occurrence of a chromatic aberration can be prevented in the optical head apparatus **121**.

An example of the utilization of the optical head apparatus **121** for various types of optical disks is described.

In cases where the optical head apparatus **121** is utilized for an optical disk device in which pieces of information recorded in a thin type of high density optical disk,**23** are recorded or reproduced and pieces of information recorded in a thick type of optical disk **25** are exclusively reproduced, the diffraction efficiency of the hologram lens **26**M or **42** in the compound objective lens **29**M, **43**, **45**, **46** or **47** for changing a beam of light to a beam of first-order diffracted light is set to a value equal to or higher than 70%. Therefore, in cases where a piece of information recorded on the thick type of optical disk **25** is reproduced in the photo detector **57**, a signal-noise ratio of each of the servo signals and the information signal obtained in the photo detector **57** can be enhanced because the transmitted light **L4**R diffracted by the hologram lens **26**M or **42** at a high diffraction efficiency is utilized to obtain the servo signals and the information signal. In other words, a utilization efficiency of the incident

light L3 can be enhanced when a piece of information recorded on the thick type of optical disk **25** is reproduced, so that the output power of the incident light L3 can be minimized. Also, even though a high intensity of the diffracted light L6 is required to record a piece of information on the high density optical disk **23**, the recording of the information can be reliably performed without increasing the intensity of the incident light L3 because the diffraction efficiency of the hologram lens **26**M or **42** for the incident light L3 and the diffracted light L6R is high. Also, in cases where a piece of information recorded on the high density optical disk **23** is reproduced in the photo detector **63**, a signal-noise ratio of each signal obtained in the photo detector **63** can be enhanced because the diffraction efficiency of the hologram lens **26**M or **42** for the light L3, L6R is high.

(Fourteenth Embodiment)

An optical head apparatus in which noises included in an information signal are reduced is described with reference to FIGS. **45**, **46** according to a fourteenth embodiment of the present invention.

FIG. **45** is a constitutional view of an optical head apparatus according to a fourteenth embodiment. FIG. **46** is a plan view of a hologram lens utilized in the optical head apparatus shown in FIG. **45**.

As shown in FIG. **45**, an optical head apparatus **131** for recording or reproducing pieces of information on or from the information medium **23** or **25**, comprises the light source **52**, a beam splitter **132** having a polarizing separation film **133** on its surface for reflecting the incident light L3 radiated from the light source **52** on an outgoing optical path and transmitting through the light L4R or L5R reflected on the information medium **23** or **25** on an incoming optical path, a collimator lens **134** for collimating the incident light L3 on the outgoing optical path and converging the light L4R or L5R on the incoming optical path, a hologram lens **135** for transmitting a part of the incident light L3 without any diffraction and diffracting a remaining part of the incident light L3, the ¼–λ plate **69**, the objective lens **27**, the actuating unit **58**, and a photo detector **136** for detecting the light transmitting through or diffracted by the hologram lens **135** on the incoming optical path.

As shown in FIG. **46**, the hologram lens **135** is formed by drawing the grating pattern P1 in a central region **135***a* of the transparent substrate **28** and a grating pattern P12 in a peripheral region **135***b* surrounding the central region **135***a*. The grating pattern P12 is drawn in a non-concentric shape. Because the grating pattern P1 are drawn in the hologram lens **135**, a compound objective lens **137** having two focal points is composed of the hologram lens **135** and the objective lens **27**. Light passing through the peripheral region **135***b* of the hologram lens **135** is detected by the photo detector **136** to cancel noises included in an information signal. An optical axis of the optical head apparatus **131** passes through a central point of the grating pattern P1 and a central axis of the objective lens **27**.

The photo detector **136** comprises the quadrant photodetector **64** having the detecting sections SE7 to SE10 and a noise cancelling photo detector **138** for detecting the intensity of light passing through the peripheral region **135***b* of the hologram lens **135**. Because the grating pattern P12 of the peripheral region **135***b* is drawn in the non-concentric shape, light diffracted in the peripheral region **135***b* is not converged on the detecting sections SE7 to SE10.

In the above configuration, the incident light L3 linearly polarized in a first direction is radiated from the light source **52** and is reflected by the beam splitter **132** because the polarizing separation film **133** functions as a mirror for the incident light L3 linearly polarized in the first direction. Therefore, the incident light L3 is directed in an upper direction and is collimated by the collimator lens **134**. Thereafter, a part of the incident light L3 incident on the central region **135***a* of the hologram lens **135** transmits through the central region **135***a* without any diffraction to form the transmitted light L4, and a remaining part of the incident light L3 incident on the central region **135***a* of the hologram lens **135** is diffracted in the central region **135***a* to form the diffracted light L5. Also, a part of the incident light L3 incident on the peripheral region **135***b* of the hologram lens **135** transmits through the peripheral region **135***b* without any diffraction to form a beam of noise cancelling light L14. Thereafter, the light L4, L5 and L14 pass through the ¼–λ plates so that the light L4, L5 and L14 linearly polarized in the first direction is changed to the light L4, L5 and L14 circularly polarized. Thereafter, the light L4, L5 and L14 are converged by the converging lens **27**.

Thereafter, in cases where a piece of information is recorded or reproduced on or from the first information medium **23** (or the second information medium **25**), the transmitted light L4 (or the diffracted light L5) is converged on the information medium **23** (or **25**) to form the converging spot S1 (or S2). Thereafter, a beam of transmitted light L4R (or a beam of diffracted light L5R) reflected by the information medium **23** (or **25**) passes through the same optical path in the reverse direction. That is, the transmitted light L4R (or the diffracted light L5R) is circularly polarized in reverse and again passes through the converging lens **27** and the ¼–λ plate **69**. Therefore, the light L4R (or L5R) is linearly polarized in a second direction perpendicular to the first direction. Thereafter, a part of the transmitted light L4R transmits through the central region **135***a* of the hologram lens **135** without any diffraction, or a part of the diffracted light L5R is again diffracted in the central region **135***a*. Thereafter, the transmitted light L4R (or the diffracted light L5R) is converged by the collimator lens **134** and passes through the beam splitter **132** without any reflection because the polarizing separation film **133** functions as a transparent plate for the light L4R (or L5R) linearly polarized in the second direction. In this case, an astigmatic aberration is generated in the transmitted light L4R (or the diffracted light L5R) in the same manner as in the seventh embodiment. Thereafter, the transmitted light L4R (or the diffracted light L5R) is incident on the detecting sections SE7 to SE10 of the photo detector **136** to form a converging spot S20 of which the shape is the same as the converging spot S10 shown in FIGS. **29**A to **29**C. The intensity of the transmitted light L4R (or the diffracted light L5R) is changed to electric current signals SC21 to SC24 in the detecting sections SE7 to SE10. Therefore, servo signals such as a focus error signal and a tracking error signal are obtained in the same manner as in the seventh embodiment, so that the position of the compound objective lens **137** is adjusted to converge the transmitted light L4 (or the diffracted light L5) on the information medium **23** (or **25**) in focus. Also, an information signal expressing a piece of information recorded on the information medium **23** (or **25**) is obtained according to an equation (12).

$$S_{in}=SC21+SC22+SC23+SC24 \quad (12)$$

Also, the noise cancelling light L14 is converged on the information medium **23** to form a converging spot surrounding the converging spot S1. Thereafter, a beam of noise cancelling light L14R reflected by the first information medium **23** passes through the same optical path in the

reverse direction. That is, the noise cancelling light L14R again passes through the converging lens **27** and the ¼-λ plate **69**, and a part of the noise cancelling light L14R is diffracted and converged in the peripheral region **135***b* of the hologram lens **135** and is incident on the noise cancelling photo detector **138**. In the photo detector **138**, an output signal SC**25** is generated according to the intensity of the noise cancelling light L14R. Thereafter, a noise cancelled information signal S_{nc} expressing a piece of information recorded on the first information medium **23** is obtained by adding all of the signals according to an equation (13):

$$S_{nc}=(SC21+SC22+SC23+SC24)+R\times SC25 \quad (13),$$

where the symbol R is a weighting factor.

In this case, because the term R×SC25 is added to obtain the information signal S_{nc}, inverse influence of noises included in the term (SC21+SC22+SC23+SC24) on the noise cancelled information signal S_{nc} can be reduced. The reason is described.

As is well known (for example, Japanese Patent Gazette No. 22452 of 1990 laid open to public inspection on Jul. 23, 1985 under Provisional Publication No. 138748 of 1985 and Published Unexamined Patent Application No. 131245 of 1986), signals expressing pieces of information recorded on an optical disk shifts to a higher frequency as the density of the information recorded becomes high. Also, the amplitude of a signal having a high frequency becomes low as compared with that of a signal having a low frequency in cases where the signals are produced according to light passing through a central region of a hologram lens. In contrast, the amplitude of a signal having a high frequency is emphasized in cases where the signal is produced according to light passing through a peripheral region of the hologram lens. Therefore, in cases where the information signal S_{nc} is obtained according to the equation (13), high frequency components included in the information signal S_{nc} is emphasized, and low frequency noise components included in the term (SC21+SC22+SC23+SC24) are comparatively reduced. As a result, a signal-noise ratio in the information signal S_{nc} can be enhanced.

Accordingly, because the compound objective lens having two focal points is utilized in the optical head apparatus **131**, pieces of information can be reliably recorded or reproduced or or from an information medium regardless of whether the information medium is thick or thin.

Also, even though pieces of information are densely recorded in a thin type of high density optical disk represented by the first information medium **23**, the information signal S_{nc} can be reliably reproduced at a high signal-noise ratio.

Also, because the intensity of the light L4R or L5R incident on the detecting sections SE7 to SE**10** of the photo detector **136** is reduced by converging the noise cancelling light L14R on the photo detector **138**, a positioning accuracy of the photo detector **136** can be coarsely lowered to 1/100.

Also, in cases where the grating pattern P12 of the peripheral region **135***b* functions as a lens for the incident light L3 diffracted in the peripheral region **135***b*, unnecessary diffracted light generated in the peripheral region **135***b* on the outgoing optical path forms a comparatively large converging spot in defocus on the first information medium **23**. Therefore, pieces of information recorded on the first information medium **23** are read by the unnecessary diffracted light, and the information are treated as a piece of averaged information in the photo detector **136** even though the unnecessary diffracted light is incident on the photo detector **136**. Accordingly, the information read by the unnecessary diffracted light does not adversely influence on the information signal S_{nc} as a noise.

Also, in cases where a transmission efficiency of the peripheral region **135***b* of the hologram lens **135** is set to agree with another transmission efficiency of the central region **135***a*, secondary maxima (or side lobes) occurring around the converging spot S1 can be lowered as compared with the first embodiment. Accordingly, a signal-noise ratio in the information signal S_{nc} can be enhanced.

(Fifteenth Embodiment)

An optical head apparatus in which noises included in an information signal are reduced is described with reference to FIGS. **47** to **49** according to a fifteenth embodiment of the present invention.

FIG. **47** is a constitutional view of an optical head apparatus according to a fifteenth embodiment. FIG. **48** is a plan view of a hologram lens utilized in the optical head apparatus shown in FIG. **47**.

As shown in FIG. **47**, an optical head apparatus **141** for recording or reproducing pieces of information on or from the information medium **23** or **25**, comprises the light source **52**, the beam splitter **82**, the collimator lens **134**, a hologram lens **142** for transmitting a part of the incident light L3 without any diffraction and diffracting a remaining part of the incident light L3, the objective lens **27**, the actuating unit **58**, and a photo detector **143** for detecting the light transmitting through or diffracted by the hologram lens **142** on the incoming optical path.

As shown in FIG. **48**, the hologram lens **142** is partitioned into a central region **142***a* in which the grating pattern P1 is drawn, a pair of side peripheral regions **142***b*, **142***c* in which grating patterns P13, P14 are drawn to cancel noises included in an information signal, and a pair of no-designed regions **142***d*, **142***e* in which no grating pattern is drawn not to reduce the intensity of light. Because the grating pattern P1 are drawn in the hologram lens **135**, a compound objective lens **144** having two focal points is composed of the hologram lens **142** and the objective lens **27**. An optical axis of the optical head apparatus **141** passes through a central point of the grating pattern P1 and a central axis of the objective lens **27**.

The photo detector **143** comprises the quadrant photodetector **64** having the detecting sections SE7 to SE**10**, a pair of noise cancelling photo detector **138***a*, **138***b* for detecting the intensity of light passing through the peripheral region **142***b*, **142***c* of the hologram lens **142**.

In the above configuration, the transmitted light L4 (or the diffracted light L5) generated in the central region **142***a* of the hologram lens **142** is converged on the first information medium **23** (or the second information medium **25**) in an outgoing optical path to form the converging spot S1 (or S2). Thereafter, the transmitted light L4R (or the diffracted light L5R) passes through the same optical path in the reverse direction. That is, the transmitted light L4R (or the diffracted light L5R) again passes through the converging lens **27**, and a part of the transmitted light L4R transmits through the central region **142***a* of the hologram lens **142** without any diffraction or a part of the diffracted light L5R is again diffracted in the central region **142***a*. Thereafter, the transmitted light L4R (or the diffracted light L5R) is converged by the collimator lens **134** and passes through the beam splitter **82**. In this case, an astigmatic aberration is generated in the transmitted light L4R (or the diffracted light L5R) in the same manner as in the seventh embodiment. Thereafter, the transmitted light L4R (or the diffracted light L5R) is incident on the detecting sections SE7 to SE**10** of the photo detector **143** to form a converging spot S21 of which the

shape is the same as the converging spot **S10** shown in FIGS. **29**A to **29**C. The intensity of the transmitted light L**4**R (or the diffracted light L**5**R) is changed to electric current signals SC**26** to SC**29** in the detecting sections SE**7** to SE**10**. Therefore, servo signals such as a focus error signal and a tracking error signal are obtained in the same manner as in the seventh embodiment, so that the position of the compound objective lens **144** is adjusted to converge the transmitted light L**4** (or the diffracted light L**5**) on the information medium **23** (or **25**) in focus. Also, an information signal recorded on the second information medium **25** is obtained according to an equation (14).

$$S_{in}=SC26+SC27+SC28+SC29 \quad (14)$$

Also, a part of the incident light L**3** incident on the peripheral region **142***b* of the hologram lens **142** transmits through the peripheral region **142***b* without any diffraction to form a beam of noise cancelling light L**15**, and a part of the incident light L**3** incident on the peripheral region **142***c* of the hologram lens **142** transmits through the peripheral region **142***c* without any diffraction to form a beam of noise cancelling light L**16**. Thereafter, the noise cancelling light L**15**, L**16** are converged on the information medium **23** to form a converging spot surrounding the converging spot S**1**. Thereafter, beams of noise cancelling light L**15**R, L**16**R reflected by the first information medium **23** passes through the same optical path in the reverse direction. That is, the noise cancelling light L**15**R, L**16**R again passes through the converging lens **27**. A part of the noise cancelling light L**15**R is diffracted and converged in the peripheral region **142***b* of the hologram lens **142** and is incident on the noise cancelling photo detector **138***a*, and a part of the noise cancelling light L**16**R is diffracted and converged in the peripheral region **142***c* of the hologram lens **142** and is incident on the noise cancelling photo detector **138***b*. In the photo detector **138***a*, an output signal SC**30** is generated according to the intensity of the noise cancelling light L**15**R. Also, an output signal SC**31** is generated according to the intensity of the noise cancelling light L**16**R in the photo detector **138***b*. Thereafter, a noise cancelled information signal S_{nc} expressing the information recorded on the first information medium **23** is obtained by adding all of the signals according to an equation (15):

$$S_{nc}=(SC26+SC27+SC28+SC29)+R\times(SC30+SC31) \quad (15),$$

where the symbol R is a weighting factor.

Accordingly, because the compound objective lens having two focal points is utilized in the optical head apparatus **141**, pieces of information can be reliably recorded or reproduced from an information medium regardless of whether the information medium is thick or thin.

Also, a signal-noise ratio in the information signal S_{nc} can be enhanced in the same manner as in the fourteenth embodiment.

Also, even though pieces of information are densely recorded in a thin type of high density optical disk represented by the first information medium **23**, the information signal S_{nc} can be reliably reproduced at a high signal-noise ratio.

Also, because the intensity of the light L**4**R or L**5**R incident on the detecting sections SE**7** to SE**10** of the photo detector **143** is reduced by converging the noise cancelling light L**15**R, L**16**R on the photo detectors **138***a*, **138***b*, a positioning accuracy of the photo detector **143** can be coarsely lowered to 1/100.

Also, in cases where the grating patterns P**13**, P**14** of the peripheral regions **142***b*, **142***c* functions as a lens for the incident light L**3** diffracted in the peripheral region **142***b*, **142***c*, unnecessary diffracted light generated by diffracting the incident light L**3** in the peripheral regions **142***b*, **142***c* on the outgoing optical path forms a comparatively large converging spot in defocus on the first information medium **23**. Also, an numerical number of each of the peripheral regions **142***b*, **142***c* is lowered as compared with that of the region **135***b* in the fourteenth embodiment because the hologram lens **142** are partitioned into many fields. Therefore, the size of the converging spot of the unnecessary diffracted light formed in defocus on the first information medium **23** becomes larger than that in the fourteenth embodiment. As a result, more pieces of information recorded on the first information medium **23** are read by the unnecessary diffracted light, and the information are treated as a piece of averaged information in the photo detector **143** even though the unnecessary diffracted light is incident on the photo detector **143**. Accordingly, the information read by the unnecessary diffracted light is moreover averaged, and the averaged information does not adversely influence on the information signal S_{nc} as a noise.

Also, as shown in FIGS. **49**A, **49**B, the unnecessary diffracted light can be prevented from being incident on the photo detector **64** in which each of the detecting sections SE**7** to SE**10** has SL**0** square in size. In detail, in cases where light generated in the peripheral region **142***c* on the outgoing optical path is again diffracted in the peripheral region **142***b* to form a beam of unnecessary diffracted light Lu_1, the light Lu_1 is converged on a first position PT**1** spaced SP**1** (SP**1**>SL**0**) from the center of the photo detector **64**. In cases where light generated in the peripheral region **142***b* on the outgoing optical path is again diffracted in the peripheral region **142***c* to form a beam of unnecessary diffracted light Lu_2, the light Lu_2 is converged on a second position PT**2** spaced SP**2** (SP**2**>SL**0**) from the center of the photo detector **64**. In cases where light generated in the peripheral regions **142***b*, **142***c* on the outgoing optical path are again diffracted in the same peripheral regions **142***b*, **142***c* to form beams of unnecessary diffracted light Lu_3, Lu_4, the light Lu_3, Lu_4 are converged on third and fourth position PT**3**, PT**4** spaced SP**3** (SP**3**>SL**0**), SP**4** (SP**4**>SL**0**) from the center of the photo detector **64**. Accordingly, the adverse influence of the unnecessary diffracted light Lu_1 to Lu_4 can be prevented.

In cases where the light source **52** is formed of a semiconductor laser, a far field pattern of the incident light L**3** incident on the hologram lens **142** is distributed in the Gaussian distribution as shown in FIG. **13**A, and a cross-sectional beam profile of the incident light L**3** distributed in the Gaussian distribution is in an elliptic shape. That is, a beam divergent angle (or a full angle at half maximum) of the incident light L**3** in a perpendicular direction is larger than that in a horizontal direction. In this embodiment, the perpendicular direction of the incident light L**3** is directed in an X2 direction shown in FIG. **48**, and the horizontal direction of the incident light L**3** is directed in a Y2 direction shown in FIG. **48**. In this case, because a transmission efficiency of the regions **142***b*, **142***c* for the incident light L**3** is smaller than that of the regions **142***d*, **142***e*, the intensity of the incident light L**3** transmitting through the hologram lens **142** without any diffraction is largely reduced in the perpendicular direction as compared with that in the horizontal direction. Therefore, the cross-sectional beam profile of the incident light L**3** is corrected to a circular shape in the hologram lens **142**. That is, the converging spot S**1** formed on the first information medium **23** is corrected to the circular shape. Accordingly, secondary maxima (or side lobes) occurring around the converging spot S**1** can be

lowered, and a signal-noise ratio of the information signal S_{nc} can be enhanced.

In the fifteenth embodiment, the noise cancelled information signal S_{nc} is obtained according to the equation (15). However, it is preferred that the noise cancelled information signal S_{nc} be obtained according to the equation (16):

$$S_{nc}=(SC26+SC27+SC28+SC29)+(R1\times SC30+R2\times SC31) \quad (16),$$

where the symbols R1, R2 are weighting factors. In this case, the noises included in the information can be moreover reduced.

(Sixteenth Embodiment)

An optical head apparatus manufactured in a small size and stably operated is described with reference to FIGS. **50**, **51** according to a sixteenth embodiment of the present invention.

FIG. **50** is a constitutional view of an optical head apparatus according to a sixteenth embodiment. FIG. **51** is a diagonal view of a light source and photo detectors utilized in the optical head apparatus shown in FIG. **50**.

As shown in FIG. **50**, an optical head apparatus **151** for recording or reproducing pieces of information on or from the information medium **23** or **25**, comprises the light source **52** for radiating the incident light L**3** linearly polarized in a non-diffracting direction parallel to an X3 axis, an holographic element **152** for transmitting through the incident light L**3** without any diffraction on an outgoing optical path and diffracting the transmitted light L**4**R or the diffracted light L**5**R linearly polarized in a diffracting direction parallel to a Y3 axis on an incoming optical path, the collimator lens **53**, the ¼–λ plate **69**, the hologram lens **26** (or **26**M, **32**, **33**, **42**, **135** or **142**), the objective lens **27**, the actuating unit **58**, and a photo detector **153** for detecting the intensity of the light L**4**R or L**5**R diffracted by the holographic element **152**.

As shown in FIG. **51**, the light source **52** and the photo detector **153** are located on a substrate **154** to precisely fix a relative position between the light source **52** and the photo detector **153**. The photo detector **153** comprises the sextant photo-detector **59** having the detecting sections SE**1** to SE**6** and the tracking photo-detectors **60***a* to **60***d*. Also, a mirror element **155** is located on the substrate **154** to direct the incident light L**3** radiated from the light source **52** in a Z**3** direction.

The holographic element **152** is produced by proton-exchanging surface parts of a lithium niobate substrate or by utilizing a liquid crystal cell, as is described in Provisional Publication No. 189504/86 (S61-189504) and Provisional Publication No. 241735/88 (S63-241735). Therefore, light linearly polarized in a non-diffracting direction parallel to an X3 axis transmits through the holographic element **152** without any diffraction. In contrast, light linearly polarized in a diffracting direction parallel to a Y3 axis which is perpendicular to the X3 axis is diffracted by the holographic element **152**.

In the above configuration, the incident light L**3** linearly polarized in a non-diffracting direction parallel to an X3 axis is radiated from the light source **52** and transmits through the holographic element **152** without any diffraction. Thereafter, the incident light L**3** is collimated by the collimator lens **53**, and the incident light L**3** linearly polarized is changed to the incident light L**3** circularly polarized by the ¼–λ plate **69**. Thereafter, a part of the incident light L**3** transmits through the hologram lens **26** without any diffraction to form the transmitted light L**4**, and a remaining part of the incident light L**3** is diffracted by the hologram lens **26** to form the diffracted light L**5**. Thereafter, the light L**4**, L**5** are converged by the objective lens **27**, and the converging spot S**1** of the transmitted light L**4** (or the converging spot S**2** of the diffracted light L**5**) is formed on the first information medium **23** (or the second information medium **25**). When the light L**4** or L**5** is reflected by the information medium **23** (or **25**) and is changed to the light L**4**R (or L**5**R), a rotational direction of the circular polarization in the light L**4** is reversed. Therefore, the light L**4**R (or L**5**R) having the reversed circular polarization passes through the same optical path in the opposite direction. That is, the transmitted light L**4**R (or the diffracted light L**5**R) again passes through the converging lens **27**, and a part of the transmitted light L**4**R transmits through the hologram lens **142** without any diffraction or a part of the diffracted light L**5**R is again diffracted by the hologram lens **142**. Thereafter, the transmitted light L**4**R (or the diffracted light L**5**R) circularly polarized in reverse is changed to the light L**4**R (or L**5**R) linearly polarized in a diffracting direction parallel to a Y3 axis by the ¼–λ plate **69**. Thereafter, the light L**4**R (or L**5**R) is converged by the collimator lens **53** and is diffracted by the holographic element **152** to form a plurality of converging spots on the photo detectors **153**. Therefore, an information signal expressing a piece of information recorded on the information medium **23** (or **25**) and servo signals such as a focus error signal and a tracking error signal are obtained in the photo detector **153** in the same manner as in the sixth embodiment.

Accordingly, because the compound objective lens having two focal points is utilized in the optical head apparatus **151**, pieces of information can be reliably recorded or reproduced or or from an information medium regardless of whether the information medium is thick or thin.

Also, because all of the incident light L**3**transmits through the holographic element **152** on the outgoing optical path and because all of the light L**4**R or L**5**R is diffracted by the holographic element **152** on the incoming optical path, a utilization efficiency of the incident light L**3** can be enhanced. Therefore, even though a radiation intensity of the incident light L**3** in the light source **52** is low, the information signal and the servo signals having a high signal-noise ratio can be reliably obtained.

Also, because no beam splitter is utilized in the optical head apparatus **151**, the optical head apparatus **151** can be manufactured at a small size, in a light weight, and at a low cost.

Also, because optical parts of the optical head apparatus **151** are located along its optical axis, the optical head apparatus **151** stably operated can be obtained even though a circumstance temperature largely varies and the apparatus is operated for a long time.

Also, because the light L**4**R or L**5**R transmitting through the holographic element **152** without any diffraction on the incoming optical path is not required, it is preferred that a diffraction efficiency of the holographic element **152** be heightened to set a transmission efficiency of the holographic element **152** to almost zero. In this case, a combination of the holographic element **152** and the ¼–λ plate **69** function functions as an isolator to prevent the light L**4**R or L**5**R from returning to the light source **52**. Therefore, in cases where a semiconductor laser is utilized as the light source **52**, any light does not return to an active layer of the semiconductor laser. Accordingly, noises induced by the light returning to the semiconductor laser can be prevented.

Also, because the light source **52** and the photo detector **153** are located on the same substrate **154**, the light source **52** and the photo detector **153** can be closely arranged each other. Therefore, a relative position between the light source **52** and the photo detector **153** can be easily set at a high

accuracy. For example, the relative position can be set at an accuracy within several μm. Accordingly, a manufacturing cost of the optical head apparatus **151** can be lowered, and the optical head apparatus **151** can be moreover manufactured at a small size, in a light weight, and at a low cost.

Also, the light source **52** is electrically connected with an external circuit through first wirings, and the photo detector **153** is electrically connected with another external circuit through second wirings. In this case, because the light source **52** and the photo detector **153** are located on the same substrate **154**, the first and second wirings can pass on an X3–Y3 plane in common. Therefore, the light source **52** and the photo detector **153** can be easily and automatically connected with the external circuits. In addition, because reference lines required to connect the light source **52** and the photo detector **153** with the external circuits are only drawn on the X3–Y3 plane, the relative position between the light source **52** and the photo detector **153** can be easily set at a high accuracy.

In the sixteenth embodiment, the optical head apparatus **151** with the holographic element **152** is described. However, in cases where the intensity of the incident light **L3** is sufficient, it is applicable that a hologram having a small grating pitch or a blazed hologram be utilized in place of the holographic element **152**. In this case, pieces of information can be reliably recorded or reproduced on or from an information medium regardless of whether the information medium is thick or thin. Also, because no beam splitter is utilized in the optical head apparatus **151**, the optical head apparatus **151** can be manufactured at a small size, in a light weight, and at a low cost. Also, because optical parts of the optical head apparatus **151** are located along its optical axis, the optical head apparatus **151** stably operated can be obtained even though a circumstance temperature largely varies and the apparatus is operated for a long time.

(Seventeenth Embodiment)

An optical head apparatus manufactured in a small size and stably operated is described with reference to FIG. **52** according to a seventeenth embodiment of the present invention.

FIG. **52** is a constitutional view of an optical head apparatus according to a seventeenth embodiment.

As shown in FIG. **52**, an optical head apparatus **161** for recording or reproducing pieces of information on or from the information medium **23** or **25**, comprises the light source **52** for radiating the incident light **L3** linearly polarized in a first direction, the collimator lens **53**, a polarizing separation film **162** formed on a front surface of a transparent substrate **162** for reflecting the incident light **L3** linearly polarized in the first direction and transmitting light linearly polarized in a second direction perpendicular to the first direction, the ¼–λ plate **69**, the hologram lens **26** (or **26M**, **32**, **33**, **42**, **135** or **142**), the objective lens **27**, the actuating unit **58**, a reflection-type hologram **164** formed on a rear surface of the transparent substrate **162** for diffracting and reflecting the light **L4R**, **L5R**, and the photo detector **57**.

In the above configuration, the incident light **L3** linearly polarized in a first direction is radiated from the light source **52** and is collimated by the collimator lens **53**. Thereafter, all of the incident light **L3** is reflected by the polarizing separation film **162** because the incident light **L3** is linearly polarized in the first direction. Therefore, the incident light **L3** is directed in an upper direction. Thereafter, the linear polarization of the incident light **L3** is changed to a circular polarization in the ¼–λ plate **69**, and a part of the incident light **L3** transmits through the hologram lens **26** to form the transmitted light **L4**. Also, a remaining part of the incident light **L3** is diffracted by the hologram lens **26** to form the diffracted light **L5**. Thereafter, the light **L4**, **L5** are converged by the objective lens **27**, and the converging spot **S1** of the transmitted light **L4** (or the converging spot **S2** of the diffracted light **L5**) is formed on the first information medium **23** (or the second information medium **25**). Thereafter, the transmitted light **L4R** (or the diffracted light **L5R**) circularly polarized in reverse again passes through the converging lens **27** in the same manner as in the sixteenth embodiment, and a part of the transmitted light **L4R** transmits through the hologram lens **26** without any diffraction or a part of the diffracted light **L5R** is again diffracted by the hologram lens **26**. Thereafter, the transmitted light **L4R** (or the diffracted light **L5R**) circularly Polarized in reverse is changed to the light **L4R** (or **L5R**) linearly polarized in a second direction perpendicular to the first direction by the ¼–λ plate **69**. Thereafter, all of the light **L4R** (or **L5R**) is refracted by the polarizing separation film **162** and is diffracted and reflected by the hologram **164**. Thereafter, the light **L4R** (or **L5R**) transmits through the polarizing separation film **162** and is converged by the collimator lens **53** to form a plurality of converging spots on the photo detector **57**. Therefore, an information signal expressing a piece of information recorded on the information medium **23** (or **25**) and servo signals such as a focus error signal and a tracking error signal are obtained in the photo detector **57** in the same manner as in the sixth embodiment.

Accordingly, because the compound objective lens having two focal points is utilized in the optical head apparatus **161**, pieces of information can be reliably recorded or reproduced on or from an information medium regardless of whether the information medium is thick or thin.

Also, because the incident light **L3** incident on the polarizing separation film **162** is collimated, a reflectivity for the incident light **L3** is uniform over the entire film **162**. Therefore, a diffraction-limited spot of the light **L4** or **L5** can be easily formed on the information medium **23** or **25**. Also, because the light **L4R**, **L5R** incident on the polarizing separation film **162** are collimated, a transmissivity for the light **L4R**, **L5R** is uniform over the entire film **162**. Therefore, an offset occurring in the servo signals can be prevented.

Also, because all of the incident light **L3** transmits through the hologram **164** on the outgoing optical path and because all of the light **L4R** or **L5R** is diffracted by the hologram **164** on the incoming optical path, a utilization efficiency of the incident light **L3** can be enhanced. Therefore, even though a radiation intensity of the incident light **L3** in the light source **52** is low, the information signal and the servo signals having a high signal-noise ratio can be reliably obtained.

Also, because a hybrid element composed of the film **162**, the substrate **163** and the hologram **164** functions as a beam splitter and a rising mirror, the optical head apparatus **161** can be manufactured at a small size, in a light weight, and at a low cost.

Also, because optical parts of the optical head apparatus **161** are located along its optical axis, the optical head apparatus **161** stably operated can be obtained even though a circumstance temperature largely varies and the apparatus is operated for a long time.

Also, a combination of the film **162** and the ¼–λ plate **69** function functions as an isolator to prevent the light **L4R** or **L5R** from returning to the light source **52**. Therefore, in cases where a semiconductor laser is utilized as the light source **52**, any light does not return to an active layer of the

semiconductor laser. Accordingly, noises induced by the light returning to the semiconductor laser can be prevented.

Also, it is preferred that the hologram **164** be blazed. In this case, because the generation of unnecessary diffracted light such as minus first-order diffracted light in the hologram **164** is prevented, a diffraction efficiency of the hologram **164** for changing light to first-order diffracted light can be set to almost 100%. Therefore, the incident light L**3** can be efficiently utilized to obtain the signals.

Also, because light incident on the hologram **164** is diffracted to first-order diffracted light, a chromatic aberration occurring in the light L**4**R, L**5**R can be compensated in the hologram **164**. Therefore, the servo signals can be stably obtained.

In the seventeenth embodiment, the collimator lens **53** is located between the light source **52** and the film **162**. However, the collimator lens **53** is not necessary in the optical head apparatus **161**.

Also, the optical head apparatus **161** with the film **162** and the ¼–λ plate **69** is described. However, in cases where the intensity of the incident light L**3** is sufficient, it is applicable that a reflection film having a reflectivity of almost ⅓ be utilized in place of the film **162** and the ¼–λ plate **69** be omitted. In this case, pieces of information can be reliably recorded or reproduced on or from an information medium regardless of whether the information medium is thick or thin. Also, because a hybrid element composed of the film **162**, the substrate **163** and the hologram **164** functions as a beam splitter and a rising mirror, the optical head apparatus **161** can be manufactured at a small size, in a light weight, and at a low cost. Also, because optical parts of the optical head apparatus **161** are located along its optical axis, the optical head apparatus **161** stably operated can be obtained even though a circumstance temperature largely varies and the apparatus is operated for a long time.

In the sixth to seventeenth embodiments, pieces of information can be reliably recorded or reproduced on or from an information medium regardless of whether the information medium represents a conventional optical disk such as a compact disk having a thickness T**2** of about 1.2 mm or a prospective high density optical disk having a thickness T**1** ranging from 0.4 mm to 0.8 mm. However, when the information recorded or reproduced on or from the information medium, it is required to examine the thickness of the information medium in advance. Therefore, in cases where a piece of distinguishing information is recorded on the information medium in advance to distinguish the thickness of the information medium, it is convenient for a user. Because no distinguishing information is recorded on the conventional optical disk, it is preferred that the distinguishing information be recorded on the prospective high density optical disk appearing on the market in. the future. Therefore, a high density optical disk with the distinguishing information is described according to eighteenth and nineteenth embodiments.

(Eighteenth Embodiment)

FIG. **53** is a diagonal view of a high density optical disk according to an eighteenth embodiment, a cross sectional view of the disk being partially shown.

As shown in FIG. **53**, a high density optical disk **171** is partitioned into an outer region **171***a* and an inner region **171***b*. The outer region **171***a* occupies a large part of the optical disk **171**, and an information recording substrate **171***c* of the outer region **171***a* has the thickness T**1**, and the information recording substrate **171***c* of the inner region **171***b* has the thickness T**2**. A plurality of first recording pits **172** are formed on the information recording substrate **171***c* of the outer region **171***a* at narrow intervals in series to record pieces of information at a high density. Also, a plurality of second recording pits **173** are formed on the information recording substrate **171***c* of the inner region **171***b* at ordinary intervals in series to record pieces of distinguishing information at an ordinary density of a compact disk. The distinguishing information inform that the optical disk **171** has the thickness T**1**. The thickness T**1** of the outer region **171***a*, for example, ranges from 0.4 mm to 0.8 mm, and the thickness T**2** of the inner region is, for example, about 1.2 mm.

In the above configuration, the diffracted light L**5** according to the first or second embodiment (or the transmitted light L**4** according to the third embodiment) is initially converged on an inner region of the information medium **23**, **25** while performing a focus control corresponding to the second information medium **25** having the thickness T**2**. In cases where the information medium **23** or **25** is the optical disk **171**, a piece of distinguishing information informing that the optical disk **171** having the thickness T**1** is converged by the light L**5** (or L**4**) is detected. Thereafter, the transmitted light L**4** (or the diffracted light L**6**) is automatically converged on the outer region **171***a* of the optical disk **171** while performing a focus control corresponding to the first information medium **23** having the thickness T**1**.

In contrast, in cases where the information medium **23** or **25** is a thick type of conventional optical disk having a thickness T**2**, no distinguishing information is detected when the light L**5** (or L**4**) is converged on the inner region **171***b* of the conventional optical disk. In this case, the focus control corresponding to the second information medium **25** is continued to detect an information signal expressing a piece of information recorded on the conventional optical disk.

Accordingly, in cases where one of the optical head apparatuses shown in FIGS. **21**, **27**, **30**, **31**, **32**, **33**, **37**, **38**, **40**A, **43**, **44**, **50** and **52** is utilized, pieces of information can be automatically recorded or reproduced on or from an information medium regardless of whether the information medium is thin or thick.

Also, because only the distinguishing information is recorded in the inner region, the inner region can be small. Therefore, a memory capacity of the optical disk **171** is not lowered by the addition of the second recording pit **173**.

(Nineteenth Embodiment)

FIG. **54** is a diagonal view of a high density optical disk according to a nineteenth embodiment, a cross sectional view of the disk being partially shown.

As shown in FIG. **54**, a high density optical disk **174** is partitioned into an outer region **174***a* and an inner region **174***b*. The outer region **174***a* occupies a large part of the optical disk **174**. The optical disk **174** has a uniform thickness of T**1**. The first recording pits **172** are formed on an information recording substrate **174***c* of the outer region **174***a* to record pieces of information at a high density. Also, a plurality of second recording pits **175** having a large size are formed on the information recording substrate **174***c* of the inner region **174***b* at wide intervals to record pieces of distinguishing information at a lower density than the ordinary density. The distinguishing information inform that the entire optical disk **174** has the thickness T**1**. The thickness T**1** of the optical disk **174**, for example, ranges from 0.4 mm to 0.8 mm.

In the above configuration, the diffracted light L**5** according to the first or second embodiment (or the transmitted light L**4** according to the third embodiment) is initially converged on an inner region of the information medium **23**

or **25** while performing a focus control corresponding to the second information medium **25** having the thickness T2. In cases where the information medium **23** or **25** is the optical disk **174**, the light L5 (or L4) is converged on each of the second recording pits **175** in defocus. However, because each of the second recording pits **175** is large in size, a converging spot of the light L5 (or L4) is reliably formed in one of the second recording pits **175**. Therefore, a piece of distinguishing information, which informs that the optical disk **174** having the thickness T1 is converged by the light L5 (or L4), is detected. Thereafter, the transmitted light L4 (or the diffracted light L6) is automatically converged on the outer region **174***a* of the optical disk **174** while performing a focus control corresponding to the first information medium **23** having the thickness T1.

In contrast, in cases where the information medium **23** or **25** is a thick type of conventional optical disk having a thickness T2, no distinguishing information is detected when the light L5 (or L4) is converged on the inner region **174***b* of the conventional optical disk. In this case, the focus control corresponding to the second information medium **25** is continued to detect an information signal expressing a piece of information recorded on the conventional optical disk.

Accordingly, in cases where one of the optical head apparatuses shown in FIGS. **21**, **27**, **30**, **31**, **32**, **33**, **37**, **38**, **40**A, **43**, **44**, **50** and **52** is utilized, pieces of information can be automatically recorded or reproduced on or from an information medium regardless of whether the information medium is thin or thick.

Also, because only the distinguishing information is recorded in the inner region of the optical disk **174**, the inner region can be small. Therefore, a memory capacity of the optical disk **174** is not lowered by the addition of the second recording pit **173**.

Also, because the thickness of the optical disk **174** is uniform, the optical disk **174** can be easily manufactured at a low cost. Also, the optical disk **174** can be thinned.

(Twentieth Embodiment)

An optical disk apparatus with one of the optical head apparatuses in which it is automatically judged whether a high density optical disk having the thickness T1 or a conventional optical disk having the thickness T2 is utilized is described.

FIG. **55** is a block diagram of an optical disk apparatus with one of the optical head apparatuses shown in FIGS. **21**, **27**, **30**, **31**, **32**, **33**, **37**, **38**, **40**A, **43**, **44**, **50** and **52** according to a twentieth embodiment. FIG. **56** is a flow chart showing the operation of the optical disk apparatus shown in FIG. **55**. FIG. **63** is a constitutional view of the optical disk apparatus of which the block diagram is shown in FIG. **55**.

As shown in FIG. **63**, an optical disk apparatus **176** for recording or reproducing pieces of information on or from the high density optical disk **171** (or **174**) or the conventional optical disk **25**, comprises the optical head apparatus **51** (or **61**, **65**, **67**, **70**, **71**, **81**, **91**, **101**, **111**, **121**, **151** or **161**), a moving means **177** such as a feed mechanism for moving the optical head apparatus **51** to a prescribed position, a rotating means **178** such as a spindle motor for rotating the high density optical disk **171** (or **174**) or the conventional optical disk **25**, an actuating means representing the actuating unit **58** (not shown in FIG. **63**), an electric circuit **179** representing a focus control means and a tracking control means for controlling the actuating means to perform a first focus control of the optical head apparatus **51** corresponding to the first thickness T1 of the optical disk **171** (or **174**) and a second focus control of the optical head apparatus **51** corresponding to the second thickness T2 of the optical disk **171** (or **174**) or **25** according to a focus error signal read by the optical head apparatus **51** and controlling the actuating means to perform a first tracking error control of the optical head apparatus **51** corresponding to the first thickness T1 and a second tracking error control of the optical head apparatus **51** corresponding to the second thickness T2 according to a tracking error signal read by the optical head apparatus **51**, and a connecting means **180** for electrically connecting the rotating means **178**, the moving means **177** and the electric circuit **179** with an electric source (not shown) to supply an electric power to the rotating means **178**, the moving means **177** and the electric circuit **179**.

In the above configuration, the high density optical disk **171** or the conventional optical disk **25** is set to a prescribed position of the optical disk apparatus **176**, and the optical disk **171** or **25** is rotated by the rotating means **178**. Thereafter, the optical head apparatus **51** is moved to a position just under an innermost recording track of the optical disk **171** or **25** by the moving means **177** in a step **211**, and the diffracted light L5 is converged on the innermost recording track of the optical disk **171** or **25** while performing a focus control corresponding to the conventional optical disk **25** of the thickness T2 in a step **212**. Thereafter, a tracking control is performed, and a piece of information recorded on the innermost recording track of the optical disk **171** or **25** is detected in a step **213**. In detail, a focus error signal and a tracking error signal corresponding to a positional relationship between the optical head apparatus **51** and the optical disk **171** or **25** are sent to the electric circuit **179**. In the electric circuit **179**, an actuating signal is generated according to the focus error signal and the tracking error signal and is sent to the actuating unit **58** to precisely move the compound objective lens **29** (or **29**M, **34**, **43**, **45**, **46** or **47**) of the optical head apparatus **51**. That is, the second focus and tracking controls of the optical head apparatus **51** corresponding to the second thickness T2 are performed to read the information. Thereafter, it is judged in a step **214** whether the information agrees with a piece of distinguishing information informing that the optical disk **171** having the thickness T1 is set to the optical disk apparatus **176**.

In cases where the high density optical disk **171** is set to the optical disk apparatus **176**, the distinguishing information is detected. Thereafter, the transmitted light L4 is automatically converged on the optical disk **171** while performing a focus control corresponding to the optical disk **171** of the thickness T1 in a step **215**. In detail, a focus error signal and a tracking error signal corresponding to a positional relationship between the optical head apparatus **51** and the optical disk **171** are sent to the electric circuit **179**. In the electric circuit **179**, an actuating signal is generated according to the focus error signal and the tracking error signal and is sent to the actuating unit **58** to precisely move the compound objective lens **29** (or **29**M, **34**, **43**, **45**, **46** or **47**) of the optical head apparatus **51**. That is, the first focus and tracking controls of the optical head apparatus **51** corresponding to the first thickness T1 are performed. Therefore, pieces of information are recorded or reproduced on or from the optical disk **171**.

In contrast, in cases where the conventional optical head **25** is set to the optical disk apparatus **176**, the distinguishing information is not detected. In this case, the convergence of the diffracted light L5 on the conventional optical disk **25** is continued while performing the focus control and the tracking control corresponding to the conventional optical disk **25** in a step **216**. Therefore, pieces of information are recorded or reproduced on or from the conventional optical disk **25**.

Accordingly, the thickness of the optical disk set in the optical disk apparatus **176** can be rapidly judged at a high accuracy. Also, pieces of information can be stably recorded or reproduced on or from an optical disk regardless of whether the optical disk is the high density optical disk **171** (or **174**) or the conventional optical disk **25**.

(Twenty-first Embodiment)

An optical disk apparatus with one of the optical head apparatuses in which it is automatically judged whether a high density optical disk having the thickness T1 or a conventional optical disk having the thickness T2 is utilized is described.

FIG. **57** is a block diagram of an optical disk apparatus with one of the optical head apparatuses shown in FIGS. **21**, **27**, **30**, **31**, **32**, **33**, **37**, **38**, **40**A, **43**, **44**, **50** and **52** according **25** to a twenty-first embodiment. FIG. **58** is a flow chart showing the operation of the optical disk apparatus shown in FIG. **57**.

As shown in FIG. **57**, an optical disk apparatus **176** for recording or reproducing pieces of information on or from a high density optical disk **182** or the conventional optical disk **25**, comprises the optical head apparatus **51** (or **61**, **65**, **67**, **70**, **71**, **81**, **91**, **101**, **111**, **121**, **151** or **161**), the moving means **177**, and a rotating means **182** such as a spindle motor for rotating the high density optical disk **182** or the conventional optical disk **25**. The high density optical disk **182** has no distinguishing information and has the thickness T1.

In the above configuration, the high density optical disk **182** or the conventional optical disk **25** is set to a prescribed position of the optical disk apparatus **181**, and the optical disk **182** or **25** is rotated by the rotating means **182**. Thereafter, the optical head apparatus **51** is moved to a position just under an innermost recording track of the optical disk **182** or **25** in a step **221** because a piece of information is reliably recorded on the innermost recording track, and the diffracted light L5 is converged on the innermost recording track of the optical disk **182** or **25** while performing a focus control corresponding to the conventional optical disk **25** of the thickness T2 in a step **222**. Thereafter, a tracking control is performed, and a piece of information recorded on the innermost recording track of the optical disk **182** or **25** is detected in a step **223**. Thereafter, it is judged in a step **224** whether the intensity of an information signal expressing the information detected is more than a threshold value. That is, the intensity of the information signal more than the threshold value denotes that the diffracted light L5 is converged in focus on the optical disk **182** or **25**, and the intensity of the information signal not more than the threshold value denotes that the diffracted light L5 is converged in defocus on the optical disk **182** or **25**.

In cases where the high density optical disk **182** is set to the optical disk apparatus **181**, the intensity of the information signal not more than the threshold value is detected. In this case, the transmitted light L4 is automatically converged on the optical disk **182** while performing a focus control corresponding to the high density optical disk **182** of the thickness T1 in a step **225**. Therefore, pieces of information are recorded or reproduced on or from the optical disk **182**.

In contrast, in cases where the conventional optical head **25** is set to the optical disk apparatus **181**, the intensity of the information signal more than the threshold value is detected. In this case, the convergence of the diffracted light L5 on the conventional optical disk **25** is continued while performing the focus control and the tracking control corresponding to the conventional optical disk **25** in a step **226**. Therefore, pieces of information are recorded or reproduced on or from the conventional optical disk **25**.

Accordingly, the thickness of the optical disk set in the optical disk apparatus **181** can be judged even though the optical disk **171** or **174** is not utilized. Also, pieces of information can be stably recorded or reproduced on or from an optical disk regardless of whether the optical disk is the high density optical disk **182** or the conventional optical disk **25**.

(Twenty-second Embodiment)

A binary focus microscope having two focal points in which two images formed on different planes are simultaneously observed is described according to a twenty-second embodiment.

FIG. **59** is a constitutional view of a binary focus microscope according to a twenty-second embodiment.

As shown in FIG. **59**, a binary focus microscope **191** for simultaneously observing a first image of a first sample SP1 put on a first sample plane PL1 and a second image of a second sample SP2 put on a second sample plane PL2, comprises an objective lens **192** having a first focal length F1 for refracting a beam of first light L17 diverging from the first image and refracting a beam of second light L18 diverging from the second image, the hologram lens **26** (or **26**M, **32**, **33** or **42**) for transmitting through a part of the first light L17 without any diffraction and diffracting a part of the second light L18 to pass the second light L18 through the same optical path as the first light L17 passes through, an inner lens **193** for converging a beam of superposed light L19 formed of the first and second light L17, L18 at an inner focal point Pf1, an ocular lens **194** for simultaneously forming the first and second images by converging the superposed light L19 diverging from the inner focal point Pf1, an inner lens-barrel **195** for moving a combination element of the inner lens **193** and the hologram lens **26** along an optical axis to adjust a distance between the combination element and the ocular lens **194**, and an outer lens-barrel **196** for moving the objective lens **192** along the optical axis to set the distance between the first sample plane PL1 and the objective lens **192** to the focal length F1 of the objective lens **192**.

The optical axis passes through the centers of the objective lens **192**, the hologram lens **26**, the inner lens **195** and the ocular lens **194**. The position of the first sample plane PL1 differs from that of the second sample plane PL2 along the optical axis.

In the above configuration, the position of the objective lens **192** is adjusted to set the distance between the first sample plane PL1 and the objective lens **192** to the first focal length F1 of the objective lens **192**. In this case, the distance between the second sample plane PL2 and the objective lens **192** is set to a second focal length F2. Also, the position of the combination element is adjusted to clearly view the first and second images. That is, a beam of first light L17 diverging from the first image on the first sample plane PL1 is collimated in the objective lens **192**, and a part of the first light L17 transmits through the hologram lens **26**. Also, a beam of second light L18 diverging from the second image on the second sample plane PL2 is refracted in the objective lens **192**, and a part of the second light L18 is diffracted in the hologram lens **26** to pass the second light L18 through the same optical path as the first light L17 passes through. Therefore, a beam of superposed light L19 is formed of the first and second light L17, L18. Thereafter, the superposed light L19 is converged by the inner lens **193** at an inner focal point Pf1 to simultaneously form the first and second images enlarged on an image plane PL3, and the superposed light L19 diverging from the point Pf1 is converged by the ocular lens **194** to simultaneously form the first and second images moreover enlarged on an operator's eye.

Accordingly, because the hologram lens **26**, **26**M, **32**, **33** or **42** is utilized to form the superposed light L**19**, the first image of the first sample SP**1** put on the first sample plane PL**1** and the second image of the second sample SP**2** put on the second sample plane PL**2** can be simultaneously observed by simultaneously focusing the binary focus microscope **191** on the first and second samples SP**1**, SP**2**.

Also, even though the intensities of the first and second light L**17**, L**18** are reduced when the light L**17**, L**18** pass through the hologram lens **26**, the intensity of the superposed light L**19** is sufficient to observe the first and second images because the intensity of the superposed light L**19** is determined by adding the intensities of the first and second light L**17**, L**18**.

Also, because the hologram lens **26** is blazed as shown in FIG. **6**, the generation of unnecessary diffracted light such as minus first-order diffracted light is reduced when the second light L**18** is diffracted in the hologram lens **26**. Therefore, the intensity of the superposed light L**19** can be increased, so that first and second images observed can be moreover brightened.

Also, as shown in FIG. **60**, in cases where the first sample SP**1** is placed at a bottom of a first sample holder **197** and in cases where the second sample SP**2** is placed at a bottom of a second sample holder **198** located under the first sample holder **197**, aberration such as a chromatic aberration is generated in the first and second light L**17**, L**18** incident on the objective lens **192** because an optical path length in the first sample holder **197** for the first light L**17** differs from that in the first and second sample holders **197**, **198** for the second light L**18**. However, the aberration can disappear in the hologram lens **26** by excessively correcting the chromatic aberration in the hologram lens **26** as is described in the first embodiment.

Also, the difference between the first and second focal lengths can be changed by moving the inner and outer lens-barrels **195**, **196** because the distance between the hologram lens **26** and the objective lens **192** is changed. Therefore, even though the thickness of the second sample holder **198** is changed, the first and second images can be reliably observed.

In the twenty-second embodiment, the ocular lens **194** is utilized in the binary focus microscope **191**. However, the ocular lens **194** is not necessarily required. Also, as shown in FIG. **61**, it is applicable that a camera **199** such as a charge-coupled device (CCD) camera be placed on the image plane PL**3** in place of the ocular lens **194**. In this case, a superposed image formed of the first and second images enlarged can be photographed with the CCD camera **199**, so that the first and second images can be simultaneously recorded.

(Twenty-third Embodiment)

In cases where a minute circuit is formed on a semiconductor wafer, a photosensitive material is coated on the semiconductor wafer, and the photosensitive material covering the semiconductor wafer is exposed to ultraviolet light through a photomask having a mask pattern in an exposure process. Therefore, the mask pattern of the photomask is transferred to the photosensitive material. In this case, the semiconductor wafer is required to be aligned with the photomask at a high accuracy in an alignment process performed prior to the exposure process. Therefore, a reference image drawn on the semiconductor wafer and the mask pattern drawn on the photomask are simultaneously observed with a conventional microscope having a deep focal depth. However, because the magnification of the conventional microscope having a deep focal depth is low, it is impossible to align the reference image and the mask pattern at an accuracy within 5 μm.

To solve the above drawback in the present invention, an alignment apparatus utilized in the alignment process in which the semiconductor wafer is aligned with the photomask at a high accuracy while simultaneously observing a reference image drawn on the semiconductor wafer and the mask pattern drawn on the photomask is described according to a twenty-third embodiment.

FIG. **62** is a constitutional view of an alignment apparatus according to a twenty-third embodiment.

As shown in FIG. **62**, an alignment apparatus **201** for aligning a first reference image RF**1** of a mask pattern drawn on a bottom surface of a photomask **202** with a second reference image RF**2** drawn on a bottom surface of a sample such as a semiconductor substrate **203**, comprises a light source **204** for radiating beams of alignment light having a particular wavelength to illuminate the first and second reference images RF**1**, RF**2**, the objective lens **192** for receiving a beam of first alignment light L**20** diverging from the first reference image RF**1** illuminated with the alignment light and receiving a beam of second alignment light L**21** diverging from the second reference image RF**2** illuminated with the alignment light, the hologram lens **26** (or **26**M, **32**, **33** or **42**) for transmitting through a part of the first alignment light L**20** without any diffraction and diffracting a part of the second alignment light L**21** to pass the second alignment light L**21** through the same optical path as the first alignment light L**20** passes through, the inner lens **193** for converging a beam of superposed alignment light L**22** formed of the first and second alignment light L**20**, L**21** at an inner focal point Pf**2**, a camera **205** such as a charge-coupled device (CCD) camera placed at the inner focal point Pf**2** for simultaneously photographing and recording the first and second reference images RF**1**, RF**2**, the inner lens-barrel **195**, the outer lens-barrel **196**, a moving means **206** for moving the photomask **202** in a horizontal direction perpendicular to an optical axis to align the first reference image RF**1** with the second reference image RF**2** along the optical axis, and a control means **207** for controlling the movement of the photomask **202** according to the first and second reference images RF**1**, RF**2** recorded in the camera **205**.

The particular wavelength of the alignment light is determined on condition that a transmissivity of the semiconductor substrate **203** for the alignment light is sufficiently high. The optical axis passes through the centers of the objective lens **192**, the hologram lens **26** and the inner lens **193**.

A binary microscope **208** is composed of the objective lens **192**, the hologram lens **26** (or **26**M, **32**, **33** or **42**), the inner lens **193**, the inner lens-barrel **195** and the outer lens-barrel **196** in the same manner as in the twenty-second embodiment.

In the above configuration, a beam of first alignment light L**20** diverging from the first reference image RF**1** is collimated in the objective lens **192**, and a part of the first alignment light L**20** transmits through the hologram lens **26**. Also, a beam of second alignment light L**21** diverging from the second reference image RF**2** is refracted in the objective lens **192**, and a part of the second alignment light L**21** is diffracted by the hologram lens **26** to pass the second alignment light L**21** through the same optical path as the first alignment light L**20** passes through. Therefore, a beam of superposed alignment light L**22** is formed of the first and second alignment light L**20**, L**21**. Thereafter, the superposed alignment light L**22** is converged at an inner focal point Pf**2** to simultaneously form the first and second reference images RF**1**, RF**2** enlarged. Thereafter, the first and second refer-

ence images RF1, RF2 enlarged are photographed and recorded by the camera **205**. Thereafter, a relative position between the first and second reference images RF1, RF2 is examined in the control means **207**, and the photomask **202** is moved in a horizontal direction by the moving means **206** under control of the control means **207** to align the first reference image RF1 with the second reference image RF2. Thereafter, as shown in FIG. **64**, a photo sensitive material coated on the semiconductor substrate **203** is exposed to exposure light radiated from an exposure light source **211** through a reflecting mirror **212** and a shutter **213**.

Accordingly, because the hologram lens **26**, **26M**, **32**, **33** or **42** is utilized to form the binary microscope **208** having two focal points, the first reference image RF1 and the second reference image RF2 can be simultaneously observed even though a focal depth of the binary microscope **208** is low. Also, because the focal depth of the binary microscope **208** can be lowered, the magnification of the binary microscope **208** can be heightened. Therefore, the first reference image RF1 of the photomask **202** can be aligned with the second reference image RF2 of the semiconductor substrate **203** at a high accuracy.

(Twenty-fourth Embodiment)

FIG. **65** is a diagonal view of an image reproducing apparatus for which the optical disk apparatus **176** is provided.

As shown in FIG. **65**, an image reproducing apparatus **221** comprises the optical disk apparatus **176** and a displaying unit **222** such as a cathode ray tube or a liquid crystal display for displaying pieces of image information recorded in the optical disk **171**, **174** or **25** of the optical disk apparatus **176** as an image.

In the above configuration, pieces of image information are recorded in the outer region **171***a* of the optical disk **171** or in the optical disk **174** at a high recording density, and the thickness T1 is, for example, 0.6 mm. Also, pieces of image information are recorded in the conventional optical disk **25** having the thickness T2 at an ordinary recording density. The conventional optical disk **25** represents a video compact disk having a thickness of 1.2 mm. Because the optical disk apparatus **176** is provided for the image reproducing apparatus **221**, regardless of whether pieces of particular image information are recorded in the optical disk **171** (or **174**) or the conventional optical disk **25**, the particular image information are read from the optical disk **171**, **174** or **25**, and a particular image can be displayed in the displaying unit **222**. Therefore, a user is not required to prepare both a conventional image reproducing apparatus for reproducing the image information recorded in the conventional optical disk **25** and an updated image reproducing apparatus for reproducing the image information recorded in an updated optical disk having a thickness of 0.6 mm.

FIG. **66** is a diagonal view of a voice reproducing apparatus for which the optical disk apparatus **176** is provided.

As shown in FIG. **66**, a voice reproducing apparatus **231** comprises the optical disk apparatus **176** and a voice reproducing unit **232** such as a speaker for reproducing pieces of voice information recorded in the optical disk **171**, **174** or **25** of the optical disk apparatus **176** as voices. The voice reproducing apparatus **231** additionally comprises a radio **233** and a cassette tape recorder **234**.

In the above configuration, pieces of voice information are recorded in the outer region **171***a* of the optical disk **171** or in the optical disk **174** at a high recording density, and the thickness T1 is, for example, 0.6 mm. Also, pieces of voice information are recorded in the conventional optical disk **25** having the thickness T2 at an ordinary recording density. The conventional optical disk **25** represents an audio compact disk having a thickness of 1.2 mm. Because the optical disk apparatus **176** is provided for the voice reproducing apparatus **231**, regardless of whether pieces of particular voice information are recorded in the optical disk **171** (or **174**) or the conventional optical disk **25**, the particular voice information are read from the optical disk **171**, **174** or **25**, and particular voices can be reproduced by the voice reproducing unit **232**. Therefore, a user is not required to prepare both a conventional voice reproducing apparatus for reproducing the voice information recorded in the conventional optical disk **25** and an updated voice reproducing apparatus for reproducing the voice information recorded in an updated optical disk having a thickness of 0.6 mm.

FIG. **67** is a diagonal view of an information processing apparatus for which the optical disk apparatus **176** is provided.

As shown in FIG. **67**, an information processing apparatus **241** comprises the optical disk apparatus **176**, an input apparatus **242** for inputting pieces of input information, a central processing unit **243** placed on a circuit substrate **244** for processing pieces of recorded information recorded in the optical disk **171**, **174** or **25** of the optical disk apparatus **176** or processing the input information to record the input information in the optical disk **171**, **174**, and a displaying unit **245** for displaying the recorded information processed in the central processing unit **243**.

In the above configuration, pieces of recorded information are recorded in the outer region **171***a* of the optical disk **171** or in the optical disk **174** at a high recording density, and the thickness T1 is, for example, 0.6 mm. Also, pieces of recorded information are recorded in the conventional optical disk **25** having the thickness T2 at an ordinary recording density. The conventional optical disk **25** represents a CD-ROM having a thickness of 1.2 mm. Because the optical disk apparatus **176** is provided for the voice reproducing apparatus **231**, regardless of whether pieces of particular recorded information are recorded in the optical disk **171** (or **174**) or the conventional optical disk **25**, the particular recorded information are read from the optical disk **171**, **174** or **25**, and a particular image can be displayed in the displaying unit **245** according to the recorded information. Also, when a user inputs pieces of input information to the inputting apparatus **242**, even though any of the optical disks **171**, **174** and **25** is set in the optical disk apparatus **176**, the input information are recorded in the optical disk **171**, **174** or **25**. Therefore, the user is not required to prepare both a conventional image reproducing apparatus for reproducing the image information recorded in the conventional optical disk **25** and an updated image reproducing apparatus for reproducing the image information recorded in an updated optical disk having a thickness of 0.6 mm.

In cases where a game program is recorded in the optical disk **171**, **174** or **25**, the user can play a game while observing a game image displayed in the displaying unit **245** and inputting pieces of operating data to the inputting apparatus **242** regardless of whether the game program is recorded in any of the optical disks **171**, **174** or **25**.

Also, in cases where the information processing apparatus **241** is utilized in a home, the information processing apparatus **241** can be utilized as an information terminal for a domestic use.

Also, as shown in FIG. **68**, in cases where a key board **245** is utilized as the inputting apparatus **242**, the information processing apparatus **241** can be utilized as a computer system **246**.

Having illustrated and described the principles of our invention in a preferred embodiment thereof, it should be readily apparent to those skilled in the art that the invention can be modified in arrangement and detail without departing from such principles. We claim all modifications coming within the spirit and scope of the accompanying claims.

What is claimed is:

1. A compound objective lens, comprising:

lens means, having a first convex surface and a second convex surface opposite to each other, for receiving a beam of incident light of one particular wavelength passing through an optical axis at the first convex surface, refracting the beam of incident light and emitting a beam of refracted light from the second convex surface; and

plural focal point generating means for receiving the beam of incident light not yet refracted by the lens means, generating from the beam of incident light a plurality of beams of divided light including a first beam of divided light and a second beam of divided light, converging the beams of divided light at a plurality of focal points which are placed on the optical axis on a side facing the second convex surface of the lens means on condition that the first beam of divided light transmits through a first substrate and is converged on an information recording plane placed at a first distance T1 from a surface of the first substrate at a diffraction limit and that the second beam of divided light transmits through a second substrate and is converged on an information recording plane placed at a second distance T2 (T1≠T2) from a surface of the second substrate at a diffraction limit.

2. A compound objective lens according to claim **1** in which the plural focal point generating means is a hologram generating from the incident light as the beams of divided light a plurality of beams of diffracted light having different diffraction orders.

3. A compound objective lens according to claim **2** in which the first beam of divided light is a beam of transmitted light which agrees with a beam of zero-order diffracted light generated by the hologram, and the second beam of divided light is a beam of first-order diffracted light generated by the hologram.

4. A compound objective lens according to claim **2** in which

the hologram is a phase modulation relief type of diffraction device,

a grating pattern of the hologram has a step-wise cross section and is formed in a concentric circle shape,

the grating pattern of the hologram is concentrically partitioned into a plurality of blocks,

a phase modulation degree of the incident light passing through the grating pattern of the hologram varies in a step-wise shape of four stairs for each of the blocks, and

a ratio of an etching width of a top stair to a length of the corresponding block and another ratio of an etching width of a bottom stair to the length of the corresponding block are respectively lowered toward an outer direction of the grating pattern of the hologram.

5. A compound objective lens according to claim **2** in which the hologram is a phase modulation relief type of diffraction device,

a grating pattern of the hologram is formed in a concentric circle shape and is concentrically partitioned into a plurality of blocks,

a phase modulation degree of the incident light passing through an inner portion of the grating pattern of the hologram varies in a step-wise shape of four inside stairs for each of the blocks,

the four inside stairs are composed of a top stair, a second stair, a third stair and a bottom stair in that order,

a ratio of an etching width of the top stair to a length of the corresponding block and another ratio of an etching width of the bottom stair to the length of the corresponding block are respectively lowered toward an outer direction of the grating pattern in the inner portion of the hologram,

another phase modulation degree of the incident light passing through an outer portion of the grating pattern of the hologram varies in a step-wise shape of two outside stairs for each of the blocks, and

a difference in width between the outside stairs is increased toward the outer direction of the grating pattern in the outer portion of the hologram.

6. A compound objective lens according to claim **2** in which

the hologram is a phase modulation relief type of diffraction device,

a grating pattern of the hologram has a step-wise cross section and is formed in a concentric circle shape,

the grating pattern of the hologram is concentrically partitioned into a plurality of blocks,

a phase modulation degree of the incident light passing through the grating pattern of the hologram varies in a step-wise shape of four stairs for each of the blocks, and

a ratio of an etching width of a top stair to a length of the corresponding block and another ratio of an etching width of a bottom stair to the length of the corresponding block are respectively lowered toward an inner direction of the grating pattern of the hologram.

7. A compound objective lens according to claim **2** in which

the hologram is a phase modulation relief type of diffraction device,

a grating pattern of the hologram is formed in a concentric circle shape and is concentrically partitioned into a plurality of blocks,

a phase modulation degree of the incident light passing through an outer portion of the grating pattern of the hologram varies in a step-wise shape of four inside stairs for each of the blocks,

the four inside stairs are composed of a top stair, a second stair, a third stair and a bottom stair in that order,

a ratio of an etching width of the top stair to a length of the corresponding block and another ratio of an etching width of the bottom stair to the length of the corresponding block are respectively lowered toward an inner direction of the grating pattern in the outer portion of the hologram,

another phase modulation degree of the incident light passing through an inner portion of the grating pattern of the hologram varies in a step-wise shape of two inside stairs for each of the blocks, and

a difference in width between the inside stairs is increased toward the inner direction of the grating pattern in the inner portion of the hologram.

8. A compound objective lens according to claim **2** in which the hologram is a phase modulation type of diffraction device and is made of a liquid crystal cell.

9. A compound objective lens according to claim 2 in which the hologram is a phase modulation type of diffraction device and is placed on a substrate of a birefringence material.

10. A compound objective lens according to claim 2 in which a positional relationship between the lens means and the hologram is fixed.

11. A compound objective lens according to claim 10 in which the hologram is formed on a lens surface of the lens means.

12. A compound objective lens according to claim 11 in which the hologram is placed on a lens surface of the lens means of which a curvature is higher than those of other lens surfaces of the lens means.

13. A compound objective lens according to claim 11 in which the hologram is placed on a lens surface of the lens means of which a curvature is lower than those of other lens surfaces of the lens means.

14. A compound objective lens according to claim 1 in which a numerical aperture of the lens means for the incident light converged at one focal point of the focal points differs from that for the incident light converged at another focal point of the focal points.

15. A compound objective lens according to claim 2 in which a grating pattern is formed in a first portion of a light-passing area of the hologram corresponding to an aperture of the lens means, and any grating pattern is not formed in a second portion of the light-passing area of the hologram.

16. A compound objective lens according to claim 15 in which a phase of the incident light passing through the second portion of the light-passing area of the hologram almost agrees with an average value of phases of the incident light passing through the first portion of the light-passing area of the hologram.

17. A compound objective lens according to claim 15 in which the grating pattern is formed in a step-wise shape having a plurality of stairs,

a surface height of the second portion of the light-passing area of the hologram in an optical direction is the same as a height of a stair selected from the stairs except a top stair and a bottom stair.

18. A compound objective lens according to claim 1 in which a numerical aperture of the lens means is equal to or higher than 0.6.

[57] **ABSTRACT**

A camera is described with objective lens and image reception carrier equipment and a focussing process. From related extension measured distances (x1–x2, x2–x3, δb), final adjusted, set-point focus values (θ_{soll}, Φ_{soll}) are obtained in the course of the focussing of various image points (B1, B2, B3) for a multiply pivotable, bellows camera which produces the pivoting angles (α, β, θ, Φ), the latter used for a double focussing compensation; by this means, the direct making of an exact spatial interval distance measurement between the objective lens carrier (OT) and the and image carrier (BT) is dispensed with, since at least a relatively accurate extension measurement (δb) at a predetermined objective lens setting is obtained and evaluated.

The optical bench (OB) can be equipped with a raster arrangement for the image carrier (B1), the objective lens carrier (OT) and be constructed in sections (OB1, OB2).

CAMERA WITH ADJUSTING DEVICE FOR OBJECTIVE LENS AND IMAGE CARRIER AND A FOCUSING PROCESS

The invention concerns a focusing process for a camera, said camera:

having an objective lens carrier and an image carrier, which are maintained positionally relative to one another in a straight line optical bench direction in which the spatial interval between them is variable, wherein the said interval changes are signaled to a microprocessor,

being equipped with an objective lens carrier and an objective lens secured to pivot about two axes, said axes being vertical to one another and to an optical bench, the two respective objective lens angles and the focal length of said lens being input to a processor,

possessing an image carrier in which an image screen, namely a frosted glass plate is secured, which screen is moveable about two axes vertically disposed to one another and to the direction of the bench, the two respective image reception angles being sent to the processor,

having in the image screen, a focusing adjustment sensor, which signals a degree of focus, and is positionable in two image reception coordinates which, together with the focus value, are conducted to the processor,

further possessing at least three select image point areas, which lie in a secondary image plane for the simultaneous adjustment of the focus,

having these said image point areas on the image screen subjected to determination of their respective image screen coordinates by means of a change in the interval between the image carrier and the objective lens sequentially for each area through focus adjustment, and the said positional changes of the image carrier are input to the processor,

obtaining, by means of the input data so collected, from the processor computer a determination of the positional parameters of the image screen as well as of the secondary image from which, together with a further image parameter necessary for computation, this latter originating in the solution of image equations, there will be calculated fixed adjustment values suitable for the pivoting of the objective lens carrier along with a value for the adjustment of the interval between the carriers of the image and the objective carrier, the results thereof being made available, so that the new image plane adjusted by these set-point values comes as close as possible to coinciding with the image screen.

A camera of this type is brought into common knowledge by DE 34 33 412 C2. In this case,

the objective lens focal length,

an image scale, based on

the spatial coordinates of the three select real image point areas, which were determined from the optical imagery of a scale of the image, to which purpose a focus sensor serves as an aid,

the angle adjustment of the objective lens and image screen inclinations and degrees of deviation,

and the spatial interval between the principal plane of the objective lens to the image screen,

are either input to the processor by a keyboard or provided direct with measured values.

From these data the processor computes the set point signal for the adjustment angle and the said interval. In this computation, the processor makes use of the Law of Scheimpflug according to which, the objective lens plane, the plane to which the real image belongs and the plane to which the focused image points belong, must mandatorily intersect in one straight line.

Thus, in accord with a preset adjustment, the selected image point area of the real subject, by means of the so called double focus compensation, is imaged as sharply as possible. With this apparatus, in addition the absolute space coordinates of the image points and the structural data of the imagery optics are required as starting point values for a final solution of the image equations. This is in order to find such a position of the image screen in relation to the setting of the objective lens, that the select image point areas lie with the sharpest possible focus in the image screen. This requires a substantial array of means of measurement having high requirements as to precision. Moreover, the Law of Scheimpflug, which was employed, is valid only for the imagery in a paraxial zone of a thin lens, making it of little meaning in practice.

Thus, it is the purpose of the invention, to achieve an automatic focus adjustment of a real image, using the camera described in the introductory passages, employing double focus compensation with the reduced demand for measurement equipment, simplified apparatus and an objective lens acceptable in practice.

The accomplishment of this purpose lies therein, in that one of the objective lens adjustment parameters can be altered in given quantity, and as this is carried out, for a selected image point, the extension difference of a extension adjustment apparatus lying between its two focus adjustments in the bench direction, is measured. This brings about a first set of the of the image equations by the use of the original objective lens adjustment parameters and an undetermined image distance, and a further set of image equations with the inclusion of the now varied objective lens adjustment parameters and the undetermined image distance. These two sets are equalized for the image distance as altered by the extension difference and solved for the set-point adjustment values. Another approach to solution is the functional derivation of the image comparisons with reference to the objective lens positional parameters and involving the prior adjustment changes made from time to time along with the measured extension difference, all included in the said derivations, and, in accord with the set-point parameters, solving for the said undetermined object distance.

Advantageous embodiments are described in the subordinate claims.

The new process renders the absolute distant measurement between the objective lens carrier and the image carrier superfluous. It now suffices, that the respective angular measurement equipment is at hand and the relative measurement of the interval, that is, the extension changes in the course of the various focus placements, as well as the coordinate determinations on the screen, are to be available.

The adjustment process may be summarized in the following sequence of operations:

The photographer adjusts the perspective by deflecting the screen and subsequently carries out a rough prefocusing of the image. He does this generally through altering the extension and in some cases by tilting the objective lens. The parameters "a_m" and "b_m" of the screen, which determine its normal vector, but not, however, its distance from the objective lens, which is

not necessary here, as well as the adjusted deflection angles θ_o and Φ_o of the objective lens are read off by the built-in goniometer in the computer.

The determination of the coordinates bi=(xi, yi, zi) from at least three image points by means of focusing is done with the aid of a CCD-sensor (or the equivalent thereof); meanwhile, the camera objective lens is swivelled through the angles θ_o and Φ_O. The X-axis is in this case, that axis parallel to the optical bench of the camera, and which penetrates the center of the objective lens. The Y-axis runs vertically thereto in a horizontal manner while the Z-axis stands in a vertical position.

The alignment of that plane, for which the sums of the square of the intervals of the measured image points are at a minimum. The parameters for this original image plane are a_o, b_o, d_o, which is then given

through: $=a_{ox}+b_{oy}+d_o$

The determination of the distance of image b from the difference in the extension δb by focusing a specific image point at a given objective lens pivoting angle change—in accord with the equations (5) to (7),

The determination of the distance of image b with an unpivoted objective lens in accord with equation (8),

The determination of the z-axis parameter d_o by equation (9),

The computation of the set-point objective lens adjustment angles θ_{soll}, Φ_{soll} and the screen intercepts xb_{soll} with the X-axis in accord with the equations (1), (2), and (3).

The starting screen plane will be depicted in the object space. The plane so produced, upon varied objective lens pivoting, will be re-imaged in the image space with the purpose, of aligning the newly obtained image plane parallel to the installed screen. The necessary objective lens adjustment angles, θ_{soll}, Φ_{soll} as well as the screen intercept xb_{soll} which is to be included, from the screen and X-axis, yield the following:

$$\sin\theta = -\frac{f\left(a_m^2 - a_m\frac{a_0 f + d_0\cos\theta_0\cos\phi_0}{f - d_0\sin\theta_0} + b_m^2 - b_m\frac{b_0 f + d_0\cos\theta_0\sin\phi_0}{f - d_0\sin\theta}\right)}{\frac{d_0 f}{f - d_0\sin\theta_0}(1 + a_m^2 + b_m^2)} \pm \tag{1}$$

$$\left[f^2\left[\left(a_m^2 - a_m\frac{a_0 f + d_0\cos\theta_0\cos\phi_0}{f - d_0\sin\theta_0} + b_m^2 - b_m\frac{b_0 f + d_0\cos\theta_0\sin\phi_0}{f - d_0\sin\theta_0}\right)^2 - a_m^2 + 2a_m\frac{a_0 f + d_0\cos\theta_0\cos\phi_0}{f - d_0\sin\theta_0} - \left(\frac{a_0 f + d_0\cos\theta_0\cos\phi_0}{f - d_0\sin\theta_0}\right)^2 - b_m^2 + 2b_m\frac{b_0 f + d_0\cos\theta_0\sin\phi_0}{f - d_0\sin\theta_0} - \left(\frac{b_0 f + d_0\cos\theta_0\sin\phi_0}{f - d_0\sin\theta_0}\right)^2\right] - \left(\frac{d_0 f}{f - d_0\sin\theta_0}\right)^2\right]^{\frac{1}{2}} \times \left[\frac{d_0 f}{f - d_0\sin\theta_0}(1 + a_m^2 + b_m^2)\right]^{-1}$$

$$\sin\phi = \frac{b_0 f + d_0\cos\theta_0\sin\phi_0 - b_m(f - d_0\sin\theta_0) - b_m d_0\sin 0}{d_0\cos 0} \tag{2}$$

$$x_b = -\frac{d_0 f}{f - d_0\sin\theta_0 - \frac{a_0 f + d_0\cos\theta_0\cos\phi_0}{f - d_0\sin\theta_0} d_0\cos\theta\cos\phi} \tag{3}$$

The image compensation of thin lenses serves exclusively as the physical basis for the above. It is yet to be proven, that the process lends itself in a simple manner also for the application of optional objective lenses, the optical characteristics of which may be modified through their focal length as well as the positioning of their two principal planes.

The objective lens, is now pivoted about the angles θ and Φ (in this case, θ=Φ=0, precisely the situation, in which the objective lens is positioned vertically on the optical bench of the camera.) The screen is to be displaced parallely, in such a manner that it intersects the X-axis at the value xb.

Generally, also the following transformation of the input data is carried out:

$$(\vec{b}_i, a_m, b_m, \theta_o, \phi_o) \rightarrow (a_o, b_o, d_o, a_m, b_m, \theta_o, \phi_o) \rightarrow (\theta, \Phi, I_l) \tag{4}$$

The two image equations of the original image plane and the new image plane which come to lie in the screen, are drawn from the invariant real image plane, on which account the two object planes are directly correlated. In this way, equations arise, which are not based on the principle of Scheimpflug, since no real image plane is defined, nor are the equations defined for an intersecting straight line between the real and the objective planes as well as the objective and image planes.

In the relationships (1), (2) and (3), for the adjustment of the camera, the following parameters of the original image plane, the screen and the objective lens, a_o, b_o, a_m, b_m, θ_o, ϕ_o are quite easy to determine : a_m, b_m,θ_o and ϕ_o are available directly from the readout from the standard applied goniometer, and a_o, and b_o, from the measurement of the extension upon focusing the image point Bi. The measuring of the further parameter d_o of the original image plane, however, does not evoke any insurmountable technical problems, except that the absolute value of the extension for each of the points Bi must be defined very precisely (i.e. on the basis of 50 . . . 100 μm tolerance). Since the value of the extension length runs to as much as one meter or more, this

means that the interval of the image point Bi from the objective lens must be directly measured within a possible error of maximum 0.1 promille. This is indeed possible, but technologically somewhat involved, on which account we have developed an indirect process for the determination of the extension length. Therefore, in accord with the invention, an indirect determination of this parameter has been undertaken.

The fact has been made use of, that the image length b of an imaged object point S from the objective lens changes when the lens is pivoted. The dimension of this image length variation δb depends in an unquestionable manner on the distance of the subject to lens distance s of the point S, so that the value of x can be determined from δb and the adjustment angle θ which was used. If s is known, the absolute value of b can be determined directly from the image distance equation. The absolute error for the value of b lies in the general range of the measurement error of the extension difference δb, which is very exactly determinable (up to ca. 50 μm) so that the relative error does not overstep the allowable limit.

This method is particularly simple, if one only pivots the objective lens about the Y-axis through the angle θ, (that is, I=0) and brings into play an object point S, which lies in the XY-plane. Then the interval of this point from the objective lens plane is given solely through its image distance s and the adjustment angle θ by:

$$\gamma = \frac{s\cos\theta}{f}$$

Valid for the computation of the image distance b of the image point S is:

$$b(s,\theta) = \frac{s}{1-\gamma} = \frac{fs}{fs - s\cos\theta} \tag{5}$$

The extension difference δb (s, θ) is defined by

$$\Delta b(s,\theta) = b(s,0) - b(s,\theta) = \frac{fs}{f-s} - \frac{fs}{f - s\cos\theta}\ . \tag{6}$$

From which is derived the following expression for the distance s of the real subject:

$$s = \left[\frac{\Delta bf(1+\cos\theta) \pm \sqrt{(\Delta bf(1+\cos\theta))^2 - 4bf^2(\Delta b\cos\theta - f(1-\cos\theta))}}{2(\Delta b\cos\theta - f(1-\cos\theta))} \right] \tag{7}$$

Only the solution employing the plus sign for the square root is relevant, because only this yields a value s=f, which leads to a real image of the point. The image distance of the point for θ=0, measured in relation to the extension differential δb, can be determined from:

$$b(s,\theta=0) = \frac{fs}{f-s} \tag{8}$$

It is now possible, to produce the absolute values of all other measured relative extensions (i.e. the x-coordinates of the image point Bi which is to be sharply imaged). This can be done without actually measuring any image distance directly, since the X-axis is now provided with a defined zero point. The y- and z- coordinates are simply to be derived from the position of the moveable CCD chip on the screen, the X-axis position there and the pivot angles α, β of the screen. From the now absolute definable intercept point of the oringinal image plane with the X- axis, x_o, the Z-axis intercept may be found by

$$d_o = -a_o x_o \tag{9}$$

and input into the equations (1), (2), and (3).

The precision of the process can be increased even to a higher degree, in that one has not only one, but several extension differentials measuring different adjustment angles θ and obtaining from these, values for s.

If, during the pivoting of the objective lens, the CCD chip is always maintained, by means of appropriate motorized control, on the tie line between the objective lens center and the start position (θ=O), a great number of δb-values for many different values of O can be determined during the objective lens pivoting procedure, whereby the precision becomes very great for the obtained values of the subject distance.

Should the occasion arise, that no appropriate object point which lies in the XY-plane is available, naturally, any optional object point may be used; the calculation, however, becomes a bit more complicated, since the interval of the point from the plane of the objective lens now also depends on its relationship to the Z-axis. The following equation serves this purpose:

$$\gamma = \frac{1}{f}\ (s\cos\theta - z_s\sin\theta) \tag{10}$$

and from this:

$$\Delta b(s,z_s,\theta) = fs\left(\frac{1}{f-s} - \frac{1}{f - s\cos\theta - z_s\sin\theta}\right). \tag{11}$$

It is necessary that there are at least two values for δb upon measuring different adjustment angles θ; with the readings of δb (θ) so obtained, then the equation (11), by means of variations of the free parameters s and z_s be applied. The parameter z_s is no longer needed, from s, in accord with (8), the image distance b (θ=O) can be determined. The exactitude of the applied parameter increases, of course, with the number of the measured values; also, it is possible here, to carry out the measurements very quickly by means of automatic back-check on the CCD-chip for very many values of θ.

Going from the fact, that during the determination of the extension differentials, the measuring CCD must always be set at the same position in the image, this proves useful in that one requires the complete information which the focusing process delivers. The process is based on the principle, that for the observed image region, a focusing value quantity is produced, which is dependent upon the interval of the measuring CCD (in the x direction) from the focus and is at a maximum when focusing is achieved. Outside of the focus, the number is a value for the interval of the CCD from the focus point. If one makes the most of this, one need only once, at the beginning, to run through the area of the focus, in order, for the observed image region, to ascertain the run of the focus measuring numbers in dependency of the relative position on the X-axis. From the lessening of the focus measuring number upon pivoting the objective lens, then the decision can quickly be made regarding the focus and then directly on the extension difference, without being required to refocus anew from time to time. This method of procedure enables a quicker measuring of the extension difference from δb in relation to the pivot angle θ of the objective lens.

The method presented here makes it possible to determine solely from the image information, all necessary parameters. In addition, there is avoided the determination of the image distances of the focussed, repetitively given image points through direct length measurement, which requires much time and trouble from a technical standpoint, and hence is costly to carry out. Instead of this, the object distance of a

principally optional subject point is computed through the measurement of the image distance of its image point at various objective lens adjustments and from this the absolute value of the image distance is determined in the case of a non-pivoted objective lens. The X-axis of the "bench fixed" camera-coordinate system is also provided with a zero point, the interval of which from the objective lens is very exactly known and relative to this, all further extension differentials can be measured with a high degree of exactness. The active length capacity of the displacement pickup can be only a few cm long.

Additionally, all problems are avoided, which can come up upon a direct interval length determination from thermal expansion of the optical bench or from the not entirely exact combination of a sectional optical bank which may involve several components. It is not at all important, whether the objective lens and image standards are generally connected with one another. The intervals, which in the screen plane must be still directly and absolutely determined (all lengths in y* and z* directions), lie in a cm-range and on this account are likewise easily determined by an economical motion pickup and within the required limits of precision.

It is common knowledge, that the so-called migration of the image point leads to undesirable perspective variation. This can be avoided by focusing with double focus compensation, when a thin lens is pivoted around such an axis that it intercepts the optical axis. On this account, in the case of the normally available mechanical pivot axes offset to the optical axis, virtual pivoting about the intersecting virtual axes is carried out, for which complicated compensation pivoting and displacement are necessary. In this case, undesired migration of the objective lens standard often occurs which leads to reaching the border position. Furthermore, often an undesired strong migration of the entire image to be focused occurs in the image field of the screen.

The migration occurs in still greater magnitude for the conventional objective lens as installed in practice, the image scaling behavior of which is described by means of good approximation by means of two principal planes. In this case, exhaustive computations show that migration can be avoided, if the pivoting axes intersect the optical axis in an area centrally located between the main plane and the main plane H'. The most favorable location of the intercept point of the axes is progressively advancing toward the main objective lens plane H' from the midpoint between the main plane, following the sequence: macro lens, normal objective lens II, normal objective lens I and wide angle objective lens.

Cognizance of these facts can be used to an advantageous simplification for objective lens adjustment, in that each objective lens is installed in the objective lens standard in accord with its optimal pivoted position which avoids migrations by means of an insert which holds the objective lens entry plane satisfactorily axially disposed at the receiving plane of the standard. By this means, with the pivoting of the standard, each installed objective lens moves about the optimal pivoting axis at any time without further compensation adjustments, so that migration is considerably reduced. The employment of this simple adapter insert simplifies not only the adjustment of the objective lens, but it also simplifies, in many cases, the focusing of an image point when a pivoting of the objective lens is undertaken.

Further, the measured differential extension values, which are of use in image computation, are well correlated to the respective pivoting angles, an advantage which allows correspondingly exact computation results.

The employment of the objective lens adapter insert is advantageous and inventive, independently of the use in the automatic adjustment system, since even with a manual, or semiautomatic adjustment of the objective lens, the up to now inescapable migrationing of the image is avoided thereby.

DESCRIPTION WITH ILLUSTRATION REFERENCES

Advantageous embodiments are presented in the FIGS. **1** to **7**, wherein:

FIG. **1** shows the camera in a simplified presentation, without bellows and with a schematic control apparatus,

FIG. **2** presents the functional dependency of the image distance on the extension difference upon various pivoting angles of an objective lens with normalized focal length,

FIG. **3** exhibits absolute error of the focal length upon given measuring errors for a 65 mm objective lens at varied pivoting angles,

FIG. **4** shows image distance error for a 1800 mm objective lens, and

FIGS. **5**, **6** and **7** show an objective lens standard frame with various adapter inserts.

FIG. **1** illustrates a camera with an optical bench (OB), which can also be assembled from several sections. Upon this, an objective lens carrier (OT) is mounted, which carries an objective lens (O), which is secured in such a manner that it can pivot about two axes (Y, Z). The pivoting angles (θ, I) are signaled to a processor (PR) by means of a goniometric pickup. If necessary, electrically controlled objective lens pivoting drives are provided (HA, VA) which are regulated by the processor (PR).

Further, on the optical bench (OB) an image carrier (BT) is installed, to carry an image reception surface (BA), which, in like manner to the said objective lens, is pivotable about two axes. This reception surface (BA), during the installation has a frosted glass, i.e. a screen, inserted. Also, the pivoting angles of said reception surface and screen (α, β) are communicated to the processor (PR) as above. Further, these pivotings are, if necessary, controllable by electrically controlled drives.

In the image reception surface is a positionable CCD-sensor (CD), by means of which, when called upon, two relative positional coordinates (Y1*, Z1*) on the screen can be communicated to the processor (PR). These positional coordinates can be taken from a positioning device of the CCD-measuring sensor (CD). Beyond this, the CCD-measuring sensor (CD) imparts focusing relevant, image point brightness signals (SS) of the currently selected area to the processor (PR) for evaluation of a focus criterion in conventional manner by means of a Fourier analyzer (FA).

The image carrier (BT) is mounted axially adjustably on the bench (OB) with an extension apparatus (AA), this also providing an adjustment signal to the processor (PR) which is interpreted as the extension distance. The extension adjustment apparatus (AA) has, if necessary, an electrically controlled drive, which is controlled by the processor (PR).

For an over view of the method of operation of the camera focusing adjustment, a Cartesian coordinate system has been drawn in, the X-axis of which runs through the principal point (H) of the objective lens (O) and parallel to the bench (OB). In case a pivotable bench is provided, the angular deviation of this with reference to the standard must be taken into consideration by an appropriate coordinate transformation. Extending upward is the Z-axis while the Y-axis

extends sidewards. In the simplest case, three real subject points (**S1**, **S2**, **S3**) are to be sharply imaged on the image reception surface (BA) and arranged in a definite perspective, one to the other.

In the manual presetting by hand, the three real points (**S1**, **S2**, **S3**) lie generally in a starting image surface which deviates from the screen and the corresponding three image points (**B1**, **B2**, **B3**). In the example, the first image point (**B1**) with the positional coordinates (**Y1***, **Z1***) is focused sharply on the screen by the sensor (CD). The second and third image points, (**B2**, **B3**) lie outside of the screen.

From this originating basic positioning, in the course of the process, the focusing adjustment is undertaken. For this said adjustment, repeated extension alterations are made, with the aid of the positioning of the CCD sensor (CD), on the second image point (likewise the third) which at the start is still not sharply seen on the screen, until sharp focus is attained. Thereby arise the extension difference data (**x1**–**x2**, **x2**–**x3**) for the position of the points in the X-direction. Now, the Y* and Z* position coordinates can be computed back to the screen, given the image carrier angle placements (α, β) in relative coordinates which describe the inclination of the original image plane.

For the further computations, it is foreseen to undertake an image distance determination, for which purpose, the objective lens (O) is pivoted about a given angle (θ) and a previously sharply adjusted measuring point is refocused anew, whereby the distance of extension change (δb) is determined. With the inclusion of the objective lens focal length (f), which is customarily transferred in electrically coded form from said lens to the processor (PR), the output signals (θ_{soll}, I_{soll}, xb_{soll}) ("soll" meaning "set value") which are valid for the angular deviation of the image points into the new image plane parallel to the screen and their corresponding parallel displacement in the X-direction, these can be computed into said plane and determined.

In FIG. **2**, the dependency of the image distance (b) on the extension difference (δb) is illustrated. Both quantities are normalized as to the focal length (f), whereby the graph becomes independent of (f). The pivot angle runs (from top to bottom):

θ=2°, 5°, 7°, 10°, 15°, 20°, 25° and 30°.

The greater the pivoting angle, just so much better can the the image distance be determined, since a small image distance calls up a large extension difference. If an individual value b_f is known, and for this, b_f does not allow itself within the bounds of measurement technology, to be greater than 1, and this serves for the corresponding (very large) subject distance s_f.

$$\frac{s_f}{f} = \frac{\frac{b_f}{f}}{\frac{b_f}{f} + 1} \quad \text{where } b_f < 0,\ s_f > 0 \tag{12}$$

With this subject distance, s_f can be found immediately as the image distance without further measuring of the focal distance (f).

The new type of apparatus requires thus no special lineal distance measuring equipment for the measurement of the objective lens to the screen interval distance. Accordingly, such an interval value or an image scale or the like are not present for input to the processor, since they have been replaced by the extension difference measurement. The means of measurement already provided were employed. The new computational procedure does not require the measurement of the absolute interval between the image points and the objective lens.

Adjustment of the angle and the extension in the data acquisition procedure can be carried out manually, whereby the focus value will be displayed by the processor, and, if required, the processor can output electrical positioning signals automatically. The input of the set-angle and the set-extension, i.e., the final corrected values thereof, can also be done by hand on the basis of processor produced placement displays or, if desired, be done directly by electric positioning means through said processor.

FIGS. **3** and **4** show error graphs for an objective lens with a 65 to 1800 mm focal length, whereby an extension precision of 10 μm and an angular accuracy of 1' are assumed. Further, a pivoting angle of θ=5°, 7°, 10°, 15°, 20°, 25° and 30° have been chosen as parameters. In the case of sizable pivoting angles, error, even in the case of large focal lengths is held at a low value. Since, however, relatively large extension lengths are to be measured in these procedures, it has proved advantageous, if, using the extension distance (AW) which said distance can be found with the required precision in accord with measurement technology, the x-coordinate determinations are taken therefrom employing a combination of a roughly incremental sample, but an exact standard of measurement. For this purpose, the optical bench (**03**), FIG. **1**, is provided with a mechanical incremental means, i.e. a regularly perforated, linear raster (**L1**–**L2**) that serves the incrementally exact positioning of the objective lens carrier (OT) and the image carrier (BT) on said optical bench by pin insertion.

Also, several bench sections (**OB1**, **OB2**) may be incrementally exactly linked together by means of pin insertion in the perforated segments. The x-coordinate determination is done thus, first as shown with a relatively large error, whereafter a resetting into the next neighboring incremental section is made and, in the corresponding raster measurement the remainder from the found raster point is added on, so that the absolute total error is only a little larger than that of the extension distance. This also permits working with small pivoting angles θ in the case of small extension distances, whereby, in spite of all, a high precision of the image distance determination is achieved.

The raster length will, in practice, be chosen smaller than the length of the extension distance, and a multiple greater than the greatest absolute error, which arises upon a given pivoting angle.

Through the hole and pin raster, there arises another alternative for indirect image distance or scale determination, in that the objective lens carrier (OT) is displaced by at least one increment length and before and after a focus point of a real point is made, whereby the extension length is ascertained.

The incremental divider on the optical bench and the related incremental devices on the standards and the bench connections are advantageous developments of the camera arrangement for the application of the of the new process of focusing placement.

As already mentioned, the given formulae extend themselves in the case of objective lenses with several principal planes. Besides this, it must be taken into consideration that the pivoting of the objective lens is often not about a principal plane axis, but parallely offset therefrom. By means of the interval d_h the principal plane yields a parallel offset h to the image plane in the direction out from the objective lens from the relationship $h=d_h \cos \alpha$

From this, can be evolved the parameter of the displaced image plane:

$$d_m^{\,v} = \tag{13}$$

$$d_m - h\sqrt{a_m^2 + b_m^2 + 1} = d_m - d_h(a_m\cos\Phi\cos\theta + b_m\sin\Phi\cos\theta - \sin\theta)$$

By conversion computing to the pivot point coordinate system, the parameters-of which are indicated with the raised "h" index, and upon introduction of the set-point objective lens pivot angle, there is obtained the extension adjustment for the doubled focus placement as seen in:

$$x_b = -\frac{d_m^{\,v}}{a_m} + \frac{d_h}{a_m}\,(a_m\cos\Phi_p\cos\theta_p + b_m\sin\Phi_p\cos\theta_p - \sin\theta_p) \tag{14}$$

and for the Z-axis section:

$$d_m^{\,v} = d_m^{\,H} + a_m A_1 \cos\phi_p \cos\theta_p + b_m A_1 \sin\theta_p \cos\theta_p - a_l \sin\theta_p \tag{15}$$

Wherein, A_1 is a displacement parameter and wherein the index sub "p" always represents the "set point" index in other equations.

In the above, various methods of solving are presented for the computation of the set-point adjustment value. In the case of the greatest simplification of the formulae, which are valid for the thin lenses, the differential relationship of the extension distance to a objective lens pivoting angle alteration is brought into the equations and a final solution for the sought after set-point position value results.

If more complex equations are applied, which produce a more exact definition of the image system, then two kinds of considerations for the solution of the equations appear. In the case of one method, for the related parameter pairs of the extension upon focusing, that is, the start extension and the start pivoting angle, are brought, as indeterminate quantities into a first equation system. The final extension, which is defined from the indeterminate values and the extension change, along with the final pivoting angle, is input into a second equation system. Then, by setting the two systems equal to one another, the indeterminate quantities eliminate themselves and the equations, because of their complexity cannot be normally solved, but in accord with known iteration methods the set points can be found. The equivalence setting of the two image side parts of the equation systems is possible, because the two object side portions of the equation systems in relation to the adjustment changing are invariant.

A further method does not proceed from two approaches together with the related equation systems, but from an entirely different point of view of the image equation system. The evolved results and the equations regarding the parameters to be varied, i.e. that of the variation dependent parameters, yield further equations, with the inserted real quantities of the measured dependencies, which equations are to be solved by the iteration method, in such a manner that the sought set-point values are found.

The determination of the mutual dependencies of the objective lens adjustment to the extension changes at any given time upon focusing, is technologically very simple to bring about without giving rise to image migrations.

This is the case when the objective lens is pivoted about a clearly defined pivoting axis which intersects with the optical axis at a definite point or in a closely localized zone. This zone lies, according to the type of objective lens, midway between the principal planes up to the plane H' and, is determinable for the conventional installation of an objective lens. The pivoting of the objective lens can be made about the optimal axis, when the said optimal axis does not coincide with the mechanical pivoting axis. This is accomplished by means of appropriate compensation displacements virtually about the optimal axis, which requires, however, corresponding calculation of the compensation displacement and related means of positional adjustment.

A particularly simple adjustability of the objective lens arises, when the optimal angular displacement axes coincide with the mechanical pivoting axes. To this end, the mechanical pivoting axes must meet with the optical axis at one point, and the objective lens must be so set in the objective lens standard, that its optimal pivoting axes conform with the mechanical pivoting axes.

As may be inferred from FIGS. **5**, **6**, and **7**, it is advantageously arranged, that between the lens holding elements (HR) of the objective lens holder (OT) currently an adapter set (E**1**–E**3**) is installed, so that the framing reference surface (SOS) exhibits a definite axial backstop to the current objective lens reference surface (BF**01**–BF**03**) and in accord with this, the pivoting axis (Y) of the objective lens carrier (OT) lies properly in the objective lens.

In the case of the first adapter (E**1**) in FIG. **5**, the objective lens is displaced in the direction of the subject. Where the second adapter (E**2**) is concerned, there is no axial positioning beyond the customary placement. In the third adapter (E**3**) arrangement, the objective lens is moved toward the screen. The various adapter inserts (E**1**, E**2**, E**3**) are thus flat or extend themselves inward or outward from the retaining frame (HR).

The understanding that the exceptional focussing, which is in accord with the purpose of the invention, of an already, prealigned, partially focussed image, requires only a refocussing of the camera within confined limits, was made use of. That is, in accord with the invention, subsequent to the determination of the gradients of the positioning parameters, with the aid of these said gradients, the necessary further parameters are solved for through iterative computation. In this process, and in a provable manner, a satisfactory precision is achieved.

The utmost sharp focussing, in accord with the process, now permits, as has been shown, the use of optimal aperture openings, which are chosen, on the one hand, to correlate the required depth of focus at moderate light requirement and on the other hand to avoid extensive diffraction blurring.

I claim:

1. A focusing process for a camera;

having an objective lens carrier (OT) and an image carrier (BT), which are maintained positionally relative to one another in a straight line optical bench direction (X) in which the spatial interval (x**1**–x**2**, x**2**–x**3**, δb)between them is variable, wherein the said interval changes are signaled to a microprocessor (PR),

equipping the objective lens carrier (OT) with an objective lens (O) secured to pivot about two axes (Y, Z), said axes being perpendicular to one another and to an optical bench direction (X), two respective objective lens angles (θ, Φ) and a focal length (f) of said objective lens being inputted to the microprocessor (PR),

the image carrier (BT) having a frosted glass plate image screen (BA), said screen being moveable about the two axes (Y, Z) perpendicularly disposed to one another and to the direction of the bench direction (X), and two respective image reception angles (α, β) thereof being sent to the microprocessor (PR),

the image screen (BA) having a focusing adjustment sensor (CD), which signals a degree of focus, and is positionable in two image reception coordinates (Y**1***, Z**1***) which, together with a focus value, are inputted to the microprocessor (PR),

further possessing at least three select image point areas (B1, B2, B3), which lie in a secondary image plane for the simultaneous adjustment of a focus having said image point areas and the focus adjustment sensor (CD) on the image screen (BA) subjected to determination of their respective image screen coordinates by means of a change in the interval between the image carrier (BT) and the objective lens (O) sequentially at a current time for each area of said image point areas through focus adjustment by means of the determination of the related screen coordinates (Y2*, Z2*, Y3*, Z3*), and said positional changes of the image carrier (BT), these being (x1–2x, x2–x3) and being inputted to the microprocessor,

obtaining, by means of input data collected from the microprocessor (PR) a determination of the positional parameters (a_o, b_o, a_m, b_m, θ_o, Φ_o) of the image screen (BA) as well as of the secondary image from which, together with a further image parameter necessary for computation, this latter originating in the solution of image equations, calculating such set point adjustment values (θ_{soll}, Φ_{soll}) suitable for the pivoting of the objective lens carrier (OT) along with a value for the adjustment of the interval between the image carrier (BT) and the objective carrier (OT), and the results thereof being made available, so that the new image plane adjusted by these set-point values (θ_{soll}, Φ_{soll}, xb_{soll}) comes as close as possible to coinciding with the image screen (BA),

therein characterized, in that one of the objective lens focusing adjustment parameters (θ, Φ, axial displacement) is altered by a predetermined amount, thus allowing a condition wherein, for a selected image point, can be measured an extension difference, which distance is determined by an extension apparatus AA in the bench direction (X) and a first set of the image equations with the input of the original objective lens adjustment parameters and an undetermined image distance (b) as well as a further set of image equations with the input of varied objective lens parameters (θ, Φ) and compensated by the image distance (b), changed by an extension difference (δb) and permitting determination of the set point values (θ_{soll}, Φ_{soll}, xb_{soll}),

functional derivations of the image equations having been created in regard to the objective lens focusing parameters (θ, Φ, axial displacement) and in regard to the current image distance (b) in accord with the focus at the time and the thereby arrived at focus change (θ, Φ, axial displacement) and the measured extension difference (δb), being inputted to the said derivations and solved for the set point signals (θ_{soll}, Φ_{soll}, xb_{soll}).

2. A process in accord with claim **1**, therein characterized, in that the selected image point, where the objective lens (O) has not been pivoted about the horizontal axis (Y) and lies in the horizontal XY-plane and the pivoting of the objective lens (O) takes place about the said horizontal axis (Y) by a predetermined pivoting angle (θ) for the determination of the extension difference.

3. A process in accord with claim **1**, therein characterized, in that the selected image point, is focussed by at least two pivoting angles and thereby the extension differences (AW) are measured and from a related equation (**11**) by means of which, through parameters, a real object distance (S) and therefrom the image distance (b) is calculated, which are inputted to the image equations for the solution thereof.

4. A process in accord with claim **1**, therein characterized, in that during an extension change, the current incremental extension changes from the image point signals (SS) of the corresponding focussing values of the selected image point are continually monitored and correspondingly stored in the microprocessor (PR) memory, and subsequent to the pivoting of the objective lens about the predetermined pivoting angle (θ), or after an objective lens displacement along given axial movement path, from the then produced image point signals (SS) the focus value is determined and, now having this value, from the stored data, the corresponding extension change (δb) is sought out, which serves for further computations.

5. A process in accord with claim **1** therein characterized, in that the image distance (b) is first approximated from the extension difference (δb) and the closest related raster incremental interval of the image carrier (BT) of a linear bench raster (L1–LN) from the objective lens carrier (OT) is determined to this so attained raster interval the extension differential, also corresponding to the raster, is added and this so computed image carrier-objective lens carrier interval is used for a more exact further image parameter in sequential computations.

6. A process in accord with one of the claims **1**, **4** or **5**, therein characterized, in that the objective lens displacement path amounts to one or more to the bench raster lengths.

7. A process in accord with claim **1** therein characterized, in that by means of image equations, the start image plane (B1, B2, B3) in the image space is on a new image plane, which is parallel to the image screen (BA), and will be brought back and the objective lens angles (θ_{soll}, Φ_{soll}) and subsequently the inserted intersection point (xb_{soll}) of the image reception plane (BA) is calculated with the X-axis.

8. A process in accord with claim **1** therein characterized, in that a parallel insert (h) of the image plane, dependent on a main lens plane interval (d_h) of the objective lens and an insert of the objective lens pivoting axis intersection point for the principal plane thereof, is taken into consideration in the computation for the set-point values (θ_{soll}, Φ_{soll}, xb_{soll}).

9. A camera for application with a focusing process in accord with claim **1** therein characterized, in that the bench thereof (OB) is provided with a raster with mechanical increments, in particular, hole and space increments, (L1–LN) and the objective lens carrier (OT) and the image carrier (BT) with raster apparatus are secured incrementally exact to one another in the said raster with appropriate means, namely raster pins.

10. A camera in accord with claim **9**, therein characterized, in that the optical bench (OB) is comprised of at least two bench sections (OB1, OB2), which are joined in exact incremental exactness by a connection piece possessing a raster apparatus for the given raster.

11. A camera in accord with claim **9**, therein characterized in that the raster length is shorter than a maximum extension path length.

12. A camera for application with a focusing process in accord with claim **1** therein characterized, in that the objective lens (O) is so placed in the objective lens carrier (OT), that the pivoting axes (Y, Z) of said lens intersect at a point and the point of intersection lies between the two principle planes (H, H') of the objective lens (O) .

13. A camera, in accord with claim **12**, therein characterized in that the intersection point for the axes (X, Y, Z) lies between the midpoint and the principal plane (H'), which said midpoint lies between the two principal planes (H, H').

14. A camera in accord with claim **12**, therein characterized in that between the objective lens carrier (OT) and the objective lens (O), a corresponding and suitable insert (E1, E2, E3), which possesses an axial partition between the

image reception surfaces (BF**01**, BF**02**, BF**03**, SOS) of the objective lens (O) and the objective carrier (OT), is placed in such a manner that the intersection point of the axes (X, Y, Z) is found in the optimal axial position for the objective lens (O) being used at that time and said point is between the principal planes (H, H').

[57] **ABSTRACT**

A focus detection function is disposed on the focal plane of an objective lens. The in-focus state of the objective lens is determined with respect to a plurality of range-finding regions in a photographic range by employing the focus detection function. A correction value of the objective lens corresponding to a predetermined range-finding region among the plurality of range-finding regions is already stored, thereby finding correction values corresponding to regions other than the predetermined region. As a result, focus detection with respect to the regions other than the predetermined region can be performed.

FOCUS DETECTION DEVICE FOR OBJECTIVE LENS

This application is a continuation of application Ser. No. 08/241,574, filed May 12, 1994, now abandoned.

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to a focus detection device suitable for photographic cameras, video cameras, and the like. More particularly, the invention relates to a focus detection device in which a pupil of an objective lens is divided into a plurality of regions and the distributions of a quantity of light with respect to a plurality of object images are formed with light transmitted through the respective regions so as to find the relative relationship of the positions of the plurality of the distributions of a quantity of light, thereby appropriately detecting an in-focus state of the objective lens with respect to the plurality of regions in the photographic range.

2. Description of the Related Art

Conventionally, the so-called "image offset method" is available for a light-receiving type focus detection method employed by utilizing light transmitted through an objective lens. The image offset method is disclosed in, for example, Japanese Patent Laid-Open Nos. 59-107311 and 59-107313.

FIG. **7** is a schematic view of an optical system of a focus detection device employing the conventional image offset method. Referring to FIG. **7**, the optical system includes an objective lens **61**, a field mask **62** placed in the vicinity of an expected focal plane of the objective lens **61**, and a field lens **63** placed in the vicinity of the expected focal plane. This system further includes a secondary optical system **64**, light-receiving means **65**, a stop **66** and an exit pupil **67** of the objective lens **61**. The secondary optical system **64** comprises two lenses **64-1** and **64-2** placed symmetrical to each other with respect to the optical axis of the objective lens **61**. The light-receiving means **65** has two arrays of light-receiving elements **65-1** and **65-2** placed to the rear of the two lenses **64-1** and **64-2**, respectively. The stop **66** has two apertures **66-1** and **66-2** in front of the two lenses **64-1** and **64-2**, respectively. The exit pupil **67** comprises two separated regions **67-1** and **67-2**.

A field lens **63** serves the function of forming an image of the apertures **66-1** and **66-2** of the stop **66** on the two regions **67-1** and **67-2** of the exit pupil **67** so that light transmitted through the respective regions **67-1** and **67-2** forms the distributions of a quantity of light on the light-receiving elements **65-1** and **65-2**, respectively.

In the focus detection device shown in FIG. **7**, when the focal point of the objective lens **61** is in front of an expected focal plane, the position of the distribution of a quantity of light with respect to the image formed on the array of the light-receiving element **65-1** is close to that formed on the array of the light-receiving element **65-2**. On the other hand, when the focal point of the objective lens **61** is behind the expected focal plane, the position of the distribution of a quantity of light with respect to the image formed on the array of the light-receiving element **65-1** is away from that formed on the array of the light-receiving element **65-2**. The displacement between the distributions of quantities of light formed on the light-receiving element **65-1** and light-receiving element **65-2** is a function of the defocusing amount of the objective lens **61**. Thus, such a defocusing amount is calculated by suitable calculation means, thereby enabling the detection of the defocusing direction and amount of movement required of the objective lens **61**.

The focus detection device shown in FIG. **7** performs range-finding corresponding to the subject which is photographed by the objective lens and is positioned substantially at the center of the subject range.

In contrast thereto, the present inventor has already proposed a focus detection device in U.S. Pat. No. 5,005,041, issued Apr. 2, 1991, which can also detect the in-focus state with respect to range-finding points other than a range-finding point at the center of the photographic range.

FIG. **8** is a schematic view of an optical system of a focus detection device for a plurality of range-finding points. Such a device is disclosed in U.S. Pat. No. 5,005,041 and includes a field mask **71**, a field lens **72**, a stop **73** having two apertures **73-1** and **73-2**, a secondary optical system **74** formed of two lenses **74-1** and **74-2**, and a sensor **75**. The objective lens **61** shown in FIG. **7** is omitted.

The field mask **71** has a plurality of apertures **71***a***1**–**71***e***1** corresponding to a plurality of fields, respectively, to be measured. Light is regulated by the field mask **71** and a plurality of pairs of the distributions of quantities of light are formed by the secondary optical system **74** so that a plurality of pairs of sensor arrays, **75***a***1** and **75***a***2**, **75***b***1** and **75***b***2**, **75***c***1** and **75***c***2**, **75***d***1** and **75***d***2**, and **75***e***1** and **75***e***2**, can receive the resulting distributions of light, respectively.

The focus detection device shown in FIG. **8** performs range-finding with respect to five regions overall, that is, a central portion and four peripheral portions of a photographing screen. It is very important that the device having such a simple construction be able to detect the in-focus state in a plurality of regions in the photograph screen when the device is applied to a camera.

Since the focus detection device shown in FIG. **8** is constructed such that two distributions of quantities of light formed on the sensor move vertically depending upon the in-focus state of the objective lens, it is only capable of range-finding with respect to objects in which the distribution of a quantity of light varies only vertically. The device is not able to perform range-finding with respect to objects in which the distribution of a quantity of light varies only horizontally, for example, a black-and-white edge pattern having a vertical boundary.

In order to solve the above-noted problems the present inventor proposes a focus detection device, which is able to perform range-finding with respect to objects in which the distribution of a quantity of light varies either only vertically or only horizontally in the central portion of the photographic region of the device and also is able to perform range-finding with respect to objects in a plurality of portions other than the central portion.

FIG. **9** is a schematic view of the focus detection device disclosed in U.S. Pat. No. 4,992,819, which issued Feb. 12, 1991.

A field mask **31** has a cross-like aperture **31-1**, two portions of which intersect with each other substantially at the center of the photographic screen formed by an objective lens (photographic lens) (not shown) and longitudinal apertures **31-2** and **31-3** at the peripheral portions of the field mask **31**. A field lens **32** comprises three regions **32-1**, **32-2** and **32-3** having respective predetermined optical characteristics corresponding to the three apertures, **31-1**, **31-2** and **31-3**, respectively, of the field mask **31**. A stop **33** comprises at the center thereof four apertures **33-1** comprising **33-1***a*, **33-1***b*, **33-1***c* and **33-1***d*, one pair at each vertical and horizontal portions at the center thereof and also one pair of apertures **33-2***a* and **33-2***b*, and another pair of apertures **33-3***a* and **33-3***b* at the peripheral portions thereof.

The regions **32-1**, **32-2** and **32-3** of the field lens **32** serve the function of forming an image of the apertures **33-1**, **33-2** and **33-3**, respectively, of the stop **33** in the vicinity of the exit pupil of the photographic lens (not shown).

A secondary optical system **34** includes a total of four pairs of secondary image-forming lenses. That is, the secondary optical system **34** comprises eight secondary image-formation lenses **34-1***a*, **34-1***b*, **34-1***c*, **34-1***d*, **34-2***a*, **34-2***b*, **34-3***a* and **34-3***b* which are placed at the rear of the respective apertures of the stop **33**.

An array of light-receiving elements (sensor) **35** has a total of 4 pairs of sensors, that is, eight sensors **35-1***a*, **35-1***b*, **35-1***c*, **35-1***d*, **35-2***a*, **35-2***b*, **35-3***a* and **35-3***b* placed in correspondence to the respective secondary image-forming lenses so that they can receive the formed image.

FIG. **10** is a schematic view of the image regions formed on the surface of the sensor **35** illustrated in FIG. **9**. Image regions **36-1***a*, **36-1***b*, **36-1***c* and **36-1***d* are the ones in which an image of the aperture **31-1** at the center of the field mask **31** is formed and show the state in which light transmitted through the central region **32-1** of the field lens **32** is regulated in the apertures **33-1***a*, **33-1***b*, **33-1***c* and **33-1***d*, respectively, of the stop **33** and an image is then formed on the surface of the sensor **35** by the secondary image-forming lenses **34-1***a*, **34-1***b*, **34-1***c* and **34-1***d*, respectively, which are placed at the rear of the respective apertures of the stop **33**.

Image regions **36-2***a* and **36-2***b* are the ones in which an image of the peripheral aperture **31-2** of the field mask **31** is formed and show the state in which light transmitted through the peripheral region **32-2** of the field lens **32** is regulated in the apertures **33-2***a* and **33-2***b*, respectively, of the stop **33** and an image is then formed on the surface of the sensor **35** by the secondary image-forming lenses **34-2***a* and **34-2***b*, respectively, placed at the rear of the respective apertures of the stop **33**.

Likewise, image regions **36-3***a* and **36-3***b* are the ones in which an image of the peripheral aperture **31-3** of the field mask **31** is formed and show the state in which light transmitted through the peripheral region **32-3** of the field lens **32** is regulated in the apertures **33-3***a* and **33-3***b*, respectively, of the stop **33** and an image is then formed on the surface of the sensor **35** by the secondary image-forming lenses **34-3***a* and **34-3***b*, respectively, placed at the rear of the respective apertures of the stop **33**.

Theoretically, the focus detection device shown in FIG. **9** detects the relative positions of the images in the direction in which a pair of arrays of sensors are disposed, in a manner similar to the conventional devices.

Since the focus detection device is constructed as described above, it is possible to perform, in the vicinity of the center of the range to be photographed or observed by the objective lens (not shown), range-finding with respect to the objects in which the distribution of a quantity of light varies either only vertically or only horizontally, and it is also possible to perform range-finding with respect to the objects positioned in correspondence to the peripheral apertures **31-2** and **31-3** of the field mask **31**.

In general, exchangeable photographic lenses used in, for example, a single-lens reflex camera, have various types of aberration inherent therein, and consequently, the amount of aberration and methods of correcting it vary depending upon the types of lenses. Hence, when the focus detection device as described above is applied to a camera including an exchangeable photographic lens and the actuation of a photographic lens (an in-focus lens) is controlled on the basis of a focus detection signal directly obtained in the focus detection device, an appropriate in-focus state may not be obtained.

In order to solve the above-mentioned problem, the following focus detection device has been proposed. A focus detection signal D, for example, representing the defocusing amount, is corrected by utilizing a correction value C inherent in each of the photographic lenses for the focus detection signal, as expressed by the following equation:

$$D_C = D - c \tag{1}$$

The actuation of the in-focus lens is controlled on the basis of the thus-obtained focus detection corrected signal D_C.

In general, the correction value C inherent in the different types of photographic lenses is also dependent upon the position of the detection region (range-finding region). Therefore, when the photographic lens has detection regions other than the center of the photographic range as shown in FIGS. **8** and **9**, it is necessary to have correction values corresponding to the respective detection regions. However, another problem arises in such a case. When the number of expected detection regions is large, a storage device with a large capacity is required in order to store correction values corresponding to all the detection regions in the photographic lens or the camera body, and the I/O control of the correction values when calculating the focus detection signals becomes complicated.

Further, a photographic system including a single-lens reflex camera or an exchangeable lens may sometimes be actuated only for a predetermined number of detection regions or placed in a predetermined position, in which case, a camera containing a focus detection device having a number of detection regions different from the predetermined number or placed in positions different from the above-described position cannot be used in such a system unless it is modified. In order to modify the above camera to make it suitable for such a system, all the new correction values must be stored in the camera body, and accordingly, a storage device having a large capacity is also required.

SUMMARY OF THE INVENTION

Accordingly, an object of the present invention is to provide a focus detection device which is capable of performing highly-precise focus detection without requiring a storage element with a high-density capacity because focus detection signals in a plurality of regions (range-finding regions) are corrected by using correction values with respect to the respective photographic lenses and employing a simple calculation process.

The invention in one aspect pertains to a focus detection device for an objective lens comprising detection means for detecting the focus state of the objective lens with respect to a plurality of regions in the field, and producing means for producing, on basis of a correction value for correcting a detection signal obtained by the detection means with respect to a predetermined region among the plurality of regions, a correction value for correcting a detection signal obtained by the detection means with respect to the region other than said predetermined region.

In order to achieve the above object, the present invention in another aspect pertains to a focus detection device comprising: an objective lens means; detection means for detecting the focus state of the objective lens means with respect to a plurality of regions in the field; storage means for storing a correction value for correcting a detection signal obtained by the detection means with respect to a predeter-

mined region among the plurality of regions; and production means for producing a correction value for correcting a detection signal obtained by the detection means with respect to each of the regions other than the predetermined region on the basis of the correction value stored in the storage means.

Further objects, features and advantages of the present invention will become apparent from the following description of the preferred embodiments with reference to the attached drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a schematic view of a portion of a first embodiment according to the present invention;

FIG. **2** is a schematic view of the range to be found shown in FIG. **1**;

FIG. **10** is a schematic view of a portion of the focus detection device shown in FIG. **9**.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

FIG. **1** is a schematic view of a first embodiment according to the present invention. FIG. **2** is an enlarged view of a portion of the first embodiment shown in FIG. **1**.

Referring to FIG. **1**, a photographic body **71** includes: a photographic lens **72**; a drive device (D.R.) **73** for shifting the entire lens system comprising the photographic lens **72** or an in-focus lens, which is a part of the lens system, so as to adjust the in-focus state of the photographic lens **72**; a storage device (S.D.) **74** such as a ROM, or the like; and lens controlling means (L.C.M.) **75** for controlling the storage device **74**.

A camera body **76** includes: a focus plate **77** on which an object image is formed by the photographic lens **72**; a pentagonal prism **78**; a finder system having an eyepiece **79**, a focus detection system having focus detection means (F.D.) **80** and control means (CONT.) **81** for controlling the detection means **80**; a main mirror **82** for introducing light from the photographic lens **72** into the finder system, and a subsidiary mirror **83** for introducing light from the photographic lens **72** to the focus detection means **80**. When connected, the photographic lens body **71** and the camera body **76** have an electric contact **84** through which information is communicated and the power is supplied.

The focus detection means **80** of this embodiment has similar components to those shown in FIG. **9** and the range-finding principle is also similar to that shown in FIG. **9**.

FIG. **2** shows the focus detection regions on the focus plate **77** illustrated in FIG. **1** when the focus detection device illustrated in FIG. **9** is employed as the detection means **80**. A cross-like region **85** at the center and peripheral narrow regions **86** the distance L away from the center form the focus detection regions corresponding to the configuration of the apertures of the field mask **31** or the arrangement of the sensor **35** shown in FIG. **9**.

The photographic lens body **71** has correction values C(O) and C(L') stored within the ROM **74** for the above focus detection signal D with respect to the central region and the peripheral regions the distance L' away from the center, respectively.

In the photographic device illustrated in FIG. **1**, when the central region, for example, is selected in advance as a focus detection region, the focus detection system is started by such means as the initial pressing of a shutter button (not shown), thereby detecting the amount of the in-focus state with respect to the central region of the photographic lens **72**, for example, the defocusing amount D(O). Subsequently, the correction value C(O) with respect to the focus detection central region stored in the ROM **74** of the photographic lens body **71** is read into the control means **81** of the focus detection system through the contact point **84**.

The final focus detection corrected signal $D_C(O)$ can be found by the following equation:

$$D_C(O)=D(O)-C(O) \tag{2}$$

The in-focus lens is actuated by the drive device **73** of the photographic lens body **71** on the basis of the above value, thereby adjusting the focus state.

Likewise, the defocusing amount D(L) is detected with respect to the focus detection peripheral regions distance L away from the center. When the following equation applies,

$$L=L' \tag{3}$$

the correction value C(L') stored within the ROM **74** of the photographic lens body **71** can be directly employed and the focus detection corrected value $D_C(L)$ can be found by the following equation:

$$D_C(L)=D(L)-C(L') \tag{4}$$

On the other hand, when the equation (3) does not apply, as being expressed by the following formula,

$$L\neq L' \tag{5}$$

the correction value C(L) is found by the following calculation in the present invention.

That is, suppose that the correction value C(x) with respect to the focus detection region distance x away from the center can be found by the following linear equation of x,

$$C(x)=ax+b \tag{6}$$

the coefficients a and b are found by the two correction values C(O) and C(L') stored within the ROM **74** of the photographic lens body **71**, thereby calculating the correction value C(x) with respect to the region any distance x away from the center.

According to the above-described simple calculation, the coefficients a and b are found by the following equations:

$$a = \frac{C(L') - C(O)}{L'} \tag{7}$$

$$b = C(O) \tag{8}$$

The equation (6) can be expressed by the following equation:

$$C(X) = \frac{C(L') - C(O)}{L'} X + C(O) \tag{9}$$

Thus, the correction value C(L) can be found by the following equation:

$$C(L) = \frac{C(L') - C(O)}{L'} L + C(O) \tag{10}$$

The focus detection corrected signal $D_C(L)$ is calculated by the above equation.

FIG. **3** is a graph illustrating the relationship of the equation (9) in which the vertical axis indicates the correction value C(x) and the horizontal axis represents the distance x. According to this equation, a correction value can be found not only when x is equal to L, but also when x is any value.

The present invention may be modified such that, for example, the following quadratic equation of x may be substituted for the linear equation including x shown in the equation (6) in another embodiment:

$$C(x)=ax^2+bx+C \tag{11}$$

Or, an equation of an even higher degree than the power of 2 may be used. Since there are three unknown coefficients in the equation (11), it is necessary to store three known correction values within the ROM **74** of the photographic lens body **71**.

If the three correction values are $C(L_1)$, $C(L_2)$, and $C(L_3)$, the coefficients of the equation (11) can be found by the following equations:

$$a = \frac{\begin{vmatrix} C(L_1) & L_1 & 1 \\ C(L_2) & L_2 & 1 \\ C(L_3) & L_3 & 1 \end{vmatrix}}{\begin{vmatrix} L_1^2 & L_1 & 1 \\ L_2^2 & L_2 & 1 \\ L_3^2 & L_3 & 1 \end{vmatrix}} \tag{12}$$

$$b = \frac{\begin{vmatrix} L_1^2 & C(L_1) & 1 \\ L_2^2 & C(L_2) & 1 \\ L_3^2 & C(L_3) & 1 \end{vmatrix}}{\begin{vmatrix} L_1^2 & L_1 & 1 \\ L_2^2 & L_2 & 1 \\ L_3^2 & L_3 & 1 \end{vmatrix}} \tag{13}$$

-continued

$$c = \frac{\begin{vmatrix} L_1^2 & L_1 & C(L_1) \\ L_2^2 & L_2 & C(L_2) \\ L_3^2 & L_3 & C(L_3) \end{vmatrix}}{\begin{vmatrix} L_1^2 & L_1 & 1 \\ L_2^2 & L_2 & 1 \\ L_3^2 & L_3 & 1 \end{vmatrix}} \tag{14}$$

wherein |A| is the determinant of the matrix A.

FIG. **4** is a graph illustrating the relationship of the equation (11) by employing the thus-obtained coefficients by way of example.

Instead of employing the three known correction values as described above, the coefficients of the square equation (11) may be determined by the two correction values C(O) and C(L') with respect to the central and peripheral regions, respectively, and on the assumption that the correction value take the extreme value with respect to the central region. According to this method, the correction value is found by the following equation:

$$C(X) = \frac{C(L') - C(O)}{L'^2} X^2 + C(O) \tag{15}$$

FIG. **5** is a graph illustrating the relationship of equation (15).

Although, in the above embodiment, the values stored in the ROM **74** of the photographic lens body **71** are used as the known correction values, the correction values may be stored in the camera body **76** and employed as the known correction values.

Also, the present invention is not limited to the above embodiment, but other forms of functions may be set according to the characteristics or the number of correction values inherent in the photographic lens body **71** or the camera body **76**.

FIG. **6** is a schematic view of a focus detection device according to another embodiment of the present invention.

In this embodiment, the secondary optical system is constructed in a manner similar to that shown in FIG. **9**. However, four apertures **31-2**, **31-3**, **31-4** and **31-5**, two each on the right and left positioned in the peripheral field are arranged, and also, the number of an array of sensors is increased to four **35-4***a*, **35-4***b*, **35-4***c* and **35-4***d*. Although the number of focus detection regions is increased, the present invention is applicable in a manner similar to the method described above.

As will be clearly understood from the foregoing description, the present invention offers the following advantages.

Since the respective components in the present invention are arranged as described above, the focus detection signals with respect to a plurality of detection regions (range-finding regions) can be corrected by employing the correction values regarding the respective photographic lenses and can be easily found by an appropriate calculation process, thus achieving a focus detection device which is capable of highly-precise focus detection without requiring a storage element with a high-density capacity.

The individual components shown in outline or designated by blocks in the Drawings are all well-known in the focus detection arts and their specific construction and operation are not critical to the operation or best mode for carrying out the invention.

While the present invention has been described with reference to what are presently considered to be the pre-

ferred embodiments, it is to be understood that the invention is not limited to the disclosed embodiments. To the contrary, the invention is intended to cover various modifications and equivalent arrangements included within the spirit and scope of the appended claims. The scope of the following claims is to be accorded the broadest interpretation so as to encompass all such modifications and equivalent structures and functions.

What is claimed is:

1. A focus detection device for an objective lens, comprising:

a storage device which contains a stored focus correction value for at least one predetermined region in a field of focus of said objective lens;

detection means for detecting a focus state of the objective lens with respect to another region located at a given distance from said predetermined region and for producing a corresponding detection signal; and

calculation means for calculating a correction value for said another region on the basis of said given distance and said stored focus correction value.

2. A focus detection device according to claim **1**, wherein said storage device contains a plurality of stored focus correction values which correspond, respectively, to each of several predetermined regions in said field of focus of said objective lens.

3. A focus detection device according to claim **1**, wherein said detection means detects the focus state of said objective lens according to a distribution of light transmitted through different regions of a pupil of the objective lens.

4. A focus detection system comprising:

objective lens means for viewing a field having a plurality of regions;

detection means for detecting the focus state of said objective lens with respect to at least one of a plurality of regions in said field, and producing a corresponding detection signal;

storage means for storing a first correction value for correcting the detection signal produced by said detection means with respect to another of said plurality of predetermined regions, said another region being located a predetermined distance from said one region; and

calculation means for calculating a second correction value for correcting said detection signal, said calculation means being constructed and arranged to calculate said second correction value based on said given distance and on said first correction value.

5. A focus detection device according to claim **1**, wherein said storage device contains a plurality of correction values corresponding, respectively, to a plurality of predetermined regions in said field of focus of said objective lens and wherein said calculation means calculates a correction value for said other region on the basis of said detection signal and on the basis of at least two of said plurality of correction values.

6. A focus detection device according to claim **5**, wherein said calculation means is constructed to calculate said correction value for said other region based on a linear equation.

7. A focus detection device according to claim **5**, wherein said calculation means is constructed to calculate said correction value for said other region based on a quadratic equation.

8. A focus detection device according to claim **5**, wherein said calculation means is constructed to calculate said correction value for said other region based on a at least three of said stored correction values.

9. A focus detection system according to claim **4**, wherein said detection means detects a focus state of said objective lens means according to a distribution of light transmitted through different regions of a pupil of said objective lens means.

10. A focus detection system according to claim **4**, wherein said storage means stores an additional correction value for another region among the plurality of regions and said calculation means calculates the second correction value on the basis of the correction values stored in said storage means.

[57] **ABSTRACT**

An apparatus is described for mounting an actuator lens within an optical disc carriage held by a baseplate assembly. The apparatus includes a frame, a cradle assembly mounted to the frame with at least one degree of freedom of motion, a tower assembly mounted to the frame, a lever assembly rotatably mounted to the frame, and a gripper assembly mounted to the lever assembly. The cradle assembly includes a baseplate alignment assembly having a source of radiant energy for projecting a beam of radiant energy, means for determining the tilt alignment of the beam with respect to the tower assembly, and a plurality of tilt actuators for aligning the tilt of the beam with respect to the tower assembly. The tower assembly includes a video camera having a camera lens, a tower magnifying lens, and a monitor for displaying a presentation of a beam of radiant energy passing through the tower magnifying lens and into the video camera. A method for mounting a lens is described which includes the steps of placing a lens in the carriage, aligning the lens by moving a baseplate assembly with respect to the tower assembly, moving the objective lens assembly with respect to the tower assembly, and moving the actuator lens with respect to the tower assembly. The lens is attached to the gripper assembly and the lever moves the gripper and lens away from the carriage. Adhesive is applied to the carriage and the lever is moved back so as to place the lens on the adhesive in the aligned position.

METHOD AND APPARATUS FOR ALIGNING AN OBJECTIVE LENS

This is a division of application Ser. No. 08/410,698, filed Apr. 7, 1995.

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to manufacturing of optical systems, and, in particular, to the manipulation and alignment of an objective lens during manufacture of an optical system.

2. Description of the Related Art

In the manufacture of prior optical systems, specific alignment of the objective lens with respect to a storage medium was not critical. In those systems, a spindle which holds the storage medium is aligned with respect to guide rails. A carriage rides along the guide rails, and the objective lens is placed within the carriage. Because of the information storage densities used in such optical systems were sufficiently low, and because manufacturing tolerances of the spindle, rails, and objective lens were sufficiently high, specific alignment of the objective lens was not necessary. The objective lens was placed, then tested for alignment within tolerable limits.

Another example of a prior optical system does perform active alignment of the objective lens. However, the objective lens is fixedly mounted to an actuator, and the objective lens/actuator combination is aligned with respect to a carriage assembly. Once aligned with respect to the carriage assembly, the actuator is mounted to the carriage assembly, which is aligned with respect to the storage medium. This prior optical system requires that the actuator be alignable with respect to the carriage assembly. Additionally, the actuator/carriage assembly combination is quite large relative to such assemblies in other optical systems.

SUMMARY OF THE INVENTION

As information storage densities increase, the alignment between the objective lens and the storage medium becomes more critical. As a result, either stricter manufacturing tolerances or improved alignment of the objective lens is necessary. Because stricter manufacturing tolerances increase manufacturing cost significantly, improved alignment of the objective lens allows higher information storage densities at an economically feasible cost.

An apparatus is described which aligns such an objective lens. The apparatus comprises a frame, a cradle assembly mounted to the frame with at least one degree of freedom of motion, a tower assembly mounted to the frame, a lever assembly rotatably mounted to the frame, and a gripper assembly mounted to the lever assembly. The cradle assembly includes a baseplate alignment assembly comprising a source of radiant energy for projecting a beam of radiant energy, means for determining the tilt alignment of the beam with respect to the tower assembly, and a plurality of tilt actuators for aligning the tilt of the beam with respect to the tower assembly. The baseplate alignment assembly may further comprise means for determining the lateral alignment of the beam with respect to the tower assembly and a plurality of lateral actuators for aligning the beam laterally with respect to the tower assembly. The tower assembly comprises a video camera having a camera lens, a tower magnifying lens, and a monitor for displaying a representation of a beam of radiant energy passing through the tower magnifying lens and into the video camera.

The gripper assembly comprises an objective lens assembly, a gripper objective lens mounted to the objective lens assembly, an objective lens alignment assembly for aligning the gripper objective lens with respect to the tower assembly and the cradle assembly, and an actuator lens tilt assembly for aligning the objective lens with respect to the tower assembly and the cradle assembly. The objective lens assembly further comprises a housing having an opening at one end for receiving an objective lens and a bellows structure on its surface to allow bending of the housing, a gripper objective lens, a non-opaque substrate mounted within the housing, and a pneumatic tube attached to the housing for creating a pressure differential between the interior and the exterior of the housing sufficient to hold the actuator lens against the opening. The objective lens alignment assembly further comprises an assembly support, a first lateral alignment support slidably mounted to the assembly support, a first lateral actuator for positioning the first lateral alignment support, a second lateral alignment support slidably mounted to the first lateral alignment support, a second lateral actuator for positioning the second lateral alignment support, a support frame having a frame base and a frame extension, mounted to the second lateral actuator, a support leaf spring mounted to the support frame and biasing the housing against the frame extension, and a focus actuator for positioning the frame extension with respect to the frame base. The actuator lens tilt assembly further comprises a flexure support ring; two flexure support plates; four flexure plates mounted at equal intervals around the flexure support ring, two of which are mounted to the housing and two of which are mounted to the flexure support plates; a first lever disposed against a flexure plate; a first tilt actuator mounted against the first lever for imparting motion on the first lever which is translated into rotational motion by the flexure support ring, the flexure support plates, and the flexure plates; a second lever disposed against a flexure plate; and a second tilt actuator mounted against the second lever for imparting motion on the second lever which is translated into rotational motion by the flexure support ring, the flexure support plates, and the flexure plates.

A method for aligning an actuator lens is described comprising the steps of moving a baseplate assembly with respect to the tower assembly, moving the objective lens assembly with respect to the tower assembly, and moving the actuator lens with respect to the tower assembly. The step of moving the baseplate assembly further comprises moving the baseplate assembly laterally with respect to the tower assembly and rotating the baseplate assembly with respect to the tower assembly. The step of moving the actuator lens further comprises moving the actuator lens laterally with respect to the tower assembly and rotating the actuator lens with respect to the tower assembly. Such a method may be used with the above-described apparatus.

For a better understanding of these and other objects of the present invention, reference is made to the detailed description of the invention which is to be read in conjunction with the following drawings, wherein:

BRIEF DESCRIPTION OF THE DRAWING

FIG. 1 is a generalized side view of one embodiment of the invention, showing the gripper assembly in a closed position.

FIG. 2 is a generalized side view of one embodiment of the invention, showing the gripper assembly in an open position.

FIG. 3 is a cross-sectional view of the tower assembly, including an embodiment of the analysis assembly.

FIG. 4 is a cross-section view of the vacuum chuck and the microscope objective lens assembly.

FIG. 5 is a view of the microscope objective lens alignment assembly.

FIG. 6 is a side view of the actuator lens tilt assembly.

FIG. 7 is a front view of the actuator lens tilt assembly.

FIG. 8 is a view of an alignment actuator.

FIG. 9 is a top view of one embodiment of the cradle assembly.

FIG. 10 is a cross-sectional view of one embodiment of the cradle assembly, taken along line 10—10 of FIG. 9.

FIG. 11 is a cross-sectional view of one embodiment of a vacuum clamp in the open position, taken along line 11—11 of FIG. 9.

FIG. 12 is a cross-sectional view of one embodiment of a vacuum clamp in the closed position, taken along line 11—11 of FIG. 9.

FIG. 13 is a top view of a baseplate assembly.

DESCRIPTION OF THE PREFERRED EMBODIMENT

Referring to exemplary FIGS. 1 and 2, according to one aspect of the invention, the apparatus comprises a tower assembly 1, a gripper assembly 2, and a cradle assembly 3. The tower assembly 1 is fixedly mounted to a frame 4. The tower assembly 1 defines a tower axis. The gripper assembly 2 is fixedly mounted to a lever assembly 5, which is rotatably mounted to the frame 4. The cradle assembly 3 is mounted to the frame 4 with at least one degree of freedom of motion. A line between the tower assembly 1 and the cradle assembly 3 is referred to as an assembly axis. In the closed position, as shown in FIG. 1, the gripper assembly 2 is between the tower assembly 1 and the cradle assembly 3 along the assembly axis. In the open position, as shown in FIG. 2, the gripper assembly 2 is not along the assembly axis.

Referring to exemplary FIG. 3, a cross-section of the tower assembly 1 is shown in more detail. The tower assembly 1 comprises a tower magnifying lens 6 and a video camera 7 having a camera lens 8. The optical axes of the camera lens 8 of the video camera 7 and the tower magnifying lens 6 are the same, and are referred to collectively as the tower optical axis. The output from the video camera 7 is connected to an analysis assembly 9. The analysis assembly 9 may be any assembly suitable for analyzing the characteristics of a radiant beam of energy. In the embodiment shown in exemplary FIG. 3, the analysis assembly 9 comprises a processor 10 and a monitor 11.

Referring to exemplary FIGS. 4, 5, 6 and 7, the gripper assembly 2 comprises a vacuum chuck 12, a microscope objective lens assembly 13, a microscope objective lens alignment assembly 14, and an actuator lens tilt assembly 15. FIG. 4 shows a cross-sectional view of one embodiment of the vacuum chuck 12 and the microscope objective lens assembly 13. FIG. 5 shows a view of one embodiment of the microscope objective lens alignment assembly 14. FIGS. 6 and 7 show two views of the actuator lens tilt assembly 15.

Referring to exemplary FIG. 4, the vacuum chuck 12 comprises a housing 16, a bellows structure 17, and an actuator lens receiving opening 18. A pneumatic tube (not shown) is connected to the housing 16. In operation, an actuator lens (not shown) is placed within the actuator lens receiving opening 18 such that the actuator lens receiving opening 18 is completely covered. The actuator lens may be an objective lens. Air is then evacuated from the housing 16 through the pneumatic tube (not shown) to create a pressure differential between the interior and the exterior of the housing 16. This pressure differential operates to hold the actuator lens against the actuator lens receiving opening 18 when the gripper assembly 2 moves. The housing 16 contains a bellows structure 17 to allow the housing 16 to bend while maintaining a pressure differential.

The microscope objective lens assembly 13 comprises a microscope objective lens 19 and a substrate 20. In operation, a beam of radiant energy will enter the housing 16 through the actuator lens receiving opening 18 and, if present, through the actuator lens. The beam will pass through the substrate 20 and through the microscope objective lens 19. The beam then passes through the housing 16 and into the tower assembly 1, where it passes through the tower magnifying lens 6 and is received by the video camera 7. Together, the microscope objective lens 19 and the tower magnifying lens 6 magnify the beam and focus the beam in the video camera 7. The tower magnifying lens 6 may be a tube lens. The substrate 20 simulates the optical properties of an information-bearing disk, and the effects of those properties on the beam. The substrate 20 is mounted such that, when the gripper assembly 2 is in the closed position, the substrate 20 is orthogonal to the tower optical axis.

Referring to exemplary FIG. 5, the microscope objective lens alignment assembly 14 comprises an X-axis lateral alignment actuator 21, a Y-axis lateral alignment actuator 22, and a focus actuator 23. Referring to exemplary FIG. 5, there is shown a reference coordinate system 24. This reference coordinate system 24 is chosen for purposes of explanation only, and it will be obvious to one skilled in the art that any convenient coordinate system could be chosen without departing from the spirit and scope of the present invention.

In the embodiment particularly shown in FIG. 5, a microscope support frame 25 having a frame extension 28 supports the housing 16 by a support leaf spring 26. The support leaf spring 26 biases the housing 16 against a cylindrical bearing 27 located between the housing 16 and a frame extension 28. The focus actuator 23 is mounted to the frame extension 28, and maintains a distance between the frame extension 28 and the microscope support frame 25 along the Z-axis, as indicated by the reference coordinate system 24. Motion of the housing 16 along the Z-axis adjusts the focus of the microscope objective lens 19 in combination with the tower magnifying lens 6.

The microscope support frame 25 is mounted on a Y-axis lateral alignment support 29 such that the microscope support frame 25 may slide relative to the Y-axis lateral alignment support 29 along the Y-axis, as indicated by the reference coordinate system 24. The Y-axis lateral alignment actuator 22 is mounted to the microscope support frame 25, and will actuate the relative sliding motion along the Y-axis.

The Y-axis lateral alignment support 29 is mounted on an X-axis lateral alignment support 30 such that the Y-axis lateral alignment support 29 may slide relative to the X-axis lateral alignment support 30 along the X-axis, as indicated by the reference coordinate system 24. The X-axis lateral alignment actuator 21 is mounted to the Y-axis lateral alignment support 29, and will actuate the relative sliding motion along the X-axis.

The X-axis lateral alignment support 30 is mounted to a lateral alignment assembly support 31. The lateral alignment assembly support 31 is mounted to the lever assembly 5. It will be apparent to one skilled in the art that the mountings between the microscope support frame 25, the Y-axis lateral alignment support 29, the X-axis lateral alignment support

30, and the lateral alignment assembly support 31 may be rearranged from the above description without departing from the spirit and scope of the present invention.

Referring to exemplary FIGS. 6 and 7, there are shown two views of the actuator lens tilt assembly 15. FIG. 6 represents a left side view of the actuator lens tilt assembly 15 according to one aspect of the invention. FIG. 7 represents a front view of the same actuator lens tilt assembly 15. The actuator lens tilt assembly 15 comprises an X-axis tilt actuator 32, a Y-axis tilt actuator 33, and a flexure assembly 34. The X-axis tilt actuator 32 is mounted to the lever assembly 5 and against an X-axis lever 35. The X-axis lever 35, at the end nearest the X-axis tilt actuator 32, is biased against the lever assembly 5, and at the other end is mounted to the flexure assembly 34. The Y-axis tilt actuator 33 is mounted to the lever assembly 5 and against a Y-axis lever 36. The Y-axis lever 36, at the end nearest the Y-axis tilt actuator 33, is biased against the lever assembly 5, and at the other end is mounted to the flexure assembly 34.

The flexure assembly 34 comprises a plurality of flexure plates 37-1, 37-2, 37-3, 37-4, a flexure support ring 38, and a plurality of flexure support plates 39. Flexure plate 37-1 is mounted at one end to the flexure support ring 38, and mounted at its other end to the X-axis lever 35 and the housing 16. Flexure plate 37-3 is mounted opposite flexure plate 37-1 to the flexure support ring 38 and to the housing 16. Flexure plate 37-4 is mounted at one end to the Y-axis lever 36 and the flexure support ring 38, and mounted at its other end to a flexure support plate 39. Flexure plate 37-4 is mounted at a 90 degree interval from both flexure plate 37-1 and flexure plate 37-3. Flexure plate 37-2 is mounted opposite flexure plate 37-2 to the flexure support ring 38 and to a flexure support plate 39. The flexure support plates 39 are mounted to the lever assembly 5.

Flexure plates 37-1, 37-2, 37-3, 37-4 each lie in a separate plane. The planes in which flexure plates 37-1 and 37-3 lie intersect along a line through an intersection point 40. The planes in which flexure plates 37-2 and 37-4 lie intersection along a line through the intersection point 40. The lines may be orthogonal to each other.

The operation of the actuator lens tilt assembly 15 will be described with respect to a downward motion imparted on each of the tilt actuators, the X-axis tilt actuator 32 and the Y-axis tilt actuator 33.

A downward motion of the X-axis tilt actuator 32 imparts a downward motion on the X-axis lever 35. This downward force produces a counterclockwise rotational force on flexure plate 37-1 about the point where flexure plate 37-1 is mounted to the flexure support ring 38. The downward force also translates into a counterclockwise rotational force on flexure plate 37-3 about the point where flexure plate 37-3 is mounted to the flexure support ring 38. These two rotational forces cause rotation about the intersection of the two planes in which the flexure plates 37-1, 37-3 lie. This intersection occurs at intersection point 40.

A downward motion of the Y-axis tilt actuator 33 imparts a downward force on the Y-axis lever 36. This downward force produces a clockwise rotational force on flexure plate 37-4 about the point where flexure plate 37-4 is mounted to the flexure support plate 39. Because of the rigidity of the flexure support ring 38, this rotational force translates into a clockwise rotational force on flexure plate 37-2 about the point where flexure plate 37-2 is mounted to the flexure support plate 39. These two rotational forces cause rotation about the intersection of the two planes in which the flexure plates 37-2 and 37-4 lie. This intersection occurs at intersection point 40.

Referring to exemplary FIG. 8, there is shown one embodiment of an alignment actuator 41. The alignment actuator 41 may be a tilt actuator or a lateral alignment actuator, as described above. The alignment actuator 41 contains a handle 42 and a threaded body 43. The threaded body 43 is threadably mounted through a fixed surface 44 and against a movable surface 45. The movable surface 45 is biased toward the fixed surface 44 by a spring 46 or other suitable biasing means. The mounting of the movable surface 45 determines whether the force by the alignment actuator 41 or the biasing by the spring 46 produces a lateral or rotational force. The alignment actuator 41 may include what is commonly referred to as a micrometer stage.

Referring to exemplary FIG. 9, there is shown a top view of the cradle assembly 3. Referring to exemplary FIG. 10, there is shown a cross-sectional view of the cradle assembly 3, taken along line 10—10 of FIG. 9. The cradle assembly 3 comprises a cradle 47 having a surface 48 and a side 49, a plurality of vacuum clamps 50, and a baseplate alignment assembly (not shown). The cradle includes side walls 52 and end walls 53 for securing a baseplate assembly (not shown) in the cradle 47. In the embodiment particularly shown in exemplary FIGS. 9 and 10, the baseplate alignment assembly (not shown) comprises a source of radiant energy 54, a Y-axis source lateral actuator 55, a Z-axis source lateral actuator 56, an X-axis cradle assembly tilt actuator 57, a Y-axis cradle assembly tilt actuator 58, a mirror 59, and an alignment analyzer 60. In another embodiment, the baseplate alignment assembly (not shown) comprises a source of radiant energy 54, an X-axis cradle assembly tilt actuator 57, a Y-axis cradle assembly tilt actuator 58, a mirror 59, and an alignment analyzer 60. In both embodiments, the mirror 59 is aligned below a hole 61 in the surface 48 of the cradle 47. Additionally, the source of radiant energy 54 and the alignment analyzer 60 may be combined in an auto-collimater or an auto-collimater/telescope.

Referring to exemplary FIG. 11, a cross-sectional view of a vacuum clamp 50 is shown in the open position. Exemplary FIG. 12 shows a cross-sectional view of a vacuum clamp 50 in the closed position. The surface 48 of the cradle 47 extends laterally beyond the side 49 of the cradle 47. A vacuum clamp 50 with a U-shaped cross-section is placed over the extension of the cradle 47, with one leg of the U-shape on each side of the extension. A pivot pin 62 is placed through each leg of the U-shape and through the extension of the cradle 47. In the open position, a baseplate assembly can be placed on the cradle 47. Once in place, a pneumatic tube (not shown) biases the vacuum clamp 50 to the closed position, securing the baseplate against movement.

In operation, as shown in exemplary FIG. 13, a baseplate assembly 63 is provided. The baseplate assembly 63 contains a spindle 64 and a spindle motor 65 for rotating an information-bearing disk, and a spindle servo (not shown) for controlling the speed of the spindle motor 65. The baseplate assembly 63 further contains an optics module assembly 66. The baseplate assembly 63 also contains a carriage motor (not shown) and a carriage assembly 67 for directing a beam of radiant energy from the optics module assembly 66 toward a position on the information-bearing disk, and a carriage control servo (not shown) for controlling the position of the carriage assembly. At this point, the carriage assembly 67 does not contain an actuator lens for focussing the beam of radiant energy on the information-bearing disk. The carriage assembly 67 may be held in place relative to the spindle 64 by a carriage stop (not shown).

The baseplate assembly 63 is placed on the surface 48 of the cradle 47 and secured with the vacuum clamps 50. A test

disk of glass or other suitable material (not shown) is placed on the spindle of the baseplate assembly **63**. The gripper assembly **2** is then lowered into the closed position.

The source of radiant energy **54** radiates two cradle alignment beams of radiant energy toward the mirror **59**. The first cradle alignment beam is reflected from the mirror **59**, then passes through the hole **61** in the cradle **47** and through the baseplate assembly **63**. The first cradle alignment beam reflects off the test disk and is received by the alignment analyzer **60**. The second cradle alignment beam is reflected from the mirror **59**, then passes through the hole **61** in the cradle **47** and through the baseplate assembly **63**. The second cradle alignment beam reflects off the substrate **20** and is received by the alignment analyzer **60**. By analyzing the relative positions of the first and second cradle alignment beams, the alignment analyzer **60** determines the tilt of the test disk with respect to the substrate **20**. It will be obvious that the mirror **59** may comprise two parallel mirrors, each reflecting one of the cradle alignment beams.

Tilt between the test disk and the substrate **20** is corrected in the following manner. The X-axis cradle assembly tilt actuator **57** tilts the cradle assembly **3** about the X-axis. The Y-axis cradle assembly tilt actuator **58** tilts the cradle assembly **3** about the Y-axis. Acting together, the cradle assembly tilt actuators **57**, **58** tilt the cradle assembly **3**, including the test disk, with respect to the substrate **20**. Because the substrate **20** is orthogonal to the tower optical axis, this action tilts the cradle assembly **3** with respect to the tower optical axis. Each of the actuators **57**, **58** may be an alignment actuator **41** as shown in exemplary FIG. **8**.

In one embodiment, lateral alignment of the cradle assembly **3** with respect to the tower optical axis is done mechanically, and is not tested or measured. In another embodiment, if the cradle alignment beam is not received by the alignment analyzer **60**, or is off-center when received by the alignment analyzer **60**, the position of the source of radiant energy **54** can be moved using the Y-axis source lateral actuator **55** and the Z-axis source lateral actuator **56**. As shown best in FIG. **9**, the mirror **59** is situated such that a change in the position of the source of radiant energy **54** along the Y-axis is translated into a change in the position of the cradle alignment beam along the Y-axis as it is received by the alignment analyzer **60**. The Y-axis source lateral actuator **55** effects this change in position. Similarly, a change in the position of the source of radiant energy **54** along the Z-axis is translated into a change in the position of the cradle alignment beam along the X-axis as it is received by the alignment analyzer **60**. The Z-axis source lateral actuator **56** effects this change in position. Each of the actuators **55**, **56** may be an alignment actuator **41** as shown in exemplary FIG. **8**.

In the embodiment particularly described below, all references to a coordinate system are made in accordance with reference coordinate system **24** shown in exemplary FIG. **5**. This reference coordinate system **24** is chosen for purposes of explanation only, and it will be obvious to one skilled in the art that any convenient coordinate system could be chosen without departing from the spirit and scope of the present invention.

Once aligned, the source of radiant energy **54** is turned off and the test disk is removed. If not previously aligned, the carriage assembly of the baseplate assembly **63** is moved in approximate alignment with the assembly axis, and an actuator lens is placed within the carriage assembly of the baseplate assembly **63** and is allowed to assume a natural rest position. The lever assembly **5** is lowered to the closed position.

A pressure differential is then created between the vacuum chuck **12** and the atmosphere. This pressure differential operates to hold the actuator lens against the vacuum chuck **12**, while maintaining the orientation of the actuator lens. Additionally, the optical center of the actuator lens is maintained at the intersection point **40**. This optical center may also be substantially at the center of mass of the actuator lens.

An adjustable power supply is attached to the radiant energy source within the optics module assembly **66**. The radiant energy source projects a lens alignment beam of radiant energy into the carriage assembly. Within the carriage assembly, the lens alignment beam passes through the penta prism and through the actuator lens. The lens alignment beam then passes through the substrate **20**, through the microscope objective lens **19**, and into the tower assembly **1**, where the lens alignment beam passes through the tower magnifying lens **6** and is received by the video camera **7**. The analysis assembly **9** then displays and analyzes the spot profile of the lens alignment beam.

If the lens alignment beam is not received by the video camera **7** and passed to the analysis assembly **9**, the X-axis lateral alignment actuator **21** and the Y-axis lateral alignment actuator **22** are used to move the microscope objective lens **19** laterally with respect to the tower assembly **1**. The X-axis lateral alignment actuator **21** and the Y-axis lateral alignment actuator **22** may be alignment actuators **41** as shown in exemplary FIG. **8**.

If the lens alignment beam is not focussed properly in the video camera **7** and analysis assembly **9**, the focus actuator **23** is used to move the microscope objective lens **19** toward or away from the tower assembly **1** until the lens alignment beam is in proper focus within the video camera **7** and analysis assembly **9**. The focus actuator **23** may be an alignment actuator **41** as shown in exemplary FIG. **8**.

Once focussed properly, the analysis assembly **9** analyzes the profile of the beam for coma and astigmatism, as the cradle alignment beam was previously analyzed. If these optical aberrations occur, the actuator lens tilt assembly **15** operates to minimize these aberrations by aligning the actuator lens. As described above, the X-axis tilt actuator **32** rotates the actuator lens about the X-axis. Likewise, the Y-axis tilt actuator **33** rotates the actuator lens about the Y-axis. Together, the actuator lens tilt assembly **15** can rotate the actuator lens in any direction with respect to the lens alignment beam, while maintaining the optical center or the center of mass of the actuator lens at the intersection point **40**.

Once the misalignment is corrected to within an acceptable tolerance, the gripper assembly **2**, including the vacuum chuck **12** and the actuator lens, is raised to the open position. A fastening agent is placed on the pedestals of the carriage assembly, and the gripper assembly **2** is again lowered to the closed position. The actuator lens is secured by the fastening agent to the carriage assembly, without changing the orientation of the actuator lens established by the actuator lens tilt assembly **15**. The fastening agent may be a selectably-curable adhesive, such as ultraviolet radiation-curable adhesive.

Once the fastening agent has cured, the actuator lens is tested for alignment. As above, a lens alignment beam is radiated through the actuator lens, the substrate **20**, the microscope objective lens **19**, the tower magnifying lens **6**, and into the video camera **7**. The analysis assembly **9** then analyzes the spot profile of the lens alignment beam. Each of the alignments described above may need to be adjusted

for this testing process. Depending on its configuration, the vacuum chuck **12** may need to be retracted or removed to avoid contacting and damaging the carriage assembly.

In another embodiment of the invention, the cradle assembly **3** may comprise a plurality of cradles **47**, a plurality of vacuum clamps **50**, and a baseplate alignment assembly (not shown). The cradles **47** may be movable with respect to the tower assembly **1**, and there may be either one baseplate alignment assembly (not shown) for each cradle **47**, or a single baseplate alignment assembly (not shown) which aligns only the cradle **47** presently in position with respect to the tower assembly **1**. Further, there may be a single source of radiant energy **54** and set of actuators **55**, **56**, **57**, **58** regardless of the number of cradles **47**, with one mirror **59** associated with each cradle **47**.

According to this embodiment, there may be a second tower assembly **1** identical to the first tower assembly **1** described above. In addition, there may be a second gripper assembly **2** associated with the second tower assembly **1** as described above. The second gripper assembly **2** will not contain a vacuum chuck **12**.

In operation, the first tower assembly **1** and first gripper assembly **2** operate as described in the previous embodiment. After fastening the actuator lens to the carriage assembly with the fastening agent, the cradle **47** containing the baseplate assembly **63** is moved beneath the second tower assembly **1** and second gripper assembly **2**. Again, a lens alignment beam of radiant energy is projected by the optics module assembly **66** through the same path in the second tower assembly **1** and second gripper assembly **2** as described with respect to the first tower assembly **1** and first gripper assembly **2**. The analysis assembly **9** associated with the second tower assembly **1** analyzes the spot profile of the lens alignment beam after the actuator lens is fastened to the baseplate assembly **63**. It will be obvious to one skilled in the art that, by allowing the vacuum chuck **12** to be removable or retractable, the first tower assembly **1** and first gripper assembly **2** may function as the second tower assembly **1** and second gripper assembly **2**, respectively.

It will be obvious to one skilled in the art that modifications to the above description of the invention may be made without departing from the spirit and scope of the invention. The scope of the invention, therefore, is indicated by the appended claims rather than the above description.

While this invention has been explained with reference to the structure disclosed herein, it is not confined to the details set forth and this application is intended to cover any modifications and changes as may come within the scope of the following claims:

What is claimed is:

1. A method for mounting an actuator lens to a carriage assembly, the method comprising the steps of:

positioning the carriage assembly in a baseplate assembly;

moving the baseplate assembly with respect to a tower assembly; moving a gripper assembly with respect to the tower assembly;

moving the actuator lens with respect to the tower assembly, wherein the baseplate, gripper and actuator lens respectively, define a baseplate optical axis, a gripper optical axis and actuator lens optical axis, and whereby the baseplate gripper assembly and actuator lens optical axes are aligned with said tower optical axis;

placing the baseplate assembly in a cradle assembly;

adjusting the focus of the actuator lens;

moving the gripper to an open position out of the tower optical axis;

applying a fastening agent to said carriage assembly; and

lowering said gripper to a closed position, whereby said actuator lens is secured to said carriage assembly by said fastening agent without changing the orientation of the actuator lens.

2. A method, as defined in claim **1**, wherein the step of moving the baseplate comprises:

moving said baseplate assembly with respect to said tower assembly laterally such that said baseplate optical axis and said tower optical axis intersect at a first intersection; and

rotating a first time said baseplate assembly with respect to said tower assembly about a first rotational axis through said first intersection and orthogonal to said baseplate optical axis and said tower optical axis.

3. A method, as defined in claim **2**, wherein said step of moving the actuator lens comprises:

moving said actuator lens with respect to said tower assembly laterally such that said actuator lens optical axis and said tower optical axis intersect at a second intersection; and

rotating a second time said actuator lens with respect to said tower assembly about a second rotational axis through said second intersection and orthogonal to said actuator lens optical axis and said tower optical axis.

4. A method, as defined in claim **3**, wherein said first rotating step comprises:

rotating said baseplate assembly with respect to said tower assembly about a first reference axis through said first intersection and coplanar with said first rotational axis; and

rotating said baseplate assembly with respect to said tower assembly about a second reference axis through said first intersection and coplanar with said first rotational axis and orthogonal to said first reference axis; whereby said baseplate assembly is rotated about said first rotational axis; and

said second rotating step comprises:

rotating said actuator lens with respect to said tower assembly about a third reference axis through said second intersection and coplanar with said first rotational axis; and

rotating said actuator lens with respect to said tower assembly about a fourth reference axis through said second intersection and coplanar with said second rotational axis and orthogonal to said third reference axis;

whereby said actuator lens is rotated about said second rotational axis.

5. A method, as defined in claim **2**, wherein said first rotating step comprises:

rotating said baseplate assembly with respect to said tower assembly about a first reference axis through said first intersection and coplanar with said first rotational axis; and

rotating said baseplate assembly with respect to said tower assembly about a second reference axis through said first intersection and coplanar with said first rotational axis and orthogonal to said first reference axis;

whereby said baseplate assembly is rotated about said first rotational axis.

6. A method, as defined in claim **1**, wherein said step of moving the actuator lens comprises:

moving said actuator lens with respect to said tower assembly laterally such that said actuator lens optical axis and said tower optical axis intersect at a second intersection; and

rotating a second time said actuator lens with respect to said tower assembly about a second rotational axis through said second intersection and orthogonal to said actuator lens optical axis and said tower optical axis.

7. A method, as defined in claim **6**, wherein said second rotating step comprises:

rotating said actuator lens with respect to said tower assembly about a third reference axis through said second intersection and coplanar with said first rotational axis; and

rotating said actuator lens with respect to said tower assembly about a fourth reference axis through said second intersection and coplanar with said second rotational axis and orthogonal to said third reference axis;

whereby said actuator lens is rotated about said second rotational axis.

8. A method for installing an actuator lens into an optical disc carriage assembly, the carriage assembly including an information bearing disc having a spindle, spindle motor, and optics module; the method comprising;

moving a first time a baseplate assembly with respect to a tower assembly, said baseplate assembly defining a baseplate optical axis, said tower assembly defining a tower optical axis, whereby said first moving step aligns said baseplate optical axis and said tower optical axis;

moving a second time an objective lens assembly with respect to said tower assembly, said objective lens assembly defining an objective lens optical axis, whereby said second moving step aligns said objective lens optical axis and said tower optical axis;

moving a third time said actuator lens with respect to said tower assembly, said actuator lens defining an actuator lens optical axis, whereby said third moving step aligns said actuator lens optical axis and said tower optical axis;

mounting the carriage assembly in said baseplate assembly;

mounting the baseplate assembly on a cradle assembly, the cradle assembly having a source of radiant energy, an analyzer and a mirror;

positioning the gripper assembly in a closed position over the carriage assembly;

determining the tilt of the optical disc;

correcting the tilt of the disc;

aligning the cradle assembly with respect to a tower optical axis;

removing the optical disc from the baseplate assembly;

positioning the gripper assembly in an open position out of the tower optical axis;

placing the actuator lens in the carriage assembly;

lowering the gripper assembly to the closed position;

temporarily securing the actuator lens to the gripper assembly while maintaining the same orientation;

projecting a lens alignment beam into the carriage assembly, through the actuator lens, and through the gripper assembly to the tower assembly, the tower assembly including an optical analyzer;

analyzing the lens alignment beam;

aligning the actuator lens in response to the analysis;

moving the gripper assembly to the open position;

applying a fastening agent to the carriage assembly;

lowering the gripper to a closed position, whereby the lens is secured to the carriage assembly without changing the orientation established thereof and;

releasing the actuator lens from the gripper assembly.

9. A method, as defined in claim **8**, wherein the gripper assembly includes a microscope objective lens and substrate.

10. A method, as defined in claim **8**, wherein the step of projecting a lens alignment beam is followed by the step of analyzing the alignment of the actuator lens using the analyzer and adjusting the X-Y position of the baseplate in response thereto.

11. A method, as defined in claim **10**, comprising the step of:

moving the microscope objective lens toward or away from the tower assembly until the lens alignment beam is in proper focus.

12. A method of installing an actuator as defined in claim **8**, wherein the step of analyzing the lens alignment beam comprises the steps of: analyzing

the focus using the analyzer; and

moving the microscope objective lens in response thereto.

13. A method, as defined in claim **8**, wherein the step of analyzing the lens alignment beam comprises the step of analyzing the lens alignment beam for coma and astigmatism and aligning the actuator lens in response thereto.

14. A method, as defined in claim **8**, wherein the step of analyzing the alignment beam includes the steps of:

receiving the lens alignment beam in a video camera and in an analysis assembly contained in the tower; and

adjusting a microscope objective toward or away from the tower until the lens alignment beam is in proper focus.

15. A method, as defined in claim **8**, wherein the carriage assembly includes one or more pedestals, and wherein the step of applying a fastening agent includes the step of applying a fastening agent to the pedestal.

16. A method, as defined in claim **8**, wherein the first moving step comprises:

moving the baseplate assembly with respect to the tower assembly laterally such that the baseplate optical axis and the tower optical axis intersect at a first intersection; and

rotating a first time the baseplate assembly with respect to the tower assembly about a first rotational axis through the first intersection and orthogonal to the baseplate optical axis and the tower optical axis.

17. A method, as defined in claim **16**, wherein the first rotating step comprises:

rotating the baseplate assembly with respect to the tower assembly about a first reference axis through the first intersection and coplanar with the first rotational axis; and

rotating the baseplate assembly with respect to the tower assembly about a second reference axis through the first intersection and coplanar with the first rotational axis and orthogonal to the first reference axis;

whereby the baseplate assembly is rotated about the first rotational axis.

18. A method, as defined in claim **8**, wherein the third moving step comprises:

moving the actuator lens with respect to the tower assembly laterally such that the actuator lens optical axis and the tower optical axis intersect at a second intersection; and

rotating a second time the actuator lens with respect to the tower assembly about a second rotational axis through the second intersection and orthogonal to the actuator lens optical axis and the tower optical axis.

19. A method, as defined in claim **18**, wherein the second rotating step comprises:

rotating the actuator lens with respect to the tower assembly about a third reference axis through the second intersection and coplanar with the first rotational axis; and

rotating the actuator lens with respect to the tower assembly about a fourth reference axis through the second intersection and coplanar with the second rotational axis and orthogonal to the third reference axis;

whereby the actuator lens is rotated about the second rotational axis.

20. A method, as defined in claim **8**, wherein the third moving step comprises:

moving the actuator lens with respect to the tower assembly laterally such that the actuator lens optical axis and the tower optical axis intersect at a second intersection; and

rotating a second time the actuator lens with respect to the tower assembly about a second rotational axis through the second intersection and orthogonal to the actuator lens optical axis and the tower optical axis.

21. A method of aligning a lens, as defined in claim **8**, wherein the first rotating step comprises:

rotating the baseplate assembly with respect to the tower assembly about a first reference axis through the first intersection and coplanar with the first rotational axis; and

rotating the baseplate assembly with respect to the tower assembly about a second reference axis through the first intersection and coplanar with the first rotational axis and orthogonal to the first reference axis;

whereby the baseplate assembly is rotated about the first rotational axis; and

the second rotating step comprises:

rotating the actuator lens with respect to the tower assembly about a third reference axis through the second intersection and coplanar with the first rotational axis; and

rotating the actuator lens with respect to the tower assembly about a fourth reference axis through the second intersection and coplanar with the second rotational axis and orthogonal to the third reference axis;

whereby the actuator lens is rotated about the second rotational axis.

22. A method as defined in claim **8** wherein the step of adjusting the focus of the actuator lens comprises the steps of:

directing a beam of radiant energy from source, through the actuator lens, and to an optical analyzer in the tower; and

analyzing the focus of the beam received by the analyzer; and adjusting the position of the gripper in response to the analysis.

23. The method as defined in claim **8** wherein the step of correcting the tilt further comprises the steps of:

directing two cradle alignment beams, from the cradle assembly radiant energy source, the first beam being directed to the mirror, to the optical disc, and to the alignment analyzer;

the second beam being directed to the mirror, the gripper and to the alignment analyzer; and

comparing the relative position of the first and second beams on the alignment analyzer and adjusting the position of the cradle in response thereto.

24. An apparatus for installing an actuator lens in a carriage assembly, the actuator lens defining as actuator optical axis and an actuator optical center within a baseplate using a beam of radiant energy, comprising:

a frame;

a cradle assembly for holding the baseplate, the cradle assembly mounted to the frame with at least one degree of freedom of motion; the carriage assembly, being mounted to the baseplate, the carriage assembly including an optical disc, and spindle motor and pedestal for holding the actuator lens;

a tower assembly defining a tower axis and mounted to the frame, the cradle assembly and the tower assembly defining an assembly axis for receiving the beam of radiant energy along the tower axis and analyzing the spot profile of the beam of radiant energy;

a lever assembly positioned in a closed position, rotatably mounted to the frame; and

a gripper assembly mounted to the lever assembly, comprising:

an objective lens defining an objective optical axis;

an objective lens assembly mounted to the objective lens, for selectively holding the actuator lens stationary relative to the objective lens;

an objective lens alignment assembly for aligning the objective lens with the tower assembly and the cradle assembly by aligning the objective optical axis laterally with respect to the assembly axis when the lever assembly is in the closed position; and

an actuator lens tilt assembly for aligning the actuator lens with the tower assembly and the cradle assembly by rotating the actuator optical axis about an axis orthogonal to the assembly axis when lever assembly is in the closed position;

whereby when the lever assembly is in the closed position the gripper assembly, the tower assembly, the cradle assembly, the baseplate, and the actuator lens tilt assembly are positioned with respect to each other such that the beam of radiant energy can be used to align the actuator lens with the baseplate by adjusting the relative position of alignment of one or more of the objective lens assembly, the cradle assembly and the actuator lens with respect to the tower assembly, and whereby when the lever assembly is in the open position and the actuator lens is removed, and a fastening agent is applied to the pedestal, when the lever assembly is closed the actuator lens is secured by the fastening agent without changing the alignment of the actuator lens.

25. An apparatus as defined in claim **24**, further comprising:

a source of radiant energy for projecting the beam of radiant energy into the tower assembly along a beam axis;

means for determining the tilt alignment of the beam axis with respect to the tower axis;

a first tilt actuator for rotating the beam axis about a first repositioning axis orthogonal to the tower axis; and

a second tilt actuator for rotating the beam axis about a second repositioning axis orthogonal to the tower axis and the first repositioning axis.

26. An apparatus as defined in claim 24, further comprising:

a source of radiant energy for projecting the beam of radiant energy into the tower assembly along a beam axis;

means for determining the lateral alignment and tilt alignment of the beam axis with respect to the tower axis;

a first lateral actuator for repositioning the beam axis laterally with respect to the tower axis along a first repositioning axis orthogonal to the tower axis;

a second lateral actuator for repositioning the beam axis laterally with respect to the tower axis along a second repositioning axis orthogonal to the tower axis and the first repositioning axis;

a first tilt actuator for rotating the beam axis about the first repositioning axis; and

a second tilt actuator for rotating the beam axis about the second repositioning axis.

27. An optical disc drive system having a carriage assembly with an actuator lens mounted therein by the method according to claim 1, 8 or 24.

28. A method for installing an actuator lens into an optical disc carriage assembly, the carriage assembly including an information bearing disc having a spindle, spindle motor and optics module; the method comprising:

moving a first time said baseplate assembly with respect to a tower assembly, said baseplate assembly defining a baseplate optical axis, said tower assembly defining a tower optical axis, whereby said first moving step aligns said baseplate optical axis and said tower optical axis;

moving a second time an objective lens assembly with respect to said tower assembly, said objective lens assembly defining an objective lens optical axis, whereby said second moving step aligns said objective lens optical axis and said tower optical axis; and

moving a third time said actuator lens with respect to said tower assembly, said actuator lens defining an actuator lens optical axis, whereby said third moving step aligns said actuator lens optical axis and said tower optical axis;

positioning the carriage assembly in a baseplate assembly;

positioning the baseplate assembly on a cradle assembly, the cradle assembly having a source of radiant energy and a mirror;

positioning the gripper assembly in a closed position over the carriage assembly determine the tilt of the optical disc;

correcting the tilt of the disc;

aligning the cradle assembly with respect to a tower optical access;

removing the optical disc from the baseplate assembly;

positioning the gripper assembly in an open position out of the tower optical access;

placing the actuator lens in the carriage assembly;

lowering the gripper assembly to the closed position;

temporarily securing the actuator lens to the gripper assembly while maintaining the same orientation;

project a light beam into the carriage assembly and through the actuator lens, and through the gripper assembly to the tower assembly, the tower assembly including an optical analyzer;

analyzing the lens alignment beam (add lens above);

aligning the actuator lens in response to the analysis;

moving the gripper assembly to the open position;

applying a fastening agent to the carriage assembly;

lowering the gripper to a closed position, where by the lens is secured to the carriage assembly without changing the orientation established thereof.

[57] **ABSTRACT**

A microscope objective, and microscope incorporating same, are disclosed. A representative embodiment of the objective comprises, arranged on an optical axis, a front lens group having positive refractive power disposed on the object side, a rear lens group having negative refractive power disposed on the image side, and a corrective lens group interposed between the front and rear lens groups. The corrective lens group is axially movable and comprises a pair of meniscus lens elements each of which having a convex surface oriented toward each other. The corrective lens group serves to correct aberrations arising from a cover glass or other refractive body situated between the specimen being observed and the objective lens. To such end, the objective preferably satisfies the conditions:

$$|1/f_c| \leqq |1/f| \times 0.02$$

$$0.95 \leqq |m| \leqq 1.05$$

wherein f is the overall refractive power of the microscope objective lens, and f_c and m are the refractive power and magnification, respectively, of the corrective lens group.

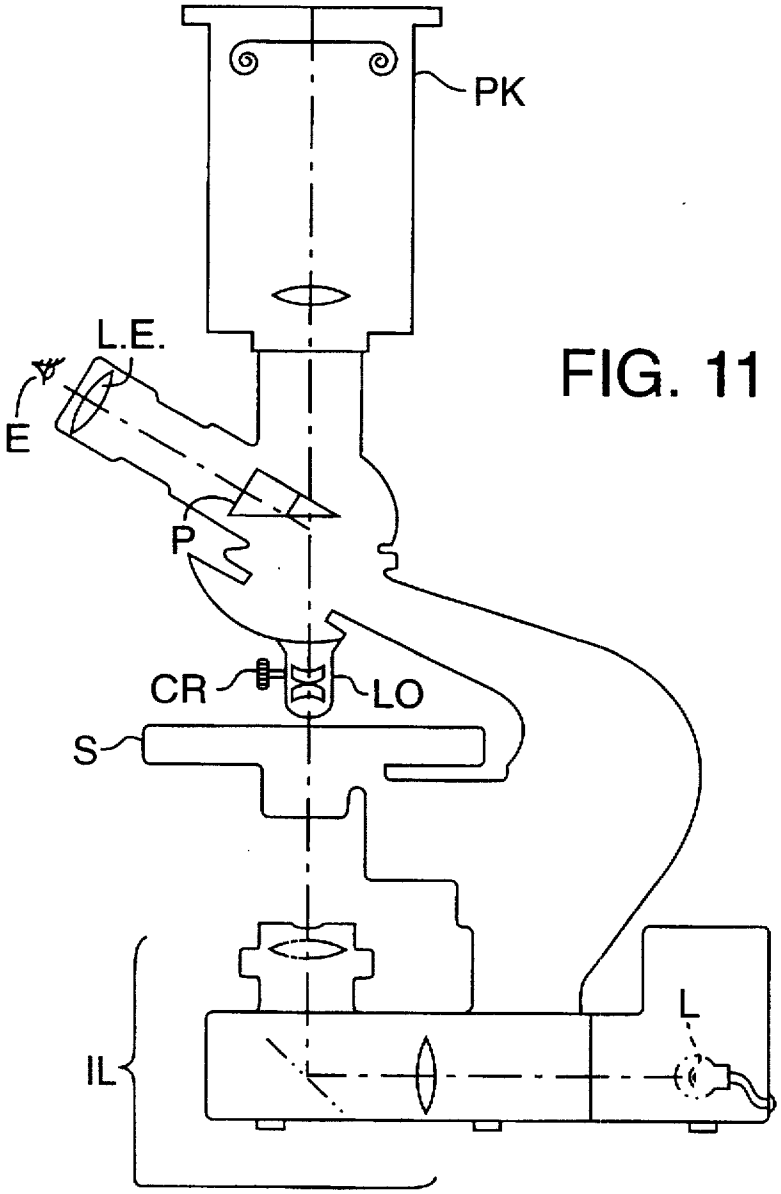

FIG. 11

MICROSCOPE OBJECTIVE LENS AND A MICROSCOPE INCORPORATING SAME

FIELD OF THE INVENTION

This invention pertains to a microscope objective lens and a microscope incorporating the objective lens. Specifically, this invention pertains to a microscope objective lens that can produce an excellent quality image of a specimen under a cover glass or other refractive body, despite any thickness variations in the refractive body.

BACKGROUND OF THE INVENTION

An objective lens on a microscope, especially a microscope used for biology or medicine, must frequently observe a specimen situated beneath a cover glass or other refractive body such as water, translucent gel or plastic, or the like. Thus, light from the specimen must pass through the thickness of the, for example, cover glass (an optical distance equal to the product of the thickness of the cover glass times the refractive index of the cover glass) and through an air layer between the cover glass and the objective. The cover glass produces a positive spherical aberration, and it is preferable that the objective lens be able to correct this aberration.

Due to manufacturing errors and/or tolerances, a cover glass can have substantial variations in thickness, although typically these variations are relatively small. Aberrations that accompany such variations in cover glass thickness are commonly corrected by moving, along an optical axis, certain lens elements or lens groups in the objective lens.

With medical and biological microscopes, substantial aberrations can also arise whenever the microscope is used to observe a specimen that is suspended in an aqueous medium in a dish such as a petri dish or cell culture dish, wherein light from the specimen must also pass through the dish before entering the objective. In such instances, the depth of the aqueous medium and thickness of the dish can vary markedly.

Japan Kôkai patent document nos. SHO 59-100409 and SHO 60-205521, (the priority documents for U.S. Pat. Nos. 4,588,264 and 4,666,256, respectively) disclose microscope objective lenses that are able to correct changes in aberrations in situations when a cover glass, a dish and water, or other variable-thickness refractive body is interposed between the specimen and the objective lens. The microscope objective lenses disclosed in these documents employ a "corrective" lens group in which a negative meniscus lens element is laminated on each side of a biconvex lens element. Such a corrective lens group, which is normally movable along the optical axis of the objective lens, is conventionally situated between a front lens group and a rear lens group in the objective lens.

Unfortunately, whereas such objective lenses provide some correction of aberrations, further improvement is desirable in view of the increasing demands placed on the performance of research microscopes. Specifically, conventional microscope objective lenses as described above can satisfactorily correct spherical and chromatic aberrations as well as image-plane distortions to a certain extent. But, coma is frequently inadequately corrected for optimum image quality under some conditions of use. In addition, conventional objectives exhibit residual movement of the image point during attempts to effect such corrections. Furthermore, the overall focal length of a conventional microscope objective lens is narrow, and the amount of variation in cover-glass thickness that can be corrected by such an objective lens is relatively small and thus inadequate for certain applications.

SUMMARY OF THE INVENTION

An object of the present invention is to provide a microscope objective lens that can sufficiently correct various aberrations and eliminate movement of the image point so as to consistently provide excellent image formation, even when the thickness of an interposed refractive body such as a cover glass, dish, or the like varies over a broad range.

Another object is to provide a microscope incorporating such an objective lens.

The foregoing objects are satisfied by a microscope objective lens, and microscope incorporating such an objective, according to the present invention.

A preferred embodiment of the objective lens comprises, in order from the object side to the image side on an optical axis, a front lens group, a rear lens group, and a corrective lens group disposed between the front and rear lens groups. The front lens group has a positive refractive power that converges light from the object. The rear lens group has a negative refractive power.

The corrective lens group is axially moveable in the air space located between the front and rear lens groups, and comprises a pair of meniscus lens elements. Each of the meniscus lens elements, which can be cemented or not cemented, has a convex surface. The meniscus lens elements are disposed on the optical axis such that the convex surfaces are oriented toward each other.

A microscope objective lens according to the present invention preferably satisfies the following conditions:

$$|1/f_c| \leqq |1/f| \times 0.02$$

$$0.95 \leqq |m| \leqq 1.05$$

wherein f is the overall refractive power of the microscope objective lens, and f_c and m are the refractive power and magnification, respectively, of the corrective lens group.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is an optical diagram showing general aspects of a preferred embodiment of a microscope objective lens according to the present invention, as well as specific aspects of Example Embodiment 1;

FIG. **2** includes various aberration diagrams for Example Embodiment 1 when used with a cover glass having "zero" thickness. Specifically, FIG. **2***a* shows spherical aberration, FIG. **2***b* shows astigmatism, FIG. **2***c* shows distortion, and FIG. **2***d* shows meriodonal coma;

FIG. **3** includes various aberration diagrams for Example Embodiment 1 when used with a cover glass having a thickness of 5 mm. Specifically, FIG. **3***a* shows spherical aberration, FIG. **3***b* shows astigmatism, FIG. **3***c* shows distortion, and FIG. **3***d* shows meriodonal coma;

FIG. **4** includes various aberration diagrams for Example Embodiment 1 when used with a cover glass having a thickness of 10 mm. Specifically, FIG. **4***a* shows spherical aberration, FIG. **4***b* shows astigmatism, FIG. **4***c* shows distortion, and FIG. **4***d* shows meriodonal coma;

FIG. **5** is an optical diagram showing specific aspects of Embodiment 2;

FIG. **6** includes various aberration diagrams for Example Embodiment 2 when used with a cover glass having "zero"

thickness. Specifically, FIG. **6***a* shows spherical aberration, FIG. **6***b* shows astigmatism, FIG. **6***c* shows distortion, and FIG. **6***d* shows meriodonal coma;

FIG. **7** includes various aberration diagrams for Example Embodiment 2 when used with a cover glass having a thickness of 9.4 mm. Specifically, FIG. **7***a* shows spherical aberration, FIG. **7***b* shows astigmatism, FIG. **7***c* shows distortion, and FIG. **7***d* shows meriodonal coma;

FIG. **8** includes various aberration diagrams for Example Embodiment 2 when used with a cover glass having a thickness of 15 mm. Specifically, FIG. **8***a* shows spherical aberration, FIG. **8***b* shows astigmatism, FIG. **8***c* shows distortion, and FIG. **8***d* shows meriodonal coma;

FIG. **9** includes various aberration diagrams for Example Embodiment 2 when used with a layer of water having a "thickness" of 10.6 mm. Specifically, FIG. **9***a* shows spherical aberration, FIG. **9***b* shows astigmatism, FIG. **9***c* shows distortion, and FIG. **9***d* shows meriodonal coma;

FIG. **10** includes various aberration diagrams for Example Embodiment 2 when used with a layer of water having a "thickness" of 16.8 mm. Specifically, FIG. **10***a* shows spherical aberration, FIG. 10*b* shows astigmatism, FIG. **10***c* shows distortion, and FIG. 10*d* shows meriodonal coma; and

FIG. **11** is an optical diagram of a representative embodiment of a microscope including an objective lens according to the present invention.

DETAILED DESCRIPTION

A "positive" distance or direction along an optical axis extends from left ("object side") to right ("image side") in an optical diagram; a "negative" distance or direction extends from right to left.

The "curvature radius" of an optical surface (such as a surface of a lens element) is "positive" whenever the center of curvature lies to the right of the surface, and "negative" whenever the center of curvature lies to the left of the surface.

An "interfacial distance" is the distance, along an optical axis, between adjacent optical surfaces on separate optical elements.

In the following description, it will be understood that a "cover glass" can be any of various refractive bodies as listed above that can be placed over a specimen for protection from physical trauma, drying, or other purpose. Other refractive bodies can also behave as a cover glass, such a clear plastic surface supporting living cells being observed using a microscope objective.

General aspects of a preferred embodiment of a microscope objective lens according to the present invention are shown in FIG. **1**. The objective lens comprises, in order from the object side to the image side on an optical axis A, a front lens group F having a positive refractive power, a rear lens group R having a negative refractive power, and a corrective lens group C interposed between the front and rear lens groups. The corrective lens group C is axially moveable in an air space located between the front and rear lens groups.

In the FIG. **1** embodiment, the corrective lens group C comprises a pair of meniscus lenses **M1**, **M2**. Each of the meniscus lenses **M1**, **M2**, which generally can be either a singlet or a cemented lens, has a convex surface **34**, **35**, respectively. The meniscus lenses **M1**, **M2** are disposed on the optical axis such that the convex surfaces **34**, **35** are oriented toward each other.

A microscope objective lens according to the present invention preferably satisfies the following conditions:

$$|1/f_c| \leq |1/f| \times 0.02$$

$$0.95 \leq |m| \leq 1.05$$

wherein f is the overall refractive power of the objective lens, and f_c and m are the refractive power and magnification, respectively, of the corrective lens group C.

The front lens group F produces a large negative spherical aberration; this negative spherical aberration is corrected a required amount by the corrective lens group C. The rear lens group R also provides spherical aberration correction, to yield an overall excellent correction of spherical aberration by the entire objective lens.

The corrective lens group C is situated in convergent light from the front lens group F. If the corrective lens group C is moved frontwardly, the height (from the axis A) of incident light entering the corrective lens group C becomes taller; thus, the corrective lens group C produces a large positive spherical aberration. Conversely, if the corrective lens group C is moved rearwardly, the height of incident light entering the corrective lens group C becomes shorter; thus, the corrective lens group C produces a small positive spherical aberration. Consequently, it is possible to correct spherical aberrations, such as spherical aberrations arising from a cover glass having a varying thickness interposed between the objective lens and an object being imaged by the objective lens, by axially moving the corrective lens group C.

The refractive power $1/f_c$ of the corrective lens group C is preferably about 2% or less of the overall refractive power 1/f of the objective lens. Thus, the corrective lens group C preferably has relatively no refractive power. Moving such a corrective lens group C along the optical axis A advantageously will effect virtually no movement of the image point, even during a change in spherical aberration.

In conventional telecentric optical systems, not limited to microscope objective lenses, used to visualize various points on an object, the effect of variations in the thickness of a cover glass or the like, disposed between the object and the optical system, on a light path is the same whether the object point is situated on- or off-axis. In other words, the optical effect of the cover glass is uniform across the entire image plane. Consequently, in a telecentric lens system, variations in the thickness of the cover glass will not directly cause coma aberration; but, coma aberration will appear to change due to the effects of changes in spherical aberration.

In addition, the thickness of a cover glass will not have any effect on the paths of principal rays in a telecentric optical system. In an objective according to the present invention, because there is virtually no movement of the image point accompanying any axial movement of the correction lens group C, there is no movement of the image point. This is because the several optical light path lengths between the object and the objective lens are always constant.

Further with respect to an objective lens according to the present invention, the front lens group F produces negative spherical aberration; but, preferably, other aberrations are preferably well corrected by this group. It is especially desirable to correct any inner and outer coma that exist at the sine condition. The corrective lens group C should also possess similar characteristics. Namely, while the corrective lens group C produces positive spherical aberration in order to correct the negative spherical aberration produced by the front lens group, other aberrations imparted by the corrective lens group C are preferably minimal; it is especially desir-

able that the corrective lens group suppress the production of inner and outer coma. In other words, it is desirable for the light flux that has passed through the cover glass, the front lens group F and the corrective lens group C to be always in the same aberration-corrected state, regardless of the thickness of the cover glass. Besides correcting spherical aberration, the corrective lens group C should not, as much as possible, produce any of its own aberrations.

For example, assuming a certain thickness of the cover glass and a certain axial position of the corrective lens group C, it is possible, by using the corrective lens group C to correct any inner coma produced by the front lens group C, to have excellent aberrational correction overall. However, if the thickness of the cover glass were to change, and if the corrective lens group C were to be moved appropriately to correct any new spherical aberration arising from the change, it is not certain that coma would remain in the same excellent state as before movement. Consequently, the corrective lens group C should suppress as much as possible the production of aberrations other than spherical aberration.

While the corrective lens group C should not produce aberrations other than spherical aberration, there is no specific restriction on the refractive power required to achieve that purpose. However, the refractive power of the corrective lens group C should be small enough so as to sufficiently minimize movement of the image point. Of course, if the corrective lens group were made of parallel planar elements rather than refractive elements, there would be no movement of the image point upon movement of the corrective lens group C. This would be due to the zero refractive power and unitary "magnification" (of an object at infinity) of planar elements. (These conditions also apply for an image magnification of 1 for an object at any object distance from the objective.) If the corrective lens group C behaved the same as parallel planar elements with respect to paraxial rays, it would be necessary for the corrective lens group C to fulfill the same conditions as parallel planar elements; i.e., it would be necessary for the refractive power of the corrective lens group C to be sufficiently small, while simultaneously having a magnification of about 1.

To perform the aberration-correction functions described above while simultaneously restricting movement of the image point, the corrective lens group C preferably comprises a pair of meniscus lenses arranged with their convex faces facing each other. Also, each meniscus lens is preferably a cemented lens so as to provide excellent correction of chromatic and spherical aberrations. Alternatively, one of the meniscus lenses can be a single lens element and the other can be a cemented lens.

In order to satisfactorily limit movement of the image point, the absolute value of the refractive power of the corrective lens group C is preferably 2% or less of the overall refractive power of the objective lens, and the magnification of the corrective lens group C is preferably within 5% of unity, i.e., in the range from 0.95 to 1.05. This is because movement of the image point becomes great if these ranges are exceeded, which increases the number of practical problems.

The magnification of the corrective lens group C when its refractive power is zero is defined as, for an object placed at infinity: (height of light rays exiting the corrective lens group)/(height of incident light rays entering the corrective lens group). The magnification of the corrective lens group C when its refractive power is not zero is defined as: (distance from the lens surface in the corrective lens group closest to the image surface to the focal point)/(focal length).

EXAMPLE EMBODIMENT 1

FIG. **1** shows specific features of Example Embodiment 1 of a microscope objective lens, comprising (in order from the object side): a front lens group F with a positive refractive power that converges the light emitted from the object, a rear lens group R with a negative refractive power, and a corrective lens group C axially interposed in the air space between the front lens group F and rear lens group R. The corrective lens group C is movable along the optical axis A.

The corrective lens group C comprises a pair of cemented meniscus lenses **M1** and **M2**, both of which being arranged on the optical axis with their respective convex faces **34**, **35** oriented toward each other. Example Embodiment 1 is telecentric on the object side, with a service magnification of 40× and an NA (numerical aperture) of 0.5.

Table 1, below, lists numeric specifications for Example Embodiment **1**. The front lens group F comprises lens elements **1** through **8**, the corrective lens group C comprises lens elements **9** through **12**, and the rear lens group comprises lens elements **13** through **15**. The interfacial distance d_{31} between the front lens group F and the corrective lens group C, and the interfacial distance d_{37} between the corrective lens group C and the rear lens group R are variable, and $d_{31}+d_{37}=38.765$. Additionally, the corrective lens group C has a focal length f_c wherein $f_c=\infty$. In other words, the refractive power ($1/f_c$) of the corrective lens group C is 0 (zero) and the magnification m of the corrective lens group C of an infinitely distant object is m=+1.000.

Table 2 shows d_{31}, d_{37}, and the image distance (distance from the most imagewise lens surface **41** to an image plane) for cover-glass thicknesses of 0, 5, and 10. FIGS. **2***a*–**2***d*, **3***a*–**3***d*, and **4***a*–**4***d* show the corresponding aberration graphs. The refractive index n_{CG} of the cover glass in this example is $n_{CG}=1.52216$, and the Abbe number ν_d is $\nu_d=58.8$. From Table 2, it can be seen that the image distance is held constant by appropriately moving the corrective lens group C, even when there is a substantial change in the cover glass thickness. As is shown in the various aberration graphs, it can be seen that the microscope objective lens of this embodiment has superior imaging properties and performance.

TABLE 2

Cover Glass Thickness	d_{31} (mm)	d_{37} (mm)	Image Distance
0	16.312	22.453	200 mm
5	21.712	17.053	200 mm
10	30.312	8.453	200 mm

EXAMPLE EMBODIMENT 2

An objective lens configuration according to Example Embodiment 2 is shown in FIG. **5**, and the numeric specifications for this embodiment are shown in Table 3. Lens elements **1** through **8** comprise the front lens group F, lens elements **9** through **12** comprise the corrective lens group C, and lens elements **13** through **15** comprise the rear lens group R. In addition, the interfacial distance d_{32} between the front lens group F and the corrective lens group C, and the interfacial distance d_{38} between the corrective lens group C and the rear lens group R are variable; furthermore, $d_{32}+d_{38}=31.5$. The focal length f_c of the corrective lens group C is $f_c=\infty$. In other words, the refractive power ($1/f_c$) of the corrective lens group C is 0 (zero) and the magnification m of the corrective lens group C (of an infinitely distant object) is m=+1.000.

The microscope objective lens in this Example Embodiment is telecentric on the object side, with a service magnification of 20 times and a numerical aperture (NA) of 0.35.

TABLE 3

42	14.744				

Table 4, below, shows d_{32}, d_{38}, and the image distance (distance from the most imagewise lens surface **42** to an image plane) for cover-glass thicknesses of 0, 9.4 and 15.0. FIGS. ***6a–6d***, ***7a–7d***, and ***8a–8d*** show the corresponding aberration graphs. The refractive index n_{CG} of the cover glass in this example is $n_{CG}=1.51454$, and the Abbe number ν_d is $\nu_d=54.6$. From Table 4, it can be seen that the image distance is held constant by appropriately moving the corrective lens group C, even when there is a substantial change in the cover glass thickness.

TABLE 4

Cover Glass Thickness	d_{31} (mm)	d_{37} (mm)	Image Distance
0	8.2	23.3	198.5 mm
9.4	16.5	15.0	198.5 mm
15.0	26.8	4.7	198.5 mm

Table 5, below, shows d_{32}, d_{38}, and the image distance in instances where water is used instead of a cover glass and the water thickness is either 10.6 or 16.8. FIGS. ***9a–9d***, and ***10a–10d*** show corresponding aberration graphs. The refractive index n_W of the water is $n_W=1.331$ and the Abbe number ν_d is $\nu_d=54.1$. As is shown in Table 5, it can be seen that the image distance is held constant by appropriately moving the corrective lens group C, even when there is a substantial change in the thickness of a water layer over the object.

TABLE 5

Water Thickness	d_{32} (mm)	d_{38} (mm)	Image Distance
10.6	16.5	15.0	198.5 mm
16.8	26.8	4.7	198.5 mm

As is shown in the various aberration graphs (FIGS. ***6a–6d***, ***7a–7d***, ***8a–8d***, ***9a–9d***, and ***10a–10d***), it can be seen that the microscope objective lens of this embodiment has superior imaging properties and performance.

FIG. **11** shows, in combination, a microscope and an objective lens LO according to the present invention. Referring to FIG. **11**, light flux exiting a light source L passes through an illumination optical system IL to provide Koehler illumination of the specimen (specimen not shown, but would normally be situated on the stage S beneath the microscope objective lens LO). The specimen is normally placed on a glass slide overlaid by a cover glass (not shown). The microscope objective lens LO, such as a lens according to either of Example Embodiments 1 and 2, and the eyepiece lens LE are used to observe the specimen, whereby the specimen is directly observed by the observer's eye E. The microscope in this embodiment is equipped with a light path-splitting prism P situated between the microscope objective lens LO and eyepiece lens LE, so that a light flux can be directed to a photographic camera PK if desired for photomicrography.

Further according to the present invention, any aberrations produced by the cover glass are corrected without moving the image point by axially moving the moveable lens group C shown in FIG. **1** and FIG. **5**. This can be conveniently performed by turning a correction ring CR that is operably connected to the correction lens group G.

With this invention, as described above, aberrations can be sufficiently corrected without imparting any movement of the image point, even when the thickness of a cover glass, water layer, dish bottom, etc., existing between the specimen and the objective lens varies over a substantial range. Thus, a microscope objective lens, and a microscope incorporating such a lens, are provided that produce consistently excellent images of the specimen.

The described embodiments are to be considered in all respects only as illustrative and not restrictive. The scope of the invention, therefore, resides within the text and spirit of the appended claims rather than by the foregoing description. All changes that come within the meaning and range of

equivalency of the claims are to be embraced within the scope of the claims.

What is claimed is:

1. A microscope objective lens, comprising in an order from a specimen side:

(a) a front lens group having positive refractive power, the front lens group being operable to converge light from a specimen disposed objectwise of the front lens group;

(b) a rear lens group having negative refractive power;

(c) a corrective lens group that is axially moveable and is situated in an air space located between the front and rear lens groups, the corrective lens group having a refractive power $1/f_c$ and a magnification m, and comprising first and second meniscus lenses each having a convex surface oriented toward the other convex surface; and

(d) wherein the objective lens has an overall refractive power 1/f and satisfies the conditions:

$$|1/f_c| \leqq |1/f| \times 0.02$$

$$0.95 \leqq |m| \leqq 1.05.$$

2. The microscope objective lens of claim **1**, wherein each of the first and second meniscus lenses is a cemented lens.

3. A microscope, comprising:

(a) the microscope objective lens of claim **1**; and

(b) an eyepiece lens axially disposed relative to the objective lens and operable to provide a viewable image of a specimen placed objectwise of the objective lens.

4. The microscope of claim **3**, further comprising

(a) a light source; and

(b) an illumination optical system for illuminating the specimen with light from the light source.

[57] **ABSTRACT**

A stereoscopic endoscope comprises an elongate inserted section, an illuminating light system, an objective optical system at the distal end of the inserted section for forming a plurality of images having parallax between them through a plurality of incident pupils, and a common relay lens system for transmitting the plurality of images to the proximal end of the inserted section. The objective optical system includes a plurality of front lens groups and a rear lens group, wherein the plurality of front lens groups comprise two negative lens units arranged in parallel with each other and the rear lens group comprises a single positive lens group. The two negative lens units are arranged to be substantially symmetrically concentric about an optical axis of the single positive lens group and spaced to be afocal. This arrangement allows the plurality of images having parallax between them to be substantially superimposed on one another for transmission by the common relay lens system or for reception by electronic image pickup devices.

STEREOSCOPIC ENDOSCOPE OBJECTIVE LENS SYSTEM HAVING A PLURALITY OF FRONT LENS GROUPS AND ONE COMMON REAR LENS GROUP

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to a stereoendoscope wherein images having passed through plural incident pupils are transmitted by common relay optical systems so that an observation providing a stereo-feel may be possible.

2. Description of the Related Art

Recently, particularly in the surgical field, there is known a so-called endoscope operation wherein, in order to reduce the burden on the patient, without opening the abdomen, a small hole is made in the abdominal part, and an endoscope is inserted through the hole for the observation and treatment. In this field, the operation has been already made by directly and stereoscopically viewing the affected part with both eyes and therefore, even in the endoscope operation, stereo-inspection is strongly desired. If the stereo-inspection can be made, the operation will be easy, the operation time will be reduced and the hardship on the patient will be further reduced.

As a stereo-inspection endoscope whereby stereo-inspection is possible, there is a first related art example suggested in a Japanese patent application No.309078/1992 shown in FIG. **1A** wherein two identical optical systems are arranged in parallel and the images formed by the objective optical systems **401** and **401'** are transmitted for a predetermined distance by the transmitting optical systems **402** and **402'** (in this case, relay lens systems) and are taken by such image taking devices **403** and **403'** as CCD's.

The taken pair of the right and left images are converted to electrical signals and are displayed in a TV monitor (not illustrated). At this time, when the displayed right and left images are switched at a high speed and simultaneously shutter spectacles synchronized with the images are used, the image for the right eye will be observed with the right eye and the image for the left eye will be observed with the left eye so as to be able to be stereo-inspected.

Also, as another type stereoendoscope, there is a second related art example suggested in a Japanese patent application No.28278/1993 shown in FIG. **2A** wherein the objective optical system **414** and the relay lens system **415** which is a transmitting optical system are formed of one axially symmetrical optical system. A prism **416** is arranged at the rear end of the relay lens system **415** and a pair of right and left images having a parallax are formed and taken in the image taking devices **417** and **417'** by spatially dividing the pupil into two with the prism. FIGS. **1B** and **2B** on the left side of FIGS. **1A** and **2A** show respective incident pupils.

In order to make a stereo-inspection, it is necessary to obtain a pair of right and left images having a parallax from each other. Therefor, the incident pupil for the right image of the optical system and the incident pupil for the left image must be spatially separated. Also, the magnitude of the stereo-feel in the case of the stereo-inspection is proportional to the center distance between the right and left incident pupils.

In the two above-mentioned related art examples, in the case of the first type in which the same two optical systems are arranged, when the objective optical systems **401** and **401'** to the image taking means **403** and **403'** are separately formed and the left and right incident pupils **407** and **407'** are separately positioned, images having a parallax from each other will be obtained. The center distance d between the left and right incident pupils **407** and **407'** coincides with the optical axis distance D between the left and right objective optical systems **407** and **407'**.

In the second type in which the pupil is divided among the above-mentioned related art, the objective optical system **414** and transmitting optical system **415** are formed of one axially symmetrical optical system and the pupil is one in this part but, when this one pupil is spatially divided into two by the pupil dividing means (in the above mentioned case, the pupil dividing prism) **416** and respective images are produced, images having a parallax from each other will be obtained. The center distance d between the left and right incident pupils **418** and **418'** is ½ the size of the incident pupil **419** of the objective lens.

In the type in which the same two optical systems are arranged, as it is formed of separate right and left parts, the number of the parts is high, thereby increasing the difficulty in assembly. Also, the magnification difference between the right and left images due to the errors of the respective parts is large, the displacement of the focusing position is large, the normal stereo-inspection cannot be made and therefore a fine adjustment is necessary.

In the type of dividing pupil, there are advantages that the parts common to the right and left light paths are many, the number of parts is low and the displacement of the right and left images can be made small. On the other hand, when compared with the same thickness, the magnitude of the parallax will be smaller than in the first type and a sufficient stereo-feel will be difficult to obtain. That is to say, there is a problem in that the center distance between the right and left incident pupils is difficult to make large. This point shall be explained with reference to FIGS. **3A** to **4B**.

FIG. **3A** is a magnified view of the objective optical system on the distal end side of the first related art example. FIG. **3B** shows its incident pupil. Also, FIG. **4A** is a magnified view of the objective optical system on the distal end side of the second related art example. FIG. **4B** shows its incident pupil.

In the type in which the same two optical systems are arranged, that is, the first related art example, against the inside diameter Φ of the objective lens frame **421** of the endoscope distal end **420**, the optical axis distance between the right and left objective optical systems is substantially Φ/2. Therefore, the center distance between the right and left incident pupils **407** and **407'** is also substantially Φ/2.

On the other hand, in the type in which the pupil is divided, against the inside diameter Φ of the objective lens frame **421** at the endoscope distal end **420**, the diameter of the incident pupil **419** of the objective optical system is smaller than Φ, because the incident pupil of the objective optical system is smaller than the pupil of the relay lens system as the NA of the endoscope is limited by the outside diameter of the relay lens system and the picture angle of the objective optical system is larger than of the relay lens system.

Therefore, the center distance between the right and left incident pupils is less then Φ/2 and is usually about Φ/6 to Φ/10. Therefore, in this type, the magnitude of the parallax is about ⅓ that in the above mentioned type. Particularly, when the distal end is thin, no sufficient stereo-feel will be obtained.

SUMMARY OF THE INVENTION

In view of such circumstances, an object of this invention is to provide a stereoendoscope wherein, as in the type in

which the pupil is divided, the commonality of parts for the right and left light paths is made as high as possible, the variations of the right and left images by the production errors or the like can be made few and images having a stereo-feel by a parallax as great as of the type in which the same two optical systems are arranged are obtained.

The stereoendoscope of the present invention comprises an objective optical system which has a plurality of incident pupils formed in different positions and forms a plurality of images passing through the incident pupils and having a parallax from each other and a common image transmitting optical system which transmits the plurality of images having a parallax from each other.

When thus formed, as the objective optical system has a plurality of independent incident pupils, irrespective of the size of the diameter of the incident pupil of the objective optical system, the parallax will be able to be made large. Also, as the plurality of images and pupils are not separately transmitted by the plurality of transmitting systems but are transmitted by the common image transmitting optical system, the number of parts will be able to be reduced. Even if a production error is present in the individual image transmitting optical system, as the images are transmitted by the common image transmitting system, the variation between the plurality of transmitted images will be able to be reduced.

In order to realize such formation, there are the following two systems (a) and (b):

(a) A formation comprising an objective optical system which forms a plurality of images having parallaxes in spatially separated positions and one image transmitting optical system which transmits the plurality of incident pupils and the plurality of images of the object optical system so that the images transmitted by this image transmitting optical system may be taken finally by one or more image taking means. More specifically, the system includes:

A stereoendoscope having an objective optical system, image transmitting optical system and image taking device, where the objective optical system comprises a plurality of optical systems arranged in parallel and forms a plurality of images having a parallax from each other and the image transmitting optical system comprises an optical system arranged along one optical axis and transmits a plurality of images formed by the objective optical system.

In this formation, as the operation common to (a) and (b) is made and the image transmitted by the image transmitting optical system is also spatially separated, the image can be stereo-inspected through an image taking means taking images or an ocular optical system making observation with the naked eyes. The image taking means can use one or more image taking devices and can take a plurality of images transmitted and spatially separated by the transmitting optical system and stereo-inspection is thereby possible.

The other formation realizing such formation is as follows:

(b) A formation comprising an objective optical system forming a plurality of images having parallaxes where they spatially substantially coincide (superimposed), jetting pupils corresponding to the plurality of incident pupils of the objective optical system and one image transmitting optical system transmitting the plurality of images, wherein the images transmitted by the image transmitting optical system are taken finally by one or more image taking means.

More specifically the system includes:

A stereoendoscope having an objective optical system, image transmitting optical system and image taking device, where the objective optical system comprises a plurality of front group optical systems arranged in parallel to take in a plurality of images having a parallax from each other and rear group optical systems arranged so as to be on the same optical axis as of the image transmitting optical system and forming images of beams from the plurality of front group optical systems where the beams are substantially superimposed. The image transmitting optical system transmits the plurality of images formed by the rear group optical systems, having a parallax from each other and substantially superimposed. The jetting pupils of the objective optical system.

In this formation, because a common operation is made and images having parallaxes are transmitted to be formed where they are substantially superimposed, the diameter of the relay optical system can be made small.

BRIEF DESCRIPTION OF THE DRAWINGS

FIGS. **1A** and **1B** show a first related art example, where FIG. **1A** is a formation view showing its stereoendoscope and FIG. **1B** is an explanatory view showing incident pupils.

FIGS. **2A** and **2B** show a second related art example, where FIG. **2A** is a formation view showing its stereoendoscope and FIG. **2B** is an explanatory view showing an incident pupil.

FIG. **3A** is a magnified sectioned view of an objective optical system part on the distal end side of the first related art example and FIG. **3B** is an explanatory view showing incident pupils of FIG. **3A**.

FIG. **4A** is a magnified sectioned view of an objective optical system part on the distal end side of the second related art example and FIG. **4B** is an explanatory view showing an incident pupil of FIG. **4A**.

FIGS. **5** and **6** relate to the first embodiment of the present invention, where FIG. **5** is a formation view showing the whole of a stereoendoscope apparatus provided with the first embodiment and

FIG. **6** is a formation view showing an image taking optical system in the stereoendoscope of the first embodiment of the present invention.

FIG. **7** is a formation view showing an image taking optical system in the second embodiment of the present invention.

FIG. **8** is a formation view showing an image taking optical system in the third embodiment of the present invention.

FIG. **9** is an explanatory view showing an arrangement example of an image taking device.

FIGS. **10A** and **10B** relate to a modification of the third embodiment, where FIG. **10A** is an explanatory view showing images formed by an objective optical system and relay optical system and a final image by the image transmission and FIG. **10B** is an explanatory view showing the arrangement of a final image and an image taking device arranged in the position in case the objective optical system and relay optical system of FIG. **10A** are used.

FIG. **11** is a formation view showing an image taking optical system in the fourth embodiment of the present invention.

FIG. **12** is a formation view showing an image taking optical system in the fifth embodiment of the present invention.

FIG. **13** is a formation view showing an image taking optical system in the sixth embodiment of the present invention.

FIG. 14 is a formation view showing a main part of an image taking optical system in the seventh embodiment of the present invention.

FIGS. 15A and 15B relate to the eighth embodiment of the present invention, where FIG. 15A is a plan view showing an objective optical system and FIG. 15B is a side view showing the objective optical system.

FIGS. 16A and 16B show the ninth embodiment of the present invention, where FIG. 16A is a plan view showing a unit formation of the ninth embodiment and FIG. 16B is a side view of FIG. 16A.

FIGS. 16C and 16D show a first modification of the ninth embodiment, where FIG. 16C is a plan view showing a unit formation of the first modification and FIG. 16D is a side view of FIG. 16C as an ocular adapter is connected.

FIGS. 17A to 17C are explanatory views respectively showing unit formations in the second to fourth modifications of the ninth embodiment.

FIGS. 18A to 18E are views respectively showing formations of objective optical system units.

FIGS. 19A to 19D are views respectively showing formations of relay optical system units.

FIG. 20 is a formation view showing an image taking optical system in the tenth embodiment of the present invention.

FIG. 21 is a formation view showing an image taking optical system in the eleventh embodiment of the present invention.

FIG. 22 is a formation view showing an image taking optical system in the twelfth embodiment of the present invention.

FIGS. 23A to 23D show a meniscus lens in a modification of the twelfth embodiment, where FIG. 23A is a sectioned plan view and FIG. 23B is a side view as seen from the side of FIG. 23A. FIGS. 23C and 23D are respectively a front view and back view as seen from the front surface and back surface sides.

FIG. 24 is a formation view showing an image taking optical system in the thirteenth embodiment of the present invention.

FIG. 25 is a formation view showing a main part of an image taking optical system in the fourteenth embodiment of the present invention.

FIGS. 26A and 26B show an objective optical system in the fifteenth embodiment of the present invention, where FIG. 26A is a plan view and FIG. 26B is a side view.

FIGS. 27A and 27B show an objective optical system in a modification of the fifteenth embodiment, where FIG. 27A is a plan view and FIG. 27B is a side view.

FIGS. 28A and 28B show an image taking optical system in the sixteenth embodiment, where FIG. 28A is a plan view and FIG. 28B is a side view.

FIGS. 29A and 29B show an image taking optical system in the seventeenth embodiment, where FIG. 29A is a plan view and FIG. 29B is a side view.

FIGS. 30A to 30G are explanatory views respectively showing unit formations of the eighteenth embodiment.

FIG. 31A to 31F are views respectively showing actual formations of front group units.

FIG. 32A to 32F are views respectively showing concrete formations of objective optical system units.

FIG. 33A to 33D are sectioned views respectively showing formations of rear group and relay lens system units.

FIGS. 34A and 34B relate to the nineteenth embodiment of the present invention, where FIG. 34A is a general formation view of a stereoendoscope apparatus provided with the nineteenth embodiment and FIG. 34B is a view of the arrangement of an objective optical system on the distal end surface of the stereoendoscope of the nineteenth embodiment.

FIGS. 35A to 35C relate to the twentieth embodiment of the present invention and FIG. 35A is a view showing the formation of a stereoendoscope of the twentieth embodiment. FIG. 35B is an elevation showing the arrangement of an objective optical system as seen from the distal end surface and FIG. 35C is an explanatory view showing the arrangement of an image taking device as seen from the distal end side.

FIGS. 36A to 36F show the formation on the distal end side of the twenty-first embodiment of the present invention, where FIG. 36A is a vertically sectioned view; FIG. 36B is an elevation of FIG. 36A;

FIG. 36C is a horizontally sectioned view;

FIG. 36D is an elevation of FIG. 36B;

FIG. 36E is a horizontally sectioned view; and

FIG. 36F is an elevation of FIG. 36F.

FIGS. 37A and 37B show the formation on the distal end side of the twenty-second embodiment of the present invention, where FIG. 37A is a vertically sectioned view and FIG. 37B is an elevation of FIG. 37A.

FIGS. 38A and 38B relate to a prior example, where FIG. 38A is a formation view showing the formation of an objective optical system in a stereoendoscope of the prior example and FIG. 38B is an explanatory view of a power arrangement for the objective optical system of FIG. 38A.

FIGS. 39 to 42 relate to the twenty-third embodiment of the present invention, where FIG. 39 is a general formation view of a stereoendoscope apparatus provided with the twenty-third embodiment;

FIG. 40 is a formation view of an image taking optical system including the objective optical system in the stereoendoscope of the twenty-third embodiment;

FIG. 41 is an explanatory view of a power arrangement of the objective optical system of FIG. 40; and

FIG. 42 is a sectioned view showing a frame structure at the distal end of the stereoendoscope in FIG. 39.

FIG. 43 is a formation view of the objective optical system and image transmitting optical system relating to the twenty-fourth embodiment of the present invention.

FIG. 44 is a formation view of the objective optical system in the twenty-fifth embodiment of the present invention.

FIG. 45 is a formation view of the image transmitting optical system including the objective optical system in FIG. 44.

FIGS. 46 to 48 relate to the twenty-sixth embodiment, where FIG. 46 is a general formation view of an endoscope apparatus;

FIG. 47A is a formation view of a plurality of visual field direction type endoscope;

FIG. 47B is a view showing the formation of a brightness diaphragm; and

FIG. 48 is a formation view of an objective optical system utilizing a pupil division.

FIGS. 49A to 54 relate to the twenty-seventh embodiment, where FIG. 49A is a formation view of a plural

visual field direction type endoscope including an objective optical system utilizing an eccentric optical system; FIG. **49B** is a formation view of an endoscope relating to a modification of the twenty-seventh embodiment;

FIG. **50** is a formation view of an objective optical system in which an eccentric optical system is utilized and an afocal part is partly in common;

FIG. **51** is a formation view of an objective optical system in which an eccentric optical system is utilized and a perspective is made by refraction;

FIG. **52** is a formation view of a design of an objective optical system in which an eccentric optical system is utilized;

FIG. **53** is a formation view of a design in which a relay lens system is combined with an objective optical system; and

FIG. **54** is an elevation of an objective optical system having three visual field directions.

FIGS. **55** to **58** relate to the twenty-eighth embodiment, where FIG. **55** is a formation view of a plural visual field direction type endoscope having a pupil switching apparatus;

FIGS. **56A** and **56B** are formation views of a plural visual field direction type endoscope in which the visual field direction can be switched by an image rotator;

FIG. **57** is a formation view of a plural visual field direction type endoscope in which the visual field direction can be switched by the movement of a solid state image taking device or the like;

FIG. **58A** is a formation view of a plural visual field direction type endoscope in which a pupil switching apparatus is provided near the pupil of an objective optical system; and

FIG. **58B** is a formation view of a plural visual field direction type endoscope different from that of FIG. **58A**.

FIG. **59A** is a formation view of a plural visual field direction type endoscope relating to the twenty-ninth embodiment. FIG. **59B** is a formation view of an endoscope in which the objective optical system is made partly common.

FIG. **60A** is a formation view of an optical system of a plural visual field direction type endoscope of the thirtieth embodiment.

FIG. **60B** is a formation view of an optical system of a plural visual field direction type endoscope of a modification of the thirtieth embodiment.

FIG. **61A** is a formation view of an optical system of a plural visual field direction type endoscope of the thirty-first embodiment.

FIG. **61B** is a formation view of an optical system of a plural visual field direction type endoscope of a modification of the thirty-first embodiment.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

The present invention shall be explained as follows with reference to the drawings.

The stereoendoscope in each of the first to the twenty-second embodiments is characterized by having an objective optical system which has a plurality of incident pupils formed in different positions and forms a plurality of images having passed through these incident pupils and having a parallax from each other and a common image transmitting optical system which transmits the plurality of images having a parallax from each other.

Each of the first embodiment to the modification of the ninth embodiment is of the formation (a). That is to say, images having a parallax from each other are formed in separated positions by a plurality of objective optical systems arranged at the distal end of an endoscope and the images separated from each other are transmitted by one common image transmitting optical system.

As shown in FIG. **5**, a stereoendoscope apparatus **1** comprises a stereoendoscope **2** of the first embodiment having an image taking optical system for stereo-inspection built-in, a light source apparatus **3** feeding an illuminating light to an illuminating light transmitting means provided in this stereoendoscope to transmit the illuminating light, a camera controlling unit (abbreviated as a CCU hereinafter) **4** processing signals for an image taking means built-in in this stereoendoscope **2**, a scan converter **5** converting the signal from this CCU **4** to a video signal, a color monitor **6** displaying the video signal put out of this scan converter **5** and shutter spectacles **27** having a shutter function for stereo-inspecting the image displayed in this color monitor **6**.

The stereoendoscope **2** has an elongate inserted section **11** to be inserted into a body cavity or the like and a gripped section formed to be large in the diameter at the proximal end of this inserted section so as to be gripped by the operator. This inserted section **11** is formed of a cylindrical rigid jacket tube made of metal such as stainless steel. That is to say, this stereoendoscope **2** is a rigid endoscope having the rigid inserted section **11**.

As is an ordinary endoscope, this stereoendoscope has an illuminating light transmitting means transmitting the illuminating light fed from the light source apparatus **3**, an illuminating optical system projecting this transmitted illuminating light out of an illuminating window and illuminating the object side and an observing optical system obtaining two images having a parallax so that the object illuminated by this illuminating optical system may be stereo-inspected.

By the way, in this specification, this observing optical system is mostly explained in an embodiment acting to form two images having a parallax on an image taking device provided with a photoelectrically converting function and is therefore also called an image taking optical system.

The gripped section **12** is provided with a light guide mouthpiece **13** and a light guide connector **15** at the other end of a light guide cable **14** removably connected at one end to this light guide mouthpiece **13** is removably connected to the light source apparatus **3**.

A lamp **16** generating a white illuminating light and a lens **17** condensing this white light are arranged within the light source apparatus **3**. The illuminating light condensed by this lens **17** is radiated on the end surface of the light guide connector **15**, the illuminating light radiated on this end surface is transmitted by the light guide within the light guide cable **14** and the transmitted illuminating light is fed to the light guide **18** side within the stereoendoscope **2** from the light guide mouthpiece **13**.

The light guide **18** used as an illuminating light transmitting means is bent within the gripped section **12** and is inserted through the inserted section **11**. This light guide **18** transmits the fed illuminating light and projects the illuminating light forward from the distal end surface fixed to the distal end **19** of the inserted section **11** and further through an illuminating lens **20** fitted to an illuminating window.

The respective optical images (represented by reference numerals *7a* and *7b* in FIG. **6**) of the object (represented by the arrow in FIG. **5**) **29** illuminated by this illuminating light

are formed in image forming positions by objective optical systems **21***a* and **21***b* fitted to two observing windows arranged adjacently to the illuminating window within the distal end **19**. The two objective optical systems **21***a* and **21***b* are of the same formation and are formed of optical lenses preferably of the same characteristics.

As shown in FIG. **5**, the two objective optical systems **21***a* and **21***b* have the respective optical axes Oa and Ob in parallel with the center axis of the inserted section, are arranged substantially superimposed in parallel on both sides of this center axis and are separated from each other by d in the distance (interval) between both optical axes Oa and Ob. Also, both optical axes Oa and Ob are arranged as separated in the diametral direction crossing the center axis and are therefore arranged symmetrically with the center axis. Two optical images large in the parallax can be formed by the objective optical systems **21***a* and **21***b* of the same formation with the optical axes arranged in parallel as separated by the distance d between them.

The images **7***a* and **7***b* are formed, as shown in FIG. **6**, in separate positions by the two objective optical systems **21***a* and **21***b* and are transmitted rearward by a common relay optical system **22**, that is, one image transmitting optical system or image transmitting means.

These images are both multiple-transmitted rearward by this relay optical system **22** and finally the same images **10***a* and **10***b* as the two images **7***a* and **7***b* by the two objective optical systems **21***a* and **21***b* are separately formed on a photoelectrically converting surface (image taking surface) of an image taking device **23** arranged within the gripped section **12**. For example, in FIG. **5**, if the separating direction in the two objective optical systems **21***a* and **21***b* is a horizontal direction, two images **10***a* and **10***b* will be separately formed in the horizontal direction on the image taking surface of the image taking device **23**.

As shown in FIG. **5**, the image taking device **23** has, for example, a square image taking surface and is arranged so that the vertical or horizontal direction of this image taking surface may coincide with the horizontal direction in which the two objective optical systems **21***a* and **21***b* are arranged as separated and the center of the image taking surface may be on the optical axis of the relay optical system.

By the way, the light guide **18** inserted through the inserted section **1** may be inserted through outside the relay optical system **22** (for example, like a ring). As shown in FIG. **5**, a part of the vertical direction intersecting at right angles with the horizontal direction of the relay optical system **22** may be contained in an incised groove **422***a* formed by incising in the axial direction a part of the vertical direction intersecting at right angles with the horizontal direction of the relay optical system **22**. (One incised groove **422***a* is shown in FIG. **5** but two incised grooves may be formed in the vertical direction.) When such an incised groove **422***a* is formed, the part which does not in principle substantially contribute to image transmission will be deleted, the image transmitting function will not be reduced, the illuminating light will be able to be transmitted and the inserted section **11** will be able to be made small in the diameter.

As the effective sectioned area of the relay optical system can be made large, the eccentricity (the distance d between the optical axes) of the two objective optical systems **21***a* and **21***b* arranged as opposed to each other eccentrically in the horizontal direction from the optical axis of this relay optical system **22** at the front end of this relay optical system **22**, that is, the parallax will be able to be made large and the stereo-inspecting function will be able to be improved. Further, there is a function of reducing the superimposing (cross talk) of two images.

The gripped section can be fittably separated into the output section **24** in which the image taking device **23** is built-in and the input section **25** on its forward side. The input section **25** has an image taking optical system (observing optical system) comprising the two objective optical series **21***a* and **21***b* and relay optical system **22**.

By making the output section **24** separable, there is made a flexible structure wherein the defective image taking device **23** can be easily repaired or can be replaced with one high in the sensitivity or the number of pixels to improve the performance and an ocular adapter can be connected to make stereo-inspection with the naked eyes. (The structure shown in the later described FIG. **19** may be adopted for the structure of the connecting part.)

The image taking device **23** is extended out of the rear end of the output section **24** and is connected with the CCU **4** through the signal cable **26** and the image taking signal photoelectrically converted by the image taking device **23** is processed. The image signal processed by this CCU **4** is further put into the scan converter **5**, is converted to a video signal and is then put out to the color monitor **6**. Two images corresponding to the optical images formed by the two objective optical systems **21***a* and **21***b* are alternately displayed in this color monitor **06**. By observing the images of the color monitor **6** with shutter spectacles **27**, the operator can stereo-inspect the images.

FIG. **6** shows the formations of the image taking optical systems, that is, the two objective optical systems **21***a* and **21***b* and relay optical system in the stereoendoscope **2** of the first embodiment.

The images **7***a* and **7***b* having a parallax from each other are formed by the plurality of (two in this embodiment) independent objective optical systems **21***a* and **21***b* arranged in the distal end section **19**. These images **7***a* and **7***b* separated from each other are transmitted by the relay optical system **22** as one image transmitting optical system.

As shown in FIG. **6**, the objective optical systems **21***a* and **21***b*, for example, the three relay lens systems **22***a*, **22***b* and **22***c* forming the relay optical system **22** and the image taking device **23** having a function of photoelectrically converting optical images are arranged in the order mentioned from the object side. The two images **7***a* and **7***b* having a parallax are formed in the spatially separated positions (in this case, in the positions separated from each other in the horizontal direction) by the objective optical systems **21***a* and **21***b* of the same formation arranged in parallel as separated from each other by d (for example, d=4 mm) of the distance between their optical axes.

The images **7***a* and **7***b* are both multiple-relayed by the relay lens systems **22***a*, **22***b* and **22***c* of the same formation arranged in series so that the optical axes may coincide with each other. That is to say, the images **7***a* and **7***b* formed on both left and right sides of the optical axis O of the relay optical system **22** (by the objective optical systems **21***a* and **21***b* arranged eccentrically on the left and right from this optical axis O) respectively form images **8***a* and **8***b* respectively on both right and left sides of this optical axis O in the rear side positions of the optical axis O by the relay lens system **22***a*. These images **8***a* and **8***b* respectively form images **9***a* and **9***b* on both left and right sides of this optical axis O in the rear side positions of the optical axis O by the relay lens system **22***b*. These images **9***a* and **9***b* respectively form images **10***a* and **10***b* on both right and left sides of this

optical axis O in the rear side positions of the optical axis O by the relay lens system **22***c*.

In this position, the image taking surface of the image taking device **23** is arranged and the images **10***a* and **10***b* are photoelectrically converted and put out. A masking means is provided so that the two images **10***a* and **10***b* on this image taking surface may not be superimposed. (As shown in the later described FIG. **8**, for example, a visual field diaphragm **30** may be provided on the image forming surfaces of the objective optical systems **21***a* and **21***b* to limit the visual field. The invention is not limited to this. The visual field diaphragm may be provided, for example, in the image forming position in the relay optical system **22**.)

The optical axes O of the relay lens systems **22***a*, **22***b* and **22***c* are respectively eccentric by the same amount on the right and left from the optical axes Oa and Ob of the objective optical systems **21***a* and **21***b*. The eccentricity can be selected in conformity with the desired parallax magnitude, that is, stereo-feel size and is d/2 (for example, d/2=2 mm) in this embodiment.

The number of relaying times is three times in this embodiment but can be set from one time to ten times and several other times depending on such specification as the brightness of the optical system.

By the way, in FIG. **6**, the reference numerals **28***a* and **28***b* respectively represent the positions of the incident pupils of the left and right objective optical systems **21***a* and **21***b* and the left and right images **7***a* and **7***b* are formed of the lights incident through the respective incident pupils **28***a* and **28***b*. The respective incident pupils **28***a* and **28***b* are transmitted by the relay lens systems **22***a*, **22***b* and **22***c* forming the relay optical system **22**.

During the transmission by the relay lens systems **22***a*, **22***b* and **22***c*, the two pupils may be horizontally displaced but the relay lens systems **22***a*, **22***b* and **22***c* had better be superimposed in order to be made small. Therefor, it is preferable that the two objective optical systems **21***a* and **21***b* are respectively formed to be telecentric optical systems, that is, the projecting pupils are formed to be infinitely far.

By the way, the magnitude of the parallax, that is, the center distance between the left and right incident pupils **28***a* and **28***b* is determined by the distance d between the optical axes Oa and Ob of the objective optical systems **21***a* and **21***b* and is independent of the brightness of the optical system.

According to this embodiment, as the relay optical system **22** is made common, the trouble of adjusting the lenses can be more extremely omitted than in the case that it is not made common (in the first related art) and a favorable stereo-observation can be made.

Also, as can be judged from FIG. **5**, as an image having a parallax can be obtained by arranging the two objective optical systems **21***a* and **21***b* as separated from each other, the parallax can be made larger than in the case of using a common objective optical system (in the second related art) and therefore the function of obtaining a stereo-feel can be made large. (The same stereo-feel as in the case that two optical systems are arranged as in the first related art can be obtained.)

Therefore, according to this embodiment, the common optical components can be made few, the adjusted parts can be made few, the cost can be made low and the image having the same stereo-feel as in the case that two optical systems are arranged in the related art can be obtained.

As the two images **7***a* and **7***b* having a parallax are transmitted by the relay lens systems **22***a*, **22***b* and **22***c* used in common with the axially symmetrical one, during the transmission, the qualities (the magnification, MTF, image position, chromatic aberration, coloring and the like) of the two images will lag little during the transmission.

That is to say, even if the individual characteristics of the relay lens system **22***a* and the others are dispersed by the production error, in this embodiment, as the left and right images are transmitted by the common relay lens system **22***a* and the others, the influence of the individual dispersion will not be substantially received. Therefore, the left and right images obtained by this embodiment will be images of a good quality having little lag.

In case an operation is made under the observation with this stereoendoscope, a good picture quality and a sufficient stereo-feel will be obtained, a picture image of an observation close to directly observing the affected part will be able to be realized and therefore an environment in which the operation is easy to make will be able to be provided.

Also, in this embodiment, as the left and right images **7***a* and **7***b* are formed in the positions spatially separated by the objective optical systems **21***a* and **21***b* and are formed in the positions spatially separated by the common relay optical system **22**, therefore a stereo-inspection will be able to be made with the image taking device or the like without using an image separating means newly spatially separating the images.

Also, in this embodiment, the final images **10***a* and **10***b* by the relay lens system **22***c* are taken by one image taking device **23**. Therefore, the output section **24** is very simplified in the structure and a light weight stereoendoscope can be realized.

By the way, the image taking device **23** may be any of various solid state image taking devices (known generally by the names of CCD, PCD, CMD, AMI and SIT) and image taking tubes (known generally by the names of Sachicon, Busicon and HARP TUBE).

Also, the sensitivity may be improved by utilizing an image intensifier or the like.

The image taking device **23** may be a device for taking color images with a single plate or may take colored images with a formation as a 2-plate or 3-plate camera. Also, as shown in FIG. **6**, the final images **10***a* and **10***b* by the relay lens system **22***c* are taken by the common image taking device **23** to reduce cost and weight.

In order that a stereo-feel optimum to the desire or operation type of the operator may be obtained, the distance between the respective optical axes of the two objective optical systems **21***a* and **21***b* may be made variable so that the magnitude of the parallax may be variable.

In this case, in order that the distal end section **19** may be made small, the two objective optical systems **21***a* and **21***b* may be made movable to the side opposite to one another in the horizontal direction vertical to the optical axis O of the relay lens systems **22***a*, **22***b* and **22***c*. However, in this case, when the objective optical systems **21***a* and **21***b* move, the final images **10***a* and **10***b* will be also moved by the relay lens system **22***c* and therefore, in case the image taking device **23** is fixed, the movement will be limited to be within the image taking range.

By the way, it has been explained that the image taking surface of the image taking device **23** is square. However, a rectangular surface having a long horizontal direction in which the objective optical systems **21***a* and **21***b* are arranged as separated may be used. In this case, the image taking range in which the image having a parallax is obtained will be able to be substantially expanded.

By the way, FIG. **5** shows a simultaneous illuminating and image taking system wherein a color image is taken by using the image taking device **23** in which such color separating filter as a mosaic filter is arranged under a white color light illumination. However, the invention is not limited to this. A surface sequential image taking system wherein a color image is taken by obtaining such color component image as of three primary colors by taking an image with an image taking device having no color separating filter under a surface sequential illumination in which illuminating lights of such wavelength ranges as of red, green and blue are sequentially emitted on the object side will also do.

By the way, in the first embodiment, instead of connecting the output section to the input section **25**, an ocular adapter **45'** shown in the later described FIG. **16**D is fitted so that the stereo-inspection may be made with the naked eyes. In this case, it is preferable to set the number of relaying times by the relay optical system **22** at an even number of times so that the left and right images **7***a* and **7***b* by the objective optical systems **21***a* and **21***b* may be respectively observed with the left and right ocular lenses. (In FIG. **16**D, the number of relaying times is four times.)

By the way, the lens data of the first embodiment are as in Table 1 shown later in the specification. FIG. **2** and others are collectively shown after FIG. **1**. In Tables 1 to 14, r1, r2, . . . , represent radii of curvatures of respective surfaces, d1, d2, . . . , represent surface distances, n1, n2, . . . , represent refractive indices of respective lenses and ν1, ν2, . . . , represent Abbe numbers of respective lenses.

In the following, the second to ninth embodiments are modifications of the first embodiment and, the same as in the first embodiment, the image having a parallax is formed in a position spatially separated by the objective optical systems **21***a* and **21***b*.

FIG. **7** shows a structure near the final images **10***a* and **10***b* of the relay lens system **22***c* of the image taking optical system in the stereoendoscope of the second embodiment of the present invention. The final images **10***a* and **10***b* are respectively taken by the two image taking devices **23***a* and **23***b*. Signal lines (not illustrated) are connected respectively to the two image taking devices **23***a* and **23***b* and are connected to a CCU partly different in the internal formation from the CCU **4** in FIG. **5**. The others are of the same formation as of the stereoendoscope **2** of the first embodiment.

By the way, in the CCU processing signals for the two image taking devices **23***a* and **23***b*, the same driving signal may be simultaneously applied, for example, to the two image taking devices **23***a* and **23***b*, may be simultaneously read out and may be memorized respectively in two frame memories. The same driving signal may be applied alternately respectively to the two image taking devices **23***a* and **23***b* and may be read out alternately and the image signal read out may be memorized alternately in the two frame memories.

The image signal simultaneously or alternately memorized in the two frame memories are alternately read out by the scan converter and are alternately displayed in the color monitor. The operator wears shutter spectacles **27** and can observe and stereo-inspect the image displayed in the color monitor **6**.

The stereoendoscope apparatus provided with this second embodiment can be realized in substantially the same formation as of the stereoendoscope apparatus **1** in FIG. **5**.

This second embodiment has an advantage that the image taking devices **23***a* and **23***b* can be focused respectively independently. If they are precisely adjusted, an image higher in the quality than in the case of a common image taking device **23** will be able to be made.

Also, the parallax can be made variable the same as in the first embodiment. However, this embodiment has an advantage that, when the left and right image taking devices **23***a* and **23***b* are moved as operatively connected with the movement of the objective optical systems **21***a* and **21***b*, the movement will not be restricted to be within the image taking range in the case of the common image taking device **23**.

That is to say, in the first embodiment, as the image taking device **23** is common, the moving range of the left and right images **10***a* and **10***b* is restricted to be within the image taking range. However, according to the present embodiment, in case the final images **10***a* and **10***b* are fixed, when the movement deviates (separates) from the imaging range, the two image taking devices **23***a* and **23***b* will be moved horizontally as operatively connected with the movement of the objective optical systems **21***a* and **21***b* and the final images **10***a* and **10***b* will be able to be maintained within the image taking range of the respective image taking devices **23***a* and **23***b*.

Therefore, there is a merit that a stereo-endoscope in which an image having a stereo-feel is obtained can be realized. The others have the same effects as in the first embodiment. By the way, the lens data of the second embodiment are the same as of the first embodiment.

FIGS. **8** and **9** relate to the third embodiment of the present invention. FIG. **8** shows an image taking optical system in the third embodiment. FIG. **9** shows as magnified the arrangement of the image taking devices **23***a* and **23***b*. In this embodiment, the two image taking devices **23***a* and **23***b* are used as in the second embodiment and the light receiving surfaces of the image taking devices **23***a* and **23***b* arranged not vertically to the optical axis O of the relay optical system **22** but as inclined from the vertical direction. In other words, in the central part of the light receiving surface of each of the image taking devices **23***a* and **23***b*, the optical axis vertical to this light receiving surface is arranged not to be parallel with the optical axis O of the relay optical system **22** but to make an angle greater than 0.

That is to say, when the light receiving surface of each of the two image taking devices **23***a* and **23***b* is inclined in conformity with the image surface curvature aberration **10***c* generated by the relay lens systems **22***a*, **22***b* and **22***c* and shown in FIG. **9**, the deterioration of the image by the curvature aberration will be reduced.

As the petzval of the relay lens systems **22***a*, **22***b* and **22***c* is positive, even if the image surface by the objective optical systems **21***a* and **21***b* is flat, in the case of the transmission by the relay lens systems **22***a*, **22***b* and **22***c*, the image surface will bend on the curved surface with the concave surface directed to the objective side.

Therefore, with the image taking surface or light receiving surface left to be arranged vertically to the optical axis of the relay lens systems **22***a*, **22***b* and **22***c*, a partial fog will likely be produced and it will be difficult to keep the entire image taking surface focused.

Therefore, in the third embodiment, as shown in FIG. **9**, the light receiving surface is inclined in conformity with the contact surface of the curved image surface. In FIG. **9**, the light receiving surface is inclined by 25.332 degrees to the surface vertical to the optical axis of the relay lens system **22***c*.

According to this third embodiment, not only the effects of the second embodiment are retained but also a picture

image having little curvature aberration is obtained. By the way, the lens data of the third embodiment are as in Table 2.

By the way, because the petzval sum of the relay lens systems **22***a*, **22***b* and **22***c* is a positive value, the petzval sum of the objective optical systems **21***a* and **21***b* may be made a negative value to control the image surface curvature aberration of the final images **10***a* and **10***b* having passed through the relay lens system **22***c*.

FIGS. **10**A and **10**B are of modifications showing this manner.

As shown in FIG. **10**A, the petzval sum of the objective optical systems **21***a* and **21***b* is made a negative value to form images **7***a* and **7***b* becoming concave on the rear side (the local radius of curvature of each image surface shall be represented by R). In case the image on the flat image surface is transmitted by the relay lens systems **22***a*, **22***b* and **22***c*, the local radius of curvature of the image surface of the final images **23***a* and **23***b* is represented by R' and, as shown in FIG. **10**, the light receiving surfaces of the image taking devices **23***a* and **23***b* are arranged on the contact surface of the curved surface of a local curvature 1/R"=1/R −1/R", the influence of the image surface curvature aberration will be further controlled by this embodiment than by the third embodiment.

By the way, in this case, 1/R −1/R"=0 or the absolute value of 1/R −1/R" may be made small.

FIG. **11** shows an image taking optical system in the fourth embodiment. The final images **10***a* and **10***b* of the relay lens system are relayed once more by adapter lens systems **32***a* and **32***b* forming an adapter optical system to connect images **36***a* and **36***b* and these images **36***a* and **36***b* are taken respectively by image taking devices **33***a* and **33***b*.

The adapter lens systems **32***a* and **32***b* are formed respectively of mirror parts **34***a* and **34***b* and lens parts **35***a* and **35***b*, a beam is parallel moved outside by the mirror parts **34***a* and **34***b* (in this embodiment, the displacement L is 6 mm) and the lens parts **35***a* and **35***b* act to re-form the final images **10***a* and **10***b* of the relay lens system at any magnification.

The optical axis of each of the lens parts **35***a* and **35***b* is eccentric by d/2 (2 mm) from the optical axis of the relay lens system **22***c* except the parallel moved part by the mirror parts **34***a* and **34***b*.

In this embodiment, when the parallel moving distance in the mirror sections **34***a* and **34***b* and the magnification in the lens sections **35***a* and **35***b* are properly set, images **36***a* and **36***b* optimum to any size image taking devices **33***a* and **33***b* will be able to be obtained.

Also, as the image taking devices **33***a* and **33***b* larger in the size than in the first and second embodiments can be used, those larger in the number of pixels in response to the size can be used and a favorable stereo-observed image high in the resolving degree can be obtained. The others have the same effects as in the second embodiment. The lens data of this embodiment are as in Table 3.

FIG. **12** shows an image taking optical system in the fifth embodiment. This embodiment is an improvement of the fourth embodiment.

The images **36***a* and **36***b* are respectively formed by further relaying once the final images boa and **10***b* of the relay lens system with the common adapter optical system **32** formed of one lens system and are taken by the image taking devices **33***a* and **33***b*. The adapter optical system **32** is formed of a lens system arranged so as to be of the same optical axis as of the relay lens systems **22***a*, **22***b* and **22***c*, the final images **10***a* and **10***b* of the relay lens system are formed again at any magnification and the image taking devices **33***a* and **33***b* are arranged in the image forming positions.

In this embodiment, the formation can be made simpler by the part having no mirror section within the adapter optical system **32** and has the operations and effects of the fourth embodiment. That is to say, when the magnification of the adapter optical system **32** is optionally set, the images **36***a* and **36***b* optimum to the image taking devices **33***a* and **33***b* of any size will be able to be obtained.

Also, in this embodiment, the same as in the third embodiment, the light receiving surface of each of the image taking devices **33***a* and **33***b* is inclined in conformity with the image surface curvature aberration generated by the relay lens systems **22***a*, **22***b* and **22***c* and adapter optical system **32** to control the deterioration of the image. In FIG. **12**, the light receiving surface is inclined by 11.902 degrees to the surface vertical to the optical axis of the relay lens system **22***c*. The lens data of this embodiment are shown in Table 4.

FIG. **13** shows an image taking optical system in the sixth embodiment.

The final images **10***a* and **10***b* of the relay lens system are further once relayed by the adapter lens systems **32***a* and **32***b* forming the adapter optical system **32** and are taken by the image taking devices **33***a* and **33***b*. The adapter optical system **32** is formed of the two inclined adapter lens systems **32***a* and **32***b* of the same formation. One lens system **32***b* and the image taking device **33***b* are parallel eccentric by d/2 (=2 mm) from the optical axis of the relay lens system **22***c* and are then inclined by 10.076 degrees with the point at which the optical axis of the lens system **32***b* intersects with the final image **10***b* of the relay lens system **22***c* as a center. The lens system **32***a* illustrated by the two-point chain lines is also inclined the same on the opposite side of the optical axis of the relay lens system **22***c*.

In this embodiment, too, the same as in the fifth embodiment, no mirror section is present and, by freely setting the magnification of the adapter optical system, the images **36***a* and **36***b* optimum to the image taking device of any size can be obtained. That is to say, this embodiment has substantially the same effects as in the fifth embodiment. The lens data of this embodiment are as in Table 5.

FIG. **14** shows a main part of an image taking optical system in the seventh embodiment of the present invention.

The final images **10***a* and **10***b* of the relay lens system are further once relayed by the adapter optical system **32** and are formed in the same positions and the common image taking device **33** is arranged in the image forming position in the formation.

In the adapter optical system **32**, the final images **10***a* and **10***b* of the relay lens system are led to the shutter means **37***e* side through an optical axis distance extending means comprising respectively lenses **37***a* and **37***b* and prisms **37***c* and **37***d* and are led to the opposed lens **37***f* and **37***g* side so that, when one is shielding light, the other will be passing light. A beam having passed through the lens **37***f* arranged as opposed to one side of the shutter means **37***e* passes through the prism **37***h*, half prism **37***i* and lens **37***j* and forms an image **36***a* in the position in which the image taking device **33** is arranged.

Also, a beam having passed through the lens **37***g* arranged as opposed to the other side of the shutter means **27***e* passes through the optical device **37***k*, half prism **37***i* and lens **37***j* and forms an image **36***b* in the position in which the image taking device **33** is arranged.

In this embodiment, the relayed images **36***a* and **36***b* are formed in the same position and are taken by one image taking device **33**. The shutter means **37***e* is arranged on the way of the adapter optical system **32** and alternately shields the beam so that two images may not be simultaneously formed by the image taking device **33**.

This embodiment has an advantage that one image taking device **33** will do and the cost can be reduced. The others have the same effects as of the fourth embodiment.

FIGS. **15**A and **15**B show a formation of an objective optical system in the eighth embodiment of the present invention.

In this embodiment, an objective optical system is formed of perspective objective optical systems **39***a* and **39***b* having a perspective front as a visual field.

In this embodiment, a beam incident from the diagonal front side is reflected by using reflecting prisms **40***a* and **40***b* as visual field direction changing means and is changed to be in a direction parallel to the optical axis O of the relay optical system **22** (FIGS. **15**A and **15**B show only a part of the relay lens system **22***a*). In this embodiment, the visual field direction is 45 degrees with the lengthwise direction (the optical axis direction of the relay optical system **22**) of the inserted section. The reflecting prisms **40***a* and **40***b* may be two separate bodies or one integral body.

The rear side formation of the relay optical system **22** may be the formation of any of the first to sixth embodiments. This embodiment has the same effects as in the first to seventh embodiments except that the visual field direction is different.

Other than the eighth embodiment, the visual field direction can be varied by varying the angles of the reflecting prisms **40***a* and **40***b*. Also, if the objective optical system parts are replaceably formed, various visual field directions, visual field angles and parallaxes will be able to be obtained by replacing only the objective optical system.

FIGS. **16**A to **16**D show the ninth embodiment of the present invention and a unit formation in its first modification.

The stereoendoscope **41** of the ninth embodiment shown in FIG. **16**A comprises an objective optical system unit **42**, relay optical system unit **43**, adapter optical system unit **44** and image taking device unit **45**.

The objective optical system unit **42** has objective optical systems **21***a* and **21***b* of uniform optical characteristics built-in. The relay optical system unit **43** has relay lens systems **22***a*, **22***b*, **22***c* and **22***d* of the same formation built-in. The adapter optical system unit **45** has a common adapter optical system **32** built-in. The image taking device unit **45** has image taking devices **33***a* and **33***b* of uniform characteristics built-in.

FIG. **16**A as seen from the side is as in FIG. **16**B. The objective optical system unit **42** has a distal end side section of a light guide **18** and an illuminating lens **20** built-in. The relay optical system unit **43** has an intermediate section of the light guide **18** built-in. The adapter optical system unit **44** has a rear end side section of the light guide **18** built-in. A light guide mouthpiece **13** is provided.

Also, in this embodiment, the relay lens systems **22***a*, **22***b*, **22***c* and **22***d* within the relay optical unit **43**, for example, (for example, are cut off in the lengthwise direction on the lower side to be in the direction vertical to the horizontal direction in which the objective optical systems **21***a* and **21***b* are arranged to secure a space to contain the light guide **18** and) make the inserted section small in diameter. Also, the adapter optical system **32** within the adapter optical system unit **44** is cut off on the light guide mouthpiece **13** side.

In this embodiment, the objective optical system unit **42** is connected to the distal end of the relay optical system unit **43**, the distal end of the adapter optical system unit **44** is connected to the proximal end of the relay optical system unit **43** and the image taking device unit **45** is connected to the proximal end of this adapter optical system unit **44** to form a stereoendoscope **41**.

Therefore, by combining the respective units different in the optical characteristics and image taking characteristics, stereoendoscopes of different characteristics can be simply realized. Therefore, the stereoendoscopes **41** of different characteristics can be provided.

In this embodiment, the connecting part of the proximal end of the relay optical system unit **43** and the distal end of the adapter optical system unit **44** corresponds to the border of the input section **25** and output section **24** shown in FIG. **5**.

By the way, in FIGS. **16**A and **16**B, the part after the adapter optical system unit **44** is made large in diameter. However, as shown in FIG. **16**C, the proximal end side of the relay optical system unit **43** may be made large in the diameter on the proximal end side, the proximal end side part of the light guide **18** may be built-in near this proximal end and the light guide mouth piece **13** may be provided there in the structure.

In this first modification, the light guide **18** need not be built-in in the adapter optical unit **44** and therefore the structure will be simple.

In this modification, the image taking device unit **45** may be fitted directly to the relay optical system unit **43** without using the adapter optical system unit **44** in the structure. In such a case, the formation of the second embodiment will be made. Further, in case one common image taking device is built-in as the image taking device unit **45**, the formation of the first embodiment will be made.

This first modification is higher in the freedom of combination than the ninth embodiment and can simply realize stereoendoscopes **41** different in the characteristics. Also, as shown in FIG. **16**D, when an ocular adapter **45'** is connected to the proximal end of the relay optical system unit **43**, a stereoendoscope by which stereo-inspection can be made with the naked eyes will be able to be formed.

The ocular adapter **45'** shown in FIG. **16**D has a structure whereby the final images by the relay optical system unit **43** can be magnified and observed respectively through prisms and ocular lenses **45"***a* and **45"***b* fitted to an ocular window corresponding to the distance between both eyes of the operator so that the left and right images by the objective optical systems **21***a* and **21***b* may be respectively stereo-inspected through the left and right ocular lenses **45"***a* and **45"***b*.

By the way, in this case, because the final images are inverted images, the ocular adapter **45'** is provided with lenses **45'***a* and **45'***b* as means for making them upright to form upright images in front of the ocular lenses **45"***a* and **45"***b*. Instead of providing the lenses **45'***a* and **45'***b*, the two prisms for extending the distance between the optical axes may consist of prisms for inverting images such as Porro prisms.

The ocular adapter for observation with the naked eye may be connectable to the relay optical system unit **43** in FIG. **16**A in the structure or may be connectable to the second to fourth modifications of the ninth embodiment shown in FIGS. **17**A to **17**C explained in the following.

In the second modification shown in FIG. 17A, in FIG. 16A, the adapter optical system **32** and the image taking devices **33***a* and **33***b* are formed of an adapter optical system image taking unit **46** as one unit.

In the third modification shown in FIG. 17B, in FIG. 17A, further, the objective optical systems **21***a* and **21***b* and the relay optical system **22** are formed of an objective optical system relay optical system unit **47** as one unit. In the fourth modification shown in FIG. 17C, in FIG. 16A, the relay optical systems **22** and the adapter optical system **32** are formed of a relay optical system adapter optical system unit **48** as one unit.

FIGS. **18**A to **18**E show more actual formations of various units used in the ninth embodiment and its modifications.

FIG. **18**A shows an objective optical system unit **42** of a visual field angle of 70 degrees. FIG. **18**B shows an objective optical system unit **42** of a visual field angle of 40 degrees. When they are replaced and are connected to a relay optical system unit **43**, any desired visual field angle will be obtained.

A male screw is formed at the proximal end of the jacket tube of the objective optical system unit **42** and can be removably connected by being screwed to a female screw at the distal end of the jacket tube of the relay optical system unit **43**. A projection is provided at the proximal end of the jacket tube of the objective optical system unit **43** and can be contacted with a level difference surface made by cutting off the inner peripheral surface on the distal end side of the jacket tube of the relay optical system unit **43** to determine the position in the lengthwise direction. By the way, both jacket tubes have the same outside diameter so that, in case they are connected with each other, no level difference will be made on the inserted section.

Also, a positioning mark and screw hole are provided as peripheral positioning means near the proximal end of the jacket tube of the objective optical system unit **42**. When this mark is made to meet a positioning mark at the distal end of the jacket tube of the relay optical system unit **43**, both screw holes will be able to be set to communicate with each other and will be able to be fixed with a screw (not illustrated).

By the way, the same connecting means or connecting mechanism as on the proximal end side of the jacket tube of the objective optical system unit **42** is provided on the proximal end side of the jacket tube of the relay optical system unit **43** and can be removably connected to the distal end of the jacket tube of the adapter optical system unit **44**.

FIG. **18**C shows an objective optical system unit **42** perspective in the visual field direction of 45 degrees. In FIG. **18**C, by replacing the reflecting prism **40**, the objective optical system unit **42** perspective in any visual field direction can be formed. By the way, FIG. **18**D shows FIG. **18**C as seen from the rear end side and a pair of objective optical systems **39***a* and **39***b* arranged on the left and right.

FIG. **18**E shows an objective optical system **42** in which the parallax is reduced and the optical axes of two objective optical systems **21***a* and **21***b* are near each other and the distance d' between the optical axes is d'<d. In this formation, the stereo-feeling will be reduced but, as the objective optical systems are arranged on the center axis side, a space for inserting them through other internal organs or the like will be able to be secured, therefore, for example, the cross-sectioned area of the light guide will be able to be made large, the illuminating light amount will be able to be increased and a bright image will be obtained.

By the way, when the image taking device unit or the adapter optical system unit is replaced, as required, in response to the optical axis distance and visual field angle of the objective optical systems **21***a* and **21***b*, an optimum stereoendoscope conforming to the equivalent will be able to be provided.

FIG. **19**A shows a formation of a relay optical system unit **43**. The proximal end of this relay optical system **43** can be removably connected to the distal end of the adapter optical system unit **44**. Also, the proximal end of this adapter optical system unit **44** can be removably connected to the image taking unit **45**.

As shown, for example, in FIG. **19**B, the relay optical system unit may be the relay optical system unit **43** in which the number of relaying times is doubled. Further, a relay optical system unit in which the number of relaying times is different depending on the length inserted into the body cavity or the like can be also used.

FIG. **19**C shows a formation of an objective optical system relay optical system unit **47** for integrating an objective optical system and a relay optical system. FIG. **19**D is a modification of FIG. **19**C and shows a unit in which the number of relaying times of the relay optical system is doubled. Various numbers of relaying times of the relay optical system can be prepared. A different length of the inserted section can be selected as required.

In the following, the tenth to eighteenth embodiments are embodiments of the formation (b) in the above mentioned paragraph of the summary. Images having a parallax with each other are taken into the plurality of front group optical systems of the objective optical systems arranged in the distal end section of the endoscope and a plurality of images in one rear group optical system are formed in substantially coinciding positions. These substantially superimposed images are transmitted by a common rear group optical system and a common image transmitting system coinciding with this rear group optical system in the optical axis. FIG. **20** shows an image taking optical system in the tenth embodiment.

An objective optical system **51** in which the object side opening part is separated into two parts, relay lens systems **52***a*, **52***b* and **52***c*, an adapter optical system **50** and image taking devices **53***a* and **53***b* are arranged in the order mentioned from the object side. The objective optical system **51** is formed of front group optical systems (abbreviated merely as front groups) **54***a* and **54***b* of the same formation which are arranged parallel as separated by the distance d (=4 mm) between the optical axes of each other and a rear group optical system (abbreviated merely as a rear group) **55** arranged to be of one same optical axis. Two images **56***a* and **56***b* having a parallax are formed in spatially substantially coinciding positions.

The images **56***a* and **56***b* form a relay optical system and are equally multiple-relayed by (for example, three) relay lens systems **52***a*, **52***b* and **52***c* of the same formation arranged in series so as to have the same optical axis.

That is to say, by the relay lens system **52***a*, the images **56***a* and **56***b* form images **57***a* and **57***b* with equal sizes in substantially the same positions in the rear of this relay lens system **52***a*. By the relay lens system **52***b*, these images **57***a* and **57***b* form images **58***a* and **58***b* with equal sizes in substantially the same positions in the rear of this relay lens system **52***b*. By the relay lens system **52***c*, these images **58***a* and **58***b* form images **59***a* and **59***b* with equal sizes in substantially the same positions in the rear of this relay lens system **52***c*.

The rear group **55** of the objective optical system **51** and the optical axis of the relay lens systems **52***a*, **52***b* and **52***c*

are on the same axis. This optical axis and the optical axis of the front groups **54***a* and **54***b* are respectively eccentric on the left and right.

The eccentricity can be selected in conformity with a desired size, that is, the size of the stereo-feel and is respectively d/2 (=2 mm) in this embodiment. An afocal beam may not be between the front groups **54***a* and **54***b* and the rear group **55**. However, this part may be of an afocal beam. An image formed by the objective optical system should be substantially superimposed.

For the picture angle of the ordinary relay system, the picture angle required by the endoscope is large. Because, as described above, the front groups **54***a* and **54***b* must be nearly afocal and because there must be few parts not in common, the front groups **54***a* and **54***b* must be formed of a concave group and a convex group from the object side.

When the plurality of images having a parallax and which are transmitted by the relay optical system are substantially superimposed, the relay optical system will be able to be made small in the diameter. Therefore, the projected pupil of the objective optical system **51** may be made substantially infinite. Therefore, the front side focal position of the rear group **55** of the objective optical system **51** will be the pupil position. So that the beam entering the front groups **54***a* and **54***b* from the object may be well transmitted to the rear group **55**, it is preferable to the projected pupil of the front groups **54***a* and **54***b* coincide. It is preferable that the final surfaces of the front groups **54***a* and **54***b* are arranged on the image side rather than in the front side focal position of the rear group **55**.

In this embodiment, there are three relaying times which can be selected and set to be usually one time to ten or more times depending on such specifications as the length and diameter of the inserted section of the endoscope and the brightness of the optical system.

The magnitude of the parallax, that is, the center distance between the right and left incident pupils, is determined by the optical axis distance d between the front groups **54***a* and **54***b* of the objective optical system **51** and is independent of the brightness of the optical system.

According to this embodiment, the same as in the first embodiment, the two images **56***a* and **56***b* having a parallax are transmitted by one axially symmetrical relay optical system and therefore little error will be generated in the various optical qualities (the magnification, MTF, image position, chromatic aberration, coloring and the like) of the two images being transmitted.

There are fewer non-common parts on the right and left of the objective optical system **51** than in the first embodiment. Therefore, the adjustment of lenses proves not to be troublesome and a favorable stereo-observed image can be obtained.

Further, in this embodiment, as spatially substantially superimposed images are transmitted by the relay optical system, when each of the front groups **54***a* and **54***b* is formed of an elliptic lens system in which, for example, the horizontal direction is a short axis and the vertical direction is a long axis and the pupil is also made elliptic, the objective optical system and relay optical system will be able to be made small in diameter without deteriorating the parallax, brightness and the like. In this case, the inserted section will be able to be made small in diameter from the distal end to the proximal end side and the applied range in which the endoscope can be inserted and used will be able to be expanded. Because the hole through which the inserted section is inserted into the abdominal part can be made small, the patient will experience a reduction in pain. By the way, even in the other embodiments, the objective optical system may be formed of an elliptic lens system.

In this embodiment, the final images **59***a* and **59***b* of the relay lens system **52***c* are in substantially the same position and therefore must be separated from each other by any means which is a pupil dividing image forming means.

Therefor a means for forming an image of a pupil transmitted by the relay optical system and a means for forming an image of a partial beam of this pupil and forming an image by spatially separating plural images having a parallax are required. The adapter optical system **50** formed of the pupil image forming lens system **61**, mirror parts **62***a* and **62***b* and image forming lens systems **63***a* and **63***b* arranged to be on the same optical axis as of the relay lens system **52***c* perform these functions.

The pupil image forming lens system **61** forms in spatially separated positions images of two pupils of the objective optical system **51** transmitted by the relay lens systems **52***a*, **52***b* and **52***c*. In the mirror parts **62***a* and **62***b*, the beams of the two pupils are moved outside (in this embodiment, the movement is 6 mm) in parallel and the image forming lens systems **63***a* and **63***b* form images **64***a* and **64***b* respectively in the image taking devices **53***a* and **53***b*.

The optical axes of the image forming lens systems **63***a* and **63***b* are eccentric by d/2 (=2 mm) from the optical axis of the relay lens system **52***c*, except for the part moved in parallel by the mirror parts **62***a* and **62***b*. By the way, the mirror parts **62***a* and **62***b* and image forming lens systems **63***a* and **63***b* are illustrated respectively only on one side.

Lest the right and left pupils should be finally superimposed, a brightness diaphragm **79** may be provided on the pupil surface (in this embodiment, on the projecting pupil surface of the pupil image forming lens) in any of the pupil position and its conjugate position to limit the beam.

In this embodiment, when the parallel moving distance in the mirror parts **62***a* and **62***b* and the magnification of the adapter optical system **50** are properly set, the images **64***a* and **64***b* optimum to the image taking devices **53***a* and **53***b* of any size will be able to be obtained.

As in FIG. **20**, the parallel moving direction of the mirror parts **62***a* and **62***b* may be any direction within or vertical to a plan containing the paper surface. When the focal distances of the image forming lens systems **63***a* and **63***b* are varied, the magnification will be able to be also varied.

In order to obtain the stereo-feel optimum to the operator's desire or a system, the optical axis distances between each other of the two front groups **54***a* and **54***b* may be made variable so that the magnitude of the parallax may be variable. In this case, in order to make the distal end section small, the two front groups **54***a* and **54***b* may be made movable in the directions reverse to each other vertically to the optical axis of the relay optical system.

However, in this case, because the projected pupil of the objective optical system is moved by the movement of the front groups **54***a* and **54***b*, it will be necessary to make the effective diameter of each lens rather large so that the beam may not be intercepted by the optical systems following the relay lens systems **52***a*, **52***b* and **52***c*.

The other operations and effects are the same as in the first embodiment. The lens data of this embodiment are shown in Table 6.

The following eleventh to seventeenth embodiments are made by modifying the formations of the tenth embodiment. The images having a parallax between each other are formed

in spatially substantially coinciding positions. All these objective optical systems **51** can be formed to be interchangeable with the objective lenses of the pupil dividing type stereoendoscope of the related art.

FIG. **21** shows an image taking optical system in the eleventh embodiment of the present invention. Images **64***a* and **64***b* are formed by further once relaying the final images **59***a* and **59***b* of the relay lens system with the adapter optical system **50** and are taken by the image taking devices **53***a* and **53***b*.

The adapter optical system **50** is formed of a pupil image forming lens system **61** and image forming lens systems **63***a* and **63***b* arranged to be of the same optical axis as of the relay lens system **52***c*. The optical axes of the image forming lens systems **63***a* and **63***b* are eccentric by 1.25d (=5 mm) from the optical axis of the relay lens system **22***c*.

By the way, the image forming lens system is illustrated only on one side. This embodiment is simpler than the tenth embodiment because there is no mirror part within the adapter optical system **50**. As in the tenth embodiment, when the magnification of the adapter optical system **50** is freely set, the images **64***a* and **64***b* optimum to any image taking device will be able to be obtained. The distance between the two pupils divided by the pupil image forming lens system **61** can be varied by adjusting the focal distance of this pupil image forming lens system **61**. The other operations and effects are the same as the tenth embodiment.

The lens data of this embodiment are shown in Table 7.

FIG. **22** shows an image taking optical system in the twelfth embodiment of the present invention. The front groups **54***a* and **54***b* of the objective optical system **51** are formed of meniscus lenses **65***a* and **65***b* having a concave surface on the object side. In this embodiment, because there are fewer non-common parts of the right and left light paths than in the eleventh embodiment, the error between the qualities of the two images will be less.

The lens data of this embodiment are shown in Table 8.

Further, when the meniscus lenses **65***a* and **65***b* are constructed as an integrally molded lens **65** as shown in FIGS. **23**A to **23**D, the error on the right and left from the objective optical system **51** to the pupil image forming lens system **61** will be able to be reduced to a level where the error will not be a practical problem and the trouble of adjusting the lenses will be well eliminated. The other operations and effects are the same as in the eleventh embodiment.

By the way, of FIGS. **23**A to **23**D, FIG. **23**A is a sectioned plan view, FIG. **23**B is a side view of FIG. **23**A as seen in the side direction and FIGS. **23**C and **23**D are a front view and back view, respectively, as seem from the front side and back side.

FIG. **24** shows an image taking optical system in the thirteenth embodiment of the present invention. The final images **59***a* and **59***b* of the relay lens system are further once relayed by the adapter optical system **50**. Because the adapter optical system **50** is of the same optical axis as of the relay lens system **52***c*, the relayed images **64***a* and **64***b* will be formed in substantially the same positions and will be taken by one common image taking device **53**.

A shutter **66** is arranged between the pupil image forming lens system **61** and image forming lens system **63** and alternately intercept the beam so that two images may not be simultaneously formed in the image taking device **53**.

This embodiment has an advantage in that only one image taking device **53** is required. The other effects are the same as in the twelfth embodiment.

The lens data of this embodiment are shown in Table 9.
